Abstract

Each year over 200,000 lumbar spine fusions are performed. Fusion can be accomplished through an anterior, retroperitoneal approach, posterior or posterolateral approach, or more recently, through the lateral or transpsoas approach as pioneered by Pimenta and colleagues. Traditionally though, anterior interbody fusion (ALIF) has been a workhorse for discogenic pain and sagittal deformity of the lower lumbosacral spine. Most commonly this procedure involves placement of an interbody device followed by anterior tension band plating. But over the past decade and a half, new implants and new fusion devices have become available, which increase the robustness of this procedure. Here we discuss the basic indications of the ALIF procedure, provide a description of the classical ALIF procedure, and discuss current technologies.

Lumbar fusion · Interbody fusion · Spinal fusion · Lumbar spondylosis · ALIF · Spinal implants

Introduction

The use of anterior lumbar interbody fusion (ALIF) to address degenerative spine pathologies was first described in 1933 by Burns, who described its use for the treatment of spondylolisthesis secondary to bilaminar fracture in a 14-year-old boy (Burns and Camb 1933). Since that time, it has become an increasingly popular option for addressing pathologies of the lumbosacral spine, including spondylolisthesis and intervertebral disc herniation, as well as lumbosacral kyphoscoliosis, in which it most commonly complements posterior instrumentation (Loguidice et al. 1988). At its basest level, the procedure involves an anterior retroperitoneal approach to the lower lumbar or lumbosacral spine with partial or complete discectomy followed by placement of an interbody with or without supplemental anterior plating. Over its years of use though, new technologies have been developed for both improved surgical access and spinal reconstruction, including the introduction of integrated fixation cages. Here we provide an overview of the ALIF procedure and describe the various pieces of instrumentation employed for spinal column reconstruction.

A Brief History of Lumbar Fusion

The first description of instrumented lumbar fusion in print is made by Berthold Hadra, who reported the treatment of a C6/7 dislocation using internal reduction and fixation with silver wire connecting the adjacent spinous processes (de Kunder et al. 2018). Hadra himself attributed this technique of interspinous fusion to the thoracolumbar fusions performed by Dr. W. Wilkins, though the former never published his results (Keller and Holland 1997; Peek and Wiltse 1990). Despite multiple interventions, de Kunder's wiring technique proved to have insufficient strength to maintain reduction of the patient's fracture dislocation, and the patient's symptoms recurred within weeks of surgery (de Kunder et al. 2018). As a result, it was evident that alternative methods were needed. The well-known alternative to emerge was a technique described roughly two decades later in 1909 by Fritz Lange. Lange utilized rigid rods made of celluloid – a precursor to modern plastics – along with 5-mm-thick steel and silk wire to correct scoliosis in pediatric patients, a technique far not too dissimilar to modern posterior fusion techniques (Tarpada et al. 2017). Then in 1933, Burns and Camb described the first anterior fusion in a 14-year-old boy being treated for spondylolisthesis secondary to a bilaminar fracture (Burns and

Camb 1933), using a technique first proposed by Capener 1 year earlier (Capener 1932). Over the subsequent decades, progress in anterior fusion technologies lagged behind that of posterior fusion technologies, including progress in interbody device implementation (de Kunder et al. 2018). This culminated in the development of the Harrington rod in 1962 by American orthopedist Dr. Paul R. Harrington, which was the workhorse of spinal instrumentation for several decades. Around this same time though, Melvin Watkins published his findings on far lateral fusion (M. B. Watkins 1953), paving the way for the modern oblique lateral (OLIF) and extreme lateral interbody fusion (XLIF) used today.

Part of the reason that anterior fusion advancement may have lagged behind those of posterior fusion may stem from the struggle of early spine surgeons attempting to identify a strong material capable of maintaining correction and providing long-term stabilization. The early celluloid implants of Lange were reasonably tolerated within the body; however, their flexural modulus, like that of the steel wires also employed by Lange and his predecessors, was insufficient to maintain correction over their long intended service life (Peek and Wiltse 1990). Conversely, carbon steel implants had high flexural modulus but were susceptible to degradation within the electrolytic solutions of native human tissue. This necessitated the invention of new implants with electrolytic resistance similar to the noble metals (e.g., gold) but with the relatively high flexural modulus of steel. The solution was concomitantly reached through the invention of Vitallium – a cobalt-chrome alloy – and stainless steel, both of which were developed in the late 1930s (de Kunder et al. 2018; Peek and Wiltse 1990). Despite these advances in posterior fusion, the implementation of metal instrumentation for anterior fusion did not occur until the middle of the century. Leading up to this point, anterior approaches to lumbar fusion had relied solely upon external bracing for reinforcement during the immediate postoperative period. Surgeons had also championed the use of fitted interbody devices, chief among them, Paul Harmon, who in the late 1950s and early 1960s used tibial peg grafts and iliac crest grafts as fitted interbody devices (Harmon 1960). The latter of were also employed by Freebody and Crock (Harmon 1960; Peek and Wiltse 1990). At this time though, the first description of instrumentation for anterior lumbar fusion was made by Humphries et al. in 1958, who reported the use of an intervertebral clamp in a series of 25 dogs (Humphries et al. 1958). In their abstract, Humphries et al. also described a matched control series fused without the anterior vertebral clamp; unlike the instrumented group, the non-instrumented group had a 100% pseudarthrosis rate, demonstrating the potential utility of instrumentation in anterior lumbar fusion. Humphries and colleagues further elaborated on this technique in their 1961 paper, where they reported the results in a small series of human patients (Humphries et al. 1961). This clamp served as the precursor to the modern anterior and lateral plates that maintain compression on the placed interbody to facilitate successful fusion. Finally, in the mid-1980s, Louis published his series of over 400 patients including several that had undergone anterior-only fusion using lag screen placement across the interbody device – a technique mechanically similar to the increasingly popular integrated fusion cages (Louis 1986).

Anterior Versus Posterior Approaches to the Lumbar Spine

Despite the greater cumulative experience of spine surgery with posterior instrumentation, there is no clearly superior option across all cases. As with any surgical procedure, it is imperative to first identify the indication for surgery and the goals for surgery. Based upon these goals, a surgical plan can then be developed, which includes the decision of whether they treat the pathology from an anterior-only approach (ALIF), lateral/anterolateral approach (XLIF, DLIF, OLIF), posterior-only (TLIF, PLIF), or combined anterior-posterior approach.

Determining the surgical goals begins by identifying the pathologies responsible for the patient's clinical picture, whether that is a mobile spondylolisthesis generating mechanical, low back pain or an eccentric disc producing unilateral radicular pain. For degenerative cases, this

includes assessing the patient's spine for the presence of any pathologic curvature (i.e., scoliosis, flat-back syndrome, or focal kyphosis), the presence and grade of spondylolistheses within the spine, the presence of fragility (e.g., vertebral body compression fracture) or iatrogenic fractures (e.g., pars fracture), the presence and extent of cord and nerve root compression, and the overall sagittal (normal <5 cm) and coronal imbalance (normal <2 cm). Having done so, it is then necessary to identify which of these structural lesions should be addressed by surgery. Many patients have clinically appreciable spinal deformity that is asymptomatic (Kebaish et al. 2011; Schwab et al. 2005). The basis for this decision is ultimately up to both the surgeon and patient but should be based upon the patient's clinical complaints/presentation and overall health. Patients presenting with chief complaints of radicular pain or functional radiculopathy may be adequately treated with a discectomy or two-level decompression without fusion, whereas those with significant kyphoscoliotic deformity and back pain as a chief complaint will likely require a larger operation to realize clinical benefit from the procedure. Extra caution must be exercised when considering the latter option though, as not all patients have enough physical reserve to successfully recover from large, multilevel reconstructions. The International Spine Study Group has recently published on this, suggesting that frail patients may benefit most from nonsurgical management given their high risk for complications (Miller et al. 2017).

The next step after having deemed a patient to be a surgical candidate and having localized the pathology is to formulate an approach. In some cases, either posterior or anterior fusion is superior to the other, as in the cases of long-construct fusion operations for deformity, which are optimally achieved through a posterior-only approach (Geck et al. 2009; S. S. Lee et al. 2006). But in other cases, such as one- or two-level pathologies of the lumbar spine, both anterior and posterior approaches are available, and the decision should be made on the exact pathology (e.g., disc herniation), patient body habitus, and surgeon familiarity with each approach.

For the lower lumbar spine and lumbosacral spine, there are several anatomic considerations that must be made when selecting an approach. At the L5/S1 level – the most common site of lumbar intervertebral disc herniation – lateral approaches are largely precluded, as the iliac crests make access essentially impossible in most patients. This is also a concern at the L4/5 level, though less commonly so, and is based upon the actual height of the patient's ilia. At higher levels, lateral approaches become a more robust option, and they may preferable for pathologies above the bifurcation of the iliac arteries, due to the decreased risk of vascular damage relative to the anterior approach and decreased blood loss relative to the posterior approach. Furthermore, above the level of the renal vessels (L1–2), the anterior approach largely ceases to be a consideration due to its requirement for diaphragm mobilization. As a result, the main indication for an anterior approach is one- or two-level disease between the L2 and S1 vertebrae. Here the anterior fusion can be used as either a stand-alone procedure or as a supplement to a posterior procedure in cases requiring significant correction of coronal Cobb or lumbar kyphosis. Of note though, we recommend against an anterior approach in cases of prior retroperitoneal surgery or obesity due to increased complexity of access. We also recommend against its use in cases of an ankylosed level with full disc space collapse or solid arthrodesis at the surgical level. We do however feel it is appropriate to perform an ALIF with an indirect foraminal decompression, if the collapsed disc space has not undergone ankylosis. Additionally, when considering a one- or two-level fusion, it is still important to take into consideration the patient's sagittal imbalance, as failure to correct sagittal imbalance and loss of lumbar lordosis is a previously identified negative predictor of surgical outcome in short-construct fusions (B. H. Lee et al. 2017).

Relative Advantages and Disadvantages of the Anterior Approach

As with any surgery, there are advantages and disadvantages to employing an anterior as

opposed to a posterior approach. Relative advantages of the anterior approach include superior visualization of the disc spaces of the inferior lumbar spine and lumbosacral junction (Giang et al. 2017) and the ability to avoid dissection of the posterior musculoligamentous structures (Mobbs et al. 2015), thereby preserving the posterior tension band and reducing in the risk of nerve root injury (Jeswani et al. 2012). Additionally, and more important to the scope of this work, the anterior approach may offer several mechanical advantages relative to a posterior (PLIF) or posterolateral (TLIF) approach. One study by Hsieh and colleagues reported a cohort of 57 patients operated for discogenic back pain (Hsieh et al. 2007). Among this cohort, 32 patients were treated via the anterior approach, and 25 patients were treated via a posterolateral approach (TLIF). The authors reported superior correction among the ALIF group in terms of restoration of foraminal height, disc angle, and lumbar lordosis. Similar findings have been observed by other groups (J. Kim et al. 2010; R. G. Watkins et al. 2014), with 10° of correction per level or upward of 20° to 30° per level with some of the more recent hyperlordotic cages (Saville et al. 2016). These larger cages can only be placed via an anterior approach due to the access restrictions posed by the exiting nerve roots in posterior and posterolateral approach, and as a result, the anterior approach may be the best option in patients requiring substantial sagittal correction. Although similar levels of sagittal correction can be achieved using pedicle subtraction osteotomies (K. Cho et al. 2005), this correction is non-physiologic in that it compresses the exiting lumbar nerve roots and may lead to postoperative radicular pain if concomitant foraminotomies are not performed. Furthermore, this approach requires compromise of the posterior tension band (Udby and Bech-Azeddine 2015), which may decrease the ability of patients to maintain large corrections postoperatively, though evidence to support this is still pending.

Despite these advantages, the anterior interbody fusion has several limitations. Chief among these is the complexity of the retroperitoneal approach (Giang et al. 2017). Multiple delicate structures must be crossed during this dissection, including the aorta and inferior vena cava in the prevertebral space above the level of L4, the hypogastric plexus within the presacral and L5 prevertebral space, and the ureters in the posterolateral retroperitoneal space. Injury to these structures can lead to significant blood loss, hydronephrosis, and retrograde ejaculation (Czerwein et al. 2011; Quraishi et al. 2013). Because of these risks and the lack of familiarity that the average surgeon may have with this approach, anterior interbody fusions often require the use of an access surgeon. This is especially true for surgically complex abdomens, such as those seen in patients with substantial abdominal obesity and in individuals who have previously undergone abdominal surgery. The latter have significant adhesions and scar tissue secondary to their prior operation(s), obscuring normal landmarks, while the former have significant abdominal soft tissue requiring retraction. This results in a narrow surgical corridor, and in the morbidly obese, extensive abdominal soft tissue may make adequate retraction impossible. Even in those cases where the anterior approach is possible, patients may also require a second, posterior approach for increased structural stability in order to prophylax against pseudarthrosis, which has been reported at a higher rate in this population (Jiménez-Avila et al. 2011).

In terms of biomechanical stability, results are mixed regarding the superiority of anterior- versus posterior-alone procedures for single-level disease. A recent cadaveric study by Liu and colleagues suggested that anterior interbody fusion with plating provides superior compressive strength compared to pedicle screw supplemented constructs (L. Liu et al. 2014). However, a previous cadaveric study by Tzermiadianos and colleagues (Tzermiadianos et al. 2008) saw superior strength with respect to lateral bending and flexion-extension in the pedicle screw fixation group. Additionally, multiple studies (Dorward et al. 2013; D. Kim et al. 2009), including recent meta-analyses by Phan et al. (2015) and Teng et al. (2017), observed no difference in fusion rates between anterior and posterior interbody techniques, suggesting that there may be no significant role for biomechanical considerations when selecting an approach for the treatment of

discogenic pain. Because of this and the similar complication rates for anterior and posterior approaches (Teng et al. 2017), we recommend that the approach employed be dictated by the familiarity of the surgeon with the approach and the indication for surgery. Anterior approaches may yield superior results in patients being treated for discogenic pain conditions with only minor subluxation deformity being treated by surgeons familiar with the retroperitoneal approach. Conversely, posterior approaches are preferable for patients with high-grade spondylolisthesis, especially if the attending surgeon is uncomfortable with the retroperitoneal approach.

Anterior Lumbar Interbody Fusion

Positioning, Draping, and Mapping of the Incision Site

As with all surgical procedures, the anterior lumbar interbody fusion begins with a review of preoperative imaging. In the context of an ALIF, the goal of preoperative imaging review is to identify the angle of the target disc level (generally L4/5 or L5/S1). Patients with greater pelvic incidences will have more caudally directed anterior disc surfaces, which may require induction of additional Trendelenburg positioning. Concomitant inducement of greater lordosis is recommended to open the ventral disc space, which can be done using a roll or cushion; this may not be necessary in patients with substantial native lordosis though (Heary et al. 2017). Additionally, preoperative imaging allows for evaluation of prevertebral soft tissues and identification of potential surgical obstacles. Structures of particular concern are the iliac vessels, which generally bifurcate at the level of L3 (veins) or L4 (arteries) and consequently must be mobilized in approaches to the mid- or upper lumbar spine.

After the angle of the disc space has been identified, the surgical procedure can begin. The patient is brought to the operating room and placed under general anesthesia. The patient is then transferred to a radiolucent table, such as the Jackson table, which is placed in mild Trendelenburg position to position the target disc space perpendicular to the floor. In patients with larger body habitus, we recommend securing the feet of the patient to the table to prevent sliding during the procedure. We also recommend rotating these patients slightly, placing them in a position intermediate to supine and lateral decubitus; this helps retract intraperitoneal structures during the approach. While placing an inflatable pillow or surgical bump underneath the patient buttocks is helpful in most patients, owing to an increase in exposure of the ventral disc space, it may need to be excluded in patients with significant pelvic incidence, as it can decrease lordosis and exposure of the lower lumbar disc spaces. Similar flexibility is offered during positioning of the patient's arms. The overall goal in positioning is to remove the distal arm from the abdominal region and surgical field, which we believe can best be accomplished by abducting the right arm and securing the left arm across the patient's chest in a standard room set up. This approach allows for adequate visualization of the discs with fluoroscopy while providing access to all members of the surgical team.

After positioning, the incision line is then drawn on the patient. Several options are available including a standard midline incision (Aryan and Berta 2014), a vertical paramedian incision of the linea semilunaris (Jeswani et al. 2012), and a right-angled incision with a horizontal arm between the umbilicus and pubic symphysis (Heary et al. 2017). For L5/S1 discs, a 7-cm-horizontal incision 2–3 cm above the pubic symphysis is preferred, whereas for L4/5 pathology, a vertical incision is preferred. This latter technique offers superior exposure at all levels and superior cosmetic results and can be easily extended under circumstances, such as vascular injury, that require additional exposure. Alternatively, a Pfannenstiel incision may be used, as is commonly performed in gynecological procedures (Aryan and Berta 2014). If a paramedian incision is utilized, placement on the left side of the patient is preferred as it facilitates aortic retraction and reduces the amount of retraction that the more fragile inferior vena cava must undergo (Heary et al. 2017). After the patient is positioned and the incision is marked, a rail for retractor attachment is connected to the table, the surgical field is cleared with appropriate skin preparation, and the patient is draped in the usual fashion.

Incision and Approach

Either a transperitoneal or retroperitoneal approach may be employed. Both procedures are effective means of accessing the disc space; however, previous evidence suggests that transperitoneal approaches have a 10x higher risk of hypogastric plexus injury and retrograde ejaculation (Heary et al. 2017). As such, we prefer a retroperitoneal approach, especially in male patients. It should be noted that for either the transperitoneal or retroperitoneal approaches though, it is recommended to utilize a vascular access surgeon in order to decrease the risk of injury to the genitourinary, vascular, and prevertebral nervous system structures. This is especially true for patients with risk factors for retroperitoneal fibrosis, e.g., prior abdominal surgery.

The procedure begins by making a 4–6 cm paramedian vertical incision along the planned incision line, centered roughly 2 cm to one side of the patient (left of midline for a right-handed surgeon). Incision should be through skin and the superficial fascia (Camper's, Scarpa's) to expose the anterior rectus sheath. The sheath, comprised of the aponeuroses of the external and internal oblique, as well as the transversus abdominis below the arcuate line, is divided, exposing the fibers of the rectus abdominis. To expose the posterior rectus sheath, the rectus fibers are then either dissected away from the linea alba and the released rectus muscle is retracted laterally or the fibers are dissected away from the semilunar line and the rectus is retracted medially. Both options are acceptable, and the decision is up to the individual surgeon. Note that during this dissection, splitting, as opposed to cutting of the rectus fibers, should be used to reduce the risk of postoperative hernia at the surgical site. The posterior sheath is then divided vertically with a scalpel and blunt; finger dissection is used to develop a plane between the posterior rectus sheath and the underlying peritoneum. Below the level of the arcuate line, the plane is developed between the peritoneum and more superficial transversalis fascia. Dissection continues laterally retracting the overlying soft tissues laterally and the peritoneum and intraperitoneal contents superomedially. Once the depth of the psoas muscle is achieved, the ureter should be immediately identified and protected to prevent postoperative complications; it is usually adherent to the peritoneum and can therefore be protected within this structure (Jeswani et al. 2012). The iliac vessels are then identified. For L4/5 pathologies, the iliac vessels are retracted medially along with the aorta and inferior vena cava, exposing the disc and overlying sympathetic chain medial to the psoas. The iliolumbar and segmental vessels are ligated to facilitate mobilization. For L5/S1 pathologies, the iliac vessels are retracted bilaterally away from the midline, and the middle sacral artery and vein are ligated and divided to expose the disc space. The sympathetic chain is then identified using forceps to avoid injury to it during discectomy. In some cases though, gentle retraction may have to be applied to the sympathetic chain in order to expose the pathologic level, though this is associated with an increased risk of sympathetic syndrome. Following completion of the approach, fluoroscopy is used to confirm the spinal level. A universal retractor ring is then affixed to the table centered on the level of the affected disc; this ring will be used as a fixation point for retractors during the discectomy and reconstruction.

Addressal of the Pathology

Discectomy

A #11 blade is used to outline the target disc in rectangular fashion using a templated trial selected based upon preoperative CT or MR imaging, which are used to measure the width and height of the target disc space. During incision, care must be taken to avoid damaging the sympathetic chain located immediately lateral to the disc space, a concern that is most important at the L4/5 level. Though an en bloc resection of the disc is preferred, in cases where this is not feasible, the disc can be longitudinally sectioned in several pieces to facilitate extraction. An ALIF system, straight osteotome, Cobb elevator, or laminae spreader is then used to distract the disc space (Heary et al. 2017). Additional distraction can be

achieved using sequential dilator; care should be taken to avoid overdistraction, which has been associated with postoperative neurapraxia (Taher et al. 2013). The remaining disc attachments are cleared from the superior and inferior end plates using a curette, concomitantly decorticating the end plates in preparation for fusion. Loosened cartilage and semi-mobilized disc fragments can be resected using a pituitary rongeur. We recommend preserving the posterior annulus in most cases, as it protects the ventral dura and helps to stabilize the cage postoperatively. The vertebral end plates are then prepared using a forward-angled curette. Trial implants are tested in the discectomy level until an implant large enough to restore the original disc height has been identified. Preoperative imaging is useful at this point, as adjacent, normal disc spaces can be used for selecting the appropriate trial size. Note that the implant should not be too large, as this may increase the risk of implant subsidence or kickout. Similarly, the trial should not be too small, as this (1) may provide insufficient sagittal plane correction and (2) may decrease the stability of the construct by reducing the compressive force exerted on the implant by the annulus (Patwardhan et al. 2003). The trial spacer is then removed, and the permanent interbody is placed. Femoral allograft, titanium, and PEEK implants are all available, and graft material (discussed later) can include demineralized bone matrix, allograft, autograft, and osteoinductive materials such as rhBMP-2. After placement of the implant, positioning is confirmed on fluoroscopy. If positioning is satisfactory, additional graft material may be placed around the interbody device. This additional graft has the potential to facilitate fusion and decrease the risk of implant subsidence (Kumar et al. 2005); it is difficult to assure that said graft remains in place however, and many surgeons only place graft in the interbody. Screws are then placed to fix the cage to the bone (in the case of integrated fixation cages), or a plate is affixed to prevent anterior subluxation of the cage. With some implants, notably integrated fixation cages, it is necessary to trim the lateral surfaces of the vertebrae bracketing the implant to allow placement of the screws.

Closure

After final positioning is confirmed on fluoroscopy, closure of the surgical corridor begins. Retractors are removed sequentially, inspecting both the ureter and the iliac vessels during removal to confirm that they have not been injured during the procedure. If these structures have been injured, it is necessary to repair them prior to closure of the wound. The risk of these injuries in the anterior retroperitoneal approach is one reason that it may be beneficial to utilize an approach surgeon for the exposure. The corridor is closed in layers with 2–0 Vicryl in the posterior rectus sheath, a few loose 0 Vicryl sutures in the rectus abdominis to facilitate muscle reapproximation, and 2–0 Vicryl sutures in the subcutaneous tissue; the skin is closed with 4–0 Vicryl or staples.

Spondylolisthesis

An anterior stand-alone procedure is not recommended for significant spondylolisthesis (above grade I), as the ability to reduce the translation is inferior to that offered by a posterior procedure (Jeswani et al. 2012). If the indication for surgery is spondylolisthesis, the anterior procedure should be performed exactly as described above for discectomy, except that a tension band plate is not placed, unless the spondylolisthesis can be reduced sufficiently on the anterior approach. Instead, a kickout plate or cancellous screw and washer construct are attached to one of the vertebrae to retain the interbody. The wound is then closed in layers, and the patient is flipped for the posterior portion of the procedure. Pedicle screw fixation is applied as described elsewhere, reducing the spondylolisthesis as the rods are applied, if desired. Fluoroscopy is then used to confirm placement of the instrumentation. If it is satisfactory, Valsalva is performed to confirm that no dural perforation has occurred. Note that this is not necessary in cases where pedicle screw instrumentation is placed percutaneously. Lumbar drains are placed, and the posterior wound is closed in layers, with 0–0 Vicryl in the deep fascia and 2–0 Vicryl in the subcutaneous fascia. The skin may be closed with Nylon sutures, steristrips, glue, or staples.

Case Illustration

A 32-year-old female presented to the clinic of the senior author for chronic low back pain and radicular, right lower limb pain secondary to compression of the right L4 nerve root. The patient had managed her back pain conservatively for years but underwent an L4/5 discectomy at an outside hospital for her leg pain 4 months prior to presenting to our clinic. This intervention had been minimally beneficial, relieving her leg pain for several weeks but ultimately failing to provide robust benefit for either her leg or lower back pain. Upon presenting she was neurologically intact and was advised to try conservative management prior to another surgical intervention. After failing 6 months of conservative management, including physical therapy and several epidural nerve blocks, the patient was offered an L4–5 ALIF to stabilize her pathologic level and relieve her discogenic pain.

Surgery proceeded by placing the patient supine on a Jackson table and identifying the target level. She was then draped, and vascular surgery was called in to make the approach as the patient had a history of two prior Cesarean deliveries, and it was felt that employing an access surgeon would minimize the risk posed by the potential scar tissue. A traditional left, retroperitoneal approach was adopted, beginning with an oblique incision inferolateral to the umbilicus, intermediate to McBurney and Battle incisions. Sharp dissection and monopolar cautery were used to divide the superficial tissues and expose the anterior abdominal wall, which was then divided using the monopolar cautery. The rectus muscle and anterior rectus sheath were mobilized medially, and the retroperitoneum was entered. The retroperitoneal plane was extended posteriorly until the iliac veins were exposed; these lay above the level of the L4/5 disc, and so the veins were mobilized bilaterally to facilitate the anterior approach. A #10 blade was then used to incise the annulus of the L4/5 disc, which was removed with a combination of rongeurs, high-speed drill, and curettages. After the superior L5 end plate and inferior L4 end plate were cleaned, trial spacers were placed until sufficient correction of the anterior defect was achieved. An allograft spacer with demineralized bone matrix was then placed, and an anterior plate connecting the L4 and L5 levels was placed to reduce the risk of graft kickout postoperatively. Lateral imaging demonstrated good placement of the graft, at which point vascular surgery reentered and completed the closure. The anterior abdominal wall was closed with a #1 Maxon suture, and the skin was closed in layers using 4–0 Vicryl and a subcuticular technique for the most superficial layer. No complications occurred intraoperatively, and the patient was discharged home on postoperative day 3 after an uneventful inpatient course. The patient reported significant improvement in both her back and leg pain by the 1-month follow-up appointment. The patient demonstrated solid fusion across her construct at last follow-up – 52 months following surgery – and reported minimal pain.

Lateral Lumbar Interbody Fusion

A more recently popularized anterior approach for lumbar interbody fusion is the transpsoas approach, also known as the extreme lateral (XLIF) or direct lateral approaches (DLIF) and popularized by Luiz Pimenta over the past 15 years (Ozgur et al. 2006). This technique has the chief advantage of being minimally invasive, as it requires minimal tissue disruption – an advantage over conventional anterior approaches. Similarly, it allows for more complete removal of the target disc without disrupting either the anterior or posterior tension bands and at the same time allowing the placement of a larger interbody graft as compared to posterior approaches (Winder and Gambhir 2016); it may also allow for more complete end plate preparation as compared to ALIF techniques of similar invasiveness (Tatsumi et al. 2015). Indications for this procedure are similar to those of the above-described ALIF, including low-grade spondylolisthesis, discogenic low back or radicular leg pain, and sagittal plane deformity.

The chief advantages of the XLIF and DLIF procedures relative to the more conventional ALIF procedure are that they (1) do not require

the assistance of a vascular access surgeon; (2) do not require retraction of the great vessels or sympathetic chain, thereby minimizing risk of injury to these structures; (3) are more easily performed on patients with significant abdominal obesity, who are not candidates for conventional ALIF; and (4) reduce risk of injury to the presacral autonomic plexus (Laws et al. 2012). One of the chief disadvantages for the DLIF/XLIF approach is that it is relatively contraindicated for fusion at the L5/S1 level, as the iliac crest blocks the approach to this level. It also has an increased risk of intraoperative injury to the nerves of lumbar plexus, specifically the genitofemoral nerve, which lies in close proximity to the retractor as it is passed through the psoas muscle (Jahangiri et al. 2010; Uribe et al. 2010). This risk, which is reportedly greatest for surgery at the L4/5 level due to the anteroinferior trajectory of the nerve, can be reduced by utilizing neuromonitoring and a stimulating retractor (Benglis et al. 2009; Kepler et al. 2011; Regev et al. 2009; Riley et al. 2018; Tohmeh et al. 2011). Additionally, this technique increases radiation exposure to both the patient and the operating room staff, as it requires serial fluoroscopy to ensure that the correct approach is being utilized. Lastly, XLIF/DLIF may have a decreased ability to increase segmental lordosis as compared to the traditional approach (Winder and Gambhir 2016), though evidence exists that this drawback can be nullified by resecting the ALL intraoperatively, thereby allowing for inducement of greater lordosis at the treated segment (Akbarnia et al. 2014; Deukmedjian et al. 2012) (Figs. 1 and 2).

Description

Positioning is extremely important to XLIF/DLIF approach, as proper placement of the interbody relies on the surgeon being able to align the plane of the target disc with the fluoroscope and surgical working plane (Winder and Gambhir 2016). This begins by placing the patient on a bendable radiolucent table in a true lateral decubitus position with the iliac crest at the level of the table break and the patient's back flush with the edge of the table. In addition to providing the surgeon with the most direct approach to the pathology, this position also has the advantage of allowing gravity to retract the intraperitoneal contents away from the spine, which is of increased benefit in patients with substantial visceral obesity. Under most circumstances, either the left or right lateral decubitus position may be chosen; however regional vascular variability may preclude approach from one side or the other, and surgeons are encouraged to consult preoperative imaging. Similarly, in cases where the patient also has

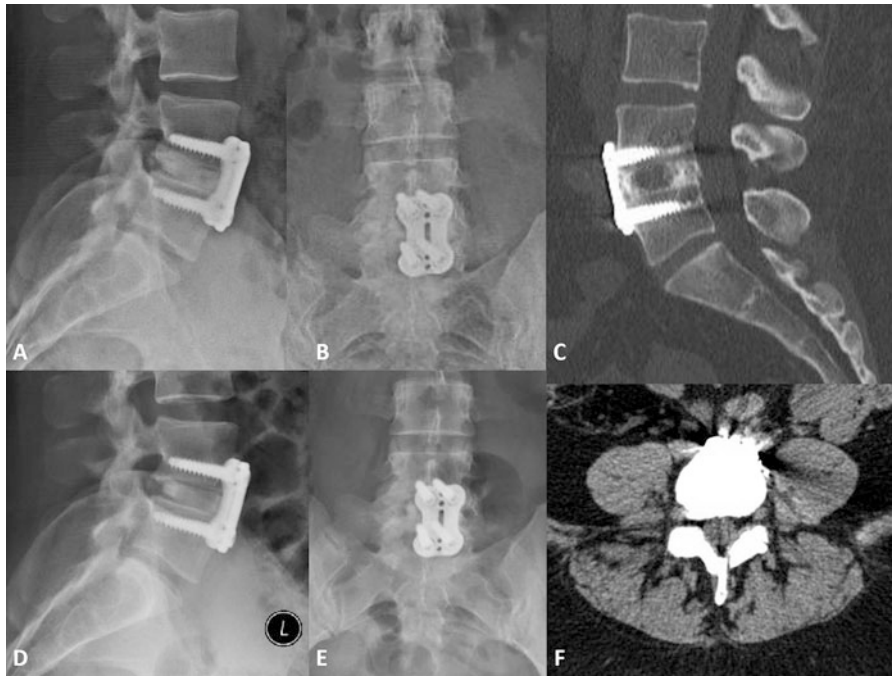

Fig. 2 (**a**) and (**b**) 3-month postoperative lateral and posterior-anterior radiographs demonstrating good alignment of the construct. (**c**) and (**f**) mid-sagittal and L4/5 axial CT views at 44-month follow-up demonstrating solid fusion with bridging of the construct by bony trabeculae. (**d**) and (**e**) Postoperative radiographs at 52-month follow-up showing successful fusion without evidence of adjacent segment disease or graft subsidence

scoliotic curvature of their lumbar spine, it is recommended that the patient be placed with the convex side facing the table (Beckman and Uribe 2017).

After the patient is placed in the lateral decubitus position on the table, their legs are flexed at the hips and knees to reduce tension in the psoas muscle, which facilitates passage of the dilators later in the procedure. Axillary and hip rolls are placed, as is a pad between the knees to reduce the risk of pressure ulcers. Positioning is then optimized using fluoroscopy to place the patient's spine in the true AP plane; the use of fluoroscopy may be most useful for patients having undergone prior lumbar surgeries, in which the native anatomy has been disturbed. It may be helpful to induce some bend at the table break to move the iliac crest out of the approach path. The patient is then secured to the table with tape at the shoulder and iliac crest, as well as at the legs, with strips parallel to the femur and tibia (Badlani and Phillips 2014). Final adjustments are then made to reestablish the true AP plane (Fig. 3a, b). Electronic monitoring leads are then placed, and preoperative signals should be acquired to establish the patient's neurologic baseline.

After skin preparation and draping, a #10 blade is used to make an incision through the dermis. As with the ALIF technique, a single 3–4 cm transverse incision can be used if only a single level is to be treated; if multiple levels are to be addressed, then a single vertical incision is planned. After passage through the dermis, monopolar cautery is used to dissect through the retroperitoneal fat until the external oblique fascia is reached. A transverse incision is formed in this fascia, and blunt dissection is used to pass through the abdominal wall musculature; examining the orientation of the fibers of the dissected muscle can be used to track that penetration of the abdominal wall has been complete. During dissection, care must be taken to remain on line with an approach to the posterior third of the disc space or middle third at the L4/5 level. Migration of the dissection

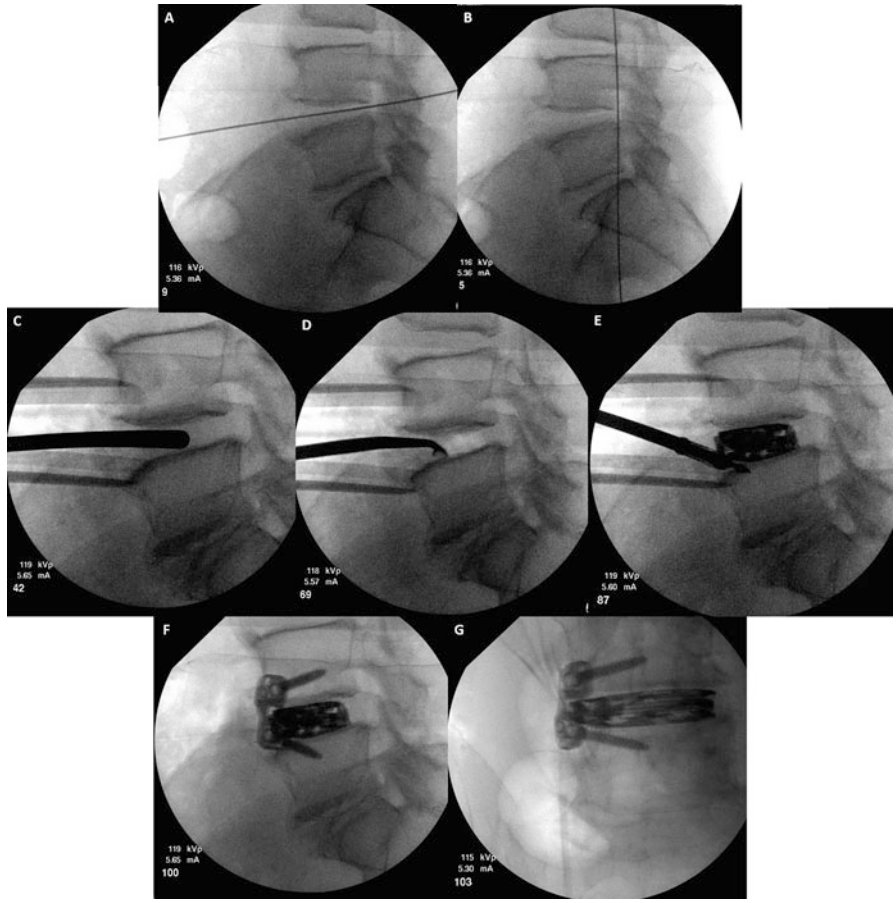

Fig. 3 (**a**) and (**b**) Fluoroscopy demonstrating effective positioning with true lateral positioning of the patient on the table. (**c**) The retractor is docked on the disc space, and a Cobb elevator is used to distract the disc space. (**d**) A forward angle curette is used to clean the superior and inferior end plates. (**e**) Titanium interbody is tamped into place, and positioning is confirmed. (**f**) and (**g**) Lateral and AP imaging demonstrating accurate positioning of the interbody and plate

path anteriorly endangers the retroperitoneal and intraperitoneal contents, whereas migration posteriorly risks damage to the nerves of the lumbar plexus.

Once the retroperitoneal space is entered, blunt finger dissection is then used to palpate the quadratus lumborum; the finger is then rotated anteriorly to palpate the psoas. The first dilator is passed along the trajectory of the finger to the top of the psoas muscle, keeping the finger anterior to the dilator to prevent injury to the retroperitoneal contents. Once the dilator has been placed, its position is confirmed on fluoroscopy, and then the dilator is passed through the psoas, docking on the intervertebral disc space; fluoroscopy is used again to confirm position. During passage of the dilator through the psoas, the target site is highly dependent upon the disc level being addressed. Previous work by Uribe et al. (2010) documenting the course of the genitofemoral nerve has established safe zones within the psoas muscle through which the retractor may be passed with minimal risk to the genitofemoral nerve. Biologic variability among patients precludes said results from eliminating nerve injury risk from the approach, but they can reduce the risk substantially. Additionally, state-of-the-art dilator models have EMG capability, which can be used during placement to prevent inadvertent

nerve injury (Tohmeh et al. 2011). For such dilators, stimulation should be performed following placement in the dilator to determine the relative position of the nerves. Low thresholds on the EMG indicate closer proximity of the nerve (threshold >11 mA are safe; <5 mA suggests direct contact); current thought is that positioning of the nerve anterior to the dilator increases the risk of nerve injury upon serial dilation. Fluoroscopy should then be performed to confirm placement. If the dilator is malpositioned on either EMG or fluoroscopy, it should be adjusted prior to serial dilation. Changes in the superoinferior plane can be accomplished without removing the dilator from the psoas muscle due to the myofiber orientation, but changes in the anteroposterior plane require removal from the psoas and reinsertion. A guidewire is then placed through the dilator, and sequential dilators are passed over the guidewire. Once the largest dilator has been placed, the retractor is passed over it and docked onto the disc space; the retractor is then fixed to the surgical bed arm, and a light source is connected to the posterior blade of the retractor. The field is inspected, and suspicious structures are stimulated with triggered EMG (tEMG) to rule out the possibility that the structure is a motor root. A protector is then placed posteriorly to prevent spinal cord injury, and retractor position is confirmed on fluoroscopy. If position is adequate, the retractor is expanded, and the anterior face of the disc is defined. Note that the goal is to minimize total retraction time (<20 min, per Beckmann (Beckman and Uribe 2017)), as extensive retraction can lead to postoperative lumbar plexopathy (Bendersky et al. 2015; Winder and Gambhir 2016).

An annulotomy is then performed using a box cutter instrument, and a pituitary rongeur is used to resect the disc; the anterior and posterior annulus are left intact to hold the interbody in place unless significant sagittal plane correction is required (C. Kim et al. 2017). A Cobb elevator is then malleted vertically along the superior and inferior end plates, making sure to continue through and disrupt the contralateral annulus (Fig. 3c). The end plates are then prepared with forward-angled curettes (Fig. 3d) and a pituitary rongeur, taking care to maintain end plate integrity. Trial interbodies are then placed until one is identified that restores adequate disc height; an equivalent interbody is then malleted into place with allograft in the central cavity (Fig. 3e). Note that some experienced centers use preoperative imaging to determine the optimal implant size and thereby spare the retraction time required for serial trial placement; this is a technique that is perhaps best left to experienced surgeons. After the interbody has been placed, hemostasis is achieved, and positioning is verified on AP and lateral fluoroscopy. It is at this point that a lateral plate can be placed to increase construct rigidity. If interbody device position is adequate (Fig. 3f, g), then the retractor is removed, and the abdominal wall musculature should return to its native position. The fascia is closed with interrupted 0 Vicryl, the subcutaneous tissue is closed with 3–0 Vicryl, and 4–0 monocryl is used to close the skin in subcuticular fashion (Beckman and Uribe 2017; Ozgur et al. 2006).

Case Illustration

A 62-year-old male presented to the neurological spine service with complaint of acute superimposed on chronic lower back pain of 7- to 8-year duration. The patient also reported minor left lower extremity radiculopathy. The patient had failed several months of conservative management, having tried epidural injections, physical therapy, and trigger point injections without robust benefit. The patient was neurologically intact on exam, and outside MR demonstrated an acute disc herniation compressing the left L5 nerve root. The patient was advised to undergo an L4–5 discectomy with pedicle screw instrumentation. The patient desired a more minimally invasive approach though. ALIF was relatively contraindicated secondary to the patient's significant abdominal obesity, and so an oblique lateral L4–5 discectomy and interbody fusion were offered.

The patient underwent a procedure as previously described in this chapter. He was placed in the left-lateral position, and sharp incision was made through the external oblique, internal oblique, and transversus abdominis in line with the muscle fibers at the level of the midaxillary line. Blunt dissection was used to navigate the retroperitoneal space and

identify the psoas muscle. The psoas was mobilized with bipolar electrocautery, and neuromonitoring was used to guide a tubular retractor to the L4/5 disc space. A subtotal discectomy was performed, leaving the anterior and posterior annulus to maintain graft position. The end plates were prepared, and a size 7 expandable cage packed with allograft was then tamped into place. Placement was confirmed on fluoroscopy, and an anterolateral plate was placed. The patient had an uneventful hospital course with near-immediate improvement of his pain. He is now 6-month postoperatively and is doing well (Fig. 4).

Indications for Plate Usage in Anterior and Lateral Lumbar Surgery

Anterior

As with surgery for degenerative conditions at other levels of the spine, the prime indication for instrumentation in anterior lumbar interbody procedures is to facilitate osseous fusion across the construct – the basis for long-term construct stability. Previous studies (Song et al. 2010) have suggested that the utilization of instrumentation in the spine construct, namely, an anterior tension band plate, can help to both improve the rate of successful arthrodesis and reduce the time to radiographic fusion, which has been reported to take up to 12 months (Blumenthal et al. 1988). Biomechanical studies, such as those of Tzermiadianos and Zhang, have suggested that the reason for these superior fusion outcomes is that the instrumentation helps to maintain positioning of and reduction onto the interbody (Tzermiadianos et al. 2008; J. Zhang et al. 2012). Said opposition is necessary to allow bony ingrowth into the interbody, the first step to osseous fusion. One recent study providing evidence to this end by Liu and colleagues (L. Liu et al. 2014) compared the biomechanical stability – axial compression, flexion, extension, lateral bending, and torsion – across three techniques for L4/5 lumbar interbody arthrodesis: ALIF without instrumentation, ALIF with an anterior fusion plate, and ALIF with posterior pedicle screw instrumentation. They observed that ALIF with anterior plate instrumentation provided superior stability relative to both the ALIF-alone and ALIF with pedicle screw instrumentation. The plate-supplemented ALIF group also had superior

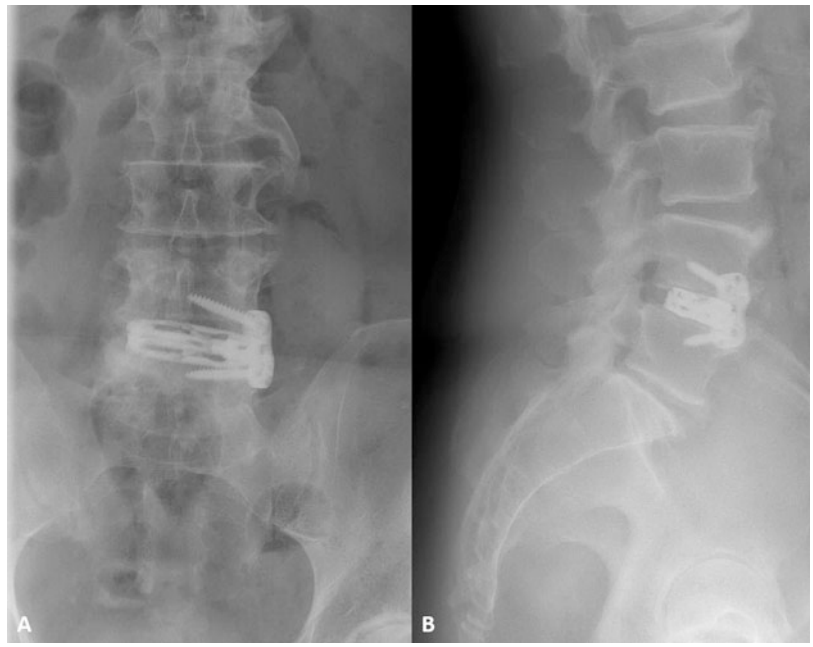

Fig. 4 (**a**) and (**b**) 6-month postoperative imaging of a patient who underwent L4–5 OLIF/XLIF with anterolateral plating for left L5 radiculopathy superimposed on chronic lower back pain

stiffness in terms of flexion, extension, lateral bending, and rotational torsion relative to the group treated with ALIF alone. Similar findings have also been reported by Gerber et al., Beaubien et al., and Tzermiadianos et al. using human cadaver models of lumbar and lumbosacral instability, though the findings of the Gerber group did not achieve the level of statistical significance (Beaubien et al. 2005; Gerber et al. 2006; Tzermiadianos et al. 2008). In all groups, supplemental stability with pedicle screw instrumentation decreased range of motion in lateral bending relative to anterior plating; Tzermiadianos also observed a significant decrease in flexion-extension range of motion relative to anterior tension band plating (Tzermiadianos et al. 2008).

In addition to facilitating long-term fusion, anterior plating can help to reduce the rate of cage migration, which is of greater concern in anterior relative to posterior procedures (Teng et al. 2017). Plating accomplishes this by having the plate function as a sort of retaining device, which traps the interbody between the plate anteriorly and the posterior longitudinal ligament posteriorly (as well as any residual portion of the annulus fibrosis). The plate also provides anterior column support, taking the role of an anterior tension band and preventing excess motion at the treated level (Yoganandan et al.). Evidence that the plate functions in this role is perhaps best supported by Bozkus et al., who compared anterolateral and lateral plating for anterior interbody fusion in a calf spine model (Bozkus et al. 2004). The authors found that while both lateral and anterolateral plates significantly decreased instability and range of motion in flexion-extension, rotation, and lateral bending relative to both sham and interbody-only constructs, the greatest decrease for each plate was in the dimension coplanar with the plate. That is to say the anterior plates provided the greatest stabilization in the flexion-extension plane, whereas lateral plates provided the greatest stabilization in the lateral bending plane, likely because the plate acts as a tension band, restricting motion that attempts to distract the anchor points of the plate.

Lateral

Indications for plating of XLIF/OLIF/DLIF constructs are similar to those of ALIF procedures. The main advantages of plating are increased construct stability (Fogel et al. 2014; Laws et al. 2012) and reduction in the risk of interbody device migration or kickout (Du et al. 2017). The latter concern is more significant in cases where the anterior longitudinal ligament has been disrupted, as such patients have lost a large portion of the annulus responsible for retaining the device. The former has received significant study in in vitro models. One series by Laws and colleagues examined stability of four constructs – stand-alone ALIF or DLIF, plated ALIF or DLIF, and DLIF with unilateral or bilateral pedicle screw fixation – under conditions of flexion-extension, lateral bending, and axial rotation (Laws et al. 2012). Plating of the DLIF construct significantly decreased range of motion in flexion-extension and axial rotation relative to unplated constructs; it also decreased range of motion in all directions relative to ALIF constructs, though these differences were not significant. These results agree with those of Heth, who also found DLIF/OLIF/XLIF to be biomechanically similar to ALIF, if not superior. Fogel et al. conducted a similar study using fresh-frozen cadaveric spines, comparing stand-alone XLIF constructs with those supplemented by either lateral plating or pedicle screw instrumentation (Fogel et al. 2014). Lateral plating provided a similar level of stability to pedicle screw fixation in lateral bending, but not flexion-extension or axial rotation (bilateral pedicle screw fixation only). All instrumentation methods provided significant reductions in axial rotation and lateral bending relative to the stand-alone construct, though the plate did not provide a significant reduction in flexion-extension range of motion. Liu et al. and Reis et al., by contrast, reported a significant reduction only in vertebral end plate stress and lateral bending with application of the plate; axial rotation and flexion-extension were not significantly decreased (X. Liu et al. 2017; Reis et al. 2016). Taken in aggregate, these results, like those of anterior plating, suggest that plates increase construct stability by functioning

as tension bands. As a result, they lead to stabilization primarily in the direction of motion that directly distracts or compresses the plate; they provide only minor stabilization when shearing forces are applied, as occurs with axial rotation and flexion-extension in lateral plates and lateral bending in anterior plates.

Anterior Plates and Other Anterior Fusion Technologies

As previously described, anterior spine fusion was developed more than seven decades ago, and dedicated instrumentation for anterior fusion has been around since at least 1953, when Wenger described the use of anterior instrumentation for the treatment of scoliosis (Dwyer et al. 1969; Ghanayem and Zdeblick 1997). These systems became increasingly popular in the late 1970s though, following the increased incidence of reports on anterior fusion techniques (Bradford and McBride 1987; Dunn 1984; Kaneda et al. 1984; Kostuik 1983; Zielke et al. 1976). Some of the earliest systems to gain mainstream acceptance were the Zielke system (Zielke et al. 1976), the Kostuik-Harrington device (Kostuik 1983), and the Kaneda system (Kaneda et al. 1984). The Zielke system was developed as a less morbid alternative to posterior Harrington instrumentation in patients being treated for scoliosis (Zielke et al. 1976). The later Kaneda system, by contrast, was developed for the treatment of thoracolumbar burst fractures, which commonly involve shorter constructs (Kaneda et al. 1984). Like the anterior Harrington device and biomechanically similar Zielke device, the Kaneda relied upon conventional screw-rod architecture, with screws placed at the superior and inferior instrumented vertebrae and rigid rods bridging the two anchor points (Kaneda et al. 1984). Contemporary in vitro biomechanical studies suggested that these devices, particularly the Kaneda, provided structural stiffness equivalent or superior to posterior Harrington rod instrumentation while requiring the instrumentation of fewer levels (Gurr et al. 1988; Zdeblick et al. 1993). And clinical work suggested that they offered superior decompression of the spinal canal (Bradford and McBride 1987; Ghanayem and Zdeblick 1997). Additionally, all three systems had the advantage of allowing for both compression and distraction. To their detriment however, all three systems were hampered by their relatively bulky nature, which had the potential to irritate prevertebral and paravertebral tissues. As a result, there was an incentive to develop new, lower-profile systems. Results of these efforts including the Z-plate, the University Plate, and the Anterior Thoracolumbar Locking Plate had the benefit of being less bulky and of creating a smaller radiograph artifact due to their titanium construction. Of these different systems, the most widely used of these was the Z-plate. The Z-plate comprised a slotted plate instrumented at the superior and inferior construct levels using two bicortical vertebral body screws at each vertebra. It was designed for short anterior fusion constructs, originally developed for the treatment of thoracolumbar burst fractures (Ghanayem and Zdeblick 1997; McDonough et al. 2004). Several in vitro studies, including those of Hitchon et al. and Dick et al., demonstrated the Z-plate to be biomechanically equivalent to the earlier Kaneda device (An et al. 1995; Dick et al. 1997; Hitchon et al. 2000; Kotani et al. 1999). Of note, Hitchon et al., Kotani et al., and Dick et al. also compared the anterolateral locking plate – the direct ancestor of modern anterolateral plating systems – to these devices. Hitchon et al. noted that the anterolateral plating system produced a less stiff construct than the earlier systems upon instrumentation, but after only 5000 cycles of flexion-extension, the Z-plate system ceased to differ significantly from the anterolateral plate (Hitchon et al. 2000). By contrast, Dick et al. and Kotani et al. found the Synthes® anterior thoracolumbar locking plate to be stiffer than the Kaneda device and Z-plate in axial compression, axial rotation, and lateral flexion (Dick et al. 1997; Kotani et al. 1999). It also had a significantly longer service life as demonstrated on fatigue testing. Since that time, this anterolateral plate and other similar designs have come to dominate the anterior fusion device market.

Currently, over a half dozen different anterior and anterolateral plate systems are commercially

available. The indications for the use of these devices are relatively uniform across manufacturers and include cases requiring anterior lumbar interbody fusion for any of the following reasons: trauma (fracture or dislocation), tumor, low-grade spondylolisthesis, spondylolysis, pseudarthrosis, deformity, and failed back syndrome. Similarly, contraindications to their use are relatively uniform, including active systemic or local infection, inadequate mechanical support (tumor infiltration, severe osteoporosis, metabolic bone disease), patient history of foreign body reaction or sensitivity to metal implants, risk factor for poor wound healing (e.g., insufficient tissue to cover implant), conditions that would place excessive load on implant during the healing period (e.g., significant obesity), and any general contraindications for surgery (e.g., concurrent drug use or psychiatric illness).

Material Selection

The majority of plates currently on the market are composed of titanium or titanium alloy. These materials are generally stronger for a given size than are stainless steel implants, which allow titanium plates to be thinner for any given combination of tensile and compressive strengths. Titanium instrumentation is also more amenable to postoperative follow-up with magnetic resonance imaging than is stainless steel or chrome-containing instrumentation. Unlike the latter, which are ferromagnetic, titanium and titanium alloy implants are paramagnetic and so produce substantially smaller artifact on MR (Do et al. 2018; Tahal et al. 2017). Additionally, the local tissues are generally thought to respond more favorably to the use of titanium implants as compared to either stainless steel or chromium-based implants (Gibon et al. 2017; Tahal et al. 2017). Chromium-based implants can be particularly irritating as they trigger cytotoxic reactions in the local tissue, which may weaken the surrounding osseoligamentous structures, though no evidence to date exists to suggest that this leads to significantly different clinical outcomes. Chromium and stainless steel-based implants are also more likely to generate delayed-type hypersensitivity reactions at the site of implantation due to the osteoclast-induced release of nickel and chromium ions from the implants (Gibon et al. 2017). Nickel and chromium ions are two of the most common causes of metal sensitivities among the general population, and so we prefer the utilization of titanium-based implants when available, unless other biomechanical considerations suggest the patient would benefit from the superior fatigue strength provided by chromium-based implants (Tahal et al. 2017).

In addition to the concern of local tissue toxicity, the propensity of an implant to serve as an infection nidus as well as implant fatigability is an important concern. The latter consideration is of biggest concern among young patients, given that the implant will undergo a substantial number of loading cycles over the course of its service life – estimated at two million cycles per year (Graham 2006). Previous research has failed to demonstrate substantial differences in the fatigue strength of titanium and titanium alloy plates relative to stainless steel implants (Pienkowski et al. 1998). However, several studies have demonstrated a lower incidence of biofilm formation and surgical site infection among those persons instrumented with pure titanium implants, as compared to either stainless steel or titanium alloy implants (Tahal et al. 2017).

Plate Design

As discussed, most commercially available anterior lumbar plates are composed of pure titanium or a titanium alloy (e.g., Ti-6Al-4 V/TC4, nitonol) due to the superior mechanical properties and greater tolerance by local tissues. The variability among implants is largely based upon implant shape, length, and screw fixation. Both straight and prelordosed plates are currently available, with the latter providing a better anatomic match to the native anatomy. This better approximation of the lumbar and lumbosacral lordosis may improve the rigidity of the construct and so reduce the rate of pseudarthrosis and need for reoperation, though no direct comparisons

currently exist. Like the more traditional straight plates, prelordosed plates are available in both one- (25–54 mm length depending upon the manufacturer) and two-level lengths (65–89 mm depending upon the manufacturer) for instrumentation at the lumbar spine or lumbosacral junction, with most manufacturers offering their plates in 3-mm size increments. Both fixed-angle and variable-angle screw systems are available, with both systems generally utilizing two 5.5–6.0 mm screws at the inferior instrumented level and one or two 5.5–6.0 mm screws at the superior instrumented level.

Variable- Versus Fixed-Angle Devices

The relative merit of a variable-angle plate, as compared to a fixed-angle plate, is rooted in the ability of the surgeon to select the screw angle when placing instrumentation. This presupposes that certain screw angles confer superior pullout strength relative to others, a conclusion that has mixed support in the current literature. Work by DiPaola et al. on cervical spine plates in a polyurethane block model has suggested that orthogonally positioned screws have superior pullout strength relative to other orientations (DiPaola et al. 2007, 2008). This is perhaps because the orthogonal angle places each thread perpendicular to the force vector, allowing it to maximally resist pullout. Regardless of the biomechanical underpinning, the said results favor the variable screw model over fixed-angle instrumentation, as the former enables the attending surgeon to place screws along optimal trajectories even in cases of suboptimal implant-bone apposition. Rodríguez-Olaverri et al. reach a similar conclusion regarding the importance of screw trajectory (Rodríguez-Olaverri et al. 2005). In their thoracolumbar calf spine model, Rodríguez-Olaverri placed bicortical polyaxial screws linked by a single 5.5 mm cobalt-chrome and then subjected the construct to 10,000 cycles of lateral bending with a 100 N load. Unlike DiPaola, they found that superior construct stabilization was provided by angled screws; however, like the former, they concluded that screw trajectory had a significant impact on construct service life. This favors instrumentation that affords the surgeon options when placing instrumentation, as is offered by a variable-angle system.

By contrast, Rios and colleagues failed to demonstrate said advantages to variable screw angle systems (Rios et al. 2012). Using a similar polyurethane block model, they investigated the relative pullout strength of anterior ALIF plates with screws fixed in one of nine different orientations, varying in both sagittal and coronal angulation (Rios et al. 2012). Though they noticed some minor but significant differences between the strongest and weakest trajectories, they failed to observe superiority of any trajectory over the neutral or "straight-in" trajectory. This suggests that the ability to select screw trajectory confers no mechanical advantages, in turn indicating the non-inferiority of fixed-angle systems. These results were replicated by Patacxil et al. and Hadley et al., the latter of whom also found no difference between variable- and fixed-angle plates in a cadaveric model (Hadley et al. 2012; Patacxil et al. 2012). Additionally, cohort studies by Oh and Hong examining radiographic outcomes in patients having undergone anterior cervical discectomy and fusion report similar findings, with the Hong group finding that fixed-angle plates may actual reduce the risk of graft subsidence (Hong et al. 2010; Oh et al. 2013). Given these mixed results, we believe that insufficient evidence exists to recommend variable-angle designs over conventional, fixed-angle designs. Rather, the plate type used should be based upon surgeon experience.

Interbody Design

Lumbar interbody devices have been used in spine surgery for more than three-quarters of a century, having been first described in 1944 by Briggs and Milligan (de Kunder et al. 2018). Their original procedures utilized a posterior approach and made use of an allograft bone peg with external fixation to facilitate fusion. Cloward published a larger series in 1953 describing a similar technique using multiple bone grafts to reduce the procedural morbidity (de Kunder et al. 2018).

From there, interbody devices remained relatively unchanged until the invention of the Bagby basket in 1986 for the treatment of Wobbler syndrome in horses – a myelopathic condition seen secondary to cervical instability in these animals (DeBowes et al. 1984; Phan and Mobbs 2016). This device was novel in that it utilized autograft-packed titanium implants, which had significant greater compressive strength than did the earlier bone graft interbody devices utilized by Briggs and Milligan (de Kunder et al. 2018). The Bagby device, or rather its successor – the BAK device – was quickly adapted by Kuslich and colleagues (Phan and Mobbs 2016), who described its use for posterior lumbar interbody fusion in 1992 (Kuslich et al. 1998). Within the decade it was approved for anterior interbody fusion, and several biosimilar devices had been presented, including the threaded cage of Ray (1997), mesh cage of Harms and Biederman, and the tapered or trapezoid-shaped cages which have become increasingly popular (Phan and Mobbs 2016). Previous in vitro analyses have suggested gross biomechanical equivalency among these different design types, though threaded cages, such as the BAK device, may provide lower intracage pressures and thereby help to protect cancellous graft placed within the cage (Kanayama et al. 2000).

PEEK and carbon fiber interbodies were also developed during the 1990s and early 2000s in order to serve as an alternative to the titanium interbodies (Brantigan and Steffee 1993; D. Cho et al. 2002; Phan and Mobbs 2016). The former had the advantage of better approximating the elastic modulus of bone and lacked the substantial radiographic artifact produced by titanium devices (Phan and Mobbs 2016). Interbody devices made from all three materials are now available, both for the traditional retroperitoneal anterior approach (ALIF) and for the lateral approaches (OLIF, XLIF). These devices offer a range of lordosis and footplate dimensions, allowing the surgeon to optimize the device to each patient. All three of these parameters – composition, lordosis, and cross section – should be considered during surgical planning.

Material

The three main materials used for anterior lumbar interbody fusion are femoral ring allograft, titanium or titanium alloy, and polyether-ether ketone (PEEK). Each material has its relative advantages and disadvantages. Ring allograft and PEEK better approximate the elastic modulus of native bone compared to titanium interbody devices (Phan and Mobbs 2016), which may reduce the risk of pistoning and implant subsidence (Niu et al. 2010; Seaman et al. 2017). Though pistoning is concern in all patients, it is most common in patients with low bone density and should be given greater consideration in osteoporotic patients, such as postmenopausal women (Melton et al. 1992).

PEEK cages and femoral ring allograft also allow for superior radiographic follow-up, as they produce no artifact on computed tomography imaging. This allows fusion across the construct to be more easily assayed than in constructs using titanium implants. Given that 11–23% of patients treated with anterior interbody fusions may experience nonunion (C. S. Lee et al. 2011), the ability to assess osseous fusion may favor the use of these materials, especially in patients at high risk of pseudarthrosis (e.g., those with current or previous history of cigarette use) (Phan et al. 2017). Despite this, studies comparing interbody fusion with PEEK vs. Ti implants have suggested that titanium interbody devices provide equal (Niu et al. 2010) or superior rates (Spruit et al. 2005) of arthrodesis. Consequently, the superior fusion monitoring available in PEEK constructs may be negated by the inferior overall fusion rates.

The reason for inferior fusion rates in PEEK implants has not been definitively established, though current evidence suggests that PEEK devices offer less bony contact per unit end plate area. This difference is most significant when comparing to the newer plasma-treated titanium interbody devices (Pelletier et al. 2016) whose porous surfaces allow for the rapid ingrowth of cancellous bone (Chang et al. 1998). Additionally, although the greater yield strength mismatch seen in constructs containing titanium interbody devices may increase the risk of implant subsidence, the high yield strength of the titanium

interbody increases the initial stability of these constructs relative to PEEK constructs (Spruit et al. 2005). As a result, such constructs are likely to better maintain graft-end plate opposition during the critical period when fusion is occurring. This may also contribute to the superior fusion rates observed in some studies. Lastly, prior in vitro studies have demonstrated PEEK to be hydrophobic and therefore biochemically inert, meaning that commercially available implants rely upon a surface coating of hydroxyapatite or biocomparable material in order to promote osseointegration (Briem et al. 2005; Dennes and Schwartz 2009; Durham et al. 2017; Noiset et al. 1999; Zhao et al. 2016).

At least some of these concerns – chemical inertness and lower contact area per end plate area – can be addressed by employing a hybrid interbody device, one comprised of a PEEK body with porous titanium face plates. The said devices have the advantage of superior osteoconduction at the titanium end plates (Han et al. 2010; X. Wu et al. 2012), while maintaining a yield modulus similar to that of natural bone. Preliminary in vivo studies by Han et al. using a rabbit model of spine fusion found that titanium-coated PEEK implants had bone-to-implant contact that was nearly twice as great as standard PEEK implants (Han et al. 2010), consistent with earlier in vitro studies demonstrating superior survival of osteoblast cell lines on titanium-coated implants (Han et al. 2010; X. Wu et al. 2012). Additionally, biomechanical analysis of an in vivo PEEK-titanium composite interbody demonstrated it to have superior strength in terms of axial rotation, flexion-extension, and lateral bending as compared to a conventional PEEK interbody device (McGilvray et al. 2017). These differences were progressively more pronounced with increasing follow-up, suggesting that their greatest advantage relative to conventional devices may be in terms of longer service life. The titanium-coated PEEK implants are not without their drawbacks though. Recently, Torstrick and colleagues reported the results of an in vitro comparison of conventional PEEK, porous PEEK, and plasma-sprayed titanium-coated PEEK interbody devices (Torstrick et al. 2018). Using a polyurethane spine model and guided weight impactor, the authors applied compressive forces to the interbody devices. While both pure PEEK devices showed minimal surface damage on SEM, the titanium-coated device showed a significant decrease in surface roughness, which may nullify the potential bone ingrowth advantages conferred by the titanium coating.

Another innovation designed to combine the advantages of PEEK and titanium interbody devices is porous titanium cages, which have only become commercially viable with the increased availability of 3D printing technologies. The first description of porous metal interbody devices for spinal fusion was by Levi et al., who described the use of porous tantalum implants in a cadaveric model of anterior cervical discectomy and fusion (Levi et al. 1998). A half-decade later, Assad and colleagues described the use of a porous titanium-nickel interbody for lumbar intervertebral fusion in a sheep model (Assad et al. 2003a, 2003b). Using standard lateral radiographs, the authors demonstrated superior bone bridging and periprosthetic radiolucency at 3 and 6 months postoperatively in animals instrumented with porous interbodies as compared to traditional titanium alloy implants (Assad et al. 2003b). Takemoto et al. reported similar findings using a porous titanium implant with 50% porosity in a canine model, which they attributed to the superior bony contact of the porous implants (Takemoto et al. 2007). Furthermore, they reported that these implants had yield compressive strengths similar to that of cortical bone – 80–120 MPa – meaning that they are theoretically less likely to suffer from implant pistoning than are traditional titanium implants. This yield strength is superior to that of porous tantalum implants, and the fact that these implants do not incorporate nickel, like those of Assad, means that they are not associated with the potential downsides of this material, namely, concerns over intraspinal metallosis and neurological deficits (del Rio et al. 2007; Takahashi et al. 2001). Fujibayashi et al. reported the first clinical series of patients treated with these implants, describing successful radiographic fusion within 6 months in five individuals who underwent TLIF with 60%

porosity implants (Fujibayashi et al. 2011). Several contemporaneous studies in animal models demonstrated that such devices had superior osseointegration as compared to PEEK implants, as well as superior mechanical stability for flexion-extension, axial rotation, and lateral bending (S. Wu et al. 2013). More recently, McGilvray and colleagues reported the result of an ovine lumbar fusion model directly comparing PEEK, porous titanium-coated PEEK, and 3D-printed porous titanium alloy interbody devices (McGilvray et al. 2018). Using micro-computed tomography and histology to evaluate fusion, and biomechanical analyses to evaluate construct stability, the authors demonstrated significant reductions in flexion-extension range of motion, increases in bony ingrowth, and increases in stiffness for the porous titanium cages relative to both the titanium-coated and convention PEEK interbody devices. The porous titanium implants are also less likely to fragment with application of compressive forces and hence may demonstrate better wear over the life of the device (Kienle et al. 2015). Further studies are required, but it appears as if the porous titanium interbodies may provide the overall best option in a cost-neutral comparison. Additionally, although some in vitro (MacBarb et al. 2017a) and in vivo animal (MacBarb et al. 2017b) evidence suggests that 3D-printed porous titanium devices are superior to conventional plasma-spray-coated implants with respect to bone infiltration, no clinical series exist to support this finding. The relative superiority of these devices is likely to depend upon the relative porosity though, with greater porosity offering greater bony ingrowth (Li et al. 2007; Taniguchi et al. 2016; de Vasconcellos et al. 2010) and lower stresses inside the implant (Z. Zhang et al. 2018) but coming at the cost of decreased construct stability (Z. Zhang et al. 2018).

Dimensions

When selecting dimensions for an anterior interbody, the goal should be to restore the native anatomy, in terms of disc height, foraminal diameter, and lumbar lordosis. To address both end points, most cage manufacturers offer their interbody devices in a variety of heights and lordosis angles, including hyperlordotic interbody devices, which may restore up to 30 degrees of lordosis per instrumented level (Saville et al. 2016). When selecting dimensions for the interbody, it is also important to consider the size of the end plates of the superior and inferior vertebral levels (Phan and Mobbs 2016). These surface areas should be determined preoperatively to select the widest interbody that can be safely placed at the discectomy level (Lowe et al. 2004). In vitro studies have shown that at bare minimum, the selected interbody should cover 30% of the end plate to prevent graft subsidence (Closkey et al. 1993). Ideally, the implant should be wide enough to engage the edges of the end plate, but not so large as to damage surrounding tissues. Doing so allows the interbody to engage cortical bone at the vertebral body in addition to cancellous bone, producing a more even distribution of stress on the adjacent vertebral levels (Kumar et al. 2005). Additionally, engaging the cortical bone, which has a significantly higher yield strength (Fyhrie and Vashishth 2000; Kutz et al. 2000), reduces the likelihood of implant subsidence – a nontrivial concern in fusions with titanium interbody devices. And there is some suggestion that the wider implants – at least for the XLIF/DLIF procedure – may provide a stiffer construct (Pimenta et al. 2012).

The risk of pistoning can be further decreased by insertion of bone graft into and around the interbody device, both of which increase the effective cross section of the implant and provide osteoconductive material to facilitate fusion (Kumar et al. 2005). Furthermore, previous research in the posterior lumbar interbody fusion literature has demonstrated fusion rates to be directly correlated to the contact area between the cage and the bony end plates. One prospective series, published by Seo et al., examined 60 patients undergoing instrumented PLIF using bilateral autograft-filled titanium cages (Seo et al. 2017). They observed that bone between the interbody devices fused in 100% of patients, whereas graft circumscribing the region bounded by the interbody devices only fused in 72.3% of patients.

Integrated Fixation Cages

Another option for interbody fusion is the use of an integrated fixation cage (IFC) or stand-alone interbody device, which first appeared on the market 15 years ago. These devices incorporate the instrumenting screws directly into the interbody and so eliminate the need for an anterior plate. This allows for a technically simpler procedure and may help to reduce operative room times.

As with any new technology, one of the questions that must be asked when considering instrumentation with an IFC is whether said device will provide similar rigidity to traditional interbody-plate constructs. A handful of publications have been presented to date directly comparing plate and IFC constructs (Beaubien et al. 2009, 2010; Kornblum et al. 2013; Palepu et al. 2017). The first of these was presented by Beaubien et al., who examined the stiffness of various interbody constructs in cadaveric spines, including traditional plate-interbody and stand-alone IFC constructs (Beaubien et al. 2009, 2010). They found that although the latter construct exhibited significantly greater motion in flexion and extension, it possessed significantly greater pullout resistances, in part, because failure required fracture of all bone surrounding the integrated screws. Similar findings were reported by Kornblum and colleagues (Kornblum et al. 2013), who noted that IFC constructs had inferior stability in flexion-extension motion relative to plate systems. More recently though, a study by Palepu and colleagues (Palepu et al. 2017) reported no difference in the flexion-extension stabilities of the two constructs. These authors compared the constructs in cadaveric human lumbar spines across 20,000 cycles of flexion-extension loading and found similar stability in flexion-extension and lateral bending motions at the time of implantation and throughout fatigue testing. Interestingly, they also found the IFC constructs to provide superior stability at implantation and throughout testing in terms of axial rotation, suggesting that newer devices may have addressed the biomechanical shortcomings of previous designs.

Of the IFC devices on the market today, the majority has similar construction – they utilize a lordosed PEEK interbody cage with an anterior titanium face plate through which 5.0 mm or 6.0 mm lag screws are placed. The interbody sizes available vary across manufacturer, but most offer interbody heights of 10–20 mm (in 2 mm increments) with anywhere between 4° and 16° degrees of lordosis and end plates between 22 × 30 mm and 28 × 40 mm. The various commercially available cages vary in the number of lag screws incorporated, using anywhere between two and four lag screws for fixation. Previous studies examining the stability of these devices (Kornblum et al. 2013) have not demonstrated significant differences between them, suggesting that cage selection should be based upon surgeon preference. Two more recent technologies include the use of variable-angle screws for fixation and the incorporation of plasma-treated titanium end plates. In a cadaveric study comparing blade-type, fixed-angle screw, and variable-angle screw devices, Freeman et al. reported that fixed-angle cages had higher pullout strengths relative to the other two technologies (Freeman et al. 2016). No confirmatory studies have been performed yet; however studies from the plate literature suggest that variable-angle and fixed-angle systems may be equivalent (Hadley et al. 2012; Patacxil et al. 2012). Similarly, no studies have been performed to compare fusion rates of the new Ti-coated PEEK IFC to those of the conventional IFC devices, but it seems likely that the former may demonstrate superior fusion rates.

BMP and Profusion Agents

As with other spine procedures, anterior interbody arthrodesis has traditionally relied on bone allograft and autograft to facilitate fusion across the construct. This bone is usually incorporated directly into the device, though as mentioned previously, it may also be packed around the implanted interbody device. Kumar et al., using a computerized model of lumbar interbody fusion, demonstrated that incorporation of cancellous graft into and around the device

decreases the load placed by the implant on the adjacent end plates, presumably by increasing the effective end plate cross section of the implant itself (Kumar et al. 2005). In so doing, this supplementation may help to decrease the risk for implant subsidence.

Other osteoinductive and osteoconductive technologies are available for use in patients who are deemed to be at higher risk for pseudarthrosis. These include demineralized bone matrix, bone graft substitutes or bone putties, hyaluronic acid, and bone morphogenic protein; in fact, the ALIF procedure is the only one for which rhBMP-2 use is currently approved by the FDA. Previous evidence has suggested that demineralized bone matrix provides similar fusion rates to traditional autograft (Fu et al. 2016), and similar findings have been reported for the other bone graft extenders, including calcium phosphate crystals and ceramic-based substitutes (Gupta et al. 2015). By contrast, numerous studies have observed superior rates of fusion in patients receiving rhBMP-2 (Boden et al. 2000; Burkus et al. 2002, 2003, 2009; Glassman et al. 2008; Gupta et al. 2015; Hustedt and Blizzard 2014), including several prospective randomized trials (Boden et al. 2000; Burkus et al. 2002), which led to its approval by the FDA in 2004. BMP use has been previously associated with higher complication rates in the cervical spine despite improving fusion rates, but evidence to support this in the lumbar spine is not conclusive. As a result, it is recommended that rhBMP-2 use be considered in all patients at high risk for nonunion, including smokers (Jackson and Devine 2016), older patients (Y. J. Kim et al. 2005, 2006), obese patients, those with low osteoblast-to-osteoclast activity (Inose et al. 2018), those with hypovitaminosis D (Ravindra et al. 2015), and those with histories of nonunion (Glassman et al. 2008). Osteoporosis, while a relative contraindication to surgery due to increased risk of implant failure, may not be a risk factor for nonunion. The evidence to support this conclusion is weak however (van Wunnik et al. 2011; Zura et al. 2016) and does not disentangle low bone density from advanced age, which has been previously associated with a decreased likelihood of nonunion (Zura et al. 2017). Obesity may similarly be a risk factor for nonunion (Zura et al. 2016) and so be an indication for the use of rhBMP-2. Evidence from the area of long bone fusion supports this (Meidinger et al. 2011), but studies on the role of obesity in spinal fusion nonunion are lacking.

Conclusion

The anterior and lateral lumbar interbody arthrodeses are robust constructs that remain an effective option for multiple pathologies of the lumbosacral spine. They allow for anatomic correction of disc height loss and for placement of larger interbody devices than can be placed through more traditional posterior interbody fusions, such as the TLIF or PLIF. Conventionally, anterior fusion has been accomplished through a combination of interbody placement and anterior plating, which reduces cage kickout and increases the stability of the construct to prevent early construct failure. In recent years, integrated fusion cages (IFC) – interbody devices with incorporated lag screws to prevent pullout – have become available. These devices allow for more expedient construct completion, and recent research suggests that they may provide stability equivalent to more traditional plate-interbody systems. Additional new technologies are being brought on the market every year, including interbody and integrated fixation cage devices with plasma-treated titanium end plates, which allow for superior osseous fusion rates relative to traditional PEEK interbody devices. Because of this continued innovation, it is apparent that the ALIF remains a valued option for select patients with pathology of the lumbosacral spine.

Contents

Abstract

Interbody cages represent an invaluable technologic advancement in the field of spinal fusion surgery, particularly anterior cervical discectomy and fusion (ACDF). Interbody cages improve sagittal alignment, aid in fusion by allowing for containment of graft material, and restore biomechanical stability after discectomy. Various design iterations and materials have been used over the last two to three decades, and advancements in materials

science and cage properties have provided improved functional utility of interbody cages in ACDF surgery. This chapter provides an overview of the history of cervical interbody cages, including improvements in design, material, and methods of manufacturing processes of cervical interbody cages that have yielded the designs most commonly utilized today.

Cervical · Interbody · Cage · Spine · Fusion · Bone graft

Introduction

The first cervical interbody fusions were pioneered by neurosurgeons in the 1950s for early anterior cervical discectomy and fusion (ACDF). These procedures were developed as alternatives to posterior fusions to treat cervical radiculopathy and myelopathy. In 1958, Cloward described an anterior approach for cervical interbody fusions. This technique utilized bone dowels inserted horizontally between the adjacent vertebrae, from an anterior to posterior direction, following the decompression (Cloward et al. 1958). The vertebral bodies were prepared with a drill, and the bone dowel was cut slightly larger than the drilled defect and seated with distraction and impaction. These bone grafts were typically iliac crest autograft or, less commonly, allograft bone cut into cylindrical dowels. Robinson and Smith described a similar technique that utilized the same anterior approach and decompression, but instead used a rectangular graft in place of a cylindrical bone dowel. This technique required less augmentation and preparation of the adjacent vertebral bodies. Another advantage of this rectangular graft is that it provided a greater surface area compared to cylindrical grafts (30% more of similar size), which was theorized to provide better contact surface for revascularization and fusion (Robinson and Smith 1958).

In 1969 Simmons and Bhalla published a modification of this same technique. They utilized the same anterior approach and decompression, but instead used a "keystone"-shaped bone graft. This keystone shape was a beveled modification of the rectangular graft, making it thicker posteriorly than anteriorly. This required the adjacent vertebrae to be modified similarly. These "keystone" grafts performed superiorly in biomechanical studies demonstrating less extrusion in comparison to simple rectangular or dowel grafts with flexion and extension of the spine. In a clinical study, they also performed more superiorly than interbody fusions performed with dowel bone grafts with 3/17 symptomatic nonunions in the dowel group compared to none in the keystone group. Various original ACDF implant designs are shown in Fig. 1.

Donor site morbidity has been reported as high as 22% (McConnel et al. 1976), and is a known disadvantage to iliac crest autograft, and led to the development of alternative graft materials. Allograft was one of the most widely studied alternatives. It initially provided mixed results in clinical trials and had the downsides of significantly increased costs, slower fusion rates, and the theoretical risk of disease transmission (An et al. 1995; Bishop et al. 1996; Brown et al. 1976); however, recent studies have shown that a ACDF with autograft vs. allograft, particularly with anterior plate fixation, is nearly equivalent clinically and radiographically (Kaiser 2002 Neurosurgery). Poly(methyl methacrylate) (PMMA) was another alternative that was described. It offered a graft with immediate stability of the adjacent vertebrae, but it provided no ability to achieve fusion and was therefore abandoned (Bent et al. 1996). Biocompatible osteoconductive polymer (BOP) and coralline hydroxyapatite were two other promising bone graft substitutes, but both were ultimately found to be inferior to autograft in clinical trials. BOP was biomechanically similar to autograft, but demonstrated little ability to incorporate into host bone (Ibanez et al. 1998). Hydroxyapatite was structurally weak and demonstrated graft subsidence and fragmentation (McConnell et al. 2003). Despite a number of different alternatives studied, autograft continually demonstrated superior outcomes in both biomechanical studies and long-term clinical trials and therefore remained the gold standard.

The failure of graft substitutes forced a shift in the pursuit of viable alternatives. In 1988, Bagby proposed the first use of interbody cages in the human spine. He adapted a technique previously described by DeBowes to treat cervical myelopathy in horses (Bagby 1988, DeBowes et al. 1984). This device consisted of a hollow cylindrical stainless steel cage with fenestrations which was placed through an anterior approach similar to ACDF. This structure allowed bone ingrowth and provided a non-compressible scaffold (Chong et al. 2015). Interbody cage designs were developed out of necessity due to the associated morbidity of iliac crest autograft harvest. Various cage designs and materials have been since been trialed and variably adopted as the technology has advanced.

Cage Design

Cervical interbody cages may circumvent donor site morbidity associated with autograft and infection associated with allograft. For example, autologous iliac crest bone harvesting has been shown to be associated with 22% long- or short-term complications (McConnell et al. 2003). Due to their ease of use, rigid cages with internal space for local autogenous bone graft or morselized allograft with or without osteoinductive materials such as platelet-rich plasma or bone marrow aspirate fragments have become increasingly popular for cervical interbody fusions. Interbody cages have shown to be a successful means of cervical interbody body fusion with associations with less post-operative pain, shorter hospital stays, and higher rates of fusion than autologous bone graft alone (Jain et al. 2016). The ideal cage provides immediate structural supports (axial compression/anterior column distraction), adequate resistance to subsidence, and avoidance of structural allograft complications. Overall goals are to stabilize the newly operated segment to allow new boney ingrowth, maintain anatomic disc height, and avoid cage subsidence until fusion has occurred (Matgé 2002). Cage subsidence is associated with neck pain, late neurologic deterioration, and significantly lower Japanese Orthopaedic Association scores (Chen et al. 2008). Stand-alone interbody cervical cage implantation has shown to be effective with good clinical and patient-reported outcomes (93–100%) despite increased subsidence rates as compared to that with plating

or cage/bone grafting hybrid techniques (Kulkarni et al. 2007).

The basic design of cervical interbody cages encompasses a small, hollow implant with upper/lower and/or lateral windows in which autogenous bone, allograft bone, and/or osteoinductive materials may be placed (Chong et al. 2015; Wilke et al. 2000). Traditionally cage designs can be categorized into threaded (screw, horizontal cylinder) and non-threaded (open box-shaped and vertical rings/cylinders) (Chong et al. 2015; Kandziora et al. 2001). Horizontal cylinders/screws are the manufactured equivalents to allograft dowel techniques, while vertical ring cages are designed to mimic cortical ring allografts. Open boxes are the equivalent of tricortical or quadricortical graft (Weiner and Fraser 1998).

Threaded Cages

Screw Cage Designs (Horizontal Cylinder)

Examples: BAK/C (Zimmer Spine), Ray Threaded Fusion Cage (Surgical Dynamics)

A variety of cervical interbody cages exist, but the most common is the threaded titanium interbody cage. Some of the earliest available cages were described as horizontal cylinder or screw design cages. These cages were based on Cloward's original technique and functioned as dowel grafts. Screw cages, also known as horizontal cylinder cages, have a circular cross section in the coronal plane. Fenestrations along the device allow for contact between prepared endplates and non-structural bone graft or osteoinductive biologic material placed into core. Reaming is usually required to allow proper fit for cages (Pisano et al. 2016). One example of this cage design is BAK-C (Zimmer Spine, Warsaw, IN) which demonstrated device stability, accelerated fusion rates, and higher stiffness when compared to more traditional non-threaded tricortical iliac crest bone graft (Matgé 2002; Chong et al. 2015; Kandziora et al. 2002) (Banco et al. 2002). Another threaded cage design, the Ray Cervical interbody cage (Surgical Dynamics, Norwalk, CT), is shown implanted at C5-6 in the representative post-operative radiograph demonstrated in Fig. 2.

Following initial success, the failures of the threaded screw design were found to be associated with decreased maximum distractive height and increased levels of cage subsidence due to adjacent vertebral endplate weakening. Additional biomechanical studies by Kandziora et al. and others showed threaded screw designs to be less stable in flexion/extension/bending in animal models (Kettler et al. 2001; Kandziora et al. 2001; Jain et al. 2016).

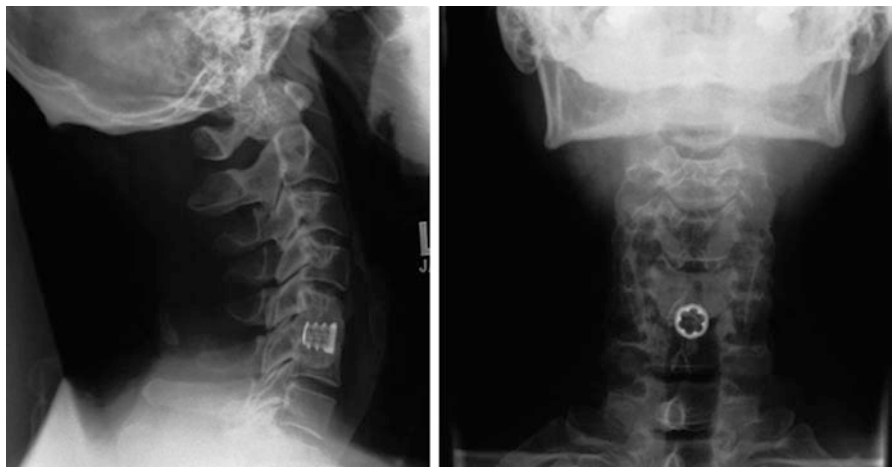

Fig. 2 (**a**) Anterior-posterior and (**b**) lateral X-rays of the cervical spine with the Ray Cervical interbody cage (Surgical Dynamics, Norwalk, CT). Used with permission from Banco et al.

By virtue of the shape of the screw cage designs, there is less space available for bone graft than obtained for either vertical ring or open box designs. The use of the BAK/C and other threaded horizontal cylinder devices has declined due to excessive endplate violation needed for insertion of device.

Non-threaded Cages

Box-Shaped Designs

Example: SynCage-C (DePuy Synthes, Raynham, MA)

Rectangular box cages initially were designed with roughened contact surfaces to improve anchorage and fusion into adjacent cervical vertebral bodies. These cages employ a design that mimics iliac crest cortical graft, with a vertically oriented box with central core allowing bone graft placement (Pisano et al. 2016). This design has demonstrated better segmental stiffness in all directions as compared to tricortical iliac crest (Kandziora et al. 2001). This design has undergone further improvements for surface fit and cage anchorage such as incorporating wedge-shaped and trapezoidal designs as well as attempting to mimic shape of vertebral endplate contours (Chong et al. 2015; Steffen et al. 2000; Kast et al. 2008). Inversely matching cervical vertebral endplate contours allows wedge-shaped box morphology to contribute to increased stability in lateral bending, axial rotation, and flexion as compared to other designs (Kast et al. 2008). Goals of wedge-like box-shaped designs are to match natural cervical lordosis by using anterior slope with 1–2 mm larger box height anteriorly than posteriorly (Gödde et al. 2003; Chong et al. 2015).

The SynCage-C (DePuy Synthes, Raynham MA) is a box form cage with both superior and inferior contact surfaces. The superior cage endplate opens to central contiguous pore (Epari et al. 2005). Within the non-threaded box-shaped design group, there is variability in manufacturer modifications. In Fig. 3, a rendition of SynCage-C is shown from the anterior view with varying superior and inferior endplate modifications.

Vertical Ring (Cylinder) Cages

Example: Harms Cage (DePuy Synthes, Raynham, MA)

Vertical ring cage design is an adaptation of cortical ring allograft interbody fusion described by Ono et al. and popularized by Kozak and O'Brien (Weiner and Fraser 1998; Kozak and O'Brien 1990; Ono et al. 1992). Vertical rings are typically cylindrical mesh cages with vertically oriented walls that have a circular cross section in the

Fig. 3 SynCage-C (DePuy Synthes) is a box-shaped design-type cage. Representative image of the cage from an anterior view, used with permission from *Epari* et al.

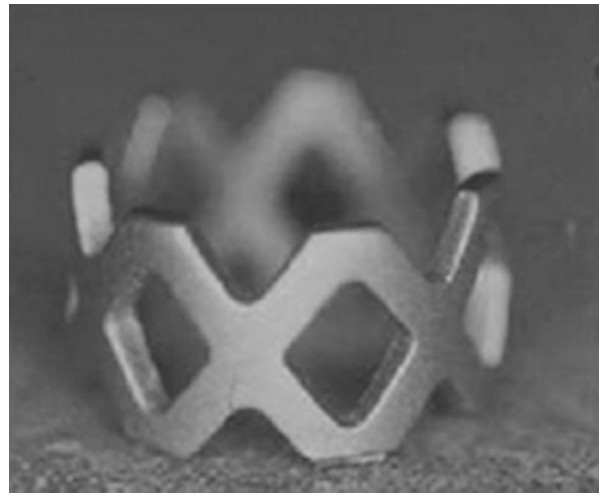

Fig. 4 An example of a Harms cage, which is a vertical cylinder of titanium mesh. Used with permission from *Epari* et al.

axial plane. With a cylindrical shape, the central portion of this graft design accepts autograft and allograft (Pisano et al. 2016). Vertical rings or cylindrical designs commonly lack superior and inferior contact surfaces in contrast to those seen in box-type non-threaded cage designs. Proponents argue that the lack of inferior and superior contact surfaces along with decreased rigidity in meshed walls results in reduced rigidity of cage and provides ingrowth path for vessels and bone (Epari et al. 2005). Cylindrical implants have been shown to subside greater than tricortical autograft, allograft, and rectangular box constructs (Wilke et al. 2000). The Harms cage is a hollow vertical cylinder design and has the largest possible pore size for its volume (Epari et al. 2005) (Fig. 4).

Due to their ability to mimic healthy cervical anatomy and confer initial stability with improvement in initial surface contact, non-threaded cages remain superior to threaded/screw design cages biomechanically (Chong et al. 2015). When comparing subsidence between a vertical ring and box design cages, Kandziora et al. showed similar amounts of endplate penetration despite having very different endplate surface area contact (Kandziora et al. 2001; Epari et al. 2005). A reduction in stiffness of interbody fusion cages in animal models has been shown to enhance interbody fusion after 6 months and up to 3 years (Epari et al. 2005; van Dijk et al. 2002). However, the clinical literature comparing cage design and shape is limited (Chong et al. 2015). Overall trends in surgeon usage had favored wedge-shaped/trapezoidal non-threaded cages, although the clinical outcome data comparing threaded versus non-threaded is sparse. These reported trends may be due to ease of implantation, restoration of cervical lordosis, and greater segmental stiffness with wedge-shaped/trapezoidal non-threaded cages (Chong et al. 2015).

Other Cage Considerations/Current Trends

Newer hybrid interbody cage devices incorporate plate and screw recesses. The cage functions as an anchored spacer with integrated screw construct allowing immediate fixation (Samandouras et al. 2001). The impetus for these new design concepts most likely is derived from increasing popularity of stand-alone cages and recognized issues of subsidence, anterior displacement, and varying results in fusion rates. In vitro studies have revealed that combined use of cage and plate is more stable biomechanically in flexion/extension than stand-alone cage constructs with bone graft (Shimamoto et al. 2001) (Keogh et al. 2008).

Expandable cages, originally used for larger oncologic en bloc resections, have become more popular for degenerative cervical conditions. Proponents of this technique tend to argue that the previously described methods for cage implantation ensure segmental endplate over-distraction

and exceedingly tight implant-endplate contact, while distraction in situ allows more precise fit (Truumees 2011).

Cages may be classified by not only design principle or geometry but also the implant material. Interbody cages may have a variety of described material properties, but more commonly the material make-up consists of titanium, polyether ether ketone (PEEK), or carbon fiber-reinforced polymers (Pisano et al. 2016; Chong et al. 2015). Design materials and designs of interbody cages have changed considerably over the last several decades. Threaded titanium alloy cages, often filled with autogenous bone graft, became popular in the 1990s due to superior fusion rates as compared to non-threaded cages and bone grafts. Non-threaded box-shaped titanium cages as well as polyether ether ketone (PEEK) cages gained popularity due to lack of flexion/extension stability and high incidence of subsidence of threaded cages (Jain et al. 2016).

Cage Materials

Cages composed of synthetic materials were originally introduced to circumvent issues with autograft, allograft, and biocomposite grafts used in ACDF. Desirable features in an interbody cage material include an elastic modulus similar to bone, biocompatibility, achievement of bony fusion, maintenance of alignment, and the ability to avoid subsidence. Bagby's initial description of ACDF in horses was using a stainless steel implant; however, the primary materials used in modern ACDF procedures have been carbon fiber-reinforced polymers (CFRP), titanium (Ti), and polyether ether ketone (PEEK). While overall results with each material have been generally favorable, differences in material properties and outcomes have been described.

Carbon Fiber

Carbon fiber-reinforced polymer implants for interbody fusion were first described by Brantigan and Steffe (1993) for use in the lumbar spine. Cages were later designed and adapted for use in arthrodesis of the cervical spine (Brooke et al. 1997), with excellent clinical results in small series with short follow-up. These initial implants were a composite material of long-fiber carbon in PEEK. The material properties of CFRP cages, such as compressive and tensile strength and isotropy, are dictated by the length, alignment, and volume of the carbon fibers. A biomechanical comparison to iliac crest bone graft by Shono et al. (1993) showed CFRP cages to be more rigid in flexion/extension testing and have higher stiffness in axial compression and rotation. CFRP cages have the benefit of being radiolucent to allow easier evaluation of the adjacent vertebral bodies and subsequent bony fusion on plain radiographs. Additionally, CT and MRI evaluation of the post-surgical spine is easier due to the lack of metal artifact. Early in their development, radiopaque tantalum beads were added in the corners of the cage to assist in visualizing the position of the cage.

Initial results of fusion with CFRP cages demonstrated reliable relief of neck and radicular pain, with authors reporting fusion rates as high as 87–98% in small series with short follow-up. Correction of cervical lordosis, another primary goal of ACDF surgery, was also reliably achieved with CFRP cages. Subsidence was noted frequently in CFRP cages, at a rate of 49% (Van der Haven et al. 2005); however, the occurrence of subsidence did not correlate with clinical outcomes. It should be noted that subsidence in the setting of cervical cages refers to the penetration of the cage through the vertebral endplate, rather than a collapse of the cage itself.

While CFRP had good initial success as a cage material, it has been largely replaced by PEEK in cage manufacturing and clinical use. Yoo et al. (2014) compared CFRP and PEEK cages and found lower fusion in CFRP cages (68.6%) than PEEK cages (82.6%), as well as a higher rate of subsidence in CFRP than PEEK (34.3% vs. 26.1%, respectively). The superior performance of PEEK in these respects is thought to be due to the difference in elastic modulus between CFRP (45 GPa) and PEEK (3.4 GPa), with PEEK more closely matching bone and therefore limiting potential stress shielding of the vertebrae (see Table 1).

Table 1 Elastic modulus of bone and cage materials

Material	*E* (GPa)
Cancellous bone	1–2
Cortical bone	12–20
PEEK	3.4
CFRP	45
Ti	106–115

Titanium

Titanium and its alloys are another material introduced early in the development of cervical cages. Like CFRP, titanium cages for vertebral arthrodesis were first described in the lumbar spine (Ray 1997) with good results and were later adapted for cervical interbody fusion, with Profeta et al. (2000) reporting favorable initial results with a threaded Ti cage compared to bone graft, noting good "immediate stability." Titanium, introduced to orthopedic practice in the 1940s, has several desirable properties for an orthopedic implant. It has a high yield strength, low density, biocompatibility, and excellent corrosion resistance due to self-passivation with titanium oxide (TiO2). With respect to cervical arthrodesis, modern Ti cages typically undergo surface modification to roughen the surface, via processes such as plasma spraying, which provides mechanical and biological advantages.

A roughened surface increases friction at the bone-implant interface, contributing to initial stability. The degree of micromotion at the bone-implant interface dictates the characteristics of bone and fibrous tissue formation; Jasty et al. (1997) demonstrated using porous-coated Ti alloy implants in an animal model that cyclic micromotion of under 40 micrometers reliably led to stable ingrowth of bone, whereas micromotion from 40 to 150 micrometers led to a proportionally increasing amount of fibrous tissue and fibrocartilage and less stable ingrowth. The use of roughened titanium cages thereby confers the potential advantage of improved stability and bone apposition at the bone-implant interface, and several authors have commented on the good perceived initial stability and handling characteristics of such cages.

Roughened Ti cages have also been shown to have potential biological advantages. When compared to PEEK (a typically smoother surface), roughened Ti surfaces have been shown in vivo to increase osteoblast maturation and the production of bone morphogenetic proteins, which may be of benefit in achieving osseointegration and ultimately bony fusion (Olivares-Navarrete et al. 2012). Due in part to this potential biological advantage, "empty" Ti cages (i.e., without bone graft material) have been trialed with good short-term outcomes reported by Krayenbuhl et al. (2008).

In contrast to CFRP and PEEK cages, Ti cages are radiopaque, rendering direct assessment of bony fusion through the cage difficult. As Profeta noted in his initial experience following patients with Ti cages, "signs of osseous consolidation can be detected around the cage," and fusion "may be deduced from the long-term stability and absence of bone rarefaction around the cage." A bigger concern with Ti cages has been early cage subsidence, which was originally reported in eight patients by Gercek et al. (2003). He described radiographic subsidence of stand-alone Ti cages in five of nine operated levels, with one patient developing recurrent radicular symptoms and foraminal stenosis after a period of initial improvement post-operatively. Other authors to follow redemonstrated the propensity of Ti cages to subside at rates of 13–62.5% with a meta-analysis showing a subsidence rate of 33/211 patients (15.6%) for Ti cages compared to 11/184 (6.0%) for PEEK cages (Li et al. 2016); however, it is important to note that this analysis failed to show a difference in functional outcomes between PEEK and Ti cages. The high elastic modulus relative to bone and the resultant potential for stress shielding has been cited as a possible contributing factor in Ti cage subsidence (see Table 1). With the advent of three-dimensional printing technology, modifications to cage surface architecture and implant porosity may improve bony ingrowth and biomechanical stability; however, long-term clinical outcomes for these new technologies are not yet readily available.

Peek

Polyether ethyl ketone was first investigated for use as an orthopedic implant in the 1980s and was used as a component of CFRP cages in early

interbody cages such as the Brantigan cage discussed previously. After CFRP cages fell out of favor, PEEK cages emerged as the primary alternative to Ti cages. PEEK is a semi-crystalline polymer, the mechanical properties of which are dependent on its molecular weight, temperature, strain rate, and crystallinity (Kurtz and Devine 2007). PEEK used in spine cages has an elastic modulus of approximately 3.4 GPa, which is similar to adjacent bone and significantly lower than its CRFP and Ti counterparts. A lower elastic modulus may lead to less stress shielding and less subsidence, as discussed above. As with CFRP cages, PEEK cages are radiolucent (with marking beads) and allow for easier, more direct visualization of bony fusion after surgery, as well as less artifact when imaging with a CT or MRI.

The structure of PEEK is very chemically stable, and as a result PEEK implants are biologically inert. While favorable in the sense that this prevents an inflammatory response or degradation, there is a concern that inertness as well as the hydrophobic nature of PEEK, which limits cellular adhesion, can lead to limited fixation to adjacent bone. An animal study on PEEK implants (Toth et al. 2006) demonstrated the development of non-osseous tissues (cartilage, fibrous tissue) at the bone-implant interface. To attempt to improve the osseointegration of PEEK implants, efforts have been made to develop PEEK cages with an altered roughened surface, which some propose accounts for differences in osseointegration between previous PEEK and Ti implants. Torstrick et al. (2017) report on the development of a PEEK cage with a porous surface microstructure, in which they showed improved histological osseointegration compared to smooth PEEK and encouraging results in early clinical application in ACDF patients.

Clinical outcomes with PEEK cages have been excellent and have led to widespread use of PEEK implants in clinical practice. PEEK has been shown to have equivalent functional and radiographic results to autograft iliac bone graft, with the expected shorter surgical time and decreased donor site morbidity expected with use of a cage (Zhou et al. 2011). PEEK has also compared favorably to Ti in several studies. Niu et al. (2010), in a prospective comparison with 12-month follow-up, showed higher fusion rates (100% for PEEK vs. 86.5% for Ti) and lower subsidence (0% for PEEK vs. 16.2% for Ti), with equivalent rates of good to excellent clinical outcomes. With a longer follow-up period of 7 years, Chen et al. (2013) demonstrated lower subsidence (5.4% compared to 34.5%), better maintenance of angular correction, and better clinical outcomes with PEEK compared to Ti while noting that fusion was achieved in all patients in both groups.

Hybrid Cages

In an effort to combine the desirable features of both PEEK and Ti cages, hybrid cages with a PEEK body and Ti coating (via plasma-spraying) have been developed. These theoretically have an elastic modulus closer to bone with a radiolucent center due to the PEEK component while incorporating the potentially better initial fixation and subsequent osseointegration of a rough Ti surface. Pre-clinical studies using this type of cage demonstrated improved bone ingrowth to the Ti-PEEK cages as opposed to PEEK alone (Walsh et al. 2015). A concern raised for this type of cage is the delamination between the Ti and PEEK layers; however, manufacturer-published biomechanical testing demonstrated no delamination at ten million cycles (Medacta 2018). Hybrid Ti-coated PEEK cages are in the early phases of clinical usage, and their long-term performance relative to other cage materials remains to be seen, though there are concerns that the coating may be susceptible to delamination during impaction (Torstrick Spine J. 2018).

Operative Technique

After standard anterior cervical spine exposure, the author's preferred surgical technique is to utilize Caspar pins for interspace distraction. Pins are placed in the midpoint of the superior and inferior vertebral bodies. Annulotomy of the intended disc space is performed with a 15-blade scalpel knife, and the interspace is then distracted. Diskectomy

is performed with a combination of pituitary rongeurs, Kerrison rongeurs, curettes, and a high-speed burr. Once a thorough diskectomy is complete, the cartilage layer on the superior and inferior endplates is removed with straight and angled curettes. Sclerotic subchondral bone is roughened with the use of a rasp. The posterior osteophytes are identified and removed with the high-speed burr, and the osseous shavings are saved as local autograft. Doing so reveals the posterior longitudinal ligament, which is then split with a nerve hook in line with the ligamentous fibers and then resected with Kerrison rongeurs. Once the posterior longitudinal ligament has been completely removed, the neural foramina are palpated and decompressed with Kerrison rongeurs. Decompression is verified using a nerve hook. Once the decompression is completed, the distracted interspace is sized for an appropriate cage. Fluoroscopic evaluation is performed to assess for alignment as well as distraction of the facet joints, to prevent "overstuffing" of the interspace. The cage is packed with local autograft, as well as osteoinductive or conductive material such as demineralized bone matrix, and distraction can be released. The cage is impacted into the interspace. The implant position is verified with intraoperative radiography. An anterior cervical locking plate is then placed in front of the cage, with screws in the cephalad and caudal vertebral bodies. Intervertebral cage devices with integrated fixation can avoid additional plating, particularly in instances such as adjacent segment degeneration above a prior fusion.

Summary

As cervical interbody fusion techniques have advanced, so too have implant designs and materials. Development of cervical interbody cages has allowed for improvements in fusion rates as well as in a reduction in the necessity of donor site morbidity for iliac crest harvest. As manufacturing processes and understanding of bone biology continue to improve, future interbody cage designs and materials will likely follow suit.

Tristan B. Fried, Tyler M. Kreitz, and I. David Kaye

Contents

Abstract

The use of interbodies as a method for lumbar fusion has been increasing over the past decades. Increased surface area and enhanced biomechanical forces for achieving fusion have made the technique more appealing than traditional posterolateral lumbar fusion. While many interbody techniques are actually less invasive than traditional open procedures, there are unique complication profiles with different approaches. The benefits of interbody fusion must be considered with the potential

Anterior Lumbar Interbody Fusion (ALIF)

Introduction

Since its description in 1932 by Capener (1932) for the treatment of spondylolisthesis, anterior lumbar interbody fusion (ALIF) has become an accepted treatment modality for many degenerative lumbar conditions. ALIF may be used as a standalone procedure or in combination with posterior instrumentation as demonstrated in Fig. 1. Anterior lumbar fusion allows for complete discectomy, indirect decompression, maximal surface area for fusion under compression, and restoration of lumbar lordosis and sagittal alignment. The benefits of anterior fusion must be considered with the potential morbidity associated with the anterior approach or combined anterior/posterior procedure. This chapter reviews the indications, perioperative considerations, and surgical technique for anterior lumbar interbody fusion (ALIF).

Indications

- Isthmic and degenerative spondylolisthesis
- Degenerative disc disease
- Discogenic back pain
- Degenerative lumbar scoliosis
- Revision transforaminal lumbar interbody fusion (TLIF)
- Pseudarthrosis after posterior fusion (Mobbs et al. 2013a)
- Sagittal malalignment
- Osteodiscitis
- Tumor
- Trauma

A thorough history and physical with review of the appropriate imaging studies is necessary prior to considering a patient for an ALIF. In the case of degenerative disc disease with associated spondylolisthesis or deformity, the patient may present with radicular symptoms. The patient should demonstrate insufficient relief of symptoms with appropriate nonoperative management including use of NSAIDs, epidural injections, and physical therapy. Surgery may be expedited in the setting of significant motor weakness or cauda equine syndrome, a constellation of findings including saddle anesthesia, urinary retention, or loss of bowel control. Discography may be selectively used to help diagnose a discogenic source in a patient with axial low back pain.

Advantages of ALIF over posterior interbody fusion techniques (PLIF, TLIF) include the potential for more thorough discectomy, maximization of surface area for fusion, the potential for greater correction of deformity, indirect nerve root decompression, preservation of posterior structures including paraspinal musculature and facet complex, and avoidance of nerve root manipulation during graft insertion (Mobbs et al. 2013a; Richter et al. 2015).

Contraindications

Spine surgery including ALIF is not indicated when other pathology is the cause of the patient's neurologic symptoms: specifically central and peripheral neuropathy (diabetes, vitamin B deficiency, multiple sclerosis, and Guillain-Barre).

Contraindications specific to ALIF include:

Fig. 1 Preoperative AP and lateral radiographs as well as sagittal and axial T2 MRI demonstrating stenosis and spondylolisthesis. Postoperative AP and lateral radiographs demonstrating lumbar 5 to sacral 1 anterior lumbar interbody fusion. A structural autograft was used as well as posterior instrumentation. Images courtesy of Department of Orthopaedic Surgery, Thomas Jefferson University Hospital

- Calcified great vessels (aorta, iliac vessels)
- Prior vascular reconstruction
- History of abdominal or retroperitoneal surgery
- History of pelvic inflammatory processes
- Medical comorbidities putting the patient at significant risk under general anesthesia

Operative Setup

Instruments and Materials Required

- Exposure surgeon: general or vascular
- Jackson radiolucent table
- Intraoperative radiography
- Surgical loupes or microscope
- Abdominal retractor system
- Standard spine instrument tray with curettes, Kerrison rongeurs
- Distractors and graft trials
- Interbody graft or cage

Graft Selection

Bone grafts may be used in isolation or in combination with cages, biologics (BMP-2), and anterior or posterior instrumentation. Iliac crest autograft (ICBG) is the "gold standard" for spinal fusion, but is associated with significant donor site morbidity including pain, infection, and neurovascular injury (Arrington et al. 1996). ICBG autograft may be used in combination with titanium cages or allograft material, reducing the necessary autograft quantity and associated morbidity while maintaining fusion potential (Newman and Grinstead 1992; Sasso et al. 2004). Alternatively, femoral ring allograft (FRA) or iliac crest structural allograft may be used. Allografts may lack the osteogenic and osteoinductive properties of autograft, but their versatility, availability, biologic superiority to cages, and avoidance of autograft donor morbidity make them an attractive option (Stevenson 1999; Sarwat et al. 2001; Mobbs et al. 2013a). Use of allograft in combination with posterior instrumentation demonstrates reliable rates of arthrodesis, greater than 90% among single-level procedures (Anderson et al. 2011; Mobbs et al. 2013b). Fusion rates may be enhanced with the addition of bone morphogenic protein-2 (rh-BMP2). The use of rh-BMP2 with allograft scaffold has demonstrated efficacy in ALIF procedures without the associated morbidity of ICBG autograft (Burkus et al. 2002; Anderson et al. 2011). Bone morphogenic protein-2 has been associated with ectopic bone formation, soft tissue edema, and excessive osteoclastic activity (Benglis et al. 2008; Chen et al. 2012). Titanium and composite interbody cages were developed to enhance biomechanical stability and improve fusion rates in standalone ALIF procedures, averting the risks and morbidity associated with combined anterior/posterior procedures. These interbody devices are used in combination with allo-/autograft and biologic materials (Burkus et al. 2009; Strube et al. 2012; Behrbalk et al. 2013). Titanium interbody cages in combination with BMP-2 demonstrate substantial fusion rates, greater than 90%, when used in standalone ALIF procedures without supplemental posterior instrumentation (Burkus et al. 2002, 2009; Boden et al. 2000). However, concern exists regarding titanium cage subsidence due to metal-bone modulus. Biocompatible composite material polyetheretherketone (PEEK) cages were developed as a load-bearing interbody device with similar modulus to bone to reduce rates of subsidence compared to metal cages (Galbusera et al. 2012; Behrbalk et al. 2013). Radiolucent PEEK cages also allow for easier radiographic assessment of fusion. Composite material cages carry the risk of fragmentation and extrusion over time. Ultimately, several bone graft and interbody device options have been developed for use with ALIF procedures, each with their own inherent advantages and disadvantages.

Positioning

The patient is placed supine on a flat Jackson table. Slight Trendelenburg and bump under the sacrum may remove obstructing pannus and decrease lordosis. The patient's arms are taped across the chest. Use of a Foley catheter is preferred. The patient is then prepped and draped in usual sterile fashion.

Surgical Technique

Step 1: Exposure

A left-sided retroperitoneal approach is performed with the assistance of an exposure surgeon. A low transverse incision between the umbilicus and pubic symphysis is preferred. Alternatively, a longitudinal curvilinear left-sided incision may be used for retroperitoneal approach. Dissection is carried through the dermis, and subcutaneous tissues are carried to the level of the rectus sheath. The anterior rectus sheath is divided transversely. The superior and inferior edges of the rectus fascia

are elevated off the underlying rectus abdominis muscles. The right and left rectus muscles are separated in the midline exposing the dorsal fascia and arcuate line. Underlying preperitoneal fat is separated, and the peritoneum is identified and preserved. Dissection is carried in a left lateral extraperitoneal plane. The psoas muscle with overlying genitofemoral nerve are encountered just lateral to the common iliac vessels (Spruit et al. 2005; Behrbalk et al. 2013). The left ureter may be encountered running beneath the peritoneum and should be protected. The lower lumbar spine and sacrum are identified. Overlying soft tissue is bluntly dissected exposing the spine. Middle sacral vessels may be clipped and cauterized. Exposure of the L5/S1 disc space is performed distal to the iliac vessels and cranial levels proximal to the vessels. A radiographic marker is placed in the appropriate intervertebral disc, and a plain radiograph is obtained to confirm the anatomic level.

Step 2: Discectomy

After confirmation of appropriate disc for excision, a long-handled knife is used to perform an annulotomy and define the perimeter of the identified disc. Electrocautery is avoided for risk of injury to the autonomic nervous system. A knife, high-speed burr, pituitary rongeur, and/or curette may be used sequentially to remove the identified disc posterior to the posterior longitudinal ligament (PLL). Sequential distraction can be used to allow better visualization and access to the posterior disc space. Vertebral endplates may be further defined using a cobb elevator.

Step 3: Endplate Preparation

Using a curette, the inferior endplate of the cephalic vertebrae and superior endplate of the caudal vertebrae are denuded of cartilage creating a roughened bleeding surface for fusion. Care is taken to not disrupt or compromise the integrity of the endplate resulting in stress riser and potential for implant subsidence.

Step 4: Insertion of Graft/Cage

Trial sizers may be used to determine appropriate graft size restoring intervertebral disc height. The bone graft may be asymmetrically machined to restore appropriate lordosis. The bone graft/cage complex may be augmented with a biologic to enhance bony fusion. Graft/cage positioning is confirmed using an intraoperative lateral radiograph.

Step 5: Closure

The wound is copiously irrigated. All bleeding should be controlled using hemostatic agents and electrocautery. The wound is closed in multiple (fascia, subcutaneous tissue, and skin) layers, and a sterile dressing placed.

Complications

- Sexual dysfunction, retrograde ejaculation in males
  - Due to damage to superior hypogastric (sympathetic) plexus located along the prevertebral tissues anterior to L5 vertebrae. Especially at risk when performing L5/S1 ALIF. Blunt dissection and avoidance of electrocautery are encouraged at this level.
- Iatrogenic injury to retroperitoneal structures (i.e., great vessels, ureters, bowel)
  - Care is taken during the approach and in retractor placement to identify and protect vital structures.
- Dural tear (CSF leak)
  - Rare as the epidural space is generally not encountered
- Nerve root damage
  - Rare as there is no direct nerve decompression; rather decompression occurs through distraction.
- Infection
- Pseudarthrosis
- Hardware/graft malposition or migration
- Medical complications
  - Patients are at risk of postoperative ileus and in rare instances bowel obstruction from the anterior approach to the lumbar spine.

Pearls and Pitfalls

- A bump can be used on the sacrum to retrovert the pelvis to allow for easier access to the disc space. This is particularly critical for L5–S1 isthmic spondylolistheses.

- Care should be taken during anterior exposure to identify and protect vital structures within the retroperitoneum. The use of an exposure surgeon is highly recommended to facilitate safe exposure.
- Use of electrocautery is avoided anterior to the L5 vertebrae to prevent injury to the prevertebral sympathetic plexus.
- A thorough discectomy and endplate preparation is critical for fusion.
- Bone graft/cage must be sized appropriately to restore alignment, achieve indirect decompression, and accomplish a large surface area of contact.

Postoperative Protocol

Early postoperative mobilization and physical therapy facilitate recovery and prevent the risk of medical complications associated with immobility. Due to the risk of postoperative ileus, patients are started on a clear liquid diet until they pass flatus and then advanced as tolerated. A bowel movement prior to discharge is encouraged.

Transforaminal Lumbar Interbody Fusion (TLIF)

Introduction

PLIF was first described in 1944 by Briggs and Milligan; however, it did not increase in popularity until it was described in 1953 by Cloward. Unlike the original description which used laminectomy bone chips as the interbody graft, Cloward's technique involved a graft made of iliac autograft (Briggs and Milligan 1944; Cloward 1953; Cole et al. 2009; Mura et al. 2011). A posterior approach had some advantages in that it could reduce some of the possible complications of ALIF including vascular injury and sexual dysfunction. The TLIF was then first described in 1982 by Harms and Jeszenszky as a modification of the PLIF procedure (Harms and Rolinger 1982; Cole et al. 2009; Mura et al. 2011). The TLIF approach is designed to approach the disc space unilaterally through the foraminal area (Kambin's triangle) to reduce complications associated during PLIF such as durotomy, radiculitis, and interoperative bleeding (Harms and Rolinger 1982; Craig Humphreys et al. 2001; Cole et al. 2009; Mura et al. 2011). TLIF has since evolved and can also be performed as a minimally invasive procedure that was popularized by Foley et al. in 2003 (Foley et al. 2003; Sonmez et al. 2013). This chapter reviews the indications, perioperative considerations, and surgical technique for transforaminal lumbar interbody fusion (TLIF). Figure 2 represents pre- and postoperative images from a typical TLIF procedure.

Indications

- Symptomatic spondylolisthesis
- Spinal stenosis with instability
- Degenerative lumbar scoliosis (Cloward 1953; Collis 1985; Lin 1985; Cole et al. 2009; Xiao et al. 2009)
- Discogenic low back pain
- Recurrent lumbar disc herniation (Cole et al. 2009)

Before the decision to perform a TLIF, a thorough history and physical exam must be performed. Prior to consideration of surgery, patients should have exhausted a course of nonoperative management such as NSAIDs, physical therapy, and consideration of injections. In addition, the patient's pain and symptoms should be concordant with advanced imaging.

TLIF has some distinct advantages over ALIF and PLIF procedures. In cases which require a posterior decompression, the performance of a TLIF vs. an ALIF can be significantly more time efficient. As a posteriorly based approach, performance of a TLIF can avoid complications uniquely associated with the anterior approach such as damage to the great vessels, damage to retroperitoneal structures, or sexual dysfunction. The TLIF also has advantages over the PLIF surgery in that it does not involve nerve retraction to the same degree which therefore decreased the risk of neurological damage. In addition, as TLIF can frequently be performed with unilateral facetectomy, preservation of bony structures on the contralateral side can aid in stability and ultimate fusion.

Fig. 2 Preoperative AP and lateral radiographs as well as T2 axial (L5–S1) and sagittal MRI demonstrating foraminal stenosis. Also, postoperative AP and lateral radiographs demonstrating lumbar 3–4 and 4–5 transforaminal interbody fusion. Contraindications

Contraindications specific to TLIF include:

- Conjoined nerve root within the foramen (Holly et al. 2006)
- Previous wide posterior decompression (relative) (Ozgen et al. 1999; Lai et al. 2004; Xiao et al. 2009)
- Severe osteoporosis (Min et al. 2008; Xiao et al. 2009)
- Medical comorbidities putting the patient at significant risk under general anesthesia

Operative Setup

Instruments and Materials Required

- Exposure surgeon: general or vascular
- Jackson radiolucent table
- Intraoperative radiography
- Surgical loupes or microscope

- Abdominal retractor system
- Standard spine instrument tray with curettes, Kerrison rongeurs
- Distractors and graft trials
- Interbody graft or cage

Graft Selection

Numerous interbody and grafting options have been developed over the past decades for use in TLIF. Although generally ICBG is the gold standard for fusion, possessing osteoindicative, osteoconductive, and osteogenic potential, ICBG is rarely used for TLIF as it has been associated with significant donor site morbidity with complication rates approaching 25% (Kurz et al. 1989; Younger and Chapman 1989; Fernyhough et al. 1992; Craig Humphreys et al. 2001; Gibson et al. 2002; Lowe and Coe 2002; Coe 2004; Mummaneni et al. 2004a). An ideal substitute should be structurally capable of maintaining the reconstructed disc space's integrity (i.e., maintain disc height and neuroforaminal height) without subsidence and help create an environment conducive to lumbar fusion (Boden 2002; Mummaneni et al. 2004b; Cole et al. 2009; Xiao et al. 2009). Allograft has been used as a comparable substitute to AIBG, and while some comparative studies found increased fusion rates with AIBG, most have concluded that there is no overall difference in fusion rates between the two (Lin 1985; Rish 1989; Rompe et al. 1995; Xiao et al. 2009). Titanium interbody cages have been increasingly used over the past 5 years. Titanium cages have been reportedly more likely to subside into the endplates of the vertebral bodies due to the increased modulus of elasticity of titanium relative to bone. In addition, accurate assessment of postoperative fusion can be challenging on CT and MR imaging secondary to metallic artifact (Weiner and Fraser 1998; Lowe and Coe 2002; Cole et al. 2009). Metal artifact reducing sequencing (MARS) on MRI has made this issue less problematic. Carbon fiber and PEEK cages were developed to minimize some of the technical issues that titanium has posed. With a modulus of elasticity closer to bone, there have been theoretical reports of decreased interbody subsidence. Additionally, PEEK cages may allow more reliable assessment of fusion mass (Weiner and Fraser 1998).

There are also bone graft substitutes that have been used; however, there is limited data on these substances. The most commonly used and widely studied biological agent used as a bone graft substitute has been recombinant human bone morphogenic protein-2 (rhBMP-2) (Resnick et al. 2005; Kaiser et al. 2014). Michielsen et al. performed a level I randomized trial comparing TLIF using PEEK interbody with BMP-2 or autograft and found that for the BMP-2 cohort, there was significantly greater interbody healing on bone deniometry up to a year postoperatively ($p = 0.014$), but no difference in overall fusion rates on CT scan (all patients fused) and no clinical differences (VAS, ODI, SF-36) postoperatively (Michielsen et al. 2013). More recently, Khan et al. published their series of 191 patients undergoing TLIF with BMP-2 or autograft and demonstrated equivalent fusion rates and overall complication rates between the cohorts, but higher rates of postoperative radiculitis and postoperative seroma for the BMP-2 patients (Khan et al. 2018). Although rhBMP-2 has certainly rivaled AIBG in terms of fusion potential, the complication profile has muted more widespread enthusiasm. rhBMP-2 has been shown in multiple studies to be associated with complications including radiculitis, osteolysis, and ectopic bone formation (Wong et al. 2008; Gray and Rampersaud 2010; Helgeson et al. 2011).

Positioning

The patient is positioned prone on a Jackson table with the hip pads positioned just below the iliac crests and the chest pad positioned just below the sternal notch. The abdomen is allowed to hang freely minimizing pressure on the abdominal cavity and helping to prevent excessive epidural bleeding.

Exposure

Although the procedure can be performed via a traditional open approach or using minimally invasive techniques, this section will focus on open techniques as MIS is discussed elsewhere. An incision is made in the midline and dissection is carried through the skin and subcutaneous tissue to the level of the fascia. The fascia is then

incised on either side of the spinous processes and subperiosteal elevation of the paraspinal musculature is performed.

Surgical Technique

Distraction across the disc space can facilitate discectomy, and therefore we frequently remove the interspinous ligament at the planned level (i.e., remove the ligament between L4 and 5 for an L4–5 TLIF) but keep the spinous processes intact to serve as a buttress for placement of a laminar spreader. The laminar spreader is then expanded which allows for expansion of the interlaminar space. We performed the TLIF from the side which is more symptomatic. Partial laminectomy may be performed with the use of a high-speed burr or Kerrison rongeurs. Laminectomy is begun at the midline and proceeds in a medial to lateral direction. Once the lamina has been at least partially removed (about 50% of the height in a cranial caudal direction, which is generally above the insertion of ligamentum flavum on the undersurface of the cranial lamina and at the region where the epidural fat begins), an osteotome may be used to remove the remaining lamina and inferior articular process (IAP) of the cranial vertebrae en bloc. This bone may be used as local autograft to be placed in the disc space after discectomy. Alternatively, a burr or Kerrison rongeur can be used to remove the remaining lamina and IAP piecemeal.

During the procedure, the ligamentum flavum may be left intact until after the TLIF is performed or may be removed before the discectomy. Leaving the ligament intact may afford an extra level of protection to the dura and nerve root, and decompression may be performed after the interbody has been placed.

A woodson elevator can be used to palpate the top of the pedicle of the caudal vertebra. The woodson may be left in place, and an osteotome may then be used to remove the superior articular process of the caudal vertebrae. Any remaining bone superior to the pedicle should be removed with Kerrisons so that there is no overhanging bone above the pedicle. Similarly, the medial wall of the pedicle should be skeletonized by removing some of the lamina of the caudal vertebrae. At this point, the majority of the bony work has been completed for performance of the discectomy.

A woodson elevator is used to palpate the medial and superior borders of the pedicle and identify the disc space which is just above the caudal pedicle. Next, a Penfield 4 can be used to dissect of the overlying soft tissue above the disc, and bipolar electrocautery can be used to ligate the overlying epidural plexus at the disc level. The working zone for the discectomy is classically described as a triangle (Kambin's) bordered by the traversing nerve root medially, the pedicle/superior endplate inferiorly, and the exiting nerve root superiorly. Identification of the exiting nerve root allows for a safer working zone and more aggressive lateral disc work. Assuming the nerve has been identified and is sufficiently lateral at the level of the disc, frequently, medial retraction of the traversing nerve and thecal sac is not required. If required, gently retract the nerve and thecal sac medially with the use of a nerve root retractor. Be sure to relax the traction at frequent intervals to prevent the development of a palsy or postoperative radiculitis.

Discectomy begins with creating a box annulotomy as largely as possible with the use of a #15 blade on a long handle. We often use a Kerrison rongeur to remove the posterior lip of the caudal vertebral body as well as define the extent of the annulotomy in all directions. We begin disc removal with specially designed shavers which efficiently remove a large amount of disc material. Once bony chatter is appreciated, we no longer upsize the shavers. The size of the final shaver is generally the size of the final interbody. After shavers have removed much of the disc material, we use a combination of straight and angled curettes to remove residual adherent disc and the cartilaginous endplate. Care is taken not to violate the bony endplates. Trialing of the interbody spacers may be performed. Once a thorough discectomy and endplate preparation have been performed, the disc space is packed with a combination of locally harvested autograft and allograft. After the space has been packed, the interbody is placed and impacted into final position. A more anteriorly

placed graft may allow for better creation of lordosis, but a more posteriorly placed graft may allow better indirect neuroforaminal decompression. Once the interbody has been impacted into final position, a woodson elevator can be used to palpate the posterior disc space and ensure bone is palpated posteriorly to the interbody.

At this point, the laminar spreader can be removed to further compress the interbody. All remaining encroaching bone and ligamentum can more easily be removed at this point. The foramen must be reexplored to ensure no remaining stenosis or bone graft remains.

If necessary, a contralateral facetectomy may be performed (akin to a Ponte osteotomy) to allow for even greater creation of lordosis.

After performing the TLIF, pedicle screws are placed in a standard fashion according to the particular surgeon's preference. By compressing the pedicle screws, the interbody can be locked in place and restore even greater lordotic alignment.

The wounds are then thoroughly irrigated and closed over drains in a layered fashion per routine.

Complications

- Radiculitis (Yan et al. 2008)
- Screw loosening or hardware failure (Yan et al. 2008)
- Paraspinal iatrogenic injury (Craig Humphreys et al. 2001; McAfee et al. 2005; Cole et al. 2009; Sakeb and Ahsan 2013; Mobbs et al. 2015)
- Dural tear (CSF leak) (Holly et al. 2006)
- Deep infection (Hackenberg et al. 2005)
- Nerve root damage
  - Radiculopathy (Hackenberg et al. 2005)
- Pseudarthrosis (Hackenberg et al. 2005)

Pearls and Pitfalls

Removing the IAP and SAP en bloc with the use of an osteotome can be time efficient and serve as an excellent source of local autograft.

Use traction on the traversing nerve root and thecal sac judiciously to prevent inadvertent neurologic injury.

Biting the posterior inferior lip of the cranial vertebrae can allow better visualization for discectomy and easier placement of interbody graft.

Endplate violation during discectomy can lead to excessive bleeding from the disc space and can predispose to interbody subsidence.

Postoperative Protocol

The standard of treatment after spinal fusion procedures includes an early regimen of physical therapy to decrease postoperative complications.

Abstract

Adult spinal deformity is a complex deformity that involves three-dimensional deformation in coronal, sagittal, and axial planes. Spinal and spinopelvic parameters such as SVA, pelvic tilt, pelvic incidence, and lumbar lordosis are important in understanding, characterizing, and treating adult spinal deformity. Treatment of adult spinal deformity needs to be tailored to each patient with respect to the nature of the curve and the patients' overall medical health. Operative techniques have changed substantially with time, from the early use of

Harrington rods to modern pedicle screws. Multiple osteotomies (SPO, PSO, and VCR) can be applied for the desired level of spinal correction. Operative management of adult spinal deformity is wrought with complexity and severe complications. Newer techniques involving minimally invasive surgery and interbody fusions are being increasingly used for deformity correction. In this chapter, we will discuss such operative techniques for spinal deformity correction.

Keywords

Adult deformity · Scoliosis correction · Corrective osteotomy · Minimally invasive surgery (MIS) correction

Introduction

Adult spinal deformity (ASD) is an expansive term that covers a wide variety of conditions that involve deformation or malalignment of the adult spine. Among others, terms for various forms of deformity include scoliosis, sagittal imbalance, and spondylolisthesis (regional deformity). Normal anatomic variation does exist that can account for small regional curves of the spine. Adult spinal deformity, however, exceeds this normal anatomic variation and can possibly impair horizontal gaze or the neutral center of the spine over the pelvis and femoral heads. Impairment of horizontal gaze has a dramatic impact on the quality of an individual's life and has associated morbidity. Prevalence of adult deformity does appear to vary based on multiple factors. The overall prevalence in US adults aged 25–74 is about 8.3% with women having twice the rate as men (10.7% and 5.6%, respectively) (Carter and Haynes 1987). Furthermore, the prevalence appears to increase with advancing age. In a 2005 study by Schwab et al., they suggest prevalence rates of adult scoliosis (Cobb angles $>10^{\circ}$) may be as high as 68% among adults 60 and older (Schwab et al. 2005). While in some cases adult spinal deformity can be asymptomatic, severe spinal deformity can present in multiple ways including back pain, hip pain, functional decline, radiculopathy, neurogenic claudication, and other neurologic symptoms.

Spinal deformity was initially simplified to deformity in the coronal plane. In particular, scoliosis was described as a lateral curvature of the spine resulting in a deformity in the coronal plane. As knowledge of deformity has grown, we have learned that deformity consists of complex three-dimensional changes that can result in changes in coronal, sagittal, and axial (rotational) planes (Stokes 1994). As understanding of the adult spinal deformity has grown, operative management has also advanced. Various corrective osteotomies can be applied for deformity correction including Smith-Petersen/Ponte osteotomy, pedicle subtraction osteotomy, and vertebral column resection. Instrumentation techniques involving wires and hooks have given way to constructs using pedicle screws and cortical screws (Fig. 1).

In this chapter we briefly discuss adult scoliosis including etiology, presentation, clinical evaluation, radiographic assessment, spinopelvic parameters, and overview on treatment. The primary focus of the chapter, however, relates to operative correction of deformity. In particular, we will discuss the corrective osteotomies that can be employed to improve spinal deformity in adult patients.

Adult Scoliosis: Definition and Etiology

Scoliosis consists of a three-dimensional deformity involving the coronal, sagittal, and axial (rotational) planes. In the sagittal planes, this can manifest as kyphotic changes impacting sagittal imbalance (Stokes 1994; Aebi 2005). The three-dimensional nature of the deformity can substantially impact the position of the head, horizontal gaze, and general positioning of the spine in relation to the pelvis.

The etiology of adult spinal deformity can be multifactorial. Some cases of ASD relate to congenital abnormalities of the vertebrae or spinal cord such as Chiari malformations or myelomeningocele (spina bifida). Neuromuscular conditions that may involve spinal deformity include cerebral palsy, Friedreich's ataxia, Charcot-Marie-Tooth, spinal muscular atrophy, muscular dystrophy, and arthrogryposis (Berven and Bradford 2002). Adult deformity can also

Fig. 1 Standing anteroposterior (AP) and lateral full-length spinal radiographs. AP radiograph demonstrates the deformity in the coronal plane as seen by the lateral curvature of thoracolumbar spine. Lateral radiograph demonstrates the sagittal deformity as seen by the positive sagittal imbalance

represent a progression of idiopathic scoliosis from childhood (infantile, juvenile, adolescent idiopathic scoliosis). Spinal deformity arising and developing in the adult population is often termed de novo or degenerative scoliosis. As the name suggests, this form of scoliosis is thought to relate to degenerative changes to spinal elements including the vertebral discs and zygapophyseal joints (Birknes et al. 2008). Other factors that can contribute to adult deformity include infection (poliomyelitis), spinal cord tumor, post-traumatic, and iatrogenic (post-surgical) (Berven and Bradford 2002; Birknes et al. 2008; Berven and Lowe 2007).

Clinical Evaluation

As with any complex condition of the spine, a complete history and physical examination is imperative. Pain is often a common presenting complaint that can vary from mild to severe and is often diffuse and ill-defined. The etiology of pain may be degenerative changes within the vertebral column (discs, facet joints), as well as paraspinal musculature (Birknes et al. 2008; Kostuik et al. 1973; Smith et al. 2009a, b). Given the imbalance of the spine over the pelvis and subsequently femoral heads, patients may also present with buttocks, hip, or leg pain. Patients may also present with symptoms of radiculopathy and/or stenosis (neurogenic claudication). Severe deformity may impair an individual's ability to maintain horizontal gaze. Different classification schemes, such as the Scoliosis Research Society (SRS) classifcation for adult spinal deformity, have been developed to help direct evaluation and management (Lowe et al. 2006). We will look at various spinal parameters below that can help guide evaluation and management. As part of the clinical evaluation, a full neurological exam should be performed to assess for weakness as well as additional issues such as myelopathy and cauda equina syndrome.

Imaging Evaluation

Initial imaging consists of standing full-length spinal radiographs, both PA and lateral views. Many of the spinopelvic parameters that are discussed below can be assessed on these radiographs alone. The PA view allows for evaluation of coronal alignment through measurements involving the central sacral vertical line (CSVL) and Cobb's angle. Pelvic obliquity can also be assessed on the PA radiograph. If the pelvic obliquity is related to a leg length discrepancy, repeat standing radiographs with blocks under the short leg may be needed. This is important in unmasking any perceived spinal deformity that may just relate to pelvic obliquity. The lateral radiograph allows for evaluation of the sagittal balance including any variation in lordosis and kyphosis in each spinal segment. The lateral radiographs also help to assess the sacral slope, pelvic tilt, and pelvic incidence. Additionally, the chin-brow to vertical angle, the angle formed between a line connecting the patient's chin to brow and a vertical line, can be measured in this view. Increasing chin-brow to vertebral angle suggests difficulty with maintaining horizontal gaze.

CT scans can prove useful in assessing bony morphology as part of planning for corrective osteotomies or placement of instrumentation such as pedicle screws. Being a supine study, CT scans can also be used to evaluate the flexibility of the curve in the sagittal plane when compared to upright x-rays. Given that patients may present with radicular or other neurological symptoms, an MRI can provide details regarding the location and etiology of areas of compression on the spinal cord and spinal nerves. If patient cannot undergo an MRI, a CT myelogram can be considered.

Spinal and Spinopelvic Parameters

Introduced in 1948, the Cobb method provides a quantitative measure of spinal curve on the coronal plane as seen on PA radiographs (Cobb 1948). The method consists of identifying the vertebral segment at the apex of the curve and most tilted vertebral bodies cephalad and caudal to the apex. Parallel lines are drawn along the superior end plate of the cephalad vertebral body and along the inferior end plate of the caudal vertebral. Perpendicular lines are subsequently drawn to each of the previously formed lines along the end plates. The angle formed between the intersections of the perpendicular lines is the Cobb angle. Traditionally, scoliosis is defined as a Cobb angle greater than 10° (Aebi 2005). The inter-observer error using the Cobb's method is about 5% (Mehta et al. 2009). Furthermore, studies suggest that an inherent error of up to 5° exists using the Cobb's method, meaning that only a change in the Cobb's angle of 5° or more is considered a real change (Morrissy et al. 1990). The Cobb's method can also be applied to lateral radiographs as a method of quantifying lordosis and kyphosis (Fig. 2).

While the Cobb method measures degree of curvature with respect to regional curves, the central sacral vertical line (CSVL) assesses overall coronal alignment (Lenke et al. 2001; Angevine and Kaiser 2008; O'Brien et al. 2004). A vertical line is made through the center of the sacrum. A second vertical line, C7 plumb line, is made centered on the C7 vertebral body. The difference between these two lines is the CSVL. A negative

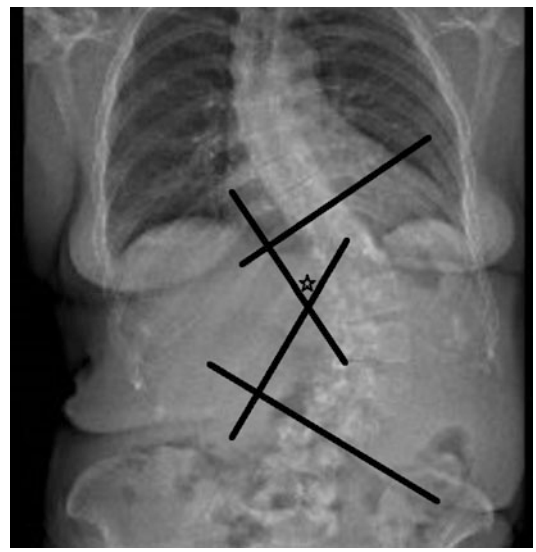

Fig. 2 Cobb's method for quantifying a curve. The star represents the Cobb's angle

value denotes that the C7 plumb line is to the left of the sacral line, while a positive value denotes that the C7 plumb line lines to the right.

The lateral radiograph provides crucial insight into the nature of the spinal deformity. Several parameters can be measured on the lateral radiographs including pelvic incidence (PI), sacral slope (SS), pelvic tilt (PT), sagittal vertical axis (SVA), and T1 pelvic angle (TPA). Pelvic incidence is the angle formed between a line perpendicular to the S1 end plate and a line between the center of the sacral end plate and the center of the femoral head (Legaye et al. 1998). Pelvic incidence also describes the sum of the sacral slope and the pelvic tilt. As a formulaic representation, PI = SS + PT. Sacral slope is the angle formed between a pure horizontal line and a line parallel to the sacral end plate. Pelvic tilt is the angle formed between a pure vertical line and a line between the center of the femoral head to the center of the sacral end plate. Of note, the pelvic tilt and sacral slope can change depending on position of the pelvis. Any movement leading to a change in pelvic inclination (i.e., increasing retroversion) will impact the pelvic tilt and sacral slope (Lafage et al. 2008; Boulay et al. 2006a; Jackson and McManus 1994; Schwab et al. 2009).

The sagittal vertical axis is also measured on the lateral radiograph. A vertical plumb line is drawn down from the center of C7 vertebral body. The distance between this plumb line and a point at the posterior-superior aspect of the sacral end plate is measured. A plumb line that lies anterior to the point on the posterior superior sacral end plate is denoted as a positive value. Normative values for the SVA are +2 to −2 cm; values outside of this range are considered positive or negative sagittal imbalance (Schwab et al. 2009; Boulay et al. 2006b; Roussouly and Nnadi 2010; Bernhardt and Bridwell 1989; Berthonnaud et al. 2005). The SVA, however, does not account for pelvic parameters and as such can be impacted by positioning and tilt of the pelvis. The T1 pelvic angle may provide more accurate insight into the overall sagittal alignment as it incorporates elements from the abovementioned pelvic parameters. The T1 pelvic angle is formed at the intersection of a line drawn from the T1 vertebral body to the center of the femoral head and a line drawn from the center of the femoral head to the center of the sacral end plate (Ryan et al. 2014). Lafage et al. introduced the TPA in 2014 as part of the International Spine Study Group. They proposed a goal/normative TPA of 10°, with a TPA greater than 20 representing a severe sagittal deformity (Ryan et al. 2014).

Scoliosis was initially viewed as a lateral curvature in the coronal plane; however, studies have not found a link between patient disability or perceived pain and degree of coronal deformity (Glassman et al. 2005a; Schwab et al. 2006a; Lazennec et al. 2009). Sagittal imbalance has been found to correlate with patient-reported pain and disability across several studies as measured by health-related quality of life measures (HRQOL). Sagittal imbalance as measured by pelvic tilt, TPA, T1 spinopelvic inclination, and SVA has been associated with worse scores on surveys such as the Oswestry Disability Index (ODI), SRS 23 Patient Questionnaire, and12-Item Short Form Health Survey (SF-12) (Glassman et al. 2005a, b; Schwab et al. 2006a; Lazennec et al. 2009; Lafage et al. 2009). In lieu of these HRQOL studies, Schwab et al. outlined ideal thresholds with regard to key spinopelvic parameters. They found severe disability with regard to ODI with SVA exceeding 47 mm, pelvic tilt greater than 25°, and pelvic incidence minus lumbar lordosis being above 11° (Schwab et al. 2006b, 2010, 2013).

Management

Non-operative management of adult spinal deformity is usually limited to patients with mild deformity, minimal to mild pain, little disability in daily functional activities, nonprogressive symptoms, and lack of worrisome symptoms such as those of cauda equina. Non-operative management can also be applied to poor surgical candidates who have high anesthetic risks given profound comorbidities. Non-operative management modalities include massage, aqua therapy, and physical therapy which can serve to strength

the surrounding paraspinal muscles and core as a whole. Additional modalities include nonsteroidal anti-inflammatory drugs, neuropathic medications (gabapentin), and epidural steroid injections (Cummins et al. 2006). The impact of non-operative modalities in improving pain and disability, however, is controversial. In 2010, Glassman et al. presented a prospective cohort study of 123 patients. Sixty-eight patients proceeded with conservative management consisting of physical therapy, bracing, bed rest, injections, and chiropractic care. Despite a mean cost of $10,815 over the course of 2 years, no significant change was found with regard to HRQOL outcomes (Glassman et al. 2010).

Indications for operative management include worsening pain, progressive deformity, declining neurological function, and failure of non-operative interventions. The spinopelvic parameters discussed earlier can help to assess the degree of deformity. Severe disability (measured with ODI) is correlated with SVA exceeding 47 mm, pelvic tilt greater than 25°, and pelvic incidence minus lumbar lordosis being above 11° (Schwab et al. 2010, 2013). In a 2009 prospective observational cohort, Bridwell et al. followed symptomatic adult scoliosis patients for 2 years. One hundred sixty patients treated either non-operatively or operatively were followed for 2 years. The non-operative cohort had no significant change in quality of life measures such as SRS and ODI. The operative cohort, however, did experience a significant improvement across all quality of life metrics (Bridwell et al. 2009). While each case of adult spinal deformity is unique, these findings do suggest that those with severe deformity and poor QOL scores may benefit from operative intervention (Bridwell et al. 2009; Smith et al. 2009c).

Operative intervention needs to be tailored to the specifics of each adult spinal deformity patient. Factors such as clinical symptoms, age, and overall medical health can help to steer direction of management. Operative modalities can include decompression, decompression with limited instrumentation, long-segment instrumentation, and corrective osteotomies. Decompression alone has a limited but important scope. Studies have shown that decompression alone may help radicular and compressive relative symptoms but risks progression of deformity (Kelleher et al. 2010). As such, decompression alone may help to address primarily compressive or radicular symptoms in an elderly individual, who may not otherwise be a candidate for extensive instrumentation or deformity correction given osteoporosis or medical comorbidities. In the following sections, we will discuss various methods of instrumentation, decision-making regarding what levels to include, and corrective osteotomies.

Early Fixation Constructs: Harrington Instrumentation, Wires, and Hooks

A key in the early development of spinal instrumentation involved the use of Harrington rods and instrumentation technique (Drummond 1988). Initially, Harrington rods were applied with the use of facet screws. However, Harrington constructs involving the use of facet screws did not prove viable in the long term as the screws were unable to accommodate the forces needed to correct spinal deformity (Harrington 1972, 1973). Subsequently, attention was directed toward new forms of spinal fixation involving sublaminar wiring and hooks. One such wiring technique, Luque wiring, was developed in Mexico. Luque wiring consisted of sublaminar wires that were twisted around rods posteriorly (Luque 1982). Since they are sublaminar, Luque wiring does place neural structures at risk during placement (Zdeblick et al. 1991). During the development of these early constructs, however, deformity was primarily understood as a problem in the coronal plane. As such, Harrington instrumentation and these early fixation models did not take into account the importance of sagittal. In the 1970s, various publications described the loss of lumbar lordosis and the development of a "flat back" resulting from Harrington distraction techniques (Doherty 1973; Grobler et al. 1978). The resultant flat back (iatrogenic fixed sagittal imbalance) made it a challenge to maintain upright posture and a horizontal gaze. To accommodate for the flat back, patient often flexes the hips and knees while extending the mobile cervical and thoracic segments (Potter et al. 2004).

Subsequent development focused on hooks as a means of providing segmental fixation that accommodated for lumbar lordosis. Examples of hooks include pedicle, laminar, supralaminar, and transverse process hooks. While adult spinal deformity is a complex malalignment involving all three vertebral columns in multiple planes, hooks primarily rely on fixation to the posterior column. Fixation through the posterior column alone may be unable to overcome the forces associated with the underlying spinal deformity required in obtaining and maintaining a correction (Rohlmann et al. 2006; Hackenberg et al. 2002). As such, these earlier techniques often involved additional anterior releases and correction to supplement the posterior fixation.

With the advent of pedicle screws, fixation could be placed across all three columns of the vertebra making it useful in deformity correction (Chang et al. 1988). Studies comparing pedicle screws versus hooks suggested that hooks had less pullout strength compared to pedicle screws (Liljenqvist et al. 2001). Clinically, pedicle screw constructs have been shown to lead to greater improvement in Cobb angles and sagittal alignment (Hamill et al. 1996). Some reports suggest increased rates of postoperative fusion with pedicle screws (Hamill et al. 1996; Gaines 2000; West et al. 1991; Thomsen et al. 1997). Multiple studies have suggested a decreased need for postoperative immobilization and bracing with the use of pedicle screws, as well as earlier process of rehabilitation (Marchesi and Aebi 1992; Suk et al. 1994, 1995). Pedicle screw placement has become safe and efficient. In particular, use of intraoperative fluoroscopy and intraoperative computed tomography and navigation has allowed for increased precision when placing pedicle screws (Miller et al. 2016; Gelalis et al. 2012).

Proximal and Distal Extent of Instrumentation

The proximal extent of the instrumentation is referred to as the upper instrumented vertebra (UIV). Generally, the UIV segment should not be at a level of segmental rotation or translation. Additionally, the UIV should not be at the apex of the curvature. Ending at a level of junctional kyphosis should be avoided. Mardjetko suggests that the UIV should be at a level within 2 cm of the coronal vertical axis and sagittal vertical axis (Shufflebarger et al. 2006). Given that spinal deformity curves may extend from the lumbar to the thoracic spine, the proximal instrumentation may need to extend to the thoracic spine. Extension to the thoracic spine, however, does raise concerns of proximal junctional kyphosis. As such, the most kyphotic range of the thoracic spine is avoided. This leaves two options for the upper instrumented vertebra: upper thoracic (T1–T6) and lower thoracic (T9–L1) (Kim et al. 2008, 2013, 2014; McCord et al. 1992). Proximal instrumentation to the upper thoracic versus the lower thoracic in adult scoliosis patients has increased operative times and blood loss but had similar levels of proximal junctional kyphosis and revision surgeries compared to UIV to the lower thoracic levels (T9–L1) (Kim et al. 2014). Mode of proximal junctional failure in the upper thoracic UIV is often ligamentous disruption compared to lower thoracic UIV in which failure is bony. While not reaching clinical significance, the total number of complications was greater with upper thoracic group, including substantial complications such as pseudoarthrosis (Kim et al. 2014).

The distal instrumented vertebra (DIV) has evolved over the years. McCord et al. defined the lumbosacral pivot point as the "intersection of the middle osteoligamentous column in the sagittal plane and the lumbosacral intervertebral disc in the transverse plane." They discuss concerns that DIV to sacrum is potentially less resistant to flexion moments and advocate for longer constructs distal to S1 and anterior to the pivot point (McCord et al. 1992). Constructs such as iliac bolts and S2-alar-iliac screws subsequently evolved to accommodate these principles. In a 2001 study, Lenke et al., they found a 95.1% fusion rate when using iliac screws for long fusions to the sacrum and severe spondylolisthesis (Kuklo et al. 2001). Another option is that of the S2-alar-iliac screws, which has a starting point at S2 with extended through the sacral

ala into the ilium (Burns et al. 2016). Biomechanical studies suggest similar load to failure in comparing iliac screws to S2AI screws with the S2AI screws having the benefit of being lower profile and lining up with the lumbosacral screws obviating the need for offset connectors. Overall, such longer constructs can potentially better resist flexion moments with lower rates of failure compared to fixation ending at L5 or S1 (Kuklo et al. 2001; Burns et al. 2016; Kebaish 2010).

Osteotomies

In cases of rigid and severe spinal deformity, instrumented fusion alone may not fully correct the deformity, and additional correction through osteotomies of the vertebral column may be needed. Several osteotomies are available to aid in deformity correction including Ponte, Smith-Petersen osteotomy (SPO), pedicle subtraction osteotomy (PSO), and vertebral column resection. These osteotomies should be viewed as a spectrum with the more complex osteotomies built on the foundation of simpler osteotomies giving a greater correction. Choice in osteotomy depends on the amount of correction that is desired. Goals for deformity correction in the sagittal plane are an SVA under 5 cm, pelvic tilt less than 25°, and pelvic incidence minus lumbar lordosis being less than 11° (Schwab et al. 2010, 2013). In 2014, Schwab et al. created the comprehensive anatomical spinal osteotomy classification, which is a system to understand vertebral osteotomies. This system classifies the osteotomies into six categories based on increasing vertebral resection and destabilization; a graphic illustration can be seen in Fig. 3 (Schwab et al. 2015). While Schwab's classification system provides a systemic framework for understanding osteotomies, we will focus the discussion on the above classically described osteotomies.

Smith-Petersen Osteotomy

Developed in 1945, the Smith-Petersen osteotomy was initially developed to address flexion deformity in patients with ankylosed spines and rheumatoid arthritis (Smith-Petersen et al. 1945). As outlined in their original paper in 1945, the SPO involves removal of elements from the posterior column. The SPO does not extend into the vertebral body itself. The overall principle behind the SPO relies on an axis of rotation through the middle column. In effect, the removal of the posterior column and subsequent closing of the posterior void lead to elongation of the anterior column through osteoclasis of the anterior disc space and anterior longitudinal ligament.

Although the terms are often used interchangeably, Ponte osteotomies are distinguished from Smith-Petersen osteotomies in patient selection. A Ponte is performed in patients with an open disc space. Although it still results in a lengthening of the anterior column, it does not involve an osteoclasis of the anterior column. It is often used in conjunction with an interbody cage which serves as a fulcrum assisting to get angular correction with posterior compression. For the purposes of this chapter, we will refer to both these techniques as SPO. A SPO consists of a standard laminectomy and resection of the inferior articular facet of cranial level and superior articular facet of caudal level. They are usually performed at multiple consecutive levels in order to achieve a gradual correction. Classically these are performed for pathology such as Scheuermann's kyphosis (Ponte et al. 2018).

SPO technique differs slightly based on location: thoracic versus lumbar spine. Overall the concept is the same, resection of posterior elements allowing for compression and angular correction of approximately 5–10°. Anatomic differences particularly in facet orientation alter the sequence of steps depending on the location.

In the thoracic spine, the first step is using an osteotome to resect the inferior articular facet of the cranial level, exposing the cartilage of the superior articular facet. Next, the spinous process of the osteotomy level is removed, exposing the interlaminar space. The amount of resection of the lamina is based on the desired angular correction. More resection will potentially lead to more correction. Ideally, after the osteotomy is performed, the lamina which is resected and the

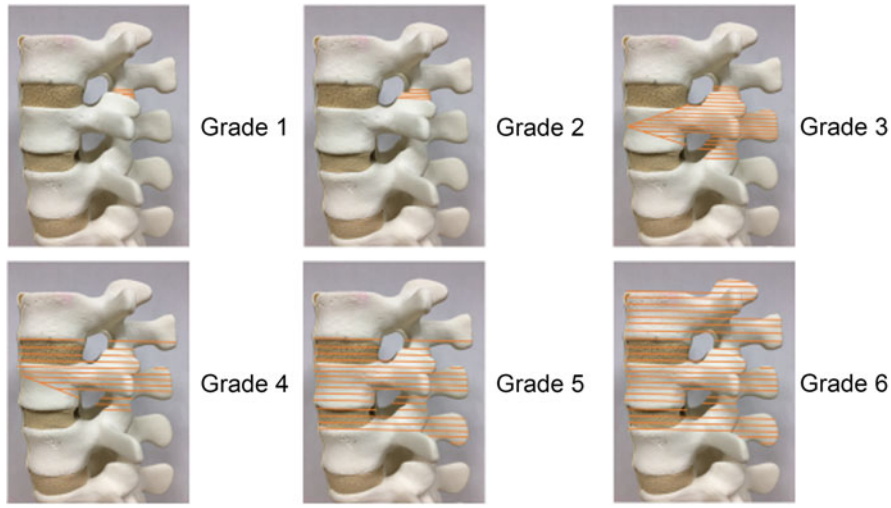

Fig. 3 Graphic illustration of Schwab et al. anatomical spinal osteotomy classification. Grade 1 involves partial resection of facet joint. Grade 2 involves complete facet joint resection. Grade 3 resects posterior elements, pedicles, and portion of vertebral body. Grade 4 resects posterior elements, pedicles, portion of vertebral body, intervertebral disc, and adjacent end plate. Grade 5 involves complete resection of vertebral segment and the adjoining intervertebral discs. Grade 6 involves complete resection of multiple vertebral segments (Schwab et al. 2015)

lamina of the caudal level should be in contact, providing a surface area for fusion. The lamina should be resected in a superiolateral direction on the midline creating a "V"-shaped bony defect. Due to the shape of the resection, these osteotomies are often referred to as chevron osteotomies. Next, the exposed ligamentum flavum is resected in the same direction exposing the spinal cord. Access to the canal can be gained through a midline defect in the ligament. After the ligament is resected, the superior articular facet of the caudal level is resected by continuing laterally with a Kerrison. Thorough excision of the ligament and superior articular facet is critical. Failure to remove these structures will lead to compression of either the spinal cord or nerve root, potentially leading to postoperative complications. If these osteotomies are performed after pedicle screws are placed, the heads of the screws may obstruct the resection of the superior articular facet. In such instances, one can either perform the osteotomy prior to placing in the screws or using a modular system where the heads are attached after the osteotomy.

In the lumbar spine, the screw heads do not interfere with the resection and therefore be inserted prior to performing the osteotomy. Additionally, due to the bony anatomy, it is not typically possible to have the resected lamina contact the caudal lamina. Therefore, a more generous laminectomy is performed. Since there is often spinal stenosis in the lumber spine which needs to be addressed as well, lamina resection at least to the origin of ligamentum flavum is recommended. Additionally, most lumbar SPOs/Ponte are performed caudal to the conus, allowing an interbody cage to be safely placed posteriorly. An appropriately placed cage can provide a pivot point to gain more angular correction. The laminectomy is performed in the usual standard fashion. Subsequently, the pars on both sides are identified and resected with a Kerrison or a drill. Our preference is to place a Woodson in the foramen, serving to protect the exiting nerve root. Subsequently, we drill away the pars in its entirety until the Woodson is visualized. The inferior articular facet is then removed as it is no longer attached to any bony or soft tissue structures. The final step is to resect the overhanging portion of the superior articular facet. Removal with a Kerrison can be challenging given overgrowth. It is our preference to use a straight osteotome and

place it in line with the superior aspect of the pedicle and remove it en bloc. There is usually venous bleeding in the foramen which can be stopped with bipolar cautery. We find this technique to be safe as the exiting nerve root typically lies in the superior third of the foramen. Therefore, even in the event of plunging with the osteotome, the exiting nerve root is safe from harm. The posterior void is subsequently closed via spinal instrumentation (Schwab et al. 2015; Bridwell 2006).

Smith-Petersen/Ponte osteotomies are best for deformities that have larger radius of curvatures as opposed to sharp curves (Cho et al. 2005). Since the anterior column is elongated, they should be avoided in cases where there is less than 5 mm of intervertebral disc present. These osteotomies allow for about 10° of correction per level performed (Cho et al. 2005).

Pedicle Subtraction Osteotomy

The pedicle subtraction osteotomy requires more resection than that for an SPO/Ponte osteotomy. While the SPO only involves the posterior column, pedicle subtraction osteotomies extend into the vertebral body at the desired level of correction, and as such is a three-column osteotomy. A PSO generally creates a triangular wedge through the vertebral body with removal of the posterior column. The osteotomy has an axis of rotation at the anterior aspect of the vertebral and shortens the posterior column without elongating the anterior column. The PSO can prove useful in patients with a rigid ALL or immobile vertebral disc, where an SPO/Ponte is usually contraindicated. Furthermore, a PSO can address sharp curves and curves that exceed 25° (Cho et al. 2005; Berjano and Aebi 2015; Chen et al. 2001). A PSO can provide 25–35° of correction (Berjano and Aebi 2015; Chen et al. 2001; Bridwell et al. 2003). Figure 4 demonstrates a case involving a PSO at L3 in conjunction with Smith-Petersen osteotomies at adjacent segments resulting in significant deformity correction.

In performing a PSO, the patient is placed prone on the operating table. When possible the PSO is below the level of the conus. There is variability as to where the conus ends; as such, it is imperative to review preoperative MRI or CT myelogram in selecting the level for the PSO. A cord-level PSO is associated with a considerably higher risk of cord injury and should be avoided when possible. The more caudal the osteotomy is performed, the greater the SVA is corrected for the same angular wedge resection. However, the more caudal the PSO is performed, the fewer fixation points will exist. For the stated reasons, L2 and L3 are commonly chosen levels. Due to significant angular correction, laminectomies are usually performed above and below the PSO site in order to prevent compression of the neural elements upon closure of the osteotomy site.

Conceptually, the building blocks of a PSO are two adjacent SPO. This will isolate a pedicle of a single level and is the first step of a PSO. The amount of angular correction is based on the angle of the wedge which is excised. This correlates to the distance between the starting points of the osteotomy along the posterior vertebral body. The limiting structures are the disc space above the pedicle and exiting nerve root below the pedicle to be excised. After two adjacent SPO are performed, these structures are identified bilaterally. The exiting nerve is followed out into the foramen. Prior to performing a PSO, all screw fixation is in place. We will routinely tap the pedicle of the osteotomy level with a large tap removing all the cancellous bone thereby making pedicle resection easier. We will also tap into the vertebral body creating a trajectory for our osteotome. The residual superior articular facet is then resected with a Leksell rongeur until flush with the transverse process. The transverse process is detached from its attachment at the lateral aspect of the pedicle. It is critical that the TP is cut flush with the lateral border of the pedicle. If it is not, when dissecting the psoas off the lateral aspect of the vertebral body, the segmental vessel is at risk. Using a large curette, the lateral wall of the pedicle and vertebral body is exposed. With the pedicle now in view circumferentially, it is removed with a rongeur. Any bony prominences need to be removed as

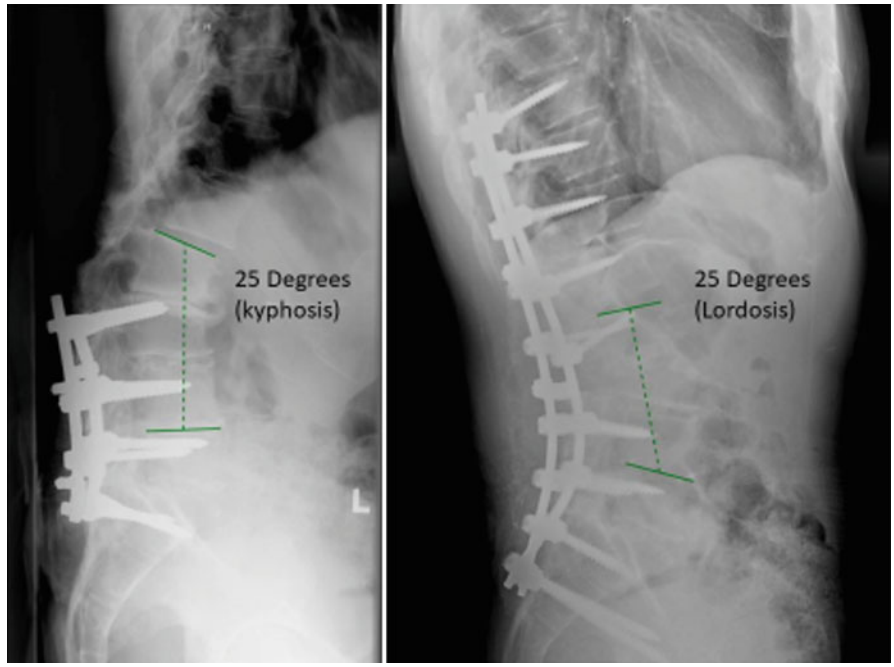

Fig. 4 A 68-year-old patient with persistent back pain status post remote L3 to S1 instrumentation and fusion. At initial evaluation, patient was found to have spinal stenosis and deformity consisting of kyphoscoliosis. Segmental Cobb angle from L2 to L4 demonstrated 25° of kyphosis. Patient underwent extension of instrumentation both proximally to T10 and distally to ilium. Additionally, a pedicle subtracting osteotomy was performed at L3 in conjunction with Smith-Petersen osteotomies at T12 to L2. Postsurgical radiographs demonstrated improvement in segmental lordosis to 25° from L2 to L4, representing an improvement in about 50°

they may cause foraminal stenosis after the osteotomy is closed. The exiting nerve root is protected with a nerve root retractor when removing the inferior wall of the pedicle. By resecting the pedicle, the two foramens have been combined making one large foramen that is housing two nerve roots. This step is performed bilaterally. A temporary stabilizing rod is now placed unilaterally, and an osteotome is used to make a wedge resection on one side. The superior cut is just caudal to the disc space above where the pedicle was, and the caudal cut is just cranial to the exiting nerve root immediately below where the pedicle was. One pass of the osteotome is directed medially and the other laterally, cutting the lateral wall of the vertebral body. The rod is moved to the opposite side, and a contralateral wedge resection is performed. The depth of the osteotome is determined by fluoroscopy or navigation. If using fluoroscopy, in the setting of a rotational deformity, the author prefers to rotate the table, so the osteotomy segment is no longer rotated. This leads to a more accurate assessment of depth of the osteotomy on fluoroscopy. After these cuts are made, a single vertical cut of the posterior vertebral body is made connecting the first two cuts. The resultant wedge is then resected and saved as autograft. Subsequently, a curette is used to remove any cancellous bone behind the remaining posterior cortex ventral to the thecal sac. A Woodson is used to develop a plane between the dura and posterior cortex. An Epstein curette or a Siefert bone tamp is used to impact the posterior wall into the defect created by removing the wedge. With the three-column osteotomy now complete, the spine should be mobile and the deformity ready to be corrected. Compression is applied on the temporary rods on either side closing the osteotomy, and wrinkling of the dura is noticed. Contact between the edges of the osteotomy marks the maximum extent of the correction obtained. If further correction is

desired, the fixation is released, and further bony resection is performed. In the osteoporotic spine, if there is concern for screw loosening with compression, the patient's hips can be extended to close the osteotomy either manually or with an axis bed (Cho et al. 2005; Chen et al. 2001; Bridwell et al. 2003; Bianco et al. 2014).

If a larger correction is needed, one can perform an extended PSO. The extended PSO involves resection of the posterior aspect of the adjoining disc space and superior end plate. This creates a larger wedge and subsequently a larger correction. In order to increase the likelihood of a fusion, this procedure is often accompanied by a TLIF with the implant placed anteriorly resting on the residual superior end plate. If a patient has a multiplanar deformity, asymmetric wedges can be resected to achieve a correction in the sagittal as well as the coronal plane.

While a pedicle subtraction osteotomy allows for substantial correction of deformity, given the complex and aggressive nature of the osteotomy, it is associated with some notable complications. Several studies have reported complications rate reaching close to 50% (Bianco et al. 2014; Kelly et al. 2014). The International Spine Study Group reported 7% rate of intraoperative complications, 39% rate of postoperative complications, and 42% rate of overall complications. Additionally, they reported an average blood loss of 55% of total blood volume. Age older than 60, a thoracic three-column osteotomy, osteotomies at two or more levels, and major blood loss were all associated with increased complications (Kelly et al. 2014).

Vertebral Column Resection

Vertebral column resection builds on a PSO and allows greater segmental correction. It entails complete removal of a vertebral segment and allows for multiplanar corrections. A VCR can also prove useful in malformed vertebral segments that are not amenable to angular osteotomies such as those encountered in congenital scoliosis. Vertebral column resection was first described in the early 1980s by Bradford as method of addressing severe and rigid spinal deformity (Bradford 1987; Lenke et al. 2010).

Setup and technique for a VCR start similar to that of a PSO. Similar to a PSO, prior to proceeding with the VCR, it is imperative to establish fixation above and below the level of correction, as the VCR will lead to destabilization of the spine. The pedicle is isolated and resected as described above. Deviating from a PSO, the authors next prepare the cranial and caudal disc spaces as one would do for a TLIF. Careful attention is paid to removing all disc material and cartilage on the inferior and superior end plates from the cranial and caudal levels, respectively. This will establish margins for resection required for a VCR and to place a cage. Subsequently, similar to a PSO, the lateral aspects of the vertebral body are accessed and protected, while the vertebral body is resected. The resection can be performed with an osteotome or a drill. Similar to a PSO, the posterior wall is resected last. Subsequently, a spacer is placed where the vertebral body was. In the lumbar spine, this can be challenging as the nerve roots block complete access to the vertebrae to be resected and to the space created during cage insertion. For this reason, we use expandable cages as they can be inserted in the interval between the nerve roots, rotated, and expanded. In the thoracic spine, the nerve roots can be resected allowing for easier access to the anterior aspect of the spine without significant neurologic repercussion. While VCRs do have the potential for significant deformity correction, they are also associated with substantial complications. In 2011 study by the Scoliosis Research Society, VCRs were associated with a complication rate of 61.1%. In contrast, they found a 28.1% complication rate in SPOs and 39.1% in PSOs (Smith et al. 2011). Suk et al. in the early to mid-2000s published several retrospective studies that detailed their preferred technique for a VCR and report outcomes. In their 2002 study, 70 patients underwent a VCR; an average correction of 61.9% in the coronal and 45.2% in the sagittal planes was achieved. Twenty-four of the 70 patients (34.2%) had a complication including 2 complete injuries to the spinal cord (Suk et al. 2002). In Suk's

2005 study, they performed 16 VCRs and achieved an average SVA correction from 4.2 to 1.6 cm. They had complications in 4 of the 16 patients (25%), including 1 involving complete paralysis (Suk et al. 2005a). These studies highlight that the potential deformity correction through a VCR comes at the cost of a technically challenging procedure with high rates of severe complications (Smith et al. 2011; Suk et al. 2002, 2005a, b).

Minimally Invasive Surgery

With technological and surgical advancements, interest has grown in minimally invasive surgery as a route to operatively address spinal deformity. Minimally invasive surgery can include use of interbody fusion through anterior and extreme lateral. A systematic review by Phan et al. in 2015 regarding direct lateral and extreme lateral interbody fusions (DLIF and XLIF) showed promise in correcting coronal deformity and regional lumbar lordosis (Phan et al. 2015). A retrospective review by Anand et al. suggests that MIS deformity correction has the potential for significant deformity correction, with less blood loss and morbidity compared to open procedures (Anand et al. 2010). Figure 5 shows correction achieved with placement of lateral retroperitoneal interbody placement in conjunction with posterior osteotomies and instrumentation.

Newer studies, however, have suggested the possibility of more substantial correction with hyperlordotic cages that can help to correct the global sagittal imbalance and improve lordosis (Gödde et al. 2003; Le et al. 2012). Additionally, the anterior longitudinal ligament resection is increasingly being appreciated as a method for additional correction. In particular, selective releases of the anterior longitudinal ligament through a minimally invasive retroperitoneal transpoas (lateral) approach can help to restore lumbar lordosis while minimizing the complex dissection and resection involved in the various posterior-based osteotomies (Deukmedjian et al. 2012a). In a 2012 cadaveric study, combination of a hyperlordotic cage and ALL releases led to an increase in 11.6° of segmental lordosis (Uribe et al. 2012). In a retrospective review of

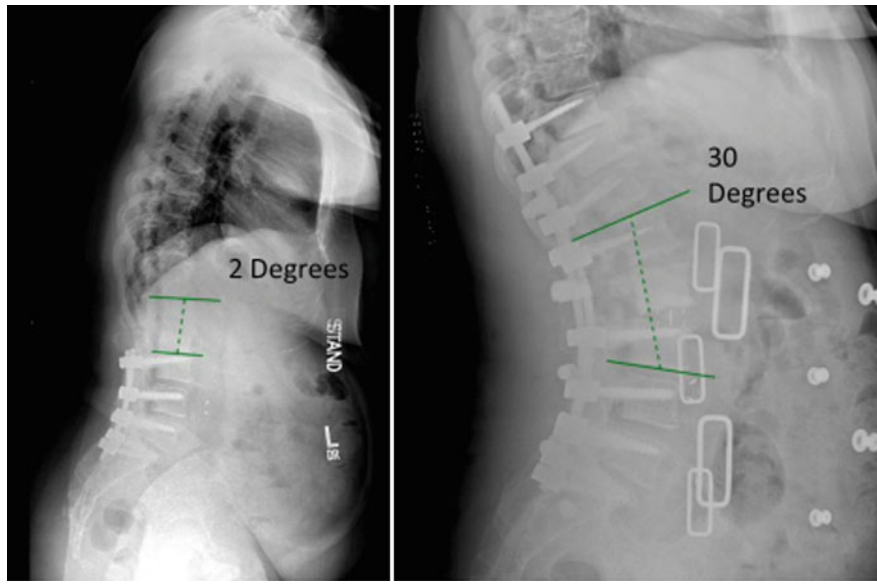

Fig. 5 A 63-year-old patient presented with global sagittal imbalance and stenosis at L2–L3. Initial radiographs on left demonstrate segmental lumbar lordosis measuring at 2° from L2 to L3. Radiographs on right demonstrate extension of fusion proximally to T10 with Smith-Petersen osteotomies at L1 and L2 with lateral retroperitoneal interbody placement at L2–L3. Segmental lumbar lordosis improved to 31°

prospectively collected data, Deukmedjian et al. assess ALL releases in patients with adult spinal deformity. In their study, they found an overall increase in lordosis of 24°, with segmental lumbar lordosis improving by 17° per level of ALL release (Deukmedjian et al. 2012b). In a cadaveric study and presentation of four clinical cases, Uribe et al. found an average increase of 10.2° per level of ALL released and 25° of overall global lumbar lordosis (Deukmedjian et al. 2012c). In a 2016 cadaveric biomechanical study by Hutton et al., they found a placement of 30° lordotic cage in addition to ALL release led to a 10.5° increase in segmental lumbar lordosis (Melikian et al. 2016). When combined with posterior facet resection and compression, one can achieve an even great degree of correction. While the individual correction values may vary in these studies, they do highlight the potential of ALL releases in deformity correction (Le et al. 2012).

Prior to performing an ALL resection, a surgeon must be comfortable performing a standard lateral interbody fusion. After prepping the disc space for the placement of an implant, soft tissue is dissected off the disc space along the anterior border of the spine. There should be a clean plane between the great vessels and the spine. If there is resistance to dissection, it is our recommendation that the ALL release should be abandoned. A retractor is then placed in front of the disc space across the anterior aspect of the spine. With a clear view of the anterior annulus and ALL, a special knife is used to cut the ALL. It is our preference to use an expanding trial to rupture any remaining fibers. We then place in a hyperlordotic implant with integrated fixation and secure it to one vertebral body in order to prevent anterior extrusion of the implant.

While MIS technology has advanced and provides a reasonable method for deformity correction in specific situations, careful patient selection and acknowledgment of MIS limitations are imperative. As in any spine case, extensive preoperative planning is critical in matching patient's diagnosis and pathology with appropriate treatment. The decision to pursue MIS, open deformity correction, or a combination of the two must match the intended degree of correction. Mummaneni et al. as part of the Minimally Invasive Section of the ISSG published an algorithm in 2014 that aimed to help in MIS and deformity decision-making (Mummaneni et al. 2014). The minimally invasive spinal deformity surgery (MISDEF) algorithm separates deformity correction into three different classes.

Class I is defined as patients with compressive symptoms relating to claudication or radiculopathy with minimal deformity. Furthermore, they use several parameters to define class I deformity: SVA less than 6 cm, PT less than 25°, LL-PI less than 10, lateral listhesis less than 6 mm, coronal Cobb angle less than 20°, and a flexible curve. They suggest that MIS techniques using decompression alone or with limited fusion are reasonable for class I deformity. Class II is defined as patients with previously mentioned compressive symptoms with a large component of back pain as well. Parameters for class II include lateral listhesis greater than 6 mm, coronal Cobb greater than 20°, and a LL-PI mismatch of 10–30°. For class II they recommend MIS surgery using decompression with multilevel interbody fusion that extends beyond just the apex of the curve (Mummaneni et al. 2014).

Class III patients are characterized by severe deformity in both coronal and sagittal imbalances. Parameters for this group include inflexible curves, SVA greater than 7 cm, LL-PI mismatch of greater than 30°, PT greater than 25°, and thoracic hyperkyphosis greater than 60. Class III patients are not readily amenable to MIS deformity correction and are better suited for traditional open deformity correction with osteotomies (as described in the previous sections). Mummaneni et al. tested the algorithm by having spine surgeons' complete surveys to classify various cases into the above classes and found MISDEF to have high intra- and inter-observer reliability (Mummaneni et al. 2014).

While algorithms like the MISDEF provide a framework to understand treatment options for deformity correction, treatment must accommodate for the unique characteristics of the patient's deformity as well as the surgeon's

comfort with various surgical techniques. Furthermore, MIS technology continues to advance, and patients that currently are treated with open corrective techniques may in the future be treated with MIS approaches.

Conclusions

Adult spinal deformity is complex deformity that involves three-dimensional deformation in coronal, sagittal, and axial planes. Spinal and spinopelvic parameters such as SVA, pelvic tilt, pelvic incidence, and lumbar lordosis are important in understanding, characterizing, and treating adult spinal deformity. Treatment of adult spinal deformity needs to be tailored to each patient with respect to the nature of the curve and the patients overall medical health. Operative techniques have changed substantially with time, from the early use of Harrington rods to modern pedicle screws. Multiple osteotomies (SPO, PSO, and VCR) can be applied for the desired level of spinal correction. Operative management of adult spinal deformity is wrought with complexity and severe complications. Newer techniques involving minimally invasive surgery and interbody fusions are being increasingly used for deformity correction.

Abstract

Surgical fixation of the sacroiliac joint (SIJ) has increased in popularity over the last few decades, especially with the recent emergence of minimally invasive techniques. The indications for this procedure are expanding and include joint dysfunction, degeneration/arthrosis, trauma, and postpartum instability, among others. With rising frequency of lumbosacral arthrodesis, interest has developed regarding the SIJ as a pain generator due to accelerated degeneration/dysfunction as an "adjacent segment" receiving more force distribution. The current body of literature suggests that a targeted history and physical examination

specific to the SIJ, and provocative testing, are paramount for appropriate patient selection. A thorough understanding of the anatomy and biomechanics involving the SIJ is essential to forming a critical review of the various surgical approaches and hardware instrumentation options as they become available. The SIJ anatomy can be approached from several open corridors including ventral-ilioinguinal, posterolateral iliosacral, and posterior sacral-alar-iliac approach. Similarly, minimally invasive approaches have been developed using posterolateral iliosacral trans-articular and posterior intra-articular techniques. Multiple hardware options are available for SIJ fixation and continue to grow, including screw-plate and screw-rod constructs, trans-articular fusion rods, intra-articular cages, trans-articular threaded screws, and hollow modular anchoring screws. The epidemic nature of low back pain will likely lead to an expanding interest in SIJ fixation, and critical appraisal of the cost and efficacy of hardware and techniques will warrant greater study.

Introduction

Low back pain (LBP) is a growing global problem and a common cause of disability and lost work days (Freburger et al. 2009). It is recognized as a major driver for morbidity across the economic spectrum from low- to high-income countries (Hoy et al. 2010). Although a wide range of etiologies exists, recent literature attention has focused on the sacroiliac joint (SIJ) as an important contributor to low back pain (Zaidi et al. 2015). The SIJ may be implicated as the pain generator in as many as 30% of patients with low back pain according to recent studies (Bernard and Kirkaldy-Willis 1987; Cohen et al. 2013). As such, a variety of conservative and surgical treatment modalities are being developed, with both open and minimally invasive approaches. As is the case with many spinal technologies, several different implant materials and styles have been trialed, including titanium fixation constructs and biologic materials.

As understanding of SIJ pathology grows, the clinical conditions for which surgical fixation is being utilized are also expanding. These conditions include degeneration/arthrosis, joint dysfunction, postpartum instability, trauma, pathologic fractures, and inflammatory arthropathies among others (Zaidi et al. 2015). Because imaging techniques have not demonstrated sufficient diagnostic value to determine which patients will see benefit from surgical fixation, the development of consensus over history and physical techniques, as well as provocative testing, is paramount (Elgafy et al. 2001; Dreyfuss et al. 2004). Further study of implantation techniques and materials will need to address postoperative complication profiles, rates of bony fusion, implant cost, and natural history of SIJ pathology.

Anatomy

The pelvic girdle constitutes a support structure that distributes force vectors from the spine as well as the legs. As the junction between the sacrum and the remainder of the bony pelvis, the SIJs have been conceptualized as "stress relievers" between the lower extremities and the trunk (Vleeming et al. 2012). Although there is considerable anatomic variability among individuals and sexes, the SIJ usually spans the majority of S1, S2, and S3 sacral levels. The joint can be conceptualized as diarthrodial, with hyaline and fibrocartilage, and a relatively irregular articulating surface (Forst et al. 2006). Because there are synarthrotic components, the joint has also been referred to as amphiarthrodial (Vleeming et al. 2012). However, there is a relative paucity of movement across the joint under normal circumstances, with generally less than 1 mm of transverse/sagittal translation and vertical movements usually less than 2 mm (Walheim et al. 1984). The articulating surface visualized

en face is roughly C-shaped, and the superior portion is predominately fibrous, whereas the inferior portion is mostly synovial (Cole et al. 1996). The overall joint orientation is arranged such that the vertical forces from gravity can be resisted (Vleeming et al. 2012). There does appear to be sexual dimorphism, with articular surface area ranging up to 18 sq. cm for females and 22.3 sq. cm for males (Sashin 1930; Miller et al. 1987).

The functional integrity of the SIJ is closely supported by several investing ligaments, including interosseous, ventral, and dorsal locations. The interosseous ligaments are also connected to the sacroiliac transverse ligaments. Ventrally, the ligamentous attachments of the SIJ form a connective tissue plane that is relatively thin and vulnerable to injury. Dorsally, the ligamentous anatomy supporting the SIJ is multilayered and more complex and includes dorsal sacroiliac ligaments categorized as long and short. These ligaments predominantly course from the crests of the sacrum to the posterior superior iliac spine. Stability across the SIJ is due in part to muscular action as well. These include the gluteus maximus, erector spinae, and multifidi, among others (Vleeming et al. 2012).

Innervation of the SIJ has been studied in both human and animal models, in an effort to help elucidate the origin of pain attributed to the joint itself. This supply appears to derive from both the ventral (L4 and L5) and dorsal rami (L5, S1, S2) and the superior gluteal nerve (Nakagawa 1966). However, subsequent analyses have determined that the majority of the supply may originate from the dorsal aspect (Forst et al. 2006). Murine neural tracer was applied to study this question in more detail and found dorsal root ganglion supply in the SIJ from the L1 to S2 levels primarily, with L1–3 innervating the ventral aspect and L4–S2 innervating the dorsal aspect. On the ventral aspect, there was innervation also emerging from the sympathetic trunk (Murata et al. 2001). Within the SIJ itself, nerve fibers were observed in human dissection that were both myelinated and unmyelinated (Grob et al. 1995), and this is consistent at least for the outer margins of the joint (Vleeming et al. 2012).

Biomechanics

An understanding of the biomechanical principles underlying the SIJ is critical to the design and implementation of instrumentation constructs and arthrodesis. Early twentieth-century literature had already established that there was a small amount of movement across the joint and that this tended to abate after approximately the fifth decade (Sashin 1930). Cadaveric analysis reveals that the adult SIJ orientation at the level of S1–2 is obliquely in the anterior-posterior direction with 20 degrees of offset from the vertical plane. Force testing showed that the bilateral natural joint construction most resisted medio-lateral vectors, with progressively more motion resulting from superior/inferior and then anterior-posterior vectors. When one joint was isolated, anterior shearing and torsion were seen to cause larger degrees of motion (Miller et al. 1987).

The largest degree of functional movement imparted by the SIJ was determined to occur with iliac rotation relative to the sacrum, on a transverse axis. This is called nutation in the forward direction and counternutation backward. When load is placed across the SIJs, when sitting or standing, the movement of nutation is seen. The degree of irregularity and surface characteristics of the articulating surfaces of the SIJ make it unique among similar human joints; it has a higher coefficient of friction than any other diarthrodial joint, which helps to resist shearing (Vleeming et al. 2012). The biomechanical properties of the SIJ differentiate it from nearby spinal segments; compared to the lumbar spine, the SIJ is more likely to fail under axial compression and axial torsion (Forst et al. 2006). In order to study motion about the SIJ, the radiostereometric analysis method has been validated and utilized (Kibsgård et al. 2012). Applied to human volunteers, this analysis has confirmed a very small degree of motion across the SIJs, approximately 0.5 degrees (Sturesson et al. 2000), which is compared to prior work showing mean rotation of 2.5 degrees, and no significant difference in motion between symptomatic and asymptomatic joints (Sturesson et al. 1989).

Etiology of Sacroiliac Joint Pathology

Over the lifespan, the human SIJ undergoes an expected degenerative process. Starting during adolescence, the joint surface is reported to become rougher with plaque formation. By the fifth decade, osteophyte formation was common along with corresponding articular surface irregularity. These osteophytes often were interdigitating across the joint by the seventh decade along with thinning of the articular cartilage (Bowen and Cassidy 1981). Aside from natural history of the joint through the aging process, a variety of pathologies can affect the SIJ to cause symptoms. These can include infection, arthritis, fracture and ligamentous injury, malignancy hypo−/hypermobility, chondromalacia, enthesitis, leg length or gait asymmetry, and scoliosis (Cohen et al. 2013).

Recent interest has surrounded SIJ pain that arises in the context of lumbosacral long-segment spinal fusion procedures. After a successful lumbosacral fusion, the distribution of motion across the SIJ increases, which can precipitate accelerated degeneration of the joint, as in the pathology of adjacent segment disease. In one prospective cohort study of lumbosacral fusion patients over 5 years of follow-up, the incidence of SIJ degeneration was 75% as determined by CT imaging. Patients were found to have degeneration regardless of the number of levels fused, and it was found that usage of iliac crest graft also had a deleterious effect on the SIJ (Ha et al. 2008). Possible causes of SIJ pathology after lumbosacral fusion is thought to be related to either adjacent segment disease as mentioned above, harvesting of bone graft in close proximity to the joint, or possibly misdiagnosis of a pre-existing SIJ syndrome. The study of the SIJ as a possible generator for LBP after long lumbosacral fusions bears considerable importance especially given the failure rate of these procedures and prevalence of LBP in this population of patients (Yoshihara 2012).

Diagnosis and Evaluation

Much of the difficulty associated with the treatment of pain originating from the SIJ derives from the variable clinical presentations that can arise as a result of this pathology. Regions of reported pain referral can include the lower back, buttocks, groin, lower extremities, and even the abdomen. However, provocative joint injections have indicated that the most common referral zone is the buttock, followed closely by lower lumbar, and patients with lower extremity pain usually localize to the posterior or lateral thigh (Slipman et al. 2000). Of the buttock region, the posterior superior iliac spine (PSIS) appears to be a common anatomic region identified by patients with SIJ pathology (Maigne et al. 1996). Further complicating the diagnosis of SIJ pain are the proximity of several other anatomic regions commonly implicated in pain from chronic degenerative disease in adults (the lumbar spine and hips, specifically) and the possibility for pain originating from these different entities concurrently.

Although many physical examination techniques have been developed for the purpose of evaluating the SIJ, none have shown sufficient sensitivity/specificity for standalone usage without more invasive testing (injection, etc.). Furthermore, the usage of multiple physical examination maneuvers did not augment the diagnostic power when compared to injection, including Gaenslen's Test, Patrick's Test, and tenderness of the sacral sulcus (just medial to the PSIS), among others. The highest sensitivity was seen with sacral sulcus tenderness (89%). Of note, there was also no consistent statistical validation for historical features such as relief when standing, sitting, walking, lying down, or aggravation with bowel movement or coughing (Dreyfuss et al. 1996). Because of the possibility of hip or lumbar spine pathology confounding diagnosis of SIJ-related pain, physical evaluation should include routine neurologic evaluation for weakness and radiculopathy, as well as provocative hip joint maneuvers. Of note, gait and leg length discrepancy are also important factors to address during the workup (Thawrani et al. 2018).

The usage of imaging (CT, MRI, bone scan, etc.) in the workup of SIJ pain has been shown to be largely unhelpful in determining whether the joint itself is likely to be the primary pain generator. However, imaging studies can be utilized to rule out other causes of pain such as the detection of fracture, neoplasm, infection, or spondyloarthropathy (Dreyfuss et al. 2004). In one

retrospective review of CT imaging findings relative to patients with injection-proven SIJ provocation, the sensitivity and specificity of CT imaging were found to be only 57.5% and 69%, respectively (Elgafy et al. 2001). Plain film imaging has also been difficult to apply to SIJ evaluation given the natural history that 24.5% of patients over 50 years of age show abnormalities on these studies (Dreyfuss et al. 1995). Although radionuclide bone scanning has received some attention in the literature as it relates to SIJ pain, it is not recommended as part of the basic workup due to the relatively low sensitivity (12–46%, Thawrani et al. 2018).

After sufficient clinical suspicion for SIJ-related pain has arisen, a percutaneous SIJ block is a generally agreed-upon test to establish this diagnosis. This is best performed using contrast media and fluoroscopic guidance, with an effort to avoid over-injecting the joint space and accidentally seeing false results due to anesthetizing the nearby lumbosacral nervous anatomy (especially ventrally). Additionally, >75% pain relief is the expected standard for diagnosis and is sometimes followed by a repeat injection block later due to placebo effect (Dreyfuss et al. 2004). The false positive rate from a single SIJ block injection is approximately 20% (Hansen et al. 2007). The usage of steroid injection into and around the joint and RF ablation technologies have been investigated and may be promising options for durable pain relief but require more establishment by the literature (Cohen et al. 2013).

Conservative Management Strategies

Targeted efforts to address the particular pathology affecting the SIJ are utilized first, which may include physical therapy or orthotic options for imbalances with gait mechanics or leg length discrepancy. Strength and flexibility training would fall under this category and can be beneficial. Similarly, trials of medications can be undertaken, including non-steroidal anti-inflammatory medications, non-opioid pain medications, and others, which may be especially efficacious in the case of inflammatory SIJ disease (Dreyfuss et al. 2004). Belt orthoses have also been trialed to relieve SIJ-related pain, as has been the case with SIJ dysfunction in the peripartum period. These belts, when worn above the greater trochanter, have shown approximately 30% reduction in joint motion, but should be weaned when able to reduce muscular weakening and dependence (Vleeming et al. 1992). Manual joint manipulation therapy has not yet been substantiated in the literature but has shown a potential benefit for certain patients (Kirkaldy-Willis and Cassidy 1985). Lastly, in addition to the aforementioned injection strategies for neurologic blockade, steroid use, and radiofrequency ablation, percutaneous viscosupplementation is also being explored (Dreyfuss et al. 2004).

Surgical Decision-Making

Surgical fixation of the sacroiliac joint was traditionally only considered in situations where joint instability was known such as fracture and/or severe ligamentous disruption from trauma and infection. However, in the mid-1980s, surgeons began considering fixation and arthrodesis techniques using a variety of instrumentation techniques for the treatment of refractory SI joint degeneration/dysfunction (Rand 1985; Smith et al. 2013), considered to be stable SI joint pathologies. Surgical treatment in these patients, however, is still largely thought of as a treatment option of last resort for patients whose symptoms have been unresponsive to all other non-surgical options. In addition to diagnosis with at least two positive SI joint injections, most surgeons require a course of non-surgical treatment lasting at least 6 months in duration. Discussions of risk in SI joint surgery should include explanation of all possible complications. These include neurovascular injury, hemorrhage requiring blood transfusion, superficial and/or deep infection, pulmonary embolism provoked by postoperative weight bearing status, refractory lower back and SI joint pain, non-union requiring surgical revision, etc.

The earliest reports supporting sacroiliac arthrodesis for non-traumatic SI joint dysfunction were published in the 1920s (Smith-Petersen and

Rogers 1926; Gaenslen 1927). However, the high level of complications, long periods of non-weight bearing, and unreliable rates of bony arthrodesis kept the technique from gaining widespread acceptance as a treatment for SI joint dysfunction. The emergence of SI joint arthrodesis garnered renewed interest over the past two decades as the creation of pain clinics sparked increasing numbers of diagnostic and therapeutic SI joint injections. Additionally, increased utilization of lumbar and lumbosacral arthrodesis procedures is thought to have brought greater attention to the SI joint as a generator of low back pain.

The modern era of SI joint arthrodesis began in the late 1980s with publication of a report by Waisbrod in which he reported a series of 21 surgical procedures performed for stable SI joint arthritis and lower back pain. He utilized an open posterior approach with intra-articular ceramic blocks and local autograft from the iliac crest, harvested during the approach. Postoperatively patients were maintained in short-leg spica casts for 8 weeks. The series achieved satisfactory results (defined by reduction of pain of greater than 50%) in 11 of 21 cases, all of which demonstrated bony arthrodesis on follow-up radiographs (Waisbrod et al. 1987). These early reports served as a demonstration that surgical instrumentation and fusion of the SI joint could be safely and effectively employed as a modality for treatment of the dysfunctional SI joint.

Although surgical fusion is now an accepted therapy for refractory lower back pain caused by the dysfunctional SI joint, many factors still need to be considered before surgery should be offered. CT imaging of the SI joints should be evaluated preoperatively to alert the surgeon to any bony sacroiliac anomalies that can affect the surgeon's ability to instrument across the joint or enter the joint space. Further, the presence of osteoporosis as a comorbid condition for patients with SI joint dysfunction may influence the decision as to whether surgical intervention is used and, if so, which approach will provide the chosen instrumentation with the greatest purchase to cortical bony surfaces. Similarly, patients with morbid obesity carry higher risk of complications when undergoing surgery for SI joint fusion. As such the surgeon will often benefit from choosing an approach that favors less traditional soft tissue dissection and favors fluoroscopy in the AP as opposed to lateral projection to avoid distortion from excess soft tissue. This will often be a posterior or posterolateral, minimally invasive approach, but surgeons should continue to evaluate these factors on a case-by-case basis. Finally, preoperative counseling on the postoperative course that can include non-weight bearing status and extensive physical therapy and rehabilitation will help establish expectations and can improve patient satisfaction and outcomes.

Instrumented Surgical Options

Open Surgical Approaches

Open Ventral-Ilioinguinal Approach

The ventral approach facilitates access to the iliac crest, entire iliac fossa, lateral sacral ala, and consequently the anterior and superior portions of the sacroiliac joint. The patient is positioned supine, ideally on a radiolucent OR table. An ilioinguinal incision is planned just inferior to the iliac crest and is taken deep through the subcutaneous tissues until the fascia overlying the external oblique muscle is encountered. This fascia is followed until the gluteus fascia is visualized. The border between these muscles is then identified and the interval is developed. The iliac crest is then identified and the external oblique muscle is elevated from the iliac crest in a subperiosteal fashion. The iliacus muscle is then identified and elevated from the iliac fossa in the same periosteal layer. Working anteromedially along the iliac fossa, the anterior sacroiliac joint capsule will be identified. Hohmann retractors can be utilized to maintain visualization of the joint capsule, with attention being paid to avoid injury of the traversing L5 nerve and superior gluteal artery and nerve inferomedially near the sciatic notch. The sacroiliac joint capsule is then incised sharply to visualize the joint. Joint cartilage is then resected using a combination of curettes and rongeurs. Morselized bone graft and other biomaterials are packed in the

joint, and instrumented reconstruction with screw-plate interface is most often used.

Open Posterolateral Iliosacral Approach

The posterolateral iliosacral approach facilitates access to the posteromedial portion of the iliac crest including the posterior superior iliac spine (PSIS), posterior surface of the sacral ala, and the posterior sacroiliac joint. The patient is positioned in the prone position. A longitudinal, linear, or curvilinear incision is planned just lateral to the PSIS, following the iliac crest. The soft tissues are divided, exposing the bone of the PSIS and iliac crest. The gluteal muscles are then elevated from the posteromedial ilium in the subperiosteal plane and reflected laterally to expose an adequate portion of bone, with care being taken to avoid injury to the superior gluteal neurovascular bundle. In the same subperiosteal plane, the multifidi muscles are elevated from the sacrum and reflected medially until adequate exposure of the posterior sacral surface is exposed. Retractors are placed to maintain bony exposure. Bone of the iliac crest and PSIS that overhang the posterior sacroiliac joint are resected using osteotomes or rongeurs. Bone is morselized for use as autograft. The sacroiliac joint capsule is then incised exposing the articular portion of the joint. Cartilage in the articular faces is then resected using a combination of curettes and rongeurs. Morselized bone graft and other biomaterials and/or synthetic cages are packed in the joint, and instrumented fixation is performed using screw-plate constructs, screw-rod constructs, or trans-articular screws.

Open Posterior Sacral-Alar-Iliac Approach

The posterior sacral approach facilitates access to the bilateral posterior sacral surfaces, bilateral posterior SI joints, and potentially the most medial portion of the adjacent ilium. The patient is positioned prone. A longitudinal, linear midline incision is made from the L3 spinous process down past the S2 spinous process and taken down to the deep lumbosacral fascia. Care is taken not to violate the deep layer of the fascia in the midline. This layer can be defined from the superficial layer, as the deep layer runs in a longitudinal fashion versus the oblique fibers of the superficial layer. Splitting the layers of fascia with electrocautery or a scalpel, the deep fascial layer is followed to its lateral attachment along the medial border of the ilium. Between the fascial layers, the PSIS and approximately 8–10 cm of the dorsal iliac wing can be palpated. Care should be taken to avoid damage cluneal nerves at the cephalad and lateral portions of the dissection. The deep fascial layer is then incised over the PSIS until bone is encountered and dissection occurs medially in a subperiosteal plane, exposing the posterior transverse iliosacral ligaments. These can be removed using a combination of rongeurs. The joint can then be accessed moving anterolaterally. The joint can be prepared by remove articular cartilage and bone with a combination of angled curettes, rongeurs, and a high-speed drill. An intra-articular cage and/or bone dowel is then sized and placed, often using fluoroscopy to confirm proper placement. The paraspinal musculature is then retracted medially at the cephalad portion of the exposure, and an S1 pedicle screw is placed. A trajectory into the ilium is then chosen using fluoroscopic guidance, CT-guided navigation, or freehand technique, and the hole is created using a high-speed drill or awl. An iliac "pedicle" screw of choice is then placed. The remainder of the visible sacroiliac joint can then be decorticated and residual morselized bone graft or orthobiologic material laid within the joint. A rod is then cut to size and secured with S1 and iliac screw heads, and a compression can be performed before the set screws are tightened.

An alternative method can also be utilized using the posterior midline incision. With this approach, the incision is taken to bone in the midline avascular plane exposing the L4, L5, and possibly L3 spinous process and the posterior-most portions of the sacral spinous processes. Elevation of the lumbosacral musculature from medial to lateral is performed until the sacral foramina are visualized. Continued dissection and elevation of muscles may be needed if visualization of the posterior portion of SI joint is desired. After achieving visualization of the S1 and S2 dorsal foramina, placement of sacral-alar-iliac screws can be performed. Starting point for

placement of this screw should be approximately half between the lateral edges of the S1 and S2 dorsal foramina. Trajectory of screw should be toward the anterior inferior iliac spine which can be approximated by palpating the top of the greater trochanter. Using freehand, fluoroscopy-guided, or intraoperative CT-guided techniques, fixation screws that traverse the sacral ala into the ilium can be safely placed. This technique is most commonly used in conjunction with lumbosacral arthrodesis procedures. The benefit of the sacral-alar-iliac screw is better alignment of the screw head with proximal S1 and lumbar pedicle screws for alignment of the fixation rod.

Minimally Invasive Approaches

Over the past 15 years, the popularity of minimally invasive approaches to SI joint arthrodesis has increased rapidly. These techniques aim to achieve joint fusion with decreased morbidity compared to open procedures. They emphasize smaller skin incisions, less traditional dissection using anatomic landmarks, and greater dissection using sequential dilation and tubular retractors. Additionally, these techniques have a far greater reliance on image guidance, both fluoroscopic guidance and CT-guided navigation. According to the International Society for Advancement of Spinal Surgery, by 2012, approximately 90% of all sacroiliac joint fusion were being performed using minimally invasive techniques. More than 15 distinct systems have been approved by the FDA for use in sacroiliac joint arthrodesis. The most often cited of these systems are the Rialto™ SI Joint Fusion System (Medtronic), SIJ-Fuse (SpineFrontier), iFuse® Implant System (SI-Bone), SImmetry® Sacroiliac Joint Fusion System (Zyga Technology), Silex™ Sacroiliac Joint Fusion System (Xtant Medical), SambaScrew® (Orthofix), the SI-LOK® Sacroiliac Joint Fixation System (Globus Medical), and the TriCor™ Sacroiliac Joint Fusion System (Zimmer Biomet). These systems employ delivery instruments and implants, specifically designed to fixate the ilium to the sacrum in a trans-articular fashion. To varying degrees, the technology also allows for bony decortication of the sacroiliac joint and delivery of grafting material.

Minimally Invasive Lateral and Posterolateral Iliosacral Trans-articular Approach

While the instrumentation systems each have different specifications for their technique, they follow many common themes. Although supine positioning is possible, most require prone positioning on a radiolucent table. Intraoperative fluoroscopy is used to plan the incision along the posterolateral gluteal region. Lateral imaging is the workhorse of these operations, but pelvic inlet and outlet views and to a lesser degree AP views will be utilized. Once a small skin incision is made, a guide wire is navigated to the lateral ilium until the cortical bone is encountered. Sequential dilators are then placed over the guide wire to facilitate docking of a tubular retractor. Each of the instrumentation systems then creates trajectories through the ilium into the sacral ala and body at different levels, and fixation devices are deployed across the joint. In addition, delivery of grafting material into the joint is sometimes required depending on the coating characteristics of fixation rod or screws.

Minimally Invasive Posterior Intra-articular Approach

Some minimally invasive approaches have emphasized attacking the joint along the longitudinal axis, perpendicular to the posterior joint capsule. Preoperative CT images should be utilized to measure the depth of the joint. Patients are positioned prone with either fluoroscopic guidance or CT-guided navigation. An incision is planned in the same area as the open posterolateral approach, by palpation of the PSIS or visualization of the PSIS using fluoroscopy. The incision is carried deep to the bone of the PSIS using blunt dissection or sequential dilators. Fluoroscopy is used to align the chosen instrumentation along

long axis of the joint, by shifting the axis of the C-arm cephalad and obliquely approximately 20–30° toward the contralateral side, so the images are shot posteromedial to anterolateral. From this point a variety of techniques can be utilized to implant the intra-articular graft into the joint. Hollow, threaded cages are commonly used in this technique for the ability to gain purchase on the sacral and iliac portions of the joint, while also facilitating the addition of grafting material and other orthobiologics, such as bone morphogenetic protein.

Evidence Supporting Different Surgical Techniques

While surgery to fixate the SI joint for patient with low back pain has been performed for approximately 100 years, until recently the literature was quite sparse regarding the safety and efficacy of SI joint fusion. Emergence of MIS techniques for these operations over the past 10 years has brought renewed attention to the problem of the dysfunctional sacroiliac joint, and the body of literature now reflects this interest. The majority of manuscripts published on the topic are derived from retrospective case series. However, during the past decade, groups have also started to study the problem and surgical interventions to treat it in a prospective, randomized fashion. Additionally, they have made efforts to measure outcomes in a more standardized, quantifiable manner using measures such as the Visual Analog Scale (VAS) for pain and Oswestry Disability Index (ODI) for functional performance.

In 2001, a single surgeon published a report of four cases in which he performed an open posterior sacroiliac joint arthrodesis using a screw-rod construct and intra-articular iliac crest autograft (Belanger and Dall 2001). The authors state that all four patients had qualitative clinical improvements with regard to lower back pain and demonstrated solid bony arthrodesis on either CT or plain radiograph. No significant complications or revisions were reported in this series, although after bony fusion was confirmed, two patient had instrumentation removed due to pain at the screw sites. This manuscript is representative of earlier reports on the topic.

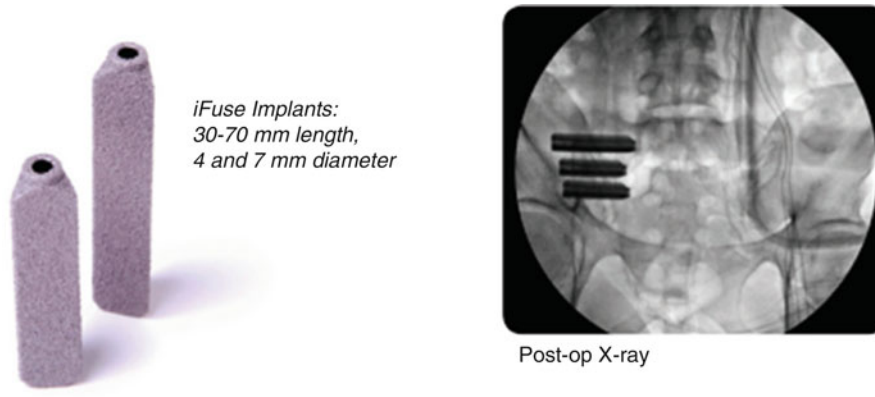

Fig. 3 Fusion rod with titanium plasma spray (TPS) coated, placed from lateral minimally invasive approach (Source: SI-Bone)

A question of whether outcomes are different between open and MIS fusion techniques has also been postulated. In 2013, a multi-centered retrospective cohort analysis of 263 patients receiving SI joint fusion was published comparing traditional, open posterior SI joint fusion to minimally invasive SI joint fusion using a series of titanium plasma spray (TPS)-coated triangular fusion rods (iFuse® system). This study found that operating room time, estimated blood loss, and length of hospitalization were all significantly lower in minimally invasive fusions than in open surgical fusions. Furthermore, the patients who had minimally invasive fusions had significantly greater reductions in their lower back pain as measured by the VAS, even when matched for age, gender, and history of lumbar spine fusion (Smith et al. 2013).

A similar retrospective cohort study was performed at single-center, comparing 27 patients who had MIS SI joint fusion to 36 patients who had open, anterior approach SI joint fusion. MIS SI fusion was accomplished using TPS-coated triangular fusion rods and CT-guided navigation, while open fusion was accomplished using anterior screw-plate constructs. Utilizing propensity score, pairwise matching of MIS, and open SI fusion patients, the study found significantly lower length of surgery, length of hospitalization, and estimated blood loss for patients in the MIS group, but no significant difference in disability score as measured by ODI. Radiographic confirmation of bony arthrodesis could not be assessed in this study.

Additionally, clinicians treating the dysfunctional SI joint have attempted to better characterize the outcomes of surgery compared to non-surgical treatment measures. A prospective, randomized trial was performed at nine European sites to explore this question. 103 patients were randomized to either MIS SI fusion (with triangular TPS-coated fusion rods) or conservative management which included medical therapy, physical therapy, and in some cases cognitive behavioral therapy, but did not include interventional procedures such as intra-articular joint injections and radiofrequency ablation. The primary endpoint was low back pain as measured using the VAS on a scale of 0–100. Patients in the SI fusion group experienced a mean improvement of 43.3 points compared to a 6.8 point mean improvement with conservative management, a statistically significant improvement. Secondary outcome measures, such as ODI, EQ-5D-3L (a quality of life assessment), and overall satisfaction, were also statistically significantly better in the SI joint fusion group at 6-month follow-up (Sturesson et al. 2017).

The INSITE, Investigation of Sacroiliac Fusion Treatment, group also performed a multicenter, prospective, randomized trial exploring outcomes of minimally invasive SI joint fusion against non-surgical management (NSM). The triangular TPS-coated fusion rod was utilized for these interventions. The NSM group received a combination of pain medications, physical therapy, SI joint steroid injections, and radiofrequency ablation, but excluded use of cognitive behavioral therapy. Cross-over was allowed after the 6-month visit, leading 102 patients to receive SI joint fusion and 46 patients to receive NSM. The SI joint fusion group had a mean improvement in VAS of pain by 55.4 at 24-month follow-up, compared to a mean improvement of 12.2 point in the NSM group, a statistically significant improvement. Furthermore, patient in the SI fusion group demonstrated statistically significant improvements on the SF-36 disability form at 6-, 12-, and 24-month follow-ups compared to NSM (Polly et al. 2016).

Given the accelerating technological advancement in instrumentation designed to fixate the SI joint, we expect the body of literature regarding sacroiliac joint fusion to continue expanding. As such, we will be able to better characterize the effects of different instrumentation techniques on outcomes when treating patient with sacroiliac joint dysfunction.

Lateral Lumbar Interbody Fusion

35

Paul Page, Mark Kraemer, and Nathaniel P. Brooks

Contents

Abstract

Lateral lumber interbody fusion is an important technique in the continually growing field of minimally invasive spine surgery. While it had previously been utilized in the early twentieth century for the treatment of traumatic injuries and Pott's disease, the current revolution of minimally invasive surgery has seen a recurrence of this approach and expansion of its clinical applications. Though this approach was largely abandoned in the late twentieth century for anterior and posterior approaches due to a high morbidity, a combination of improved technology and understanding of lumbar plexus anatomy has allowed for

its resurgence. Clinical applications of the retroperitoneal trans-psoas and pre-psoas approaches are continually expanding and frequently include scoliosis, neoplasms, traumatic injuries, and a variety of degenerative disorders. Here we describe the clinical utility of this approach, review the pertinent clinical anatomy, and describe the procedure in detail.

Introduction

Interbody fusion in the lumbar spine is an established treatment for a wide variety of spinal disorders ranging from trauma, infection, degenerative disease, deformity correction, and neoplasms. The use of interbody fusion provides additional biomechanical advantages because of the ability to place a large interbody graft that provides support to the anterior and middle columns of the vertebral segment. Additionally, the ability to extend the graft across the thicker bone of the apophyseal ring of the vertebral body limits subsidence or fracture. Restoration of interbody height by interbody fusion allows for indirect decompression of the neural elements. The goals of treatment and surgical approaches to the spine vary based upon the spinal pathology. The options are circumferential, including the posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF), lateral lumbar interbody fusion (LLIF) either pre-psoas or trans-psoas, and anterior lumbar interbody fusion (ALIF). Of these techniques, the lateral interbody approach is growing in popularity due to avoidance of the vasculature anteriorly and the thecal sac posteriorly. Additionally, there is minimal disruption of the existing ligamentous structures and surrounding musculature. The LLIF has multiple trade names depending on the company. The trans-psoas approach is called the direct lumbar interbody fusions (DLIF) or extreme lateral interbody fusion (XLIF). The pre-psoas approach is called the oblique interbody fusions (OLIF).

Compared to traditional anterior and posterior approaches to the lumbar spine, the minimally invasive lateral interbody fusion is a relatively new approach as it relates to common practice. But it is important to note that variations of this approach have been described historically. Although lateral approach to the lumbar spine was originally described and utilized in the treatment of Pott's disease in the early twentieth century by Drs. Menard and Capener, it remained infrequently used due to injury to the traversing lumbar plexus and nerve roots. Despite this neurologic morbidity, the approach became more commonplace in the treatment of Pott's disease through the twentieth century. With the emergence of the minimally invasive revolution in the late twentieth century, this approach reemerged and expanded to include a wide variety of disease pathologies. This expansion is largely attributed to recent advances in minimally invasive technologies and a better understanding of the anatomic relationships of the exiting lumbar nerve roots that form the lumbar plexus. While the traditional lateral approach accessed the vertebral column using a trans-psoas corridor, Mayer in 1997 described an oblique retroperitoneal approach in which instrumentation is performed anterior to the psoas with the benefit of fewer neural injuries (Mayer 1997). Once these anatomic limitations were identified and techniques developed to limit nerve injury, lateral approaches to the lumbar spine have proven to be versatile tool in modern spine practice.

The lateral lumbar interbody fusion has demonstrated some distinct advantages compared with the anterior or posterior approaches to the lumbar spine. Compared with traditional approaches, there is minimal disruption of the posterior elements, which may provide some benefit in the stability of the construct and postoperative pain. Additionally, lateral approaches allow for a larger access to the disc space and increase the size of interbody graft compared to posterior approaches. Research has demonstrated decreased blood loss and operative time as compared with traditional approaches. One review evaluating extreme

lateral lumbar interbody fusion (XLIF) demonstrated overall short operative times, 199 min, and relatively minimal blood loss of 155 ml (Youssef et al. 2010).

Compared to traditional ALIF approaches, lateral interbody fusion demonstrated similar degrees of foraminal height gain. However, there was less segmental lordosis correction than ALIF. In previous studies the amount of foraminal height following ALIF has demonstrated improvements in foraminal height of approximately 2.7 mm. Alimi et al. demonstrated similar foraminal height improvements, 2.5 mm on average, in their series of 145 patients who underwent interbody fusion from a lateral approach (Alimi et al. 2014). As compared to ALIF, however, segmental lordosis correction in lateral interbody fusion is generally less due to retention of the anterior longitudinal ligament. While specific degrees of improved lordosis vary, ALIF generally provides approximately 4.5° of lordosis, but only 2.5° following a lateral approach (Winder and Gambhir 2016).

Indications and Contraindications

The indications of the lateral lumbar interbody fusion are primarily to improve intervertebral height and to reduce deformity. Common indications are degenerative disease with loss of disc height and foraminal stenosis, spondylolisthesis, coronal imbalance, lateral vertebral subluxation, and revision of adjacent segment degeneration.

The contraindications of this approach are primarily related to anatomical considerations such as aberrant vascular anatomy, prior retroperitoneal approach, or prior abdominal infections or surgeries with associated adhesions in the retroperitoneal corridor. A high-riding iliac crest or low-lying rib is a relative contraindication.

Relevant Anatomy

The lateral lumbar approach traverses anatomy that is rarely encountered in traditional approaches. Given the narrow operative corridor, a detailed understanding of the relevant anatomy is crucial for safe, effective surgery. Traversing the retroperitoneal space involves significant risk to major vascular structures and vital organs. Evaluation of the preoperative imaging and understanding the location of these structures and their relationship to the disc space is a critical part of preoperative planning and intraoperative crisis management. Furthermore, if concern for major vessel injury arises preoperatively or intraoperatively, the surgeon should seek vascular surgery consultation.

When accessing the retroperitoneal space, care must be taken to first identify the external oblique fascia, external oblique, internal oblique, and transversus abdominal muscles at the beginning of the approach (Fig. 1). It is important to recognize the trajectory of the iliohypogastric and ilioinguinal nerve as they course through the psoas before innervating the internal and external oblique muscles. When unclear as to which muscular layer is being visualized, the surgeon should recognize the direction of the muscle fibers for reorientation. Once these muscular layers have been traversed, a layer of adipose tissue is identified in the retroperitoneal space. Deep to this, the peritoneum will be identified. Dissection is best performed bluntly with either finger dissection or use of cotton kittners. It is easier to dissect along the interior of the abdominal wall, palpate the iliac crest, and then identify the psoas than to try and dissect along the peritoneum. Further dissection leads to the lateral aspect of the psoas (Fig. 2). Care must be taken to expose the anterior psoas as it is easy to fall into a plane behind the psoas that leads to the spinal canal and foramen. The ureter typically will mobilize with the peritoneum and reflect anteriorly. However, if it is taking an unusual course, it can be identified by its visually identifying peristalsis with manipulation. Care should be taken to not overly compress or stretch the ureter. A keen awareness of the location of the great vessels anterior to the vertebral bodies is paramount. These can be palpated but care should be taken to avoid manipulation or retraction without adequate visualization. Segmental arteries will arise from the aorta in the midpoint, "valleys," of the vertebral bodies. Occasionally, the iliolumbar vein or veins will be

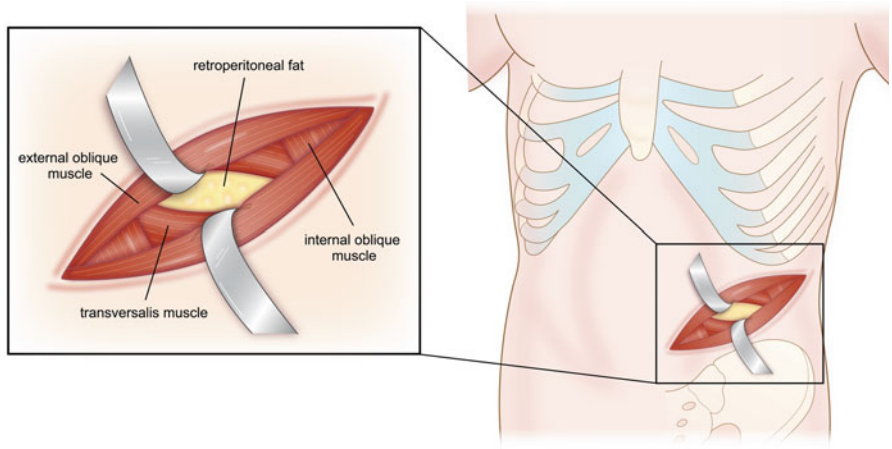

Fig. 1 This illustration shows the oblique incision, which is centered over the disc of interest and oriented along the fibers of the external oblique. Blunt dissection is performed through the external, internal, and transversalis abdominal muscles to reveal the retroperitoneal fat pad. (Reprinted with permission, University of Wisconsin © 2018. All Rights Reserved)

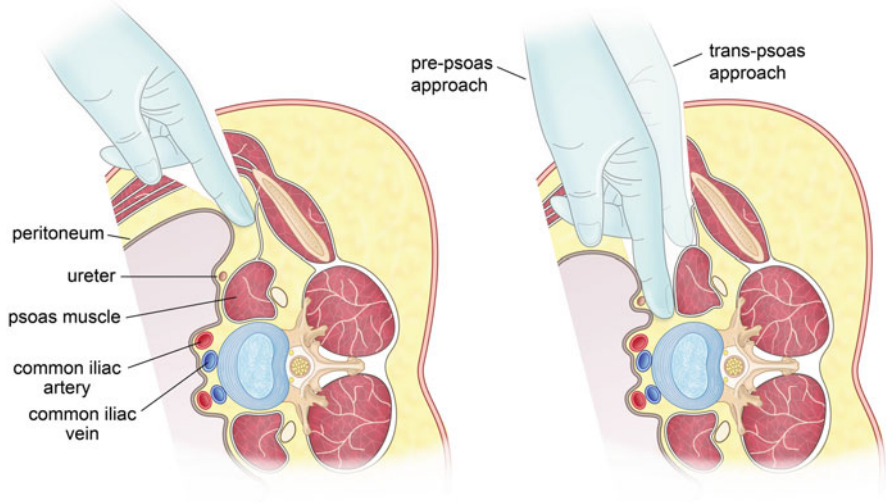

Fig. 2 Schematic demonstrating blunt dissection of the retroperitoneal fat pad from the transversalis fascia and anterior retraction of the aorta. The transverse process is first palpated before isolating the psoas muscle. If electing to perform a trans-psoas approach, instrumentation is then directed through the psoas under imaging guidance and neuromonitoring (triggered and free-running EMG). In the pre-psoas approach, the anterolateral portion of the vertebral body is identified (left) and the psoas is retracted posteriorly. Care should be taken to avoid dissection of the psoas medially, as this may irritate exiting nerve roots. (Reprinted with permission, University of Wisconsin © 2018. All Rights Reserved)

seen coursing from underneath the aorta usually at L4–L5 interval. This vein could be isolated and ligated to avoid avulsion of the vein from the inferior vena cava which can create a vascular injury that is very difficult to repair. During the course of dissection, if there is aberrant or overly large vascular anatomy, then strong consideration should be given to (1) obtaining vascular surgeon consultation, (2) aborting the procedure, and (3) operating via a posterior approach. Furthermore, a

thorough review of preoperative imaging is important to understand the relation of adrenal glands, kidneys, ureters, and renal vasculature that may be encountered when utilizing this approach.

Lumbar Plexus

The lumbar plexus is deeply integrated into the psoas muscle and contains innervation from subcostal contributions from the T12 as well as the ventral rami of the first four lumbar nerve roots. The fourth lumbar nerve root additionally supplies contributions to the sacral plexus. The lumbar plexus is ultimately divided into two divisions named the anterior and posterior division. The posterior division provides innervation to the main motor component of the posterior leg via the femoral nerve with contributions from the L2 to L4, while the anterior division provides motor innervation via the obturator nerve. Sensory innervation is chiefly accomplished by the iliohypogastric, ilioinguinal, genitofemoral, lateral femoral cutaneous, and anterior femoral cutaneous nerves.

Understanding the course of the ilioinguinal and iliohypogastric nerve is vital to avoiding complications. Both nerves run posterior to the psoas major on its proximal lateral border of the vertebral bodies and then travel along the anterior border to the quadratus lumborum. After traveling anterior to quadratus lumborum, the ilioinguinal nerve pierces the lateral abdominal wall after traveling at the level of the iliac crest to supply sensory innervation to the external ring, the area over the pubic symphysis, and the lateral area of the scrotum or labia majora. Comparatively the iliohypogastric provides motor innervation to the abdominal internal oblique and transverse abdominis until it provides a terminal cutaneous branch supplies which the skin above the inguinal ligament.

The lateral cutaneous nerve consequently pierces the psoas directly through a lateral approach most frequently in the middle location of the psoas muscle. Given its location directly through the psoas muscle, this nerve is at risk during a lateral lumbar approach. Once it emerges from the psoas, it then courses across the iliacus muscle obliquely and continues to the anterior superior iliac spine. At this point it crosses under the inguinal ligament over the sartorius muscle into the thigh.

The femoral nerve is the longest and largest nerve of the entire lumbar plexus and supplies both sensory and motor innervation to the anterior compartment of the superior leg. Contributions from the lumbar plexus arise from the L2, L3, and L4 nerve roots. After arising distal to the nerves to the psoas muscles directly, it courses through the femoral triangle lateral to femoral artery.

Vascular Anatomy Considerations

When considering a lateral retroperitoneal approach, important consideration of the major vascular structures such as the inferior vena cava, abdominal aorta, and common iliac arteries and veins must be given. In order to limit the potential injury to vascular structures, a careful review of the preoperative imaging is vital. While risk to the great vessels is highest at the L4–L5 level due to their lateral migration, major vasculature injury could occur at any level. In addition to knowledge of the great vessels, care should be taken to identify and avoid avulsion of any of the segmental vessels or iliolumbar veins crossing into the disc space during removal of the annulus that could result in avulsion of the aorta or vena cava.

Preoperative Planning and Operative Window

In considering the operative corridor during interbody fusion, it is vital to understand what constitutes a safe and effective operative window. Avoiding injury to the traversing nerve roots and lumbar plexus and great vessels is paramount. It is also important to consider that surface anatomy: a high-riding iliac crest or low-riding ribs can

make the approach more difficult. These surface limitations can be managed by removing rib or positioning the hip over a bump or table break. Care should be taken to not overextend the torso as this can cause thigh pain and weakness.

Trans-psoas

The trans-psoas approach avoids the great vessels but puts the lumbar plexus and peripheral nerves at greater risk of injury. The anatomy of the plexus cannot be well discerned on preoperative imaging. So, determination of an operative window is made intraoperatively via a combination of general knowledge of the lumbar plexus anatomy, visual and fluoroscopic inspection, and the use of neuromonitoring (triggered and free-running EMG).

Despite attempts to simplify the anatomical association of the lumbar plexus and the psoas muscle, the authors have demonstrated enormous variability. The plexus generally tends to migrate anteriorly as the psoas muscle enters the pelvis. Due to this relationship, the plexus is often at highest risk of injury at the L4–L5 disc space. A key development occurred in 2010 when Uribe et al. published a cadaveric study in which the zones of safest psoas disruption were identified (Uribe et al. 2010a). In this system four quartiles along the sagittal axis of the vertebral body were defined at each vertebral level. At the L1 and L2 disc space, the middle of this quartile was shown to have the lowest risk for injury to the nerve roots or lumbar plexus; however, at lower levels, the safest location migrates slightly anteriorly until the L4–L5 disc space. At the L4–L5 disc space, the safest location was the midpoint of the vertebral body. Additionally, the authors noted that the genitofemoral nerve was the nerve at most risk in the third quartile. This nerve must be a consideration to the surgeon as given its sensory function it will not be recognized by EMG and can be easily injured. This "safe entry zone" should not be considered universal, and as previously discussed, significant variation in patient anatomy may be present. Ultimately visual inspection and neuromonitoring are critical in minimizing risk to traversing nerves. In general, triggered EMG thresholds below 5 mA indicate direct contact, 5–10 mA indicate that the stimulation is in close proximity, and 11 mA indicates a farther distance from the lumbar plexus (Uribe et al. 2010b).

Pre-psoas

The key difference of the lateral pre-psoas approach is the intent of docking instrumentation between the psoas muscle and the great vessels. Due to the more anterior location on the vertebral body, there is a higher risk to the great vessels anteriorly, and it is frequently cited at a rate similar to the anterior approaches. Currently existing literature demonstrates a rate of vascular complication cited from 1.1% to 2.8% with damage to segmental arteries being the most common complications (Xu et al. 2018). Conversely, the risk of injury to the lumbar plexus is lower because the psoas is not blindly traversed. Determination of the operative window is made by preoperative planning and intraoperative visual and fluoroscopic inspection and dissection. Neuromonitoring is not necessary for this approach but can be considered.

Procedural Details

Surgical Positioning

Proper positioning is essential for successful lateral lumbar interbody fusion. The patient should be placed in the lateral decubitus position with the left side up. Right-sided approach may be considered, but this is generally discouraged due to increased risk of injuring the relatively thin-walled inferior vena cava during manipulation. If such an approach is undertaken, a trans-psoas corridor should be considered to decrease risk of IVC injury. Additionally, lateral jack-knife position may be used to improve access and visualization in certain cases, but this should be avoided if possible to avoid transient neurologic deficits (Molinares et al. 2016). An axillary roll is

placed to avoid brachial plexus injury. Care should be taken to position the patient perpendicular to the floor. The fluoroscope is then brought into the field, and minor table adjustments are used to obtain a perpendicular lateral view of the target disc. Similarly, the flouroscope should be easily maneuverable to obtain a clear orthogonal AP view of the disc. Alternatively, computerized stereotactic navigation may be used, in which case the registration pin is placed into the iliac crest projecting posteriorly after prepping and draping. A small amount of hip flexion may be used to relax the psoas, which also serves to position the L4 and L5 nerve roots more posteriorly. At this time neuromonitoring (EMG) may be attached. If approaching the vertebral column using a trans-psoas approach, neuromonitoring should be used to avoid the risk of nerve injury while traversing the psoas. The patient's abdomen and flank should be prepped and draped widely despite the plan for a small incision. This will allow the laparotomy incision to be enlarged in the case of difficulty with dissection or complication.

Incision and Retroperitoneal Dissection

Under fluoroscopic or navigation guidance, the intervertebral disc of interest is identified before marking its caudocranial and anteroposterior projections on the skin. For the trans-psoas approach, a 4 cm incision is centered over the disc of interested and oriented obliquely (Fig. 1). If approaching anterior to psoas, the incision should be positioned more anteriorly from the center of the disc space (approximately 5 cm) to facilitate psoas mobilization and vertebral body visualization. The external oblique fascia is then sharply divided, and splitting of the external, internal, and transversalis abdominal musculature is performed using a Kelly clamp or bluntly. The underlying transversalis fascia is identified and divided before entering the retroperitoneal fat pad. Using a gloved index finger, the fat pad is gently dissected from the transversalis fascia before advancing more medially and posteriorly and along the anterior boarder of the quadratus lumborum to palpate the transverse process of the vertebral body (Fig. 2). After palpating the transverse process, blunt dissection is used to retract the peritoneal contents anteriorly to identify the vertebral disc space. Fluoroscopy is then used to confirm the correct intervertebral disc level.

Retractor Positioning

Trans-psoas

Fluoroscopy or navigation is used to localize the planned position to dock the retractor in the disc space. This is done by placing a k-wire in the disc space and using serial dilation to split the psoas muscle fibers. Neuromonitoring (triggered and free-running EMG) is monitored as each dilator and eventually the retractor blades are advanced. The electrical contacts are different for each company and should be studied and understood prior to surgery to evaluate the direction of stimulation. Typically, one small area of each dilator will have exposed uninsulated metal, and stimulation can proceed in quadrants to look for EMG firing. This can help the surgeon determine the direction of any at-risk nerves and reposition the retractor accordingly. If the EMGs demonstrate irritation, the retractor can be repositioned away from the direction of nerve root firing. The retractor blades can be pinned into the vertebral bodies above and below the disc space firmly into position. An ideally placed retractor will be overlying the disc at about the anterior 1/2 of the disc space, parallel to the endplates and in the coronal plane (Fig. 3). Fluoroscopy should be used to verify this position.

Pre-psoas

In the pre-psoas approach, the psoas is mobilized posteriorly for exposure of the ideal operative window. This space need only be slightly wider than the planned implant. Self-retaining retractors are then placed to retract the abdominal contents and psoas. The retractors can be rotated and slid slightly above the disc space to allow the disc prep tools and implants to be positioned in the coronal plane. A second retractor is placed medially to protect the peritoneum and great

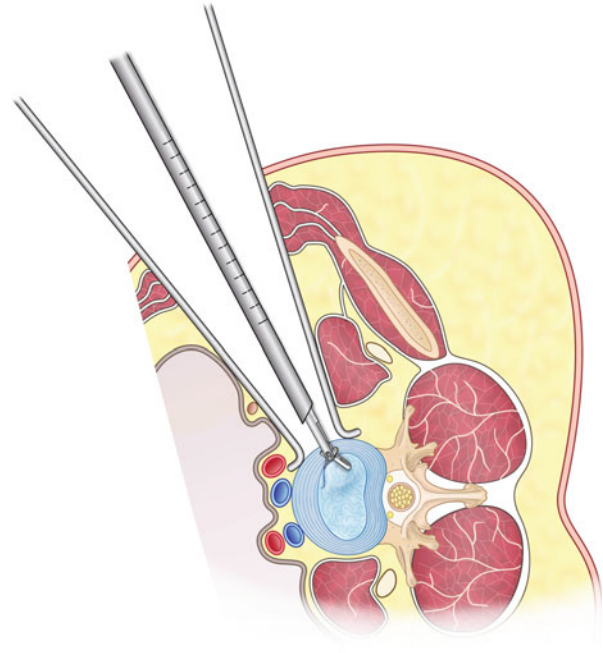

Fig. 3 In the pre-psoas approach, instrumentation is docked at the anterolateral disc space and a small annulotomy is performed followed by complete discectomy. (Reprinted with permission, University of Wisconsin © 2018. All Rights Reserved)

vessels, and if needed, a third retractor can be placed in the caudal aspect of the incision to protect peritoneal contents. Various retractor setups are available. This can also be done with handheld retractors if desired.

Disc Preparation and Implant Placement

An annulotomy is then performed followed by complete discectomy and removal of the cartilaginous endplates. This will ensure that a large surface area is available for effective fusion. Care should also be taken to bilaterally release the annulus to avoid coronal imbalances after implant placement. This may be performed by rotating a Cobb across the distal annulus of the disc space (Orita et al. 2017). Care should be taken to maintain a coronal trajectory. Failure to work in the coronal plane can lead injury to the vasculature anteriorly or neural elements posteriorly. The disc space is then sequentially distracted using spacers until the ideal height is reached. A lordotic cage filled with graft is then placed and positioned parallel to the disc space (Fig. 4) on the AP view and in line with the posterior aspect of the vertebral bodies on the lateral view. To avoid inserting the cage in a rotated alignment on the lateral view, the trials and rasps should be placed so that they are aligned with the posterior aspect of the vertebral bodies, allowing the cage to simply follow the created path.

Ideal implant placement involves adjusting the midpoint of the cage to the center of the vertebral body on AP view and between the anterior and middle-third on lateral view. Implant placement in the trans-psoas approach is directly perpendicular to the vertebral body along the planned trajectory. However, special attention needs to be used to place pre-psoas implants. The pre-psoas implant is placed obliquely from the 10 o'clock position on the disc, advanced 1/2 way into the disc space, and then the handle is rotated posteriorly perpendicular to the OR table to place it across the disc space. This is sometimes called the "orthogonal maneuver."

The surgical field is then copiously irrigated, and meticulous hemostasis is achieved before removal of the self-retaining retractor and wound closure. The surgical corridor should be inspected for any injury to the peritoneum or retroperitoneal structures.

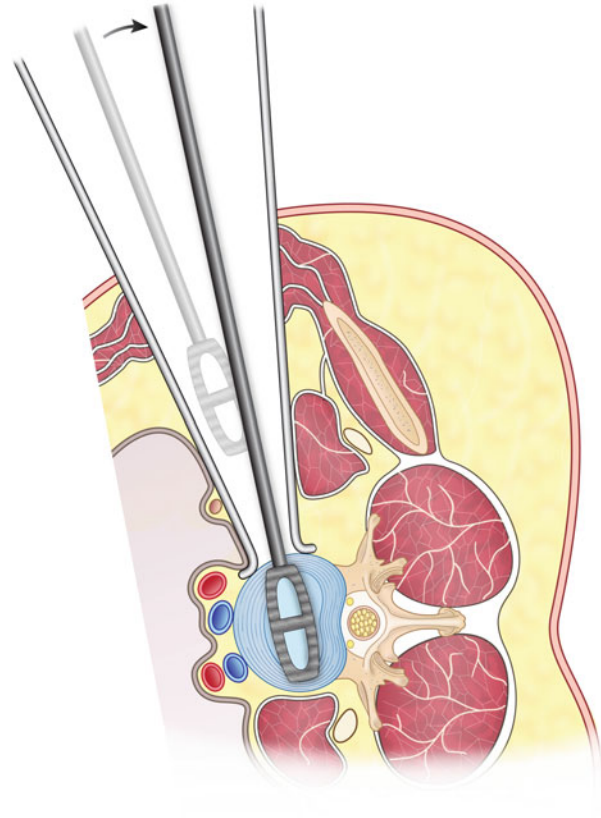

Fig. 4 Illustration demonstrating interbody graft placement using an pre-psoas approach. Ideal graft placement is midline on the lateral view and parallel to the disc space. (Reprinted with permission, University of Wisconsin © 2018. All Rights Reserved)

Posterior Instrumentation and Fusion

Posterior instrumentation can be considered to achieve a stable construct and increase the likelihood of fusion. This may be performed in multiple ways, but unless otherwise contraindicated, we prefer repositioning the patient in a prone position and performing bilateral percutaneous pedicle screw fixation using either fluoroscopic or stereotactic guidance.

Pre-psoas L5–S1

This is an advanced surgical technique but the pre-psoas approach does allow access to the L5–S1 level. This is performed by using a more anterior and medial incision and carefully docking the retractors between the bifurcation of the aorta and vena cava. An annulotomy is then performed, and discectomy and endplate preparation are completed. An anterior interbody cage is then implanted using a specially designed oblique introducer. Centering the implant can be challenging because of this oblique trajectory.

Complications and Their Management

Complications of the lateral approach are similar to those seen with ALIF with major complications related to damage of surrounding vascular, visceral, and neurologic structures. Yet, because there is generally no retraction of major vascular structures in the lateral approach, large series have reported no vascular or intraoperative injuries (Rodgers et al. 2011). If a vascular injury is identified, the first step is to obtain temporary control of the bleeding. This is often done using pressure from a kittner, suction, or sponge stick. If it is a large injury, then anesthesia should be notified to have blood products prepared to be administered. The second step will be to obtain improved access by making the incision larger. The third step will be to get adequate visualization of

the injury. Primary repair can be attempted. Typically, prolene suture is used to suture vessels. Venous injuries must be repaired with care as the thin walls of the vessel can often tear. At any point, a vascular or general surgery consultation is encouraged to be obtained.

Other major complications include injury to the exiting nerve roots, particularly the L4 root. Permanent motor deficits have been reported between 0.7% and 3.4% (Knight et al. 2009) (Rodgers et al. 2011). Yet, when compared to other approaches, there is a high rate of transient groin and thigh pain after lateral approach which ranges from 10% up to 30%. These transient injuries, often hyperalgesia in the distribution of the iliohypogastric or ilioinguinal cutaneous nerves, are likely due to a combination of stretch and compression injury during the approach and retraction during surgery. Trans-psoas approaches are generally associated with higher complications rates (32.8%) versus oblique psoas-sparing approaches (13.5%) due to a higher likelihood of encountering the lumbar plexus during muscle dissection (Abe et al. 2017). Hip flexor weakness has also been reported and relates to manipulation of the psoas.

If the peritoneum is torn or injured, this is not typically a serious complication. Inspection should be performed to verify that no intestinal injury has occurred as this can be life-threatening if not identified. The peritoneum can be stitched closed with absorbable suture to avoid herniation of intestines. The surgery can continue.

If the intestines or abdominal organs are injured, then general surgery should be consulted for repair. Strong consideration should be given to aborting the procedure as the infection risk is very high in this situation. It can be helpful to have the patients undergo a bowel preparation prior to the surgery in order to minimize spillage of visceral contents, decrease likelihood of infection in case of incidental enterotomy, and increase the rate of repair.

Ureter injury is uncommon, but if it is encountered, then a urologist should be consulted to repair the ureter. The risks and benefits of proceeding should be weighed. Urine is typically sterile so the infection risk should be lower compared to intestinal injury.

As with ALIF, there is a risk of incisional hernia. If this occurs, then a referral to general surgery for repair is warranted.

Limitation of the parallel trajectory of the cage relative to the disc space secondary to a high-riding iliac crest is not technically a complication. However, it is often encountered at the L4–L5 level. In these cases, the senior author has proceeded with a discectomy without violating the contralateral annulus and placed a shorter cage to avoid neural compression in the canal or neural foramen.

Another key consideration when comparing anterior interbody to lateral interbody fusion is the risk of subsidence, which is defined as the potential loss of height within the neural foramen following indirect decompression with an interbody graft. While the gold standard for reducing the risk of subsidence is the anterior interbody fusion with an average of 10% risk of any subsidence without any events of neurologic consequence, both LLIF and OLIF have significant risks of subsidence and are important considerations with approach. Stand-alone LLIF has been shown to have subsidence rates of up to 30% when using standard 18 mm grafts (Marchi et al. 2013).

Conclusions

The lateral lumbar interbody fusion is a useful technique for the spine surgeon to have in his/her armamentarium. The keys to performing this technique safely and effectively are appropriate patient selection, safe lateral positioning, appropriate targeting of disc space with fluoroscopy or computerized stereotactic navigation, careful dissection and retractor placement to identify and avoid injury to intraperitoneal contents or pre-vertebral vascular structures, and aligning the tools to prepare the disc space and implant the graft in the coronal plane. If performing a trans-psoas approach, then neuromonitoring (triggered and free-running EMG) should be used to limit nerve injury. The outcomes of this procedure are similar to anterior lumbar interbody fusion but with less muscular dissection because of the lateral trajectory.

Abstract

This chapter explores the basic principles and concepts of minimally invasive spine surgery (MIS). It provides technical insight into how these procedures are performed safely. By utilizing MIS techniques, one can largely treat the same conditions, which historically have been treated in the open fashion. Both short- and long-term advantages will be discussed including but not limited to decreased blood loss, decreased postoperative pain, and faster return to baseline. The application of these methods to deformity correction surgery and interbody fusions will also be explored. The roles of navigation and robotics in this rapidly expanding field and how they

What Is Minimally Invasive Spine Surgery (MIS)?

Minimally invasive spine surgery (MIS) strives to correct surgical pathology, which is typically treated with larger incisions and greater tissue destruction, with the goal of better short- and long-term patient outcomes. Although long-term benefits are debatable, the short-term benefits, including decreased blood loss, decreased postoperative pain, decreased hospital stays, and faster return to baseline, have been well established (Lombardi et al. 2014; Tullberg et al. 1993; Obenchain 1991; Shamji et al. 2015; Terman et al. 2014; Parajon and Hartl 2017; Costanzo et al. 2014). Additionally, MIS techniques have been shown to decrease both the direct and indirect costs associated with certain surgical procedures (Shamji et al. 2015). By decreasing operative time, blood transfusions, and length of stay, the direct cost is significantly impacted. Earlier return to work and fewer postoperative hospital visits significantly decrease indirect costs. The goal of this chapter is to present the reader with current MIS techniques as well as a brief insight into the future of MIS.

Advantages and Disadvantages of MIS

There are several advantages and disadvantages of MIS techniques. A steep learning curve is associated with the safe implementation of MIS into one's practice, resulting in a lower than expected adaptation of this technique. Numerous studies have demonstrated that the first 20–30 cases of a surgeon's implementation of MIS may be associated with higher rates of complications (Sclafani and Kim 2014; Shamji et al. 2015; Fujibayashi et al. 2017). In addition to the steep learning curve, another barrier to adaption of MIS techniques is increased radiation exposure to the surgeon due to reliance on fluoroscopy. However, this risk may be minimized with the usage of intraoperative navigation.

Though introduced several decades ago, MIS techniques have made significant progress recently due to numerous technological advancements which have resulted in a numerous advantages of a less invasive approach. In utilizing an MIS approach, there is no need to detach the paraspinal muscles from their insertions on the spinous processes as compared to open techniques, thus minimizing muscle dissection and stripping (Pishnamaz and Schemmann 2018). Muscle injury in spinal surgery correlates with the length of time and force of the muscle retraction (Kawaguchi et al. 1996). With prolonged retraction, capillary perfusion is decreased and leads to accelerated rates of muscle fiber degeneration secondary to changes in cellular metabolism. The mechanism of this degeneration and necrosis are not yet fully elucidated, but most of these changes are believed to be associated with destruction of the sarcolemma and subsequent mitochondrial damage (Heffner and Barron 1978). Postoperative MRIs have demonstrated decreased cross-sectional area of paraspinal muscle, supporting the idea of muscle fiber atrophy following open surgery (Bresnahan et al. 2017) (Fig. 1). Stevens and colleagues used high-definition MRI to study the multifidus muscle postoperatively in patients undergoing MIS TLIF vs open TLIF. They observed significant intermuscular and intramuscular edema at the 6-month mark in those patients undergoing open TLIF. In patients who underwent MIS TLIF, no edema was present and overall the muscle appeared normal (Stevens et al. 2006). Levels of creatine kinase have also been used as a marker for muscle fiber injury. Open techniques have been shown to have a direct correlation with postoperative rises in creatine kinase levels, as compared to MIS, which show lower levels of CK

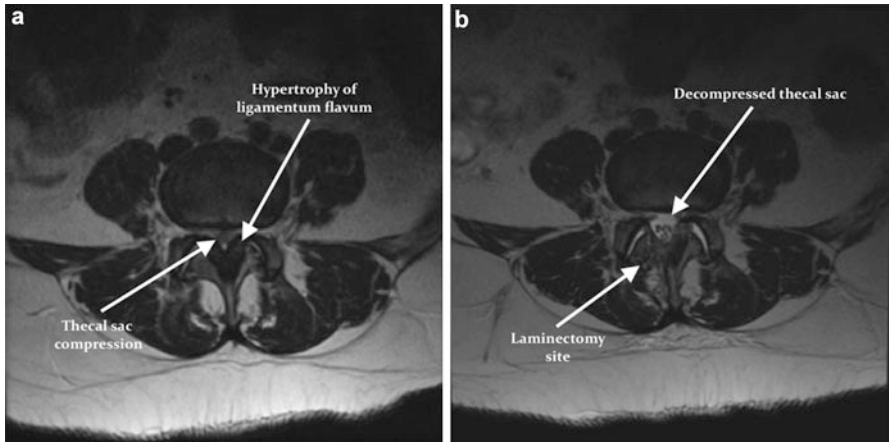

Fig. 1 (**a**–**b**) Comparison of pre-post op MIS laminectomy MRIs

(Wang et al. 2017). Cawley et al. were able to show that patients undergoing open surgery had abnormal postoperative EMG activation patterns in the lumbar multifidus as compared to those patients undergoing the same procedure via an MIS technique (Cawley et al. 2013). In evaluation of the sacrospinalis muscle using EMG, Wang et al. concluded that MIS TLIF was associated with reduced muscle damage as compared to open TLIF (Wang and FZ 2011). Newer data even suggest that with MIS techniques, the overall inflammatory state of the patient is decreased and this aids in shorter recovery periods as compared to open procedures (Lombardi et al. 2014). This is supported by lower levels of CRP, IL-6, and IL-10 following MIS procedures as compared to their conventional alternatives (Kim et al. 2006; Huang et al. 2005).

History of MIS

As a way to avoid excessive muscular retraction in spinal surgery, Wiltse et al. proposed a paraspinal sacrospinalis-splitting approach to the lumbar spine in 1968 (Wiltse 1973). The plane that Wiltse identified was an intermuscular plane between the multifidus muscle medially and the longissimus muscle laterally (Guiroy et al. 2018). Wiltse advocated that care must be taken to avoid overexposure of the vertebrae, as he had some concept of the negative consequences associated with excessive muscle stripping and damage. Because this approach utilizes an intermuscular plane, soft tissue trauma is minimized, and the posterior tension band of the spine and the supportive elements of the contralateral side are preserved (Anderson 2014). All of these taken together helped to improve patient outcomes following spinal surgery at the time.

MIS Discectomy

Disc herniations are painful and often debilitating conditions, which have a substantial impact on the function and quality of life of patients. There are also considerable social and economic impacts to society as most patients with disc herniations are of working age (Anderson et al. 2017). Given this, MIS discectomy may help mitigate some of the risks of surgery compared to open techniques and should be discussed with the patient if possible. Open surgery has been shown to be associated with longer operative times, longer incisions, increased bony resection, and increased retraction and damage to the paraspinal muscles as compared to MIS techniques (Ditsworth 1998; Rasouli et al. 2013; Alvi et al. 2018). MIS discectomy has been shown to have a shorter period of time off work, less opioid analgesia, less blood loss, and shorter hospital stays

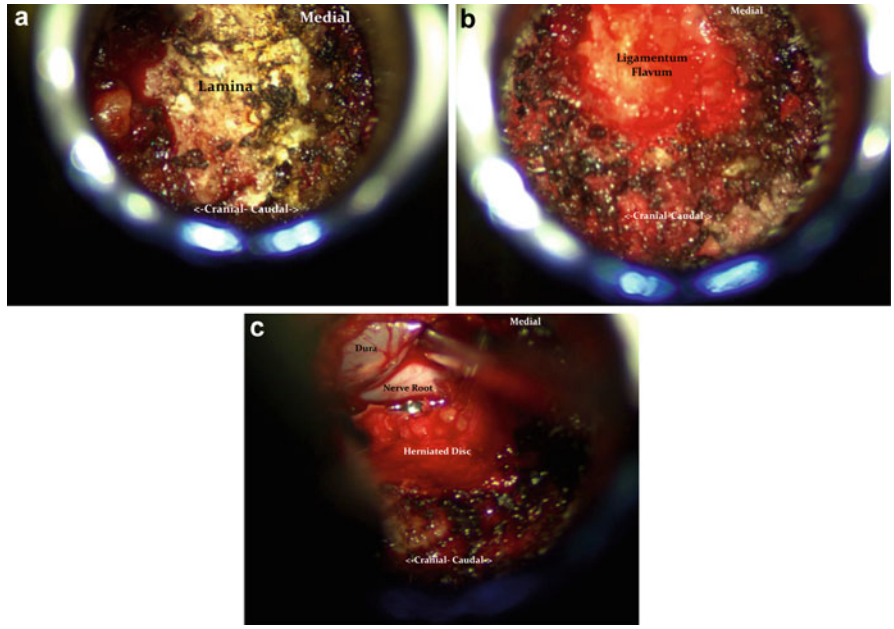

Fig. 2 (**a**–**c**) Intraoperative photos of discectomy through tubular dilator

(Tullberg et al. 1993; Kotil et al. 2007). It should be noted, however, that VAS scores both in short-term and long-term follow-up are essentially equivalent between groups of patients undergoing open procedures and those undergoing MIS procedures (Dasenbrock et al. 2012). Thus, both procedures ultimately decompress the neural elements and achieve pain relief.

As such, indications for MIS discectomy parallel those set forth for open procedures. Patients, who have failed conservative measures for a minimum of 6 weeks, have progressive motor weakness, or disabling pain can all be surgical candidates. As is standard, surgical indications should be evaluated on a case-by-case basis. The patient should always be included in the decision for surgery and appropriate informed consent should be obtained prior to surgery.

Obenchain described the first laparoscopic lumbar discectomy and was soon followed by Faubert and Caspar who published reports of lumbar percutaneous discectomy using a muscular retractor system in the early 1990s (Obenchain 1991; Faubert and Caspar 1991). This was the foundation by which Foley et al. built upon. Foley and colleagues used successive tubular dilators to achieve a desired diameter portal to which an endoscope was attached (Foley and Smith 1997). Foley's techniques were termed microendoscopic discectomy (MED) (Fig. 2).

Present day, usage of tubular retraction systems are common and are very much similar to Foley's initial description (Foley 2015). The patient should be positioned prone on a radiolucent spinal frame and prepped and draped in the usual fashion. Initially a 22-gauge spinal needle is introduced directed toward the facet joint. Careful attention is made to ensure that the needle does not aim midline, as this trajectory could puncture the dural sac and lead to a spinal fluid leak (Phillips et al. 2014). The location of the needle is confirmed using C-arm after obtaining orthogonal x-rays. Once the location is confirmed, the needle is removed, and a small, paraspinal incision is made, generally 2–2.5 cm lateral to midline. In cases where decompression of the contralateral is desired, the incision should be 3–4 cm lateral of the midline. If only an ipsilateral decompression is warranted, then the standard 2 cm from midline incision is sufficient. The incision should roughly be the same size as the

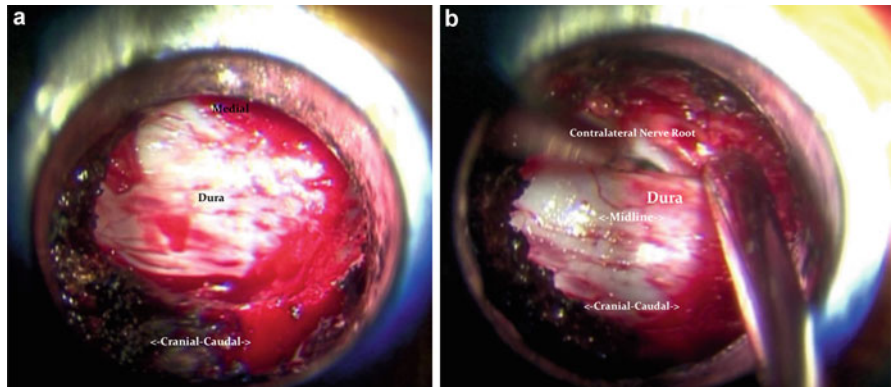

Fig. 3 (**a**–**b**) Intraoperative photos of Ipsilateral and contralateral laminectomy through tubular dilator

diameter of the intended tubular dilator (Phillips et al. 2014) (Fig. 3). Of note, in obese patients (BMIs >30), a more lateral incision may be necessary to obtain adequate visualization. There will be two distinct fascial layers present deep to skin incision. The superficial fascia represents that thoracodorsal fascial, and the deeper, thinner fascia represents that of the multifidus muscle (Schwender 2018). Both fascial incisions should extend slightly beyond that of the skin incision to allow for small adjustments by the surgeon. Once through the fascia of the multifidus, sequential tubular dilators are then used. The initial and smallest dilator is placed (docked) at the caudal edge of the lamina. Larger dilators are then placed over the initial dilator until an appropriately sized surgical window is created. Different procedures call for different diameter retractors. In the case of a microdiscectomy, 16–18 mm retractors are usually large enough for the procedure. The dilators are then removed and the retractor is placed in the muscular window. The retractor is then secured to the surgical table using a bracket mounted to the bed frame. Its location is then confirmed once again using fluoroscopy. Using a high-speed drill, a laminotomy is performed until the level of the ligamentum flavum. The flavum is then excised in a medial to lateral fashion using a Kerrison. The exposed nerve root is identified and protected and is gently retracted medially using a nerve root retractor. Using a bayonetted disc blade, an incision is made through the annulus fibrosis (Kimball and Yew 2013). Careful attention is paid to confirm the adequate decompression of the neural elements: thecal sac, nerve roots, and neural foramen. The surgical portal is then irrigated with saline, hemostasis is ensured, and the retractors are removed. The incision is closed in a layered, watertight fashion (Kulkarni et al. 2014).

MIS Laminectomy

A laminectomy in an appropriate selected patient can lead to significant reduction in neurogenic pain and its associated disability. It also has been shown to significantly improve patient-reported health-related quality of life (Shamji et al. 2015). Laminectomies are most often used to treat multilevel spinal stenosis, which is common in the aging population.

When evaluating the literature surrounding MIS laminectomy compared to open laminectomy, evidence supports that MIS procedures may be associated with less operative blood loss and shorter hospital stays (Terman et al. 2014). In a meta-analysis, Phan and Mobbs (2016) demonstrated that patients undergoing MIS laminectomies reported lower VAS scores as compared to the open approach, high rates of satisfaction, lower rates of blood loss, and thus lower rates of transfusions. They did note that reoperation rates were similar between both groups.

Much like the MIS discectomy, the MIS laminectomy utilizes the same overall approach.

The main differences that should be noted are the size of the tubular retractor is larger and there is more extensive bone and ligamentum flavum resection in order to obtain adequate neural decompression. Also it should be noted that the level of intended decompression will largely determine the necessary position for the tubular retractor. If the intended decompression is L1–L4, then the tubular retractor will be oriented more vertical and closer to the midline as compared to a decompression of L4–L5 or L5–S1 (Parajon and Hartl 2017). This is based on the anatomical bony structure of the vertebral bodies at those levels. Once the retractor is placed appropriately, a laminectomy is performed. The ligamentum flavum is then identified and removed. In cases where contralateral decompression is needed, the tube is repositioned medially; careful attention is needed as to not entrap soft tissue into the tube (Parajon and Hartl 2017). The table is then tilted away from the surgeon. The base of the spinous process is then drilled and undercut. The contralateral lamina is now removed using a high-speed drill and a Kerrison. Attention is now taken to the ligamentum flavum of the contralateral side and is removed. Some surgeons may benefit from utilization of a 90° Kerrison to aid them at this point. Once all of the flavum is removed, the table is then returned to its original position, hemostasis is ensured, and retractors are removed (Phillips et al. 2014; Watkins III and Watkins IV 2015).

MIS Transforaminal Lumbar Interbody Fusion (TLIF)

First described in early the 2000s, the TLIF provided an alternative to the standard posterior lumbar interbody fusion (PLIF) (Moskowitz 2002). A standard PLIF requires a midline incision through which exposure of the entire spinous process, bilateral lamina, and disc space is needed. This approach also places a fair amount of stress on the nerve roots as they are retracted out of the surgical field in order to garner access to the disc space. In the TILF a more lateral approach is made over the paraspinal muscles and directed toward the midline. This approach also allows for preservation of the contralateral side and requires less mobilization of the thecal sac and less risk of injury to a nerve root. There are also minimal retraction of the spinal nerves and decreased approach-related complications and morbidity as compared to the PLIF (Rosenberg and Mummaneni 2001). As a way to minimize the soft tissue trauma associated with open fusion procedures, Isaacs and colleagues described the minimally invasive transforaminal lumbar interbody fusion (MIS TLIF) (Hartl and Gelb 2017). In his original study, Issacs et al. compared their novel MIS TLIF techniques to standard single-level posterior interbody fusions at the same institutions. The authors concluded that patients undergoing the MIS TLIF had decreased hospital length of stay, decreased intraoperative blood loss, and received approximately 50% less postoperative narcotics as compared to the standard PLIF group (Isaacs et al. 2005). These outcomes were directly related the surgical approach in which normal tissue destruction was minimized. Common indications for a TLIF are foraminal stenosis, sagittal deformity, and central stenosis in patients with instability.

Following the same principles of tubular surgery described above, the MIS TLIF can be accomplished (Ozgur et al. 2006). Certain initial differences that should be highlighted are for one, the start point. The incision is initially made 4–5 cm lateral to the midline. This allows for an oblique entry into the spinal canal. As previously mentioned, the start point may have to be adjusted for larger patients. The desired visualized field for a TLIF is the inferior articulating facet joint of the level to be fused. In this, the capsule of the facet complex is entered and removed, and then the superior facet is resected down to the superior aspect of the pedicle (Hartl and Gelb 2017). The pedicle is then skeletonized. The ligamentum flavum is now exposed and can be removed in a piecemeal fashion using a Kerrison. The disc should now be visualized, and a discectomy is performed. Once the desired portion of disc is removed, the space is inspected to ensure adequate decompression. Bone graft and a structural implant are inserted to help preserve height and fuse the level. A MIS posterior fusion can

sometimes be indicated. Because transverse processes are not exposed in the approach, the only surface area exposed following the decompression is the interbody space.

Lateral Interbody Fusion

First described by Pimenta at the Brazilian Spine Society Meeting in 2001 and via publication by Ozgur in the early 2000s, the lateral interbody fusion was a way to gain access into the lumbar spine via a minimally invasive far lateral approach. The procedure is performed via incisions that dissect down through the retroperitoneal fat and psoas muscle on to the vertebral body. The procedure provides good access of the anterior portion of the spine and accomplishes this without having to approach the spine via an anterior trans-peritoneal route (Ozgur et al. 2006). The use of a general surgeon is also avoided, as a spine surgeon can accomplish this minimally invasive method safely. In his report Ogzur notes that possible advantages of this procedure as compared to a standard anterior approach to the spine include no need for a general surgeon, no need to retract the aorta and IVC, simple operative technique as compared to laparoscopic methods, and avoidance complications of laparoscopic and open approaches. The entire procedure is performed under direct vision, and there is little to no impairment of the surgeon's depth perception. Serious complications of the standard anterior approach, damage to great vessels and superior hypogastric nerve plexus, are avoided because of the lateral entry. Some the most common complications associated with the lateral approach are sensory nerve injury and psoas muscle weakness (Fujibayashi et al. 2017).

Some of the main indications for patients to undergo a lateral interbody fusion are lumbar scoliosis, spondylolisthesis, foraminal or central stenosis, and according to newer reports corpectomy and stabilization in trauma patients (Isaacs et al. 2010). In this procedure, the patient is placed in the lateral decubitus position on a table that is able to flex. Attention is made to pad all bony prominences. The greater trochanter of the patient is located at the apex of the bend in the table. Of note, in choosing the entry side, a few considerations should be made. If the patient lacks a coronal plane deformity, then the preferred entry site is the left side of the patient, as the great vessels are located more anterior as compared to the right side (Pawar et al. 2015). If the patient has a coronal plane deformity, then the spine should be approached from the concavity of the lumbar curve. This allows for access to multiple levels of the spine, with a single skin incision. Once the desired side is chosen and the patient is positioned appropriately, the patient is secured to the table using tape or straps. Using fluoroscopy, true AP and lateral x-rays are taken, and the anterior and posterior borders of the vertebral body are identified. The patient is then prepped and draped in the usual sterile fashion (Fig. 4).

A skin incision is made in an oblique fashion from the anterior inferior caudal vertebral body to the posterior superior portion of the next adjacent vertebral body. The deep dissection continues through the subcutaneous fat and abdominal muscles to the retroperitoneal space. When dissecting through the abdominal muscles, attention is made to split muscles in line with the fibers. Between the internal oblique and the transverse abdominal muscle lie the iliohypogastric and ilioinguinal nerves, so care is made as to not cause excessive trauma to this region. Once at the retroperitoneal level, the surgeon can gently sweep the peritoneum anteriorly, lifting it off of the psoas muscle. Using intraoperative neuro-monitoring the fibers of the psoas muscle are splint in the anterior to middle third of the muscle (Ozgur et al. 2006). This location, coupled with neuro-monitoring, ensures that lumbar plexus nerve roots are not harmed. Once the level of disc space is reached, the location is confirmed with fluoroscopy. Now using tubular dilators, the surgical portal is enlarged until a self-retaining retractor is then introduced and secured. A discectomy is then performed in a standard fashion, and a structural implant is placed. Posteriorly, percutaneous pedicle screws can then be inserted as required.

Fig. 4 Image demonstrating patient positioning for lateral interbody fusion

Sacroiliac (SI) Joint Fusion

The SI joint is a complex synovial joint that connects the spine to the pelvis via many ligamentous and muscular attachments. Imbalance between any of these can lead to altered biomechanics, which often lead to pain and disability (Hungerford et al. 2003). Often this pain is overlooked as a pain generator as patients may report many non-focal symptoms such as back, groin, or gluteal pain. Prior trauma to the pelvic region, prior lumbar fusion, and large body habitus are all risk factors for SI joint dysfunction. Once the SI joint is isolated as the source of the pain, non-operative treatments are initially recommended. Treatments such as physical therapy, exercise, steroid injections, NSAIDs, and in some cases nerve ablation are all recommended prior to surgery. If these measures fail and the patient reports persistent pain lasting greater than 6 months or a sudden worsening of nerve function, then surgery would be indicated. Historically the SI fusion initially was performed without any screws via an incision made over the posterior superior iliac spine, articular cartilage was removed, and bone graft was placed (Smith-Petersen 1921). This method called for long periods of external stabilization by either bracing or casting, to ensure that fusion occurred. Internal fixation for SI fusions began to appear in the literature in the 1980s. This eliminated postoperative bracing, but due to the morbidity of the approach, extent of bone grafting, and lengthy hospital stays, this was not favored among patients (Moore 1997). With the advent of MIS approaches to the SI joint, the open procedure fell out of favor. A 2012 survey of spine surgeons globally noted that 85% of SI joint fusions were occurring via MIS techniques (Smith et al. 2013). In comparing open fusions to MIS SI joint fusions, MIS has shown to have shorter surgical times, less blood loss, shorter duration of hospital stays, and larger decreases in postoperative VAS scores (Smith et al. 2013).

For a MIS SI fusion, the patient is positioned prone on radiolucent spine operating room table. The patient is then prepped and draped in the usual sterile fashion. Using fluoroscopy, the affected joint is localized. Using a lateral view in which the sacral slopes are super-imposed, the appropriate trajectory is identified (Miller and Block 2014). Next a 2 cm lateral incision is made. The tissue is dissected and a dilator is advanced through the incision until it contacts

bone. Its location can be confirmed with fluoroscopy. Next the dilator is removed and guide pin is drilled, first into the outer cortex of the ilium. Once this location is confirmed and the pin is perpendicular to the SI joint, it is advanced until it abuts the sacral cortex. The guide pin remains in place, and a 9 mm dilator is placed over it. Attention is paid to ensure that no soft tissue becomes entrapped in the dilator. Next a cannulated drill is passed over the guidewire and only the ilium is drilled. These shavings of cortex are saved on the back table for use later in grafting. Attention is now turned to preparing the SI joint for fusion. This is accomplished via insertion of a flexible decorticator (Kube). The cartilage is removed and the joint space is partially decorticated. The joint is then irrigated with saline, and dilators are reinserted. Bone graft is inserted into the cavity. A guidewire is then replaced and passed into the sacral cortex; its location is confirmed with C-arm. A cannulated screw is then placed over the guidewire and into the sacrum. Wound closure occurs in a watertight fashion.

Application of MIS to Deformity Correction

The previous sections discussed both the origins and the applications of MIS techniques to common spinal procedures: discectomy, laminectomies, and single-level fusions. In this section we will explore the literature surrounding the usage and benefits of MIS application to the field of adult deformity surgery (ADS). Historically deformity correction surgery in adults was associated with a major complication rate around 7.6% (Glassman et al. 2007) and an overall complication rate as high as 70% (Anand et al. 2014a). Major patient risk factors for complications are a sagittal vertical axis (SVA) great than 4 cm, age greater than 60 years old, and more than three medical comorbidities (Auerbach et al. 2016). As is the case with other procedures in spinal surgery, the overall goals of deformity surgery are to decompress the neural elements that are being impinged and establish/restore the global sagittal alignment. It has been demonstrated in great detail that kyphosis is poorly tolerated in lumbar region of the spine and has a direct correlation with the severity of patient-reported symptoms (Glassman et al. 2004). In attempting to measure outcomes following major ADS, Lafage et al. (2009) noted that both SVA and pelvic tilt as a measure of pelvic position have the highest correlation with health-related quality of life. Failure to restore a SVA <50 mm and a pelvic tilt less than 20° has been show to be associated with poor clinical outcomes. These goals can now be accomplished using the MIS techniques previously described and in some instances have better patient outcomes than conventional open procedures. Each clinical scenario is unique and requires a thoughtful and methodical process in planning for surgery. While MIS techniques are often sufficient to accomplish the goal, at times, there is a mix of MIS procedures and open surgery, termed hybrid surgery.

Percutaneous pedicle screw fixation's (PPSF) role in spinal deformity and spine trauma has been shown to be a safe and efficacious alternative to open surgery. Briefly, in this application, the patient is positioned prone on a radiolucent spine table, with bony prominences padded. The type of intraoperative imaging used is at the discretion of the surgeon as both navigation and fluoroscopy have been shown to be safe for pedicle screw placement (Park et al. 2010). This overview details usage of intraoperative biplanar fluoroscopy. X-rays are taken in the AP plane prior to any incisions to ensure that the superior endplate is flat (Anderson et al. 2007) and the pedicle-spinous process interface form an imaginary inverted "V." In the lateral view, careful attention is made to ensure that a single flat superior endplate and only a single pedicle shadow are identified. In obtaining orthogonal views, the relative positions of landmarks are identified (Fig. 5) (Aleem et al. 2017). An incision is then made approximately 4.5 cm lateral to the pedicle border. The fascia is incised and blunt dissection is used to obtain access to the junction between the transverse process and facet. A Jamshidi needle is then used to violate the dorsal pedicle in a lateral to medial fashion. Using AP and lateral imaging, the Jamshidi is advanced to the posterior cortex of the

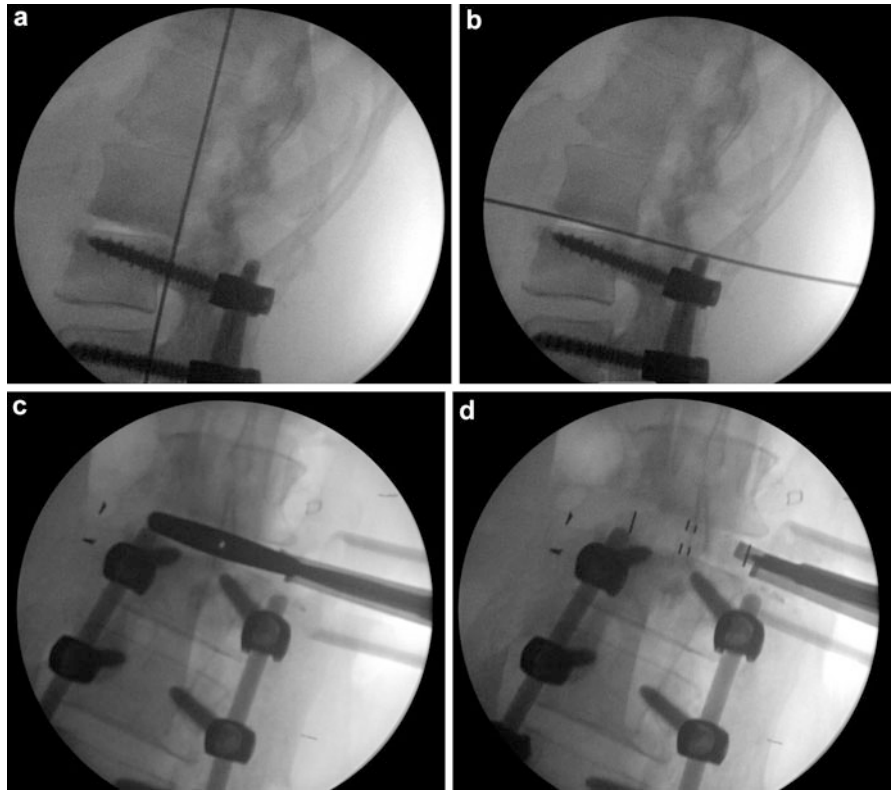

Fig. 5 (**a**–**d**) Intraoperative fluoroscopic images demonstrating level confirmation, endplate preparation, and implant plantation

pedicle (Figs. 6 and 7). The needle should be located in the center of the pedicle on lateral imaging, and it should never cross the medial border of the pedicle on AP imaging. Once in a satisfactory location, the needle is removed and replaced with a guidewire. A tap is used over the guidewire to expand the cortical opening. The guidewire should not be advanced beyond its initial placement, as this could potentially injure the great vessels located deep to it. Once tapping is completed, the tap is removed and replaced with a cannulated pedicle screw (Fig. 8). This process is then repeated, as indicated by the pathology. Once all screws have been placed, a rod is introduced usually from the most proximal screw's incision, and the desired reduction is performed. Aleem et al. described the technique of MIS screw fixation in detail (Fig. 9).

In his study Tinelli et al. demonstrated that using a MIS system in the setting of spinal trauma, his group was able to accurately place almost 98% of 682 pedicle screws in 131 fractures. The remaining 2% of screws were suboptimally placed, but not to the extent where revision surgery was necessary (Tinelli et al. 2014). Anand et al. were able to show that correction of adult lumbar degenerative scoliosis could be corrected with PPSF. He reported that multi-segment spinal corrections could be performed with less blood loss and less morbidity than open corrections (Anand et al. 2008).

Intraoperative fluoroscopy is a necessity in most cases when attempting PPSF in patients with deformity. For proper screw placement, it is imperative that both tilting view and wig-wag views are obtained if the case calls for it. As a technical note, one must ensure that one is orthogonal to the targeted pedicle to ensure proper location. If the operative case is not technically demanding and the surgeon is

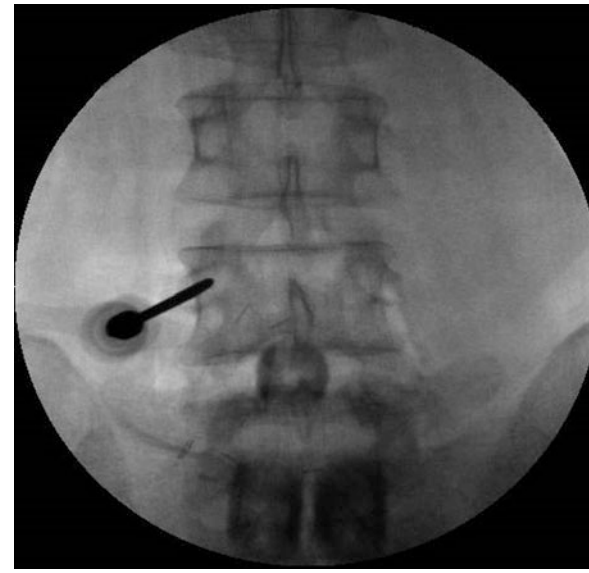

Fig. 6 AP image showing Jamshidi needle docked at start point on lateral edge of the pedicle at roughly the 9 o'clock position

Fig. 7 Lateral fluoroscopic image showing Jamshidi needled in center of pedicle

experienced enough, use of a single anteroposterior C-arm can be sufficient for proper screw placement. Ahmad and Wang (2014) demonstrated this, when 410 pedicle screws were placed in patients with at least 10° of axial rotation. He noted that he had 15 grade 1 violations, 6 grade 2 violations, and 8 grade 3 violations and only 2 screws were required to be revised. Of note the Gertzbein classification is most often used when discussing pedicle screw placement and location relative its medial or lateral wall. There are four grades in the classification ranging from 0 to 3. Grade 0 indicates that there is no breech of pedicle; grade 1, <2 mm breech; grade 2, 2–4 mm breech; and grade 3, >4 mm breech of the pedicle.

Role of Lateral Interbody Fusions

Lateral MIS approaches to the spine have numerous advantages compared to anterior approaches and however may be limited in their ability to sufficiently correct sagittal deformities in adults in isolation (Costanzo et al. 2014). In his systematic review, Costanzo et al. looked at the role of MIS lateral lumbar interbody fusions in sagittal balance and spinal deformity. He concluded that there is no clear answer with regard to how well MIS can correct sagittal balance and noted that open posterior osteotomies would continue to be the gold standard in sagittal balance

correction (Costanzo et al. 2014). Acosta et al. performed a retrospective radiographic study looking at changes in coronal and sagittal plane alignments following lateral interbody fusions. Statistical improvements in the visual analog scale (VAS), the Oswestry Disability Indices (ODI), and the coronal Cobb angle were noted; however, no statistically significant change in the overall sagittal alignment was identified by a postoperative SVA measurements. They concluded that direct lateral interbody fusions alone are insufficient to correct for sagittal imbalance (Acosta et al. 2011). Deukmedjian et al. evaluated a novel technique for attempting to restore a normal SVA. In their study, they utilized a MIS lateral approach to first release the anterior longitudinal ligament and place a 30° hyperlordotic cage. Following this, percutaneous pedicle screws were placed posteriorly to help stabilize the construct. This resulted in a 17° segmental lordosis increase per level as well as an overall SVA decrease of 49 mm and a 7° pelvic tilt (Deukmedjian et al. 2012). Manwaring noted that a two-stage MIS procedure was comparable to Smith-Peterson osteotomies (SPO), because of its ability of providing disc height and correcting coronal imbalance (Manwaring et al. 2014). The first stage of the procedure involved lateral interbody fusions with or without anterior column releases (ACR). The second stage involved PPSF. A 12° improcvement in segmental lordosis and a 31 mm improvement in SVA per ACR level released were noted. Anand et al. have since adopted these principles of staged MIS procedures and proposed a protocol for MIS correction of adult spinal deformity (Anand et al. 2017). Much like Manwaring, Anand proposed that a lateral interbody fusion should occur in the first stage, with or without an ACR. He reports that avoiding an open surgery can avoid potentially serious postoperative complications.

Wang et al. (2014) described the ceiling effects for deformity correction of three different spinal surgery techniques: stand-alone (lateral MIS procedure), circumferential MIS (combined lateral with posterior), and hybrid procedures. The authors note that the ceiling effect in the coronal plane for all three procedures were as follows: 23° for stand-alone, 34 for cMIS, and 55° for the hybrid procedure. A statically significant alteration in the SVA occurred only in the hybrid procedure group, but this was overshadowed by high rates of complications in the hybrid group. Anand et al. (2014b) previously reported that the max SVA correction obtainable is 10 mm utilizing MIS techniques without osteotomies.

Limitations of MIS in ADS

As already noted, not all patients can or should undergo a MIS procedure. The decision to undergo a MIS procedure is ultimately left up to the shared decision-making of the surgeon as well as the patient. The goal should be to safely address surgical pathology and provide the best clinical outcome for the patient. In cases where the decision to proceed with a MIS procedure for ADS is made, some important patient factors should be considered, such as presenting symptoms, physical exam findings, and radiographic findings. Utilizing MIS in deformity surgery presents some unique limitations such as limited sagittal correction, decreased ability for in situ bending and compression, concern for sub-optimal correction, and pseudoarthrosis if interbody fusions are not performed. Since MIS procedures contain some level of a learning curve, inexperienced surgeons are likely to have increased operative times and increased cost of service as well as potentially increased radiation exposure to the patient and surgical team.

As a way to help surgeons select patients that can possibly benefit from MIS, the International Spine Study Group (ISSG) published a rational framework for decision-making in 2014. In this algorithm radiographic parameters are used to guide decision-making. The parameters used in the decision-making tree are SVA, PT, LL-PI mismatch, coronal Cobb angle, curve flexibility, and amount of listhesis. At its core the algorithm is based upon the idea that MIS is limited in its ability to treat sagittal plane deformities (Mummaneni et al. 2014).

Role of Navigation in MIS

As surgical technologies continue to advance, their contributions to surgical procedures are continually investigated. In the last 20 years, image guidance and navigation have come a long way in assisting the surgeon in accurate and safe positioning of hardware. Tajsic et al. (2018) evaluated and compared C-arm navigated, O-arm navigated, and conventional 2D fluoroscopy-assisted MIS techniques. Outcomes that were analyzed included operating time, radiation exposure, and the accuracy of pedicle screw placements. They concluded that pedicle screws placed with the assistance of the O-arm had the lowest rate of malpositioning (1.23%) and screws placed with 2D fluoroscopy were misplaced 5.16% of the time. However, O-arm usage was associated with highest rate of single image radiation exposure as compared to the other two modalities. Among all three modalities, operating room time was comparable. They concluded that given increased accuracy of pedicle screw placement, acceptable doses of overall radiation exposure, and comparable operating room time, the O-arm is the best form of intra-op navigation. Other studies have validated the usage of O-arm in MIS surgeries (Kleck et al. 2018; Chachan et al. 2018).

Robotics in MIS

As surgeons attempt to tackle more complex cases in the aging population, the indications for surgical fixation continue to evolve. As such, methods of attempting to reduce overall radiation to the patient and surgical team also evolve. The use of robotic-assisted pedicle screw placements has been discussed in the literature as a way to circumvent excessive intra-op radiation exposure. To our knowledge there has been only one randomized controlled trial comparing MIS robotics to open fluoroscopic-guided posterior lumbar interbody fusion (Hyun et al. 2017). The average per-screw radiation in the robotic-assisted surgeries was 37.5% of the per-screw exposure in the fluoroscopic group. Over all there was a mean reduction in radiation of 62.5% in the group undergoing robotic-assisted surgery. The results of the study are promising, but further data is needed to validate the routine use of robotics in MIS spinal surgeries.

Abstract

An in depth understanding of cervical spine anatomy is essential to the diagnosis and management of cervical spine pathology. From the osseous anatomy down to the soft tissues structures that function to stabilize, maintain, and protect the spinal cord clinicians must be able to appreciate the biomechanics and the complex anatomy. For patients managed operatively, appropriate surgical planning and operative technique rely heavily upon a sound understanding of the intricate anatomy in this region. In this chapter we detail the cervical spine anatomy with particular emphasis on the osseous, muscular, ligamentous, and neurovascular tissues with the goal of providing clinicians a comprehensive review that they can depend on and refer to when treating patients with cervical spine disease.

Keywords

Anatomy · Cervical spine · Vertebrae · Review

Introduction

The cervical spine consists of seven vertebrae. Each is named according to its corresponding order from C1 cranially to C7 caudally. After completion of embryonic development first two vertebrae are unique in that they do not contain a typical vertebral body and are referred to as the "atlas" (C1) and "axis" (C2), respectively (Fig. 1). These two vertebrae form the atlantoaxial complex of the upper cervical spine. The remaining vertebra (C3–C7) is referred to as the subaxial cervical spine. The overall sagittal plane alignment is concave posteriorly, resulting in an overall lordotic curvature to a normal cervical spine. Each vertebra has an associated nerve root exiting bilaterally above the pedicle and through the foramina, which are referred to as C1–C7. The C8 nerve root exits below the pedicle of C7.

Atlantoaxial Complex

C1

The C1 vertebra (*atlas*) is a ring-shaped structure that is unique from C3 to C7 in that it lacks a robust vertebral body. It instead has an anterior tubercle, which is the attachment site for the longus colli muscle. On the posterior aspect of the ring is the posterior tubercle, which provides attachment points for the rectus capitis posterior minor muscle and the suboccipital membrane. Both the lateral aspects of the anterior and posterior tubercles create semicircular structures called the anterior and posterior arches. The junction of these arches on the lateral-most aspect of the rings

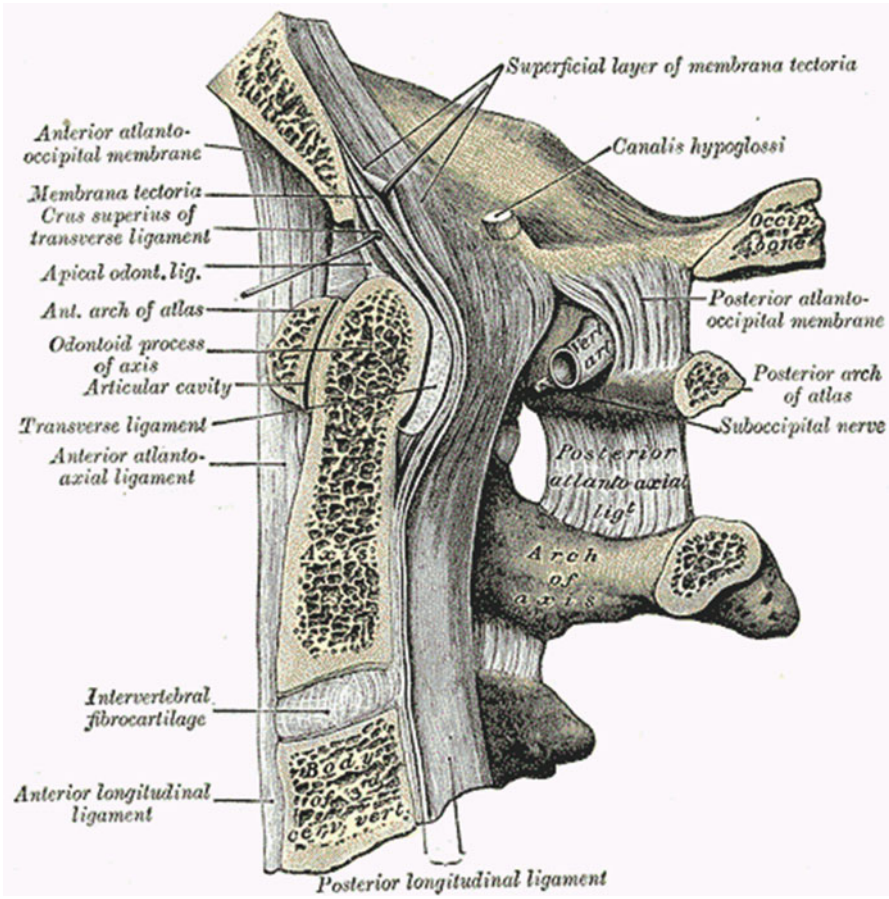

Fig. 1 Midsagittal graphical representation of the upper cervical spine. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 308, Public Domain)

form the lateral masses. Each lateral mass is composed of an articular process on both the superior and inferior aspects of the lateral mass. The superior articular process is concave and oriented inferiorly and medially, allowing for a congruent articulation with the occiput bilaterally. Inferiorly, the processes are oriented with a sloped angle inferiorly and laterally, allowing for an articulation with the superior articular processes of C2 (*axis*) (Daniels et al. 1983; Parke and Sherk 1989). Just posterior to the lateral mass is a subtle groove, in which the vertebral artery courses. The atlas' superior and inferior articulations allow for primarily flexion and extension, as well as lateral bending (Panjabi et al. 1991a). On the posterior aspect of the anterior tubercle, on the inner aspect of the anterior arch at the midline, is a subtle indention that allows for an articulation with the dens of the axis (Fig. 2). Additionally, there are insertion sites just anterior and medial to the lateral masses on the inner aspect of the ring for the transverse ligaments, which also attach to the posterior aspect of the dens of the axis. Extending laterally from each lateral mass is the transverse process. The transverse process at this level houses the vertebral arteries before they exit the vertebral column and enter the foramen magnum in order to become an intracranial structure. A subset of the population has an anatomic variation consisting of an osseous bridge that covers the ridge containing the vertebral artery; this variation is termed an arcuate foramen or ponticulus posticus and is estimated to have a 3–15% prevalence in the population.

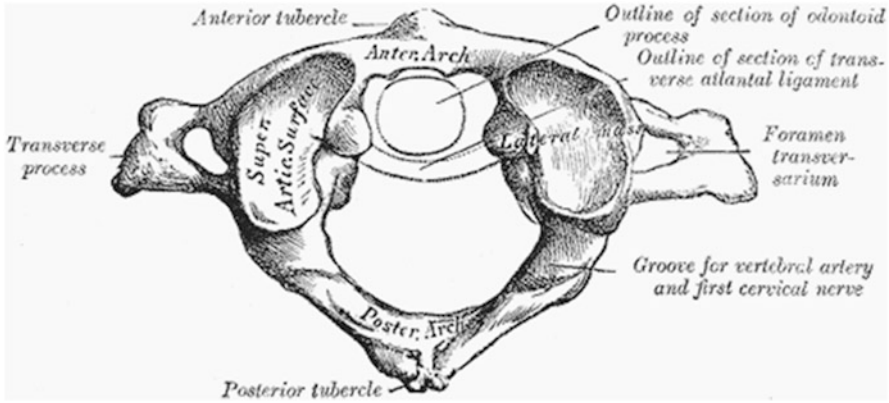

Fig. 2 Axial representation of the C1 vertebra, or atlas. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 86, Public Domain)

C2

Like C1, the C2 vertebra (*axis*) is unique in that has a bony prominence that projects cranially termed the odontoid process or dens. Anteriorly, the odontoid has a synovial articulation with the posterior aspect of the anterior tubercle of the atlas. This articulation allows for nearly half of the rotatory movement of the head and cervical spine. The posterior aspect of the odontoid has two subtle prominences that are the attachment sites of the alar ligaments, which span the atlas and attach medial to the posterior occipital condyles. These ligaments insert laterally at the base of the skull and provide stabilization of the atlantoaxial complex. The apical ligament attaches at the apex of the odontoid, which subsequently attaches to the anterior aspect of the foramen magnum at the midline. The primary stabilizer of the odontoid to the atlas is the transverse ligament, which is a structure that spans the anterior arch of the atlas and is a restraint to lateral displacement of the odontoid. The transverse ligament also has cephalad and caudal projections at the midline termed the cruciform ligaments which provide additional stability to the atlantoaxial complex. Posteriorly, the axis contains a bifid spinous process that serves as the attachment site for the rectus capitis posterior major and obliquus capitis inferior muscles attach. On the lateral aspects of the axis, there are both superior and inferior articular processes which articulate with the analogous structures on the adjacent vertebrae. The superior facet is sloped inferior laterally, congruent with the inferior facets of the lateral masses of the atlas. It is important to note that the sagittal diameter of the spinal canal in the upper cervical spine is greater than that of the lower cervical spine, allowing for adequate space for both the odontoid and the spinal cord. Steel's rule of thirds classically states that one-third of the canal diameter is occupied by the odontoid, one-third by the spinal cord, and the remaining one-third as free space preventing compression of the cord (Ebraheim et al. 1998). The transverse processes of the axis are directed caudally, containing the foramen transversaria that houses the vertebral arteries (Fig. 3).

Subaxial Cervical Spine

Unlike C1 and C2, the osteology of the five subaxial vertebrae share much in common. Each consists of a vertebral body anteriorly, which are separated by an intervertebral disc, bilateral transverse processes containing a foramen, pedicles, as well as two facet joints and a spinous process posteriorly. The subaxial spine, much like the entirety of the vertebral column, is to resist the compressive loads that are placed upon it. Additionally, the bony structures of the cervical spine act to protect important neurovascular structures and provide stability while allowing for functional flexion, extension, and lateral bending (Fig. 4a, b).

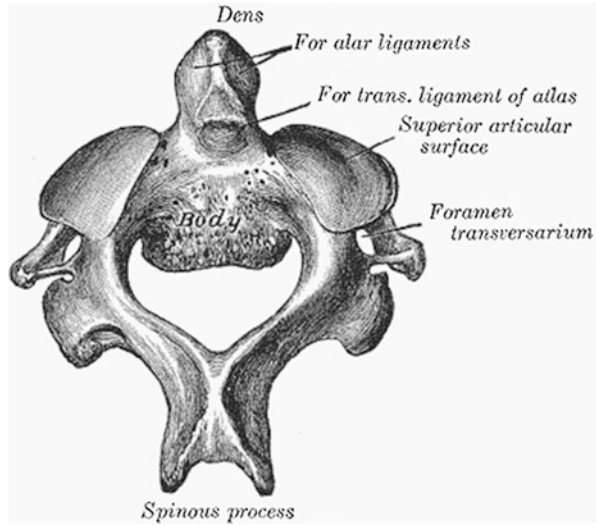

Fig. 3 Axial representation of the C2 vertebra, or atlas. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 87, Public Domain)

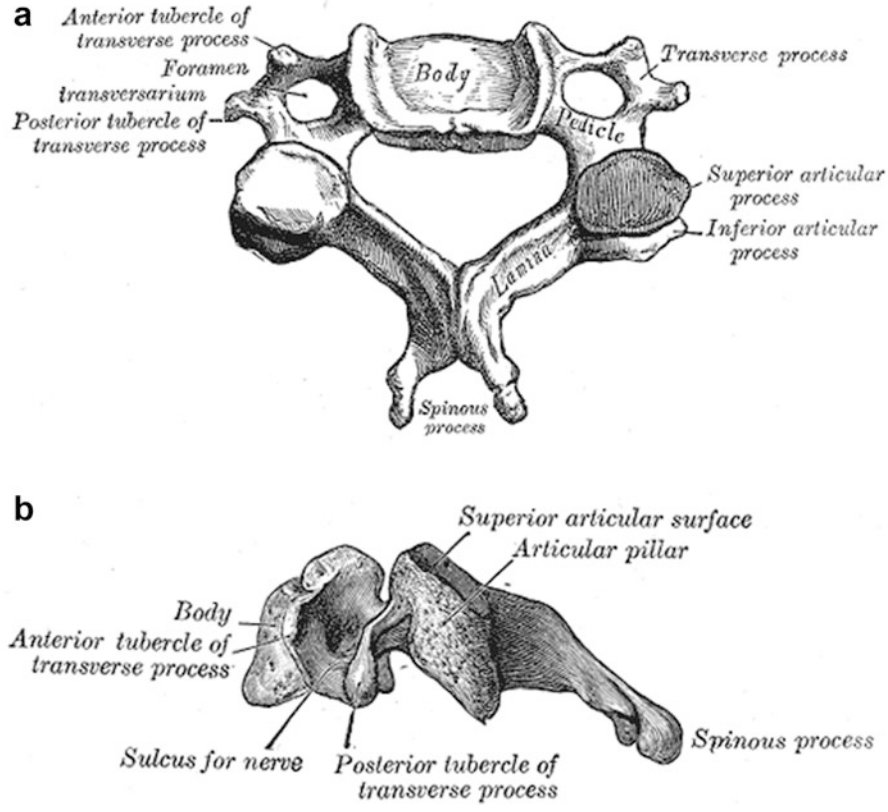

Fig. 4 (**a**, **b**) Axial and lateral representations of a subaxial cervical vertebra. (From: Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body*, Plate 84–85, Public Domain)

Vertebral Body

The anterior aspect of the vertebra is a relatively cylindrical structure called the vertebral body. The body withstands the majority of the compressive loads placed on the vertebral column, and each is separated by an intervertebral disc that functions as a shock absorber. With descending levels down the spinal column, the height of the body slightly increases in height, with the occasional exception of C6, which can be shorter than C7. Each level is larger in the coronal plan than in the sagittal plane. The diameter of each body in the coronal plane is larger than that in the sagittal plane. The superior aspect is concave, and the inferior aspect is convex. Both the superior and inferior aspects contain a shell of cortical bone called the end plate, which eventually transitions into the fibrocartilaginous intervertebral disc. In the coronal plane, the lateral superior aspects of the body demonstrate a lip of bone that projects cranially is congruent with the inferior and lateral aspects of the adjacent cranial body and make up the uncovertebral joint, or joint of Luschka. The uncovertebral joint is important in resisting lateral translation of the vertebra and helps limit lateral bending. Intraoperatively, the uncovertebral joints are important anatomical landmarks that aid in identifying the lateral extent of the body and can act as a reference point for identifying the midline when placing implants during anterior-based procedures.

Pedicles

Projecting dorsolaterally each side of the body is the pedicle, which connects the body to the posterior arch. Unlike the pedicles of the thoracic and lumbar regions, those in the subaxial spine are located midway between inferior and superior end plates of the body on the coronal plane. Descending down the subaxial spine from C3 to C7, the pedicle height increases from an average 5.1 to 9.5 mm, and width increases from 3 to 7.5 mm. Average width and height increase from 5 to 7 mm, respectively (An et al. 1999; Ebraheim et al. 1997; Panjabi et al. 1991b). Additionally, the pedicle angle transitions from 45° to 30° as it descends down the subaxial spine.

Transverse Process

Projecting laterally off of the posterior aspect of the body, anterior to the pedicle, are the bilateral transverse processes. Each transverse process contains both an anterior and posterior tubercle. The anterior tubercle is the origin of the longus colli cervicalis, anterior scalene, ventral intertransverse, and longus colli muscles. The posterior tubercle is the origin of the longissimus, levator scapulae, middle scalene, posterior scalene, splenius cervicalis, and iliocostalis muscles. The anterior tubercle of the C6 transverse process is also referred to as the carotid tubercle and is an important anatomical landmark, as it marks the transverse proves that separates the carotid artery from the vertebral artery. The transverse processes of C1 through C7 each contain a transverse foramen. The vertebral artery and vein travel through the transverse foramen of C1 through C6, and in the majority of cases, not through C7. The transverse foramen is bound by the lateral aspect of the pedicle, the posterior aspect of the anterior tubercle, and the anterior aspect of the posterior tubercle. Additionally, each transverse process contains a groove on its superior surface that runs posterior to the transverse foramen. This groove carries the exiting nerve at the corresponding level after it exits the neural foramen. For example, the groove on the C3 transverse process contains the exiting C3 nerve root.

Facet Joint

Projecting from both the superior and inferior aspects of the lateral mass is an articular process that is congruent with the adjacent articular process of the neighboring vertebra, which together comprises the facet joint. The superior articular process of the vertebra articulates with the inferior articular process of the cephalad vertebra, and the inferior facet of the vertebra articulates with the

facet of the superior articular process of the caudal vertebra. The facet joint is a diarthrodial joint with a relatively lax capsule that allows for appropriate motion to occur. In the sagittal plane, these joints are oriented obliquely from anterior-superior to posterior-inferior at approximately 45° (Fletcher et al. 1990). This orientation differs from the relatively vertically oriented facet joints in the coronal plane of the lumbar spine, and in conjunction with the relatively lax capsule, allows for a broad range of motion in flexion, extension, lateral bending, and rotation (Bland 1987). Just as in other diarthrodial joints throughout the body, the facet joint is susceptible to degenerative changes such as joint swelling, cartilage thinning, and osteophyte formation. Given its close proximity to the neural foramina and spinal canal, these changes can have significant clinical implications.

Spinal Canal

The cervical spinal canal is bordered ventrally by the posterior aspect of the vertebral body, ventrolaterally by the pedicles transverse near the location of the neural foramina, laterally by the lateral masses, and posteriorly by the lamina and spinous process. The lateral diameter of the spinal canal is larger than the anterior-posterior (AP) diameter at all levels of the subaxial spine. The AP diameter is approximately 17 mm at the C3 level and decreases to 15 mm at C7, which has the lowest cross-sectional area.

Lateral Mass

Located dorsolateral to the pedicle is a cylindrical piece of bone termed the lateral mass. The lateral mass is analogous to the pars interarticularis of the thoracic and lumbar spinal regions, as it is the structure that connects the superior and inferior articular surfaces that make up the cephalad and caudal facet joints. It is directly dorsal to the midportion of the transverse process, and as such it is in very close proximity to the exiting nerve root. It has a bony projection dorsomedially, which becomes confluent with the lamina. The lateral masses of the subaxial cervical spine have an average depth and width of approximately 13 mm and 12 mm, respectively, and slightly decrease at each descending level to C7 where it is thinnest (Mohamed et al. 2012). Given the relatively small pedicle size in this region of the spine, screw fixation within the lateral mass is sometimes a desired treatment option, and thus a proper understanding of the lateral mass size is crucial in avoiding complications.

Lamina and Spinous Process

The dorsomedial projection from the lateral masses is termed the lamina. As they continue posteriorly bilaterally, they merge to form the posterior-most bony prominence called the spinous process. The C2 through C6 vertebra are normally bifid, but the C7 spinous process is not. The lamina and the spinous process make up the posterior aspect of the spinal canal. An important anatomic landmark is the junction of the lamina and spinous process posteriorly.

Ligaments

The subaxial cervical spine contains an array of ligaments. The ligaments contribute significantly to the stability and alignment of the bony structures in the region and allow for motion in various planes while restricting extremes of motion that could compromise proper anatomic alignment and integrity of the local structures.

The anterior and posterior aspects of the vertebral bodies and intervertebral discs are bound by both the anterior and posterior longitudinal ligaments. The anterior longitudinal ligament (ALL) is composed of longitudinal fibers that run in a cranial and caudal direction spanning the base of the skull to the sacrum. The ALL attaches to the anterior surfaces of the vertebral bodies and intervertebral discs and acts as a restraint to hyperextension of the mobile segments of the vertebral column. The ALL is narrow and thick over the concave surface of the vertebral

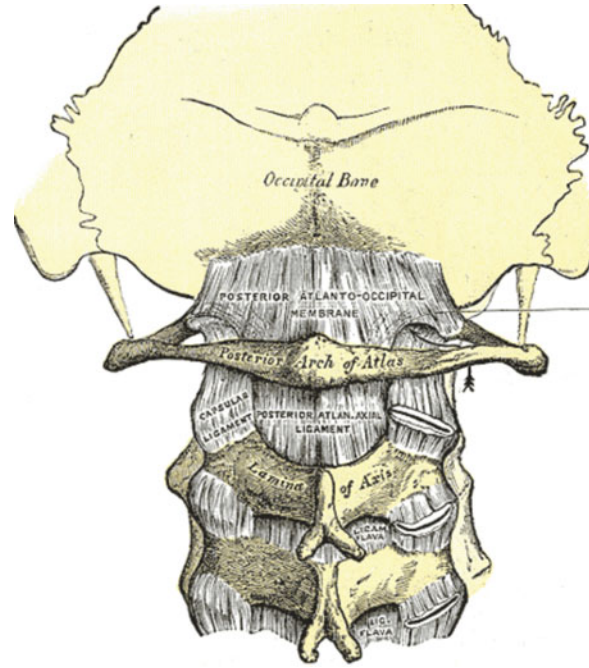

Fig. 5 Posterior representation of the upper cervical vertebra. (From: Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body*, Plate 305, Public Domain)

bodies but becomes more wide and thin over the discs. The posterior longitudinal ligament (PLL) also spans the length of the vertebral column, fanning out to form the tectorial membrane at its most cranial aspect, and attaches to the sacrum caudally. Just like the ALL, the PLL is more narrow over the bodies and wide over the discs (Parke and Sherk 1989) (Fig. 1).

The ligamentum flavum is a grouping of sequential ligaments located in the posterior segment of the vertebra, with the name arising from the relatively yellow appearance (Fig. 5). Each ligament traverses adjacent lamina, attaching anteriorly near the midportion of the cephalad lamina and running obliquely to attach to the superior most margin of the caudal lamina. These ligaments have a high elastin content that have the propensity to lose their elasticity along with the aging process. In such situations, anterior buckling of the ligaments may occur during extension which may in turn produce a mass effect in the spinal canal and contribute to spinal cord compression.

The ligamentum nuchae is composed of the interspinous and supraspinous ligaments. The interspinous ligament is a relatively thin structure that connects the spinous processes of adjacent vertebra. It runs obliquely from the anteroinferior aspect of the cephalad spinous to the posterosuperior aspect of the caudal spinous process. It is bound by the ligamentum flavum anteriorly and the supraspinous ligament posteriorly. The supraspinous ligament connects the posterior tips of the spinous processes along the length of the vertebral column. However, in the subaxial spine, these two ligaments are less distinct as individual structures until the level of C7 but rather form a complex of thick ligamentous elastic tissue that is referred to the ligamentum nuchae. The ligamentum nuchae runs from the inion of the occiput to the spinous process of C7 and acts as an attachment point for the nuchal musculature in the region.

Intervertebral Disc

The cervical spine contains six intervertebral fibrocartilaginous discs which separate the vertebral bodies (Fig. 1). There is no disc between the occiput and the atlas or between the atlas and the axis. The first disc is located between C2 and

the C3 body. The junction of the disc with the adjacent bodies is lined by a cartilaginous layer termed the end plates. The disc itself is composed of two primary components – the nucleus pulposus and the annulus fibrosus. The nucleus pulposus is the centrally located portion of the disc that is the remnant of the primitive notochord and is comprised with primarily type II collagen, proteoglycans, and water. This makeup of the nucleus pulposus results in a gelatinous type substance that allows for force dissipation to the annulus fibrosis and both end plates when compression is applied to the vertebral column. The annulus fibrosus is the component of the disc that surrounds the nucleus pulposus circumferentially and composed of type I collagen, proteoglycans, and water. It is characterized by multiple circumferential layers of fibers that run in an oblique pattern from the cephalad to caudal vertebral bodies. The annulus fibrosus has a high tensile strength that contributes to the stability within a pair of vertebra, which is assisted in the lateral direction by the uncovertebral joint. As the aging process progresses, the margin between the nucleus pulposus and annulus fibrosus becomes more difficult to distinguish (Bland and Boushey 1990). In the coronal view, the superior aspect of the disc is concave, and the inferior aspect is convex as to contour its respective adjacent end plates. The height of the intervertebral disc is slightly larger anteriorly than posteriorly, which contributes to the lordotic curvature of the cervical spine.

Fascia

Investing

The deep cervical layer of the neck is separated into compartments that can be used as landmarks during dissection. The investing layer is the most superficial layer and provides broad coverage to the trapezius posteriorly and wraps around anteriorly to enclose the sternocleidomastoid (SCM) as well. Superiorly, it reaches the hyoid bone and the caudal extent of the mandible and then dives inferiorly to capture both the suprasternal space and form the ceiling of both the ventral and dorsal cervical triangles (Fig. 6).

Pre-tracheal

The next layer is the pre-tracheal layer, which houses many structures and likewise is referred to by multiple names including the middle cervical fascia or the visceral layer. This multifaceted aponeurosis envelops the infrahyoid muscles as well at the omohyoid muscles which lie just superficial to the visceral space. This space is residence to important soft tissue structures such as the thyroid gland, larynx, trachea, and esophagus and deep to this layer run the thyroid vessels. Its superior attachments are the hyoid and thyroid cartilage and inferiorly to the clavicles and sternum. The carotid sheath makes up its lateral margin (Fig. 6).

Prevertebral

The prevertebral layer is a thick fascial plane that surrounds the vertebral column and its muscles. This layer includes the longus and the scalene muscles. The longus colli is a notable structure that aids in establishing midline during an anterior cervical approach. Identifying this structure also helps protect the cervical portion of the sympathetic chain during anterior dissection by retracting laterally. The alar layer is also included as part of the prevertebral layer and encloses the carotid sheath, which houses the vagus nerve, carotid artery, and internal jugular vein (Fig. 6).

Muscles

Ventral

The anterior cervical muscles can be divided into superficial and deep. The platysma is the most superficial layer and is a thin wispy muscle that begins from the mandible spreading inferiorly and laterally to the second rib and acromion process. It has neurovascular bundles that integrate into

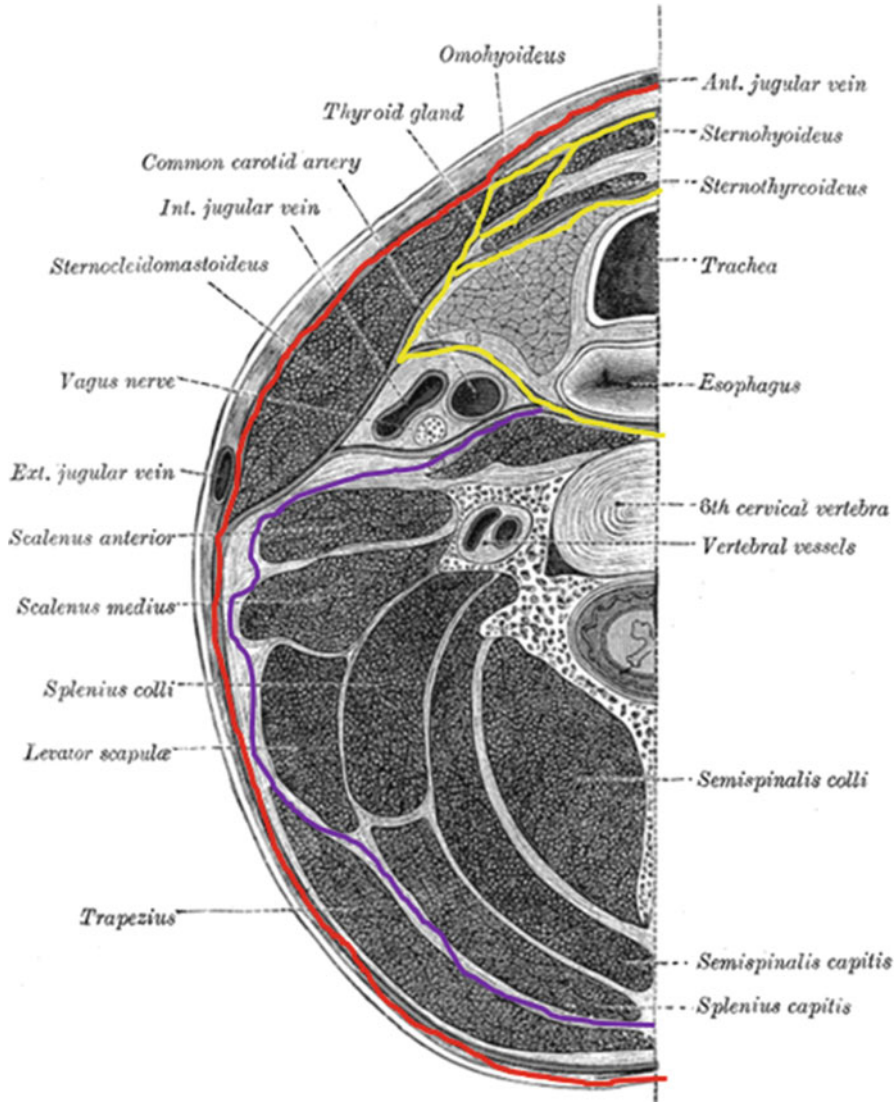

Fig. 6 Axial cuts of the neck at the level of the sixth cervical vertebrae demonstrating fascial arrangements: investing fascia (red), prevertebral fascia (purple), pretracheal fascia (yellow). (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 384, Public Domain)

the skin with its main function aiding in facial expression. Just below this lies the sternocleidomastoid (SCM) which has two heads of origin: the medical clavicle and the sternum that attach to the mastoid and occipital bones. It runs obliquely and functions to turn the head the contralateral side as well as flexion to the ipsilateral side (Fig. 7). It also separates the neck into different triangles, its contents which will be discussed later.

The next layer of muscles is the infrahyoid, scalene, and longus group. The infrahyoid muscles are a group of muscles, as the name implies, that attach to the hyoid bone. These include the mylohyoid, stylohyoid, geniohyoid, digastric, and omohyoid. The strap muscles of the larynx are the sternothyroid and sternohyoid which are important structures to landmark during an anterior approach because they have no direct

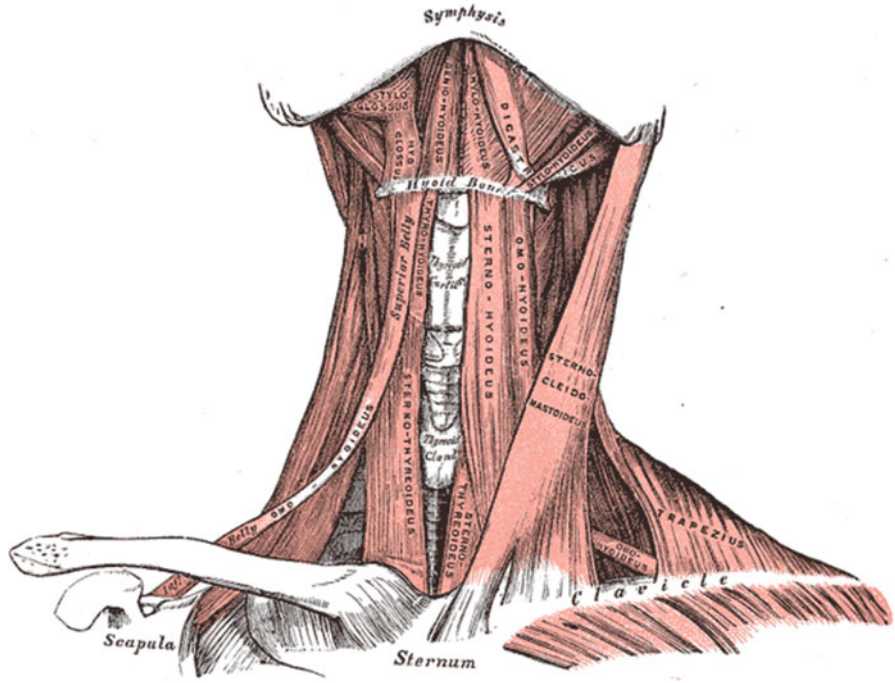

Fig. 7 Superficial ventral muscles of the neck. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 386, Public Domain)

involvement in cervical motion. The scalene group is made up of the anterior, medial, and posterior scalene muscles. The anterior muscle originates from the transverse process of the C3 to C6 vertebrae and inserts into the first rib. The medial arises from the posterior transverse process of C2 to C7 and also inserts on the first rib. The posterior scalene muscle has more variable course but originates from the posterior transverse process of C4 to C6 and inserts onto the second rib. This muscle group is well-known for its contribution to thoracic outlet syndrome, which results from neurovascular compression of either the subclavian artery or brachial plexus. The longus muscle group is composed of the longus colli, capitis, and rectus lateralis and as previously discussed are found within the prevertebral fascia. The longus colli originates from the anterior aspect of C3 to C6 and extends obliquely from C1 to T3 to attach onto the anterior atlas. The longus capitis arises from the anterior transverse process of C3 to C6 and attaches on the basilar aspect of the occiput. The rectus has two heads, an anterior and lateral head which originate from the lateral mass of the atlas and transverse process of the atlas, respectively. The anterior head will insert into the base of the occipital bone, while the lateral head will attach to the jugular process of the occiput (Fig. 8).

Dorsal

The dorsal muscle groups provide tension to the vertebrae to keep them in an upright position and deliver balance as well. These muscles are innervated by the dorsal rami. The erector muscles take advantage of the tension band principle to provide sagittal support and symmetric balance in an effort to preserve lordosis of the cervical region. Loss of strength, often attributed to pain, can lead to progressive loss of lordosis and a relative kyphotic deformity. In the coronal plane, the lateral tension bands provide support. Imbalance in any of these

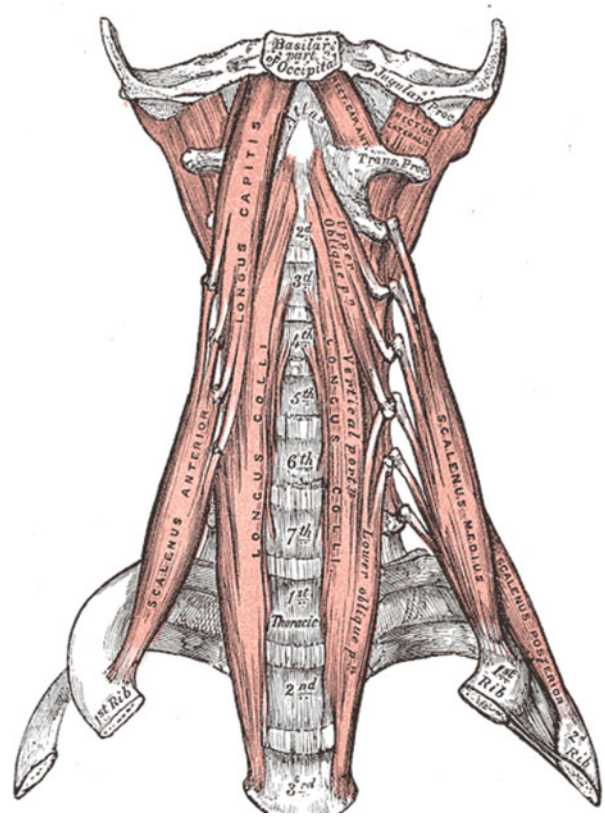

Fig. 8 Deep ventral muscles of the neck. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 387, Public Domain)

planes can lead to deformity seen in abnormal cervical spine curves. All the muscles in the dorsal compartment spread out into three layers discussed below.

Superficial Layer

From superficial to deep, this layer includes trapezius, splenius, and levator scapulae. These muscles work synergistically to rotate the head, extend, and laterally bend. The trapezius has a broad origin that extends along the cervical and thoracic spine. Its upper division begins at the occipital protuberance and attaches at the medial 1/3 of the clavicle. The splenius group consists of the capitis and the cervicis. The capitis begins from the ligamentum nuchae and the spinous process of C6 and inserts along the lateral 1/3 of the superior nuchal line and mastoid. The cervicis inserts along the posterior aspects of the transverse process of C1–C4. The levator scapulae originates along the same posterior tubercles of C1–C4 transverse process and insert along the medial border of the scapula between the superior medial angle and scapular spine (Fig. 9).

Intermediate Layer

This layer includes the erector spinae group which has a common original at the iliac crest, sacrum, and lumbar spinous process. These muscles consist of the iliocostalis, the longissimus, and the semispinalis from lateral to medial. They work together to extend and bend the neck in the coronal plane. The iliocostalis group inserts into the posterior tubercles of the C4–C6 transverse process; the longissimus group inserts on the mastoid process. The semispinalis group inserts along the spinous process of the cervical spine (Fig. 10).

Deep Layer

The transversospinalis group makes up the deepest layer and lies along the spinous process and lamina of the cervical spine. They consist of the multifidus and rotator muscles. They are

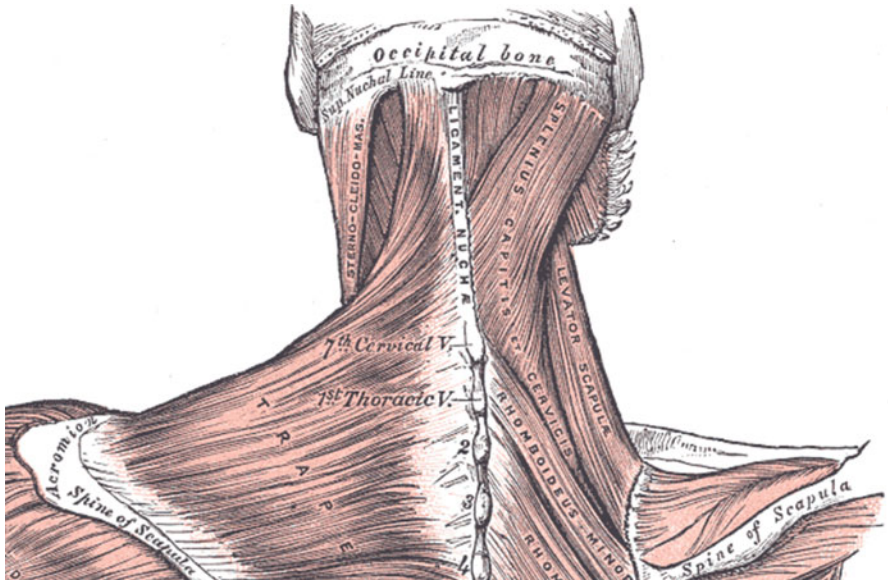

Fig. 9 Superficial dorsal muscles of the neck. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 409, Public Domain)

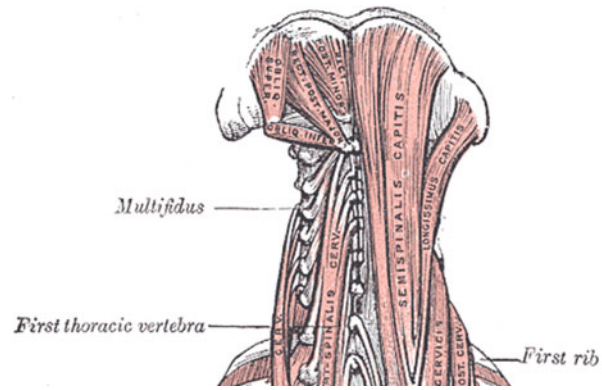

Fig. 10 Intermediate and deep dorsal muscles of the neck. (By Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body: Gray's Anatomy*, Plate 389, Public Domain)

innervated by the dorsal rami of the spinal nerves of the cervical spine (Fig. 10).

Neurovascular Structures

Spinal Cord

Though a detailed description of spinal cord neuroanatomy is beyond the scope of this chapter, basic anatomic understanding is necessary. The spinal cord exits the intracranial space through the foramen magnum and terminates at approximately L2 as the conus medullaris. The spinal cord is widest at C6, measuring an average of 38 mm in circumference, which provides enough space for the increased density in neurologic structures such as the brachial plexus (Parke and Sherk 1989). The inner cord is made up gray matter which houses the nerve cell bodies and branching dendrites. It is separated into anterior, lateral, and posterior segments (horns). The anterior horn contains motor neurons controlling the skeletal muscles and is the column where the cell bodies of the alpha motor neurons are located. The posterior horn contains sensory neurons that

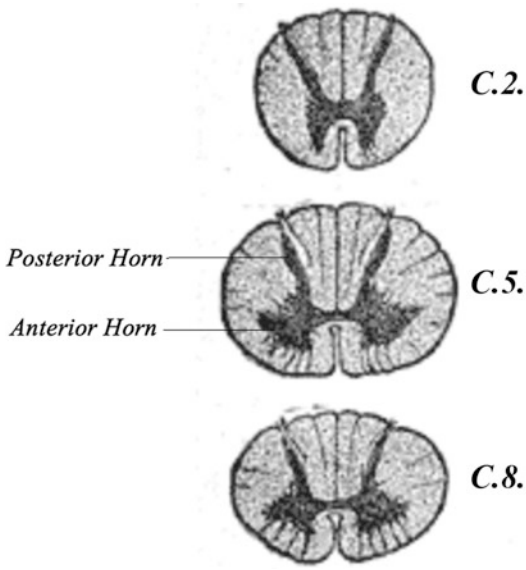

Fig. 11 Transverse section through cervical spinal cord with labeled anterior and posterior horns of the inner gray matter. (From: Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body*, Plate 666, Public Domain)

transmit sensory information from the body that includes fine touch, proprioception, and vibration (Fig. 11). The lateral segment is located only within the thoracic and upper lumbar regions and contains components of the sympathetic nervous system.

The outer circumferential layer is the white matter and is composed of myelinated axons. In a similar manner to the gray matter, it is separated into posterior, lateral, and anterior columns. The lateral column houses the lateral corticospinal tract which provides efferent motor innervation control ipsilateral extremity motion. Also within the lateral column is the lateral spinothalamic tract which is sensory pathway that transmits contralateral pain and temperature. This tract decussates to the other side of the spinal cord at the anterior white commissure, usually 1–2 spinal nerve segments above the entry point. The posterior column, composed of the fasciculus gracilis and cuneatus, is the structure responsible for ascending sensory signals transmitting proprioception, vibration, and fine touch. Sensory information from this pathway is also from the contralateral extremity although its crossover is much higher, located in the brain stem. The anterior column houses both sensory and motor systems, as well as the anterior spinothalamic tract which is responsible for crude touch.

Meninges and Dura

The meninges enclose the spinal cord and are composed of three layers: the pia, arachnoid, and dura matter. The innermost layer is the pia, followed by the arachnoid and then the dura mater. The pia has lateral projections between exiting nerves that attach to the arachnoid and dura. These projections are known as the denticulate ligaments and with the aid of CSF act as a bolster for the spinal cord. The space between the pia and arachnoid is known as the subarachnoid space and contains CSF and nerve rootlets. The space between the dura and vertebral canal is the epidural space and has a rich venous plexus and adipose tissue (Fig. 12).

Nerve Roots

In the cervical spine, there are eight rootlets that exit the spinal cord that unite and form the dorsal and ventral roots. These form nerve roots at each corresponding level and pass through the dura to the intervertebral foramina. In the cervical spine, the nerve roots pass above the corresponding pedicle, except for the C8 nerve root which travels underneath the C7 pedicle. These nerves also leave the spinal cord at an angle that approximates a right angle and explains why foraminal and central herniations will affect the same nerve root. In the foramen, the nerve root takes up one-third of the space, medially it is located at the caudal portion of the superior articular process and as it travels laterally adopts a more inferior position above the pedicle (Daniels et al. 1986). When the neck is extended, the foramen size decreases in overall volume, and the nerve takes up a more superior position within the foramen; when flexed, the foramen size increases, and the nerve root assumes a position in the caudal half of the foramen (Rauschning 1991). The remaining space is filled with fat, which provides cushion to the nerve (Flannigan et al. 1987).

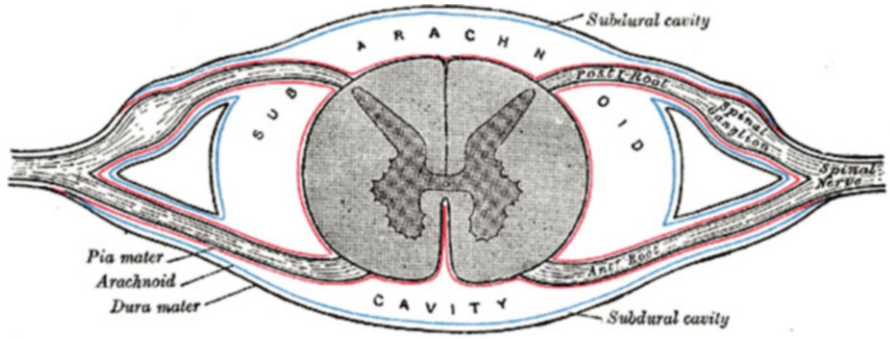

Fig. 12 Transverse section through cervical spine with labeled membranes and spinal nerve roots. (From: Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body*, Plate 770, Public Domain)

Spinal Cord Blood Supply

The vertebral arteries are the primary blood supply to the cervical spine which branch of the subclavian arteries and ultimately form the basilar artery. In general, each vertebral artery enters the transverse foramen at C6 and courses rostrally until C1 (Rickenbacher et al. 1982). It is important to note, during an anterior approach that the vertebral artery is located in the middle one-third of the vertebral body, just lateral to the uncinated process. At the atlas, the vertebral arteries curve around and enter the foramen magnum to unite with the contralateral artery to become the basilar artery. Throughout their course, they give off feeding branches to the spinal cord known as the anterior and posterior spinal arteries. The anterior spinal artery supplies the anterior two-thirds of the spinal cord, while the posterior spinal artery assumes the remaining one-third.

Venous outflow of the spinal cord consists of three anterior and three posterior veins. The most prominent are the anterior venous structures and are located medial to the pedicles. The posterior venous plexus surrounds the spinal cord.

Important Ventral Structures

Carotid Sheath

The carotid sheath contains the internal jugular vein, the vagus nerve, and the common carotid artery from lateral to medial. A small branch of the hypoglossal nerve can sometimes be seen crossing anteriorly. The common carotid artery branches approximately 1 cm above the superior border of the thyroid cartilage within this triangle. The carotid sinus lies just inferior to the bifurcation and is prominent baroreceptor regulating blood pressure. The vagus nerve, lying just dorsal, gives off two important branches to the neck: the superior and inferior laryngeal nerves (Fig. 13).

Vertebral Artery

The vertebral artery is divided into four segments and has an average diameter of 4.5 mm. It travels medial to the anterior scalene muscles and enters the C6 foramen in roughly 90% of the population. After entering cranially through the foramen transversarium of C2 and C1, it then changes course and heads medially along the superior arch of C1 at which point it goes further cranially into the foramen magnum. During a posterior approach to C1, it is critical to avoid dissection greater than 1.5 cm lateral to the midline as injury to the vertebral artery is greatest in this region (Fig. 14).

Superior Laryngeal Nerve

A branch off the vagus nerve, the superior laryngeal nerve runs medial to the carotid sheath and bifurcates at the level of the hyoid to provide motor function the inferior pharyngeal

constrictors. It also has sensory branch that provides sensation to the base of the tongue and the larynx. Injury to this nerve can be manifested with poor gag reflex and voice control especially with high pitches. Loss of the gag reflex can be most debilitating as these patients are often at increased risk for aspiration.

Inferior (Recurrent) Laryngeal Nerve

The inferior laryngeal nerve, commonly known as the recurrent laryngeal nerve, has a U-shaped course in the thorax, specifically in the tracheoesophageal groove. As it pierces the inferior pharyngeal constrictor, it provides motor function to the intrinsic laryngeal muscles. Its course in the neck is not symmetric. On the left, it loops under the aortic arch, and on the right, it loops under the right subclavian artery.

Hypoglossal Nerve

The hypoglossal can be located in the carotid triangle, deep to the belly of the digastric muscle, and as previously discussed, in between the carotid artery and internal jugular vein. Before heading toward the oral cavity to innervate the tongue, it gives off a branch to innervate the strap muscles, which is termed the *ansa cervicalis*.

Sympathetic Chain

The sympathetic chain resides in the prevertebral fascia, just ventral to the longus colli muscles. It surrounds the vertebral artery during its ascension toward the cranial vault. Injury to this structure during an anterior approach can cause ipsilateral Horner syndrome, which is characterized by ptosis, miosis, and anhidrosis.

Surgical Anatomy: The Cervical Triangles

Ventral (4 Types)

The borders of the anterior cervical triangle are the medial edge of the SCM, the inferior mandibular border, and midline of the neck. Within this triangle reside four subtriangles. The submental triangle is formed by the hyoid and the two anterior bellies of the digastric muscles; the floor of which is made up the two mylohyoid muscles. Next is the submandibular triangle, its margins being the ventral and dorsal bellies of the digastric muscle, the inferior mandibular border with the floor consisting of the hyoglossus, mylohyoid, and middle pharyngeal constrictors muscles. Important to note, is the hypoglossal nerve which passes through this triangle. The carotid triangle is bordered by the anterior margin of the SCM, the superior border of the omohyoid and inferior border of the digastric muscle. This triangle is particularly important as the common carotid artery, internal jugular vein, and the vagus nerve are found within this structure. Last, is the muscular triangle which is formed by the medial margin of the SCM, the superior belly of the omohyoid and median plane of the neck (Fig. 15).

Dorsal (2 Types)

The dorsal triangle is bordered by the lateral edge of the SCM, ventral trapezius border, and middle third of the clavicle. The floor is made up the scalene muscle group and prevertebral fascia, and the ceiling is made up of the deep cervical fascia. This triangle is divided into two smaller triangles, the occipital and subclavian triangle. The external jugular vein runs caudally through this triangle at the angle of the mandible (Fig. 16).

Abstract

Degenerative arthropathy, trauma and congenital anomalies, as well as focal abnormalities such as facet overgrowth and disk herniations render each patient unique, and these abnormalities can impact surgical approach. The goal of this chapter is to discuss anatomic considerations that impact surgical planning and to provide a framework for thinking about patient-specific anatomy when approaching the thoracic and lumbar spines.

Keywords

Thoracic spine · Lumbar spine · Degenerative arthropathy · Intraoperative localization

Thoracic Spine

The thoracic spine is composed of 12 rib-bearing vertebrae, separated by intervertebral disks and connected posteriorly by the interspinous ligament (Fig. 1). Each thoracic vertebra has a body, a spinous process, and superior and inferior articulating facets in addition to inferior, superior, and transverse costal facets to articulate with the head of the rib. The pedicles of thoracic spinal vertebrae vary in size, with T1 pedicles being narrow and subsequent pedicles increasing in width approaching the thoracolumbar junction (Fig. 2).

The angulation of the thoracic pedicles further changes, with more caudally oriented trajectories

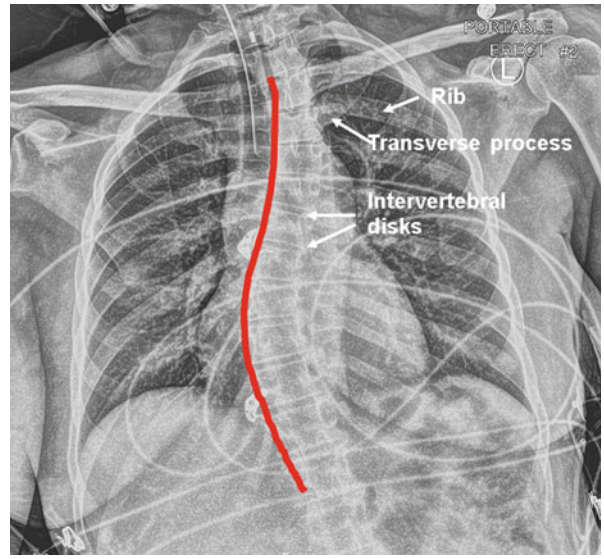

Fig. 1 Anterior-posterior x-ray of the thoracic spine demonstrating coronal scoliosis in the thoracic spine. Ribs, intervertebral disks, and bodies are shown. The red line indicates the lateral aspect of the vertebral bodies

in the upper thoracic spine. Thoracic instrumentation can be challenging due to this variability, and navigation or fluoroscopy-based techniques can assist in planning thoracic pedicle screw trajectories.

The thoracic spine is more rigid than the cervical or lumbar spine, as it is fixed to the sternum via the ribs, limiting the range of motion in the thoracic spine. The cervicothoracic junction and thoracolumbar junctions are more mobile points of transition and are thus more likely to succumb to traumatic pathology. Degenerative pathologies of thoracic spine include sagittal kyphotic deformity, typically secondary to progressive compression fractures, and coronal scoliosis (Fig. 1). Adolescent scoliosis is a common childhood disorder affecting thoracic spine alignment, and in adult patients, iatrogenic or degenerative scoliosis with coronal curvature may affect thoracic spine alignment.

Common traumatic thoracic pathologies include disk herniations and fractures. Thoracic disk herniations may occur with minimal trauma, and over time these disk herniations may become calcified (Oppenlander et al. 2016). If a thoracic disk herniation is noted on magnetic resonance imaging (MRI), computed tomography (CT) can be useful to identify the degree of calcification prior to surgical planning. If a thoracic disk is calcified and causing cord compression and neurological deficit, a transpedicular approach may be required to safely access and drill down the calcified component (Fig. 3).

In older patients with osteoporosis, falls are a common cause of compression fractures in the thoracic spine. Thoracic compression fractures may also be seen in patients with metastatic cancer involving the vertebral bodies. Pain with axial loading (i.e., standing) is a common symptom in thoracic compression fractures. Patients may develop myelopathy from cord compression following fracture or severe, radicular chest pain along the chest wall from neuroforaminal narrowing. Due to the overall stability of the thoracic spine, severe thoracic spine fractures require high velocities such as motor vehicle accidents. If the thoracic spinal column is fractured and displaced, there will likely be associated rib and sternal fractures. Spinal cord transection, although rare, can happen with these types of injures. Patients with diffuse idiopathic skeletal hyperostosis (DISH) or ankylosing spondylitis (Rustagi et al. 2017) are more likely to experience thoracic spine fractures with low velocity accidents (Fig. 4).

Intraoperative localization in the thoracic spine can be challenging if the lesion is not readily identifiable on standard radiographic studies or

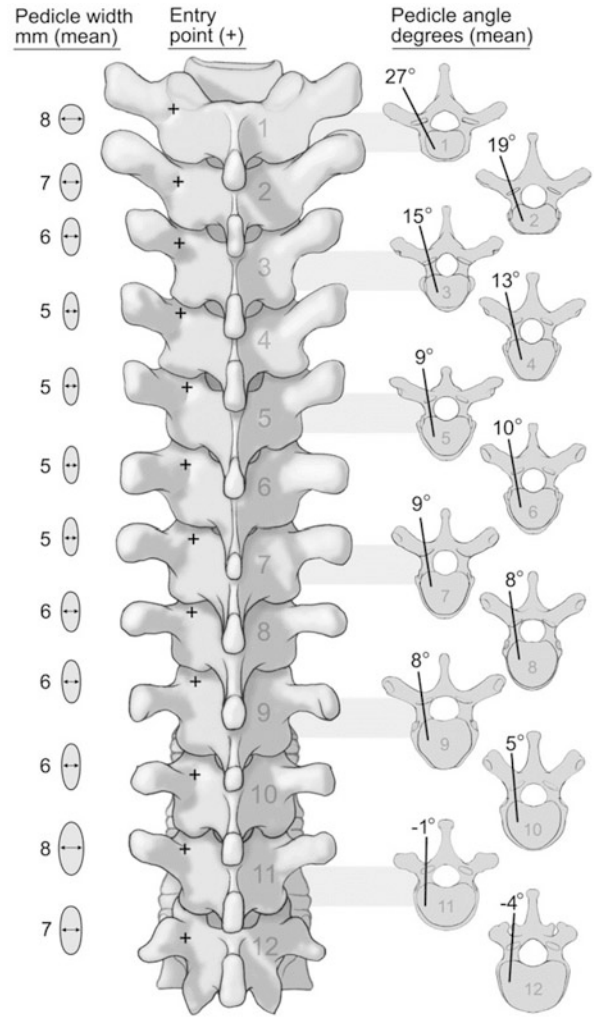

Fig. 2 Illustration showing some morphometric characteristics of the thoracic vertebrae from T1 to T12. The widths of the isthmus of the transverse pedicle are listed on the left. The pedicle entry points (+) and their relationship to the transverse process, laminae, and facets are shown in the center. The transverse pedicle angles are listed on the right. fluoroscopy. Unlike cervical and lumbar spine localization, there is no distinct body (i.e., sacral endplate or dens) available as a reference for counting. Preoperative thoracic and lumbar x-rays may be helpful to determine the true number of ribbed and non-ribbed vertebrae. This may help to correlate with the MRI if the patient has a transitional S1 that may be lumbarized or hypoplastic or an abnormal number of ribbed vertebrae.

Preoperative CT or MRI scans for localization may be obtained prior to surgery incorporating a reference body (i.e., sacral endplate, dens, or other identifiable structure). A radiologist can provide labeling of the localization scan to confirm the precise thoracic body affected. This allows congenital anomalies, such as sacralized lumbar vertebrae, or an abnormal number of rib-bearing vertebrae to be identified. These studies can be correlated with preoperative plain films to reduce the likelihood of wrong-level surgery.

Intraoperative anterior-posterior and lateral fluoroscopic images may be taken to localize the surgical level. Live intraoperative fluoroscopy may also be used for level confirmation, typically by counting up from the sacrum. Intraoperative 3-D imaging, if available, may also help to provide more definitive surgical localization. Prior instrumentation, kyphoplasty cement, or unique fractures may further help to confirm the target level.

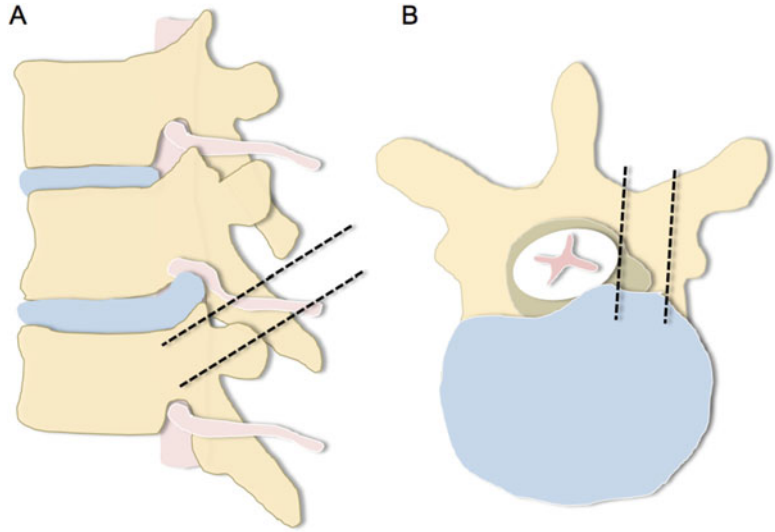

Fig. 3 Transpedicular approach for resection of calcified thoracic disk. (**a**) Lateral view of herniated thoracic disk causing deformation of exiting nerve root. Black lines indicate transpedicular approach to the calcified thoracic disk. (**b**) Axial diagram depicting approach to calcified thoracic disk

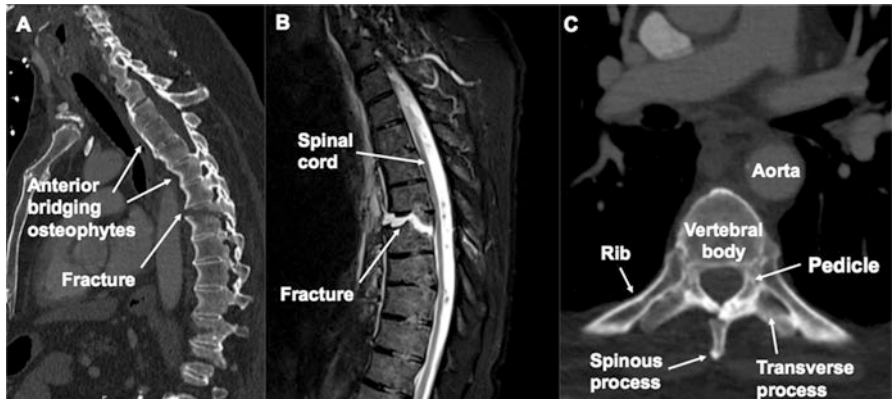

Fig. 4 T8 fracture extending though vertebral body, pedicle, and spinous process in a patient with ankylosing spondylitis. (**a**) Sagittal CT scan demonstrating anterior bridging osteophytes consistent with ankylosing spondylitis and fracture line extending through the T8 vertebral body, pedicle, and spinous process. (**b**) Sagittal T2-weighted fat-suppressed MRI demonstrating T2 hyperintensity along fracture line. The spinal cord can be seen draped ventrally along the posterior aspect of the vertebral bodies. (**c**) Axial CT scan through mid-thoracic vertebra demonstrating relationship of the rib, spinous process, transverse process, and pedicle

It is important to note that technical and patient factors (obesity, surgical position, non-radiolucent OR tables, and others) may interfere with the correct interpretation of these studies. In these instances, consultation with a radiologist should be undertaken.

Direct anterior approaches to the thoracic spine are uncommon, as the aorta and vena cava abut the ventral aspect of the thoracic vertebrae and the lungs and other key structures obstruct direct access (Fig. 5). En bloc resection of thoracic spinal tumors or metastatic pathology may merit anterior approaches (Xu et al. 2009), and these surgeries are often conducted with a cardiothoracic access surgeon. Anterolateral approaches to the thoracic spine include costotransversectomy with removal of the transverse costal facet and rib head for access to the lateral vertebral body and the lateral extracavitary approach, which removes portions of the rib head lateral to the transverse process for greater access to the vertebral body. Careful coordination is necessary when planning

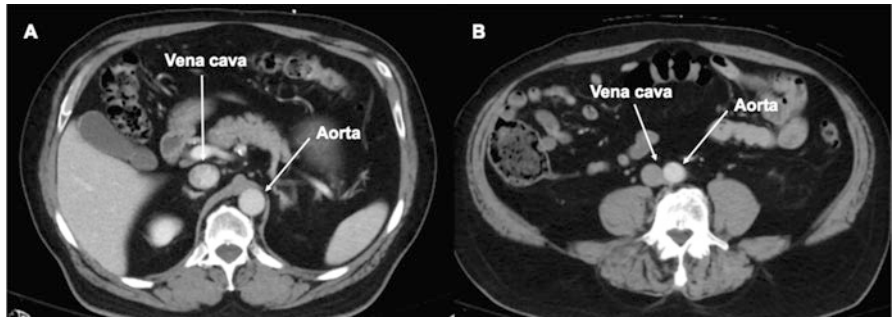

Fig. 5 Sagittal CT scan through (**a**) T12 and (**b**) L3 levels illustrating the relationship of the aorta to the thoracic and lumbar spines

an anterior thoracic approach, as the patient may be intubated with a dual-lumen endotracheal tube. This allows the anesthesiologist to selectively hold respirations in the lung adjacent to the surgical field, facilitating access to the vertebral body. Injury to the lung pleura puts patients at an increased risk of pulmonary complications in some studies, and a chest tube may be electively placed to reflate the lung and prevent pneumothorax or large pleural effusions after anterior thoracic spine approaches. Other treatments such as the application of talc powder or mechanical abrasion of the pleural surfaces to promote pleural adhesion may also be considered. Minimally invasive and endoscopic techniques have also been described to reduce complications for anterior spinal surgeries (Borm et al. 2004).

Posterior and posterolateral approaches to the thoracic spine provide limited access to the posterior vertebral body for debulking of metastatic tumors and decompression of fracture fragments. Following laminectomy, unilateral or bilateral pedicles can be resected via careful drilling to access the ventral vertebral body. In the thoracic spine below T2, nerve roots do not provide significant motor contributions, and these roots may be sacrificed lateral to the dorsal root ganglion to further expand the exposure and improve access to the ventral disk space. Nerve root avulsion or compression should be avoided as this may result in postoperative radicular pain.

For calcified disk herniations, pedicle resection can be an effective way to access the disk space. If the pedicle is sacrificed for access, unilateral or bilateral posterior fusion may be required to limit segmental motion and collapse. Posterior fusion of the thoracic spine typically involves placement of pedicle screws, and preoperative evaluation should take into account pedicle length and width. Medialized screws in the thoracic spine result in cord compression, while lateralized screw trajectories can incorporate rib or injure thoracic viscera. Intraoperative navigation is a useful tool to decide optimal screw trajectory.

Bullet Points

- Ventral disk herniations in the thoracic spine may be calcified.
- Thoracic spine localization requires careful preoperative planning.
- Unilateral nerve roots T2-12 can be sacrificed to improve surgical exposure in posterior and posterolateral approaches.

Lumbar Spine

The lumbar spine is composed of five vertebrae in lordotic alignment, joined by intervertebral disks and posteriorly via facet joints (Fig. 6). Lumbar vertebrae are composed of a body, two pedicles, two transverse processes, and a superior and inferior articulating facet. The transverse processes project laterally and may become fractured during an assault or trauma, leading to musculoskeletal discomfort. There is no load-bearing function of

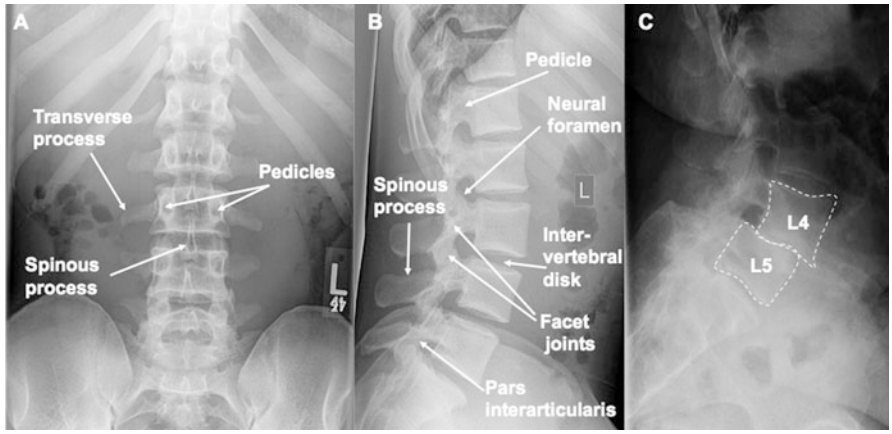

Fig. 6 (**a**) AP and (**b**) lateral x-rays of the lumbar spine illustrating the transverse process, pedicles, spinous process, facet joints, and neural foramen of the lumbar spine. (**c**) Lateral x-ray of the lumbar spine of a different patient, illustrating spondylolisthesis of L4 on L5. The vertebral bodies are outlined with dotted white lines

the transverse processes, and these do not need to be repaired in the case of fracture. The iliopsoas muscle attaches at the transverse processes along the lumbar spine and inserts on the trochanter of the femur. During posterior instrumented fusion, the transverse processes may serve as a surface to encourage fusion. The midportion of the transverse process, as determined in a superior-inferior direction, generally correlates with the midpoint of the lumbar pedicle (again as determined in the superior-inferior axial plane). This landmark can be used to help localize the starting point for pedicle probe or drill insertion.

Intraoperative localization for lumbar spine surgery is typically achieved with lateral radiographs, and the levels are identified by counting from the L5 to S1 disk space. In some patients the fifth lumbar vertebrae may be sacralized, meaning its orientation mimics a typical S1 caudal orientation. This anatomic variant should be identified prior to surgery, as it affects intraoperative localization. Spina bifida occulta may be recognized in patients undergoing evaluation for other spinal issues, and laminar defects may be identified prior to surgery. Another congenital anomaly in the lumbar spine is a pars defect. In this variant, the pars interarticularis (the bony bridge between the superior and inferior articulating facets) fails to develop. The pars interarticularis resists the vector of anterolisthesis, and when the pars is compromised, patients may be at increased risk of developing progressive spondylolisthesis (Fig. 6).

Many patients with lumbar stenosis experience worsening of symptoms with axial loading and ambulation. In contrast, MRI and CT images are traditionally acquired in a supine position. Standing, 36-in. x-rays with neutral leg position (i.e., no compensatory knee bend) provide a more accurate illustration of a patient's global alignment. Spinopelvic parameters can help surgeons to establish how much correction is needed if a lumbar fusion surgery is planned (Celestre et al. 2018). Among these measurements, pelvic incidence and lumbar lordosis are particularly relevant to lumbar spinal anatomy. Lumbar lordosis is measured by the angle between the lower T12 endplate and S1 endplates (Fig. 7).

The pelvic incidence is measured as the angle between a line drawn perpendicular to the center of the S1 endplate and a second line from the center of the S1 endplate to the center of the femoral heads. A patient's lumbar lordosis should be comparable (within 10°) to their pelvic incidence; otherwise an iatrogenic "flat-back" deformity of the lumbar spine may occur.

Common lumbar pathologies include lumbar stenosis, facet arthropathy, spondylolisthesis, and disk herniations (Issack et al. 2012). The posterior facets are prone to degenerative arthritis from

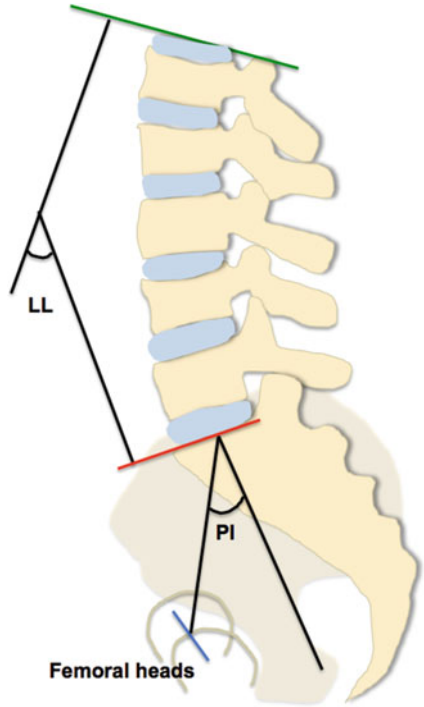

Fig. 7 Pelvic incidence (PI) and lumbar lordosis (LL). The green line indicates the interior endplate of T12 and the superior endplate of S1 (red line). Pelvic incidence is depicted as the angle subtended from the perpendicular line to the S1 endplate and the midpoint of a line drawn (blue) between the femoral heads

repeated abnormal motion, leading to facet overgrowth and synovial cyst formation (Fig. 8). These arthritic changes can compress the spinal canal and contribute to lumbar stenosis. Patients will manifest with radicular symptoms or lumbar claudication in cases of severe stenosis. In cases of spondylolisthesis (Fig. 8), subadjacent vertebral bodies may angle away from the surgeon, complicating the initial dissection. If facet overgrowth is suspected, removal of facet osteophytes may be necessary to identify the anatomic laminar edge.

Posterior approaches to the lumbar spine include laminectomy, hemilaminectomy with discectomy, and instrumented lumbar fusion. Hemilaminectomy is appropriate for patients with unilateral symptoms and a focal disk herniation; however, if the disk herniation is large or central (Fig. 9), a full laminectomy may be completed. If decompression without fusion is planned, the surgeon should avoid manipulation of the facet joint, as removal of the bone may disrupt facet integrity and lead to progressive instability. When fusion is planned, removal of facet overgrowth via rongeur or drilling can improve the surgical exposure and help to identify the laminar edge.

Anterior approaches to the lumbar spine are typically achieved with the help of an access general surgeon or vascular surgeon. The anterior lumbar interbody fusion (ALIF) involves removal of the intervertebral disk, placement of a disk replacement, and securing the disk replacement with an anterior plate and screws (Phan et al. 2017). This approach is complicated by the presence of the lumbosacral plexus (L5-S1) and the iliac bifurcation (L4-5). Anterior approaches may be utilized for patients with failed posterior fusion or in patients with severe deformity requiring anterior and posterior instrumentation to facilitate strength and reduce the risk of failure. Anterior lumbar approaches can be challenging in obese patients if the abdominal girth exceeds the length of surgical instruments. Further, retrograde ejaculation is a reported complication in men at a rate of 7.4–9.8% following manipulation of the lumbosacral plexus in ALIFs, thus compromising male fertility (Lindley et al. 2012).

Bullet Points

- Lumbar degenerative arthropathy can obscure the laminar edge on initial dissection.
- Sacralized lumbar vertebra can complicate intraoperative localization.
- Anterior lumbar fusions may be challenging in obese patients and carry the risk of retrograde ejaculation in male patients.

Conclusion

Careful patient examination and review of available preoperative imaging is crucial for success in spine surgery. CT scans provide key information regarding calcifications, and MRI scans are necessary to identify disk herniations. Prior to

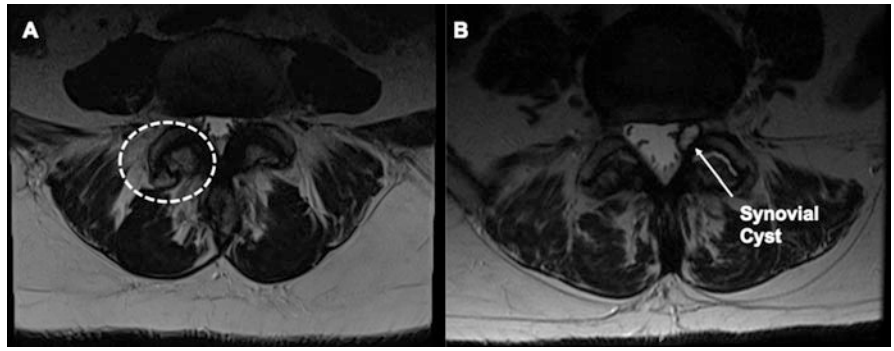

Fig. 8 Axial T2-weighted MRIs of the lumbar spine demonstrating (**a**) spine facet arthropathy with osteophytes noted at the superior and inferior articulating facets. (**b**) Synovial cyst with impingement of spinal canal

Swelling of nerve roots is noted caudal to the disk herniation. Heterogeneous T2 signal abnormality can be seen within the vertebral bodies of adjacent spinal levels

entering the operating suite, technical aspects of the surgery should be decided, including the type of surgical instrumentation if indication. Patient anatomical anomalies, such as sacralized vertebrae, abnormal rib-bearing vertebrae, osteophytes, and overgrown facets, should also be reviewed in detail. Upright or standing radiographs can complete the picture, as they may highlight loss of lordosis or spondylolisthesis. While knowledge of general spinal anatomy is crucial to form the foundation of spine surgery, patient-specific details must be considered to ensure the optimal outcome.

Abstract

Cervical total disc replacement is a routinely used treatment for radiculopathy due to degenerative disease of the cervical spine. The procedure originated to avoid some of the complications seen with the traditional anterior cervical discectomy and fusion. Appropriate patient selection is paramount to obtain acceptable patient outcomes, with particular indications and contraindications for these procedures. As the procedure gained more acceptance, several cervical artificial discs have been developed and, subsequently, approved by the US Food and Drug Administration (FDA). Each of the eight FDA-approved devices is briefly reviewed in this chapter including outcomes from device-specific studies.

Keywords

Artificial disc · Cervical · Disc replacement · FDA-approved · Outcomes

Introduction

Anterior cervical decompression and fusion (ACDF) is one of the most common surgeries done worldwide to decompress the cervical canal, provide stabilization, and restore the normal lordosis of the cervical spine (Cloward 2007; Smith and Robinson 1958). It has been utilized in the treatment of degenerative disc disease, cervical radiculopathy, myelopathy, instability, and segmental deformity. Fusion rates for ACDFs are reported above 95%, and this fusion has been shown to cause a change in motion characteristics of the adjacent segments (DiAngelo et al. 2003; Eck et al. 2002). The change in the kinematics of adjacent levels may be responsible for increased risk of adjacent segment degeneration (Hilibrand et al. 1999; Dohler et al. 1985).

Cervical total disc replacement was developed to avoid some of these complications seen with ACDF. Preservation of the motion segments after total disc replacement surgery may reduce or delay the progression of adjacent segment disease by maintaining motion as well as normal segmental lordosis and anatomic disc space height (Fuller et al. 1998). Indications and contraindications are reviewed in this chapter as not all patients who are candidates for ACDF are candidates for total disc replacement.

Acceptance of this procedure has led to the development of numerous artificial disc designs. Eight devices have been approved by the US Food and Drug Administration (FDA) after thorough investigation through investigation device exemption (IDE) studies. Each of the eight FDA-approved devices (Prestige ST, Bryan, ProDisc-C, Secure-C, PCM, Mobi-C, Prestige LP, M6-C) and their outcomes are briefly discussed in this chapter. All eight artificial discs are FDA-approved for one-level use from C3-7. Only two artificial discs, Mobi-C and Prestige LP, are FDA-approved for two-level use. Most of the artificial disc designs have either uni- or biarticulating surfaces, although the newest FDA-approved device, M6-C, has a non-articulating, compressible core. Most of these discs are metal-on-polymer (M-o-P), although the Prestige ST and Prestige LP represent metal-on-metal (M-o-M) designs. Despite the controversy surrounding M-o-M total hip arthroplasty implants, there have been no widespread reports of M-o-M cervical artificial discs causing complications such as elevated serum metal ion levels, osteolysis or pseudotumor formation (Coric et al. 2011).

Rationale for Total Disc Replacement

As mentioned, despite long-term clinical success of ACDF, it has been associated with the development of adjacent segment degeneration. This

degeneration can be associated with symptoms such as radiculopathy, myelopathy, or neck pain and may necessitate additional interventions. Due to loss of motion at the fused segment, the kinematics are changed at the levels above and below the fused segment. This has been shown in biomechanical studies to cause increase in intradiscal pressure and motion at the adjacent levels (Eck et al. 2002). It is still unclear whether this degeneration is a result of the natural progression seen with aging or a result of the change in biomechanical stresses seen with ACDF.

In contrast, biomechanical studies have reported that total disc replacement does not disrupt the kinematics at adjacent levels and allow for restoration of more normal load transfer (DiAngelo et al. 2003). Additional studies report that there are reduced stresses at adjacent levels in total disc replacement when compared to levels adjacent to a fusion (Pickett et al. 2005).

Indications/Contraindications

Cervical spondylosis is a common condition and can result in radiculopathy and myelopathy. Patients presenting with these symptoms should undergo appropriate work-up including radiographic evaluation and nonsurgical management. Radiographic evaluation, including MRI and CT imaging, can reveal single versus multilevel disease, presence of facet arthropathy, overall cervical spine alignment, kyphotic deformity, instability, and the location of compressive pathology (anterior, posterior, or both). The results of radiographic evaluation are crucial in determining whether a patient is an appropriate candidate for a total disc replacement.

In the setting of normal cervical alignment and mobility with failure of medical management, appropriate indications for total disc replacement include:

- Radiculopathy due to paracentral or central disc pathology or foraminal stenosis
- Myelopathy due to anterior compression by herniated disc

Contraindications for total disc replacement include:

- Significant multiple level degenerative disc disease (> two levels) with baseline motion abnormalities or advanced degeneration of the facet joints
- Abnormal global spinal alignment
- Cervical Instability (translation >3 mm and/or >11° rotational difference to that or either adjacent level)
- Active or prior discitis
- Osteoporosis (T-score < −1.5)
- Traumatic instability (ligament disruption or facet injury)
- Ossified posterior longitudinal ligament (OPLL) or the presence of bridging osteophytes
- Known allergy to implant materials

FDA-Approved Devices

Starting in 2006, eight cervical artificial disc devices have become available in the United States for one-level use, two of which, Mobi-C and Prestige LP, are approved for two-level use (Table 1). These devices vary in size, shape, materials, and articulating surfaces. They can be categorized based on biomechanical design, biomaterials, and type of fixation (Fig. 1) (Mummaneni and Haid 2004; Mummaneni et al. 2007).

Bryan Cervical Disc

Device Description

The Bryan cervical disc was developed in the early 1990s by neurosurgeon Vincent Bryan. The device is made of two titanium alloy shells with a polyurethane nucleus, which makes it a biarticulating contained bearing design. This is a non-modular disc. Fixation is achieved via milled vertebral end plates, and it allows end plate bony ingrowth through a porous end plate design (Fig. 2).

Table 1 Comparison of the eight FDA-approved artificial disc devices

Name	Design	Modular	Articulating method	Implant composition	Primary fixation	Manufacturer
Bryan	Metal-on-polyurethane, Biarticulating contained bearing	No	Biarticulating	Titanium, polyurethane core	Milled vertebral end plates	Medtronic
PCM	Metal-on-polyethylene Ball-and-socket	No	Uniarticulating	Cobalt - chromium, UHMWPE	Ridged, V-tooth design	NuVasive
ProDisc-C	Metal-on-polyethylene, ball-and-socket	Yes	Uniarticulating	Cobalt-chromium, UHMWPE	Central keel	DePuy Synthes (recently sold to Paradigm Spine)
Prestige ST	Metal-on-metal Ball-and-trough	No	Uniarticulating	Stainless steel	Locked vertebral body screws	Medtronic
Prestige LP	Metal composite, ball-and-trough	No	Uniarticulating	Titanium/ ceramic composite	Dual rails	Medtronic
Mobi-C	Metal-on-polyethylene, mobile core	Yes	Biarticulating	Cobalt - chromium, UHMWPE	Lateral self-retaining teeth	LDR
Secure-C	Metal-on-polyethylene, mobile core	No	Biarticulating	Cobalt - chromium, UHMWPE	Ridged central keel	Globus Medical
M6-C	Metal on polyurethane	No	Nonarticulating Compressible	Titanium/ Polyurethane UHMWPE	Triple fins	Spinal Kinetics

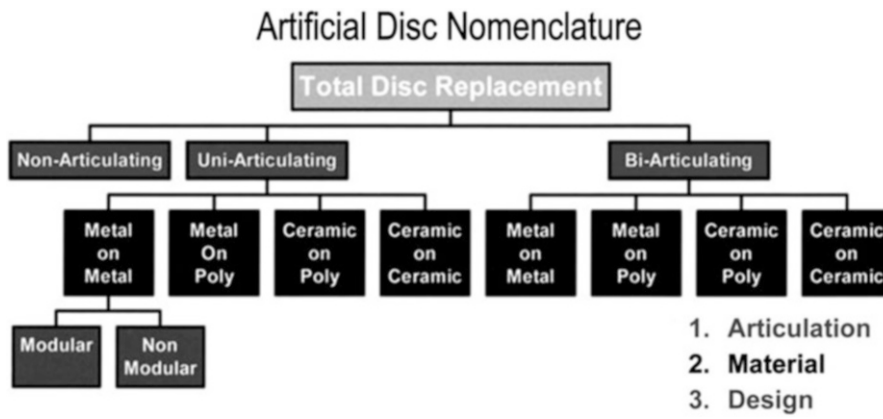

Fig. 1 Nomenclature for artificial disc implants based on design, articulation, and materials. (Permission for the reprint of figure obtained from Journal of Neurosurgery: Spine)

Outcomes

Recently, Goffin et al. reported results in 89 patients treated with the Bryan disc. Ten-year follow-up was available for 72 cases (81%). Maintenance or improvement of the neurological state was seen in 89% of patients. SF-36 patient reported scores improved significantly at all follow-up points. Mean angular motion of the

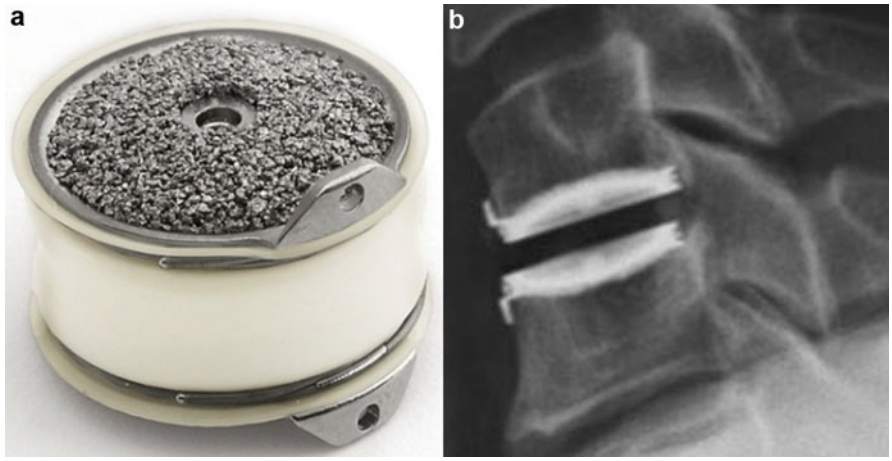

Fig. 2 Bryan artificial disc: (**a**) device; (**b**) lateral X-ray after implantation

prosthesis at 10-year follow-up was 8.6°. Mobility of the device, defined as >2° of angular motion, was reached in 81% of patients. During their study period, 21 patients (24%) developed new or recurrent radiculopathy or myelopathy; the majority of these patients were treated conservatively. Seven patients (8%) required 8 additional spine surgeries to treat persistent or recurrent symptoms. Of these, two patients (2%) were reoperated on at the index level, and five (6%) patients underwent surgery at an adjacent level (Goffin et al. 2003).

Heller et al. presented the results of a randomized controlled multicenter clinical study in 2009 with 242 patients in the investigational group (Bryan arthroplasty) and 221 patients in the control group (single-level ACDF). They showed statistically significant favorable results in the investigational group in various parameters like NDI, neck pain, and return to work and comparable results in other parameters like arm pain and SF 36 physical and mental components. At 24 months, overall success was achieved in 82.6% of the patients in the investigational group and 72.7% in the control group. This difference of 9.9% was statistically significant ($P = 0.010$), and a similar difference was noted at the 12-month follow-up interval ($P = 0.004$) (Heller et al. 2009).

Porous Coated Motion (PCM) Prosthesis

Device Description

The porous coated motion prosthesis is designed to have a metal-on-polyethylene articular surface. This device is a uniarticulating design, which is not modular. It is made up of cobalt-chromium-molybdenum alloy end plates with a TiCaP porous coating for bony ingrowth. Fixation is achieved with a central V-tooth design in a "press fit" fashion (Fig. 3).

Outcomes

In 2015, Philips et al. published the long-term outcomes of the FDA IDE prospective, randomized controlled trial, which compared the PCM prosthesis to anterior cervical discectomy and fusion. The total patient pool of 293 patients (163 PCM, 130 ACDF) was evaluated at 5-year follow-up, and 110 patients had 7-year follow-up. They reported that at 5-year follow-up, all patient-reported outcomes – neck and arm pain visual analogue scale score, neck disability index, and general health (36-Item Short Form Health Survey physical and mental component scores: physical component summary, mental component summary) – were significantly improved from baselines in both groups. Mean scores were

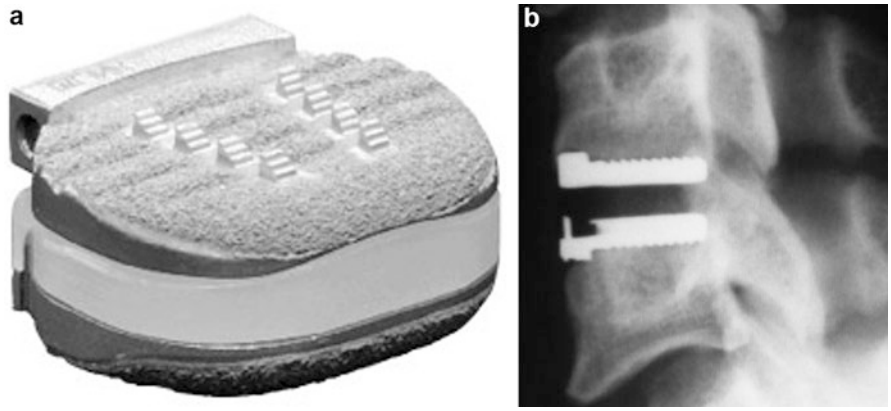

Fig. 3 Porous coated motion prosthesis: (**a**) device; (**b**) lateral X-ray after implantation

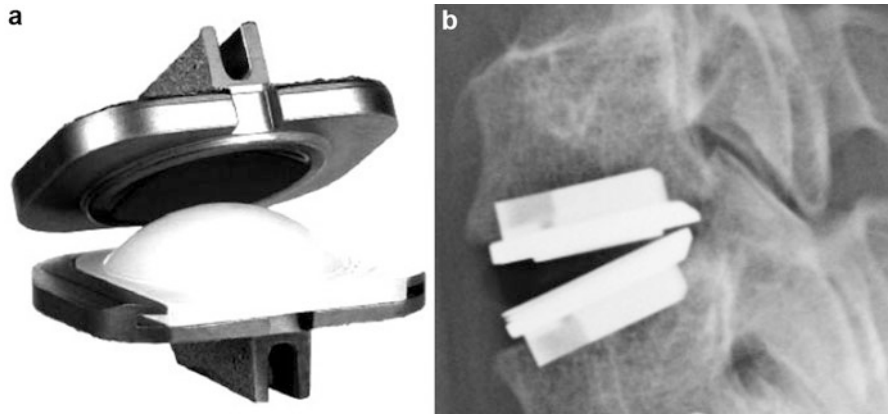

Fig. 4 ProDisc-C cervical disc: (**a**) device; (**b**) lateral X-ray after implantation

significantly better in the PCM group for neck disability index, neck pain, general health, and patient satisfaction. PCM patients trended toward fewer 2- to 7-year device-related serious adverse events and secondary surgical procedures. Adjacent-level degeneration was radiographically more frequent after ACDF and was the primary indication for the increase in late-term secondary surgical procedures after ACDF (Phillips et al. 2015).

ProDisc-C Cervical Disc

Device Description

The ProDisc-C cervical disc is similar in its design to the ProDisc lumbar disc prosthesis. It is a modular ball-and-socket type uniarticulating design. It consists of two cobalt-chromium-molybdenum end plates with an ultrahigh molecular weight polyethylene (UHMWPE) core. Fixation is achieved via a central keel (Fig. 4).

Outcomes

In 2016, Loumeau et al. published data from a randomized controlled trial comparing 7-year clinical outcomes of one-level symptomatic cervical disc disease following ProDisc-C total disc arthroplasty versus ACDF. A total of 22 patients were randomized to each arm of the trial. The authors reported that neck disability index (NDI) scores improved with the ProDisc-C greater than with ACDF. Total range of motion and neck and arm pain improved more in the ProDisc-C group

compared to the ACDF group. Patient satisfaction remained higher in the ProDisc-C group at 7 years. Six additional operations (two at the same level; four at an adjacent level) were performed in the ACDF group; however, no reoperations were performed in the ProDisc-C group. They concluded that ProDisc-C implants appear to be safe and effective for the treatment of cervical disc disease and had a lower reoperation rate than those patients treated with an ACDF (Loumeau et al. 2016).

Prestige ST Cervical Disc

Device Description

The Prestige ST was designed by Mr. Brian Cummins and was the first cervical total disc replacement to receive FDA approval in 2006. It is a stainless steel disc, which has a ball-and-trough design with biarticulating surfaces. It is secured to the vertebral body with screws. The superior and inferior surfaces, which contact the end plates, are treated to promote bone integration (Fig. 5).

Outcomes

A FDA IDE randomized controlled study reported by Mummaneni et al. compared cervical disc replacement using the Prestige ST device versus a single-level ACDF. Two-, 5-, and 7-year results have been published. Out of the 541 total patients in the study, 395 patients (212 Prestige ST, 183 ACDF) completed a 7-year follow-up. They found significantly improved NDI scores and neurological improvement scores in the investigational group as compared to the control group. Additionally, rates for subsequent surgical procedures that involved adjacent levels were significantly lower in the Prestige ST group (4.6% vs. 11.9%). They concluded that cervical disc arthroplasty using the Prestige ST cervical disc had the potential for preserving motion at the operated level while providing biomechanical stability and global neck mobility and could result in a reduction in adjacent segment degeneration (Burkus et al. 2014).

Prestige LP Artificial Disc

Device Description

The Prestige LP artificial disc has the same ball-and-trough articulation as the Prestige ST disc. However, the Prestige LP is made from a titanium ceramic composite material. It is anchored to the vertebral bodies via dual rails on the superior and inferior end plates. It also has a porous titanium spray coating to facilitate fixation and bone ingrowth (Fig. 6).

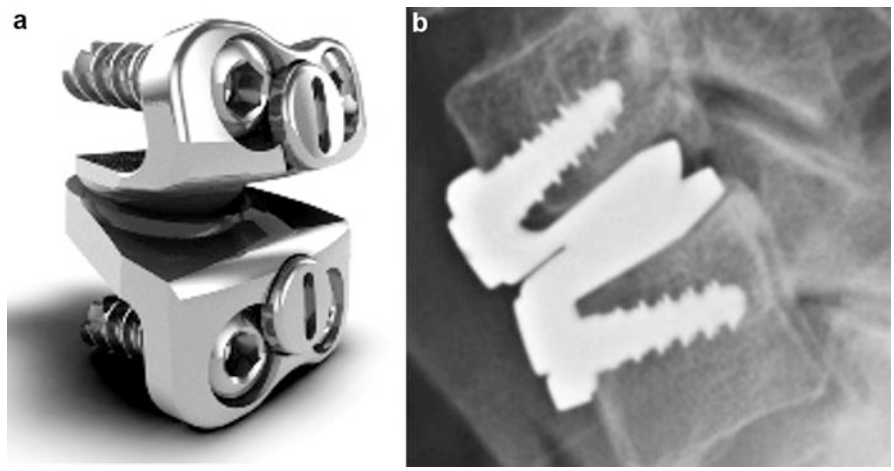

Fig. 5 Prestige ST cervical disc: (**a**) device; (**b**) lateral X-ray after implantation

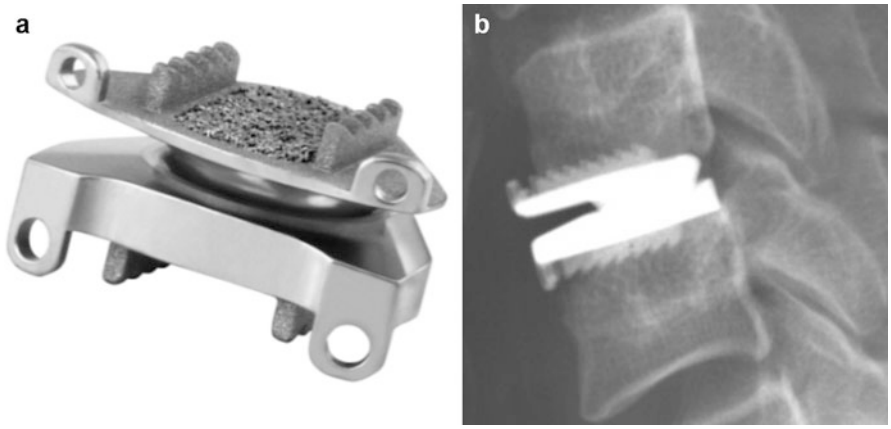

Fig. 6 Prestige LP cervical disc: (**a**) device; (**b**) lateral X-ray after implantation

Outcomes

The results of a randomized control study, investigating the Prestige LP device, were published by Gornet et al. in 2017. They assessed the long-term clinical safety and effectiveness in patients undergoing total disc replacement using the Prestige LP prosthesis to treat degenerative cervical spine disease at 2 adjacent levels compared with ACDF. The study was conducted at 30 centers in the United States with a total of 397 patients (209 Prestige LP, 188 ACDF). At 84 months, the Prestige LP demonstrated statistical superiority over fusion in overall success, NDI improvement, and neurological success. There was no statistically significant difference in the overall rate of implant-related or implant/surgical procedure-related adverse events up to 84 months. The Prestige LP group had fewer serious (Grade 3 or 4) implant- or implant/surgical procedure-related adverse events (3.2% vs. 7.2%,). Patients in the Prestige LP group also underwent statistically significantly fewer second surgical procedures at the index levels (4.2%) than the fusion group (14.7%). Angular range of motion at the superior- and inferior-treated levels on average was maintained in the Prestige LP group up to 84 months (Gornet et al. 2017).

Mobi-C Cervical Disc

Device Description

The Mobi-C cervical disc was first implanted in 2004. This device has a biarticulating design of metal plates articulating on a polyethylene modular core. It has lateral self-retaining teeth on the superior and inferior metal plates, which are pressed into the bone for fixation. The plates are coated with hydroxyapatite to enhance bone integration (Fig. 7).

Outcomes

Hisey et al. published their results in 2016 of a prospective, randomized, controlled study which was conducted as a FDA IDE trial across 23 centers with 245 patients randomized (2:1) to receive total disc replacement with Mobi-C cervical disc or ACDF. The 60-month follow-up rate was 85.5% for the Mobi-C group and 78.9% for the ACDF group. The composite overall success was 61.9% with Mobi-C vs. 52.2% with ACDF, demonstrating statistical non-inferiority. Improvements in NDI, VAS neck and arm pain, and SF-12 scores were similar between groups and were maintained from earlier follow-up through 60 months. There was no significant difference between Mobi-C and ACDF in adverse events or

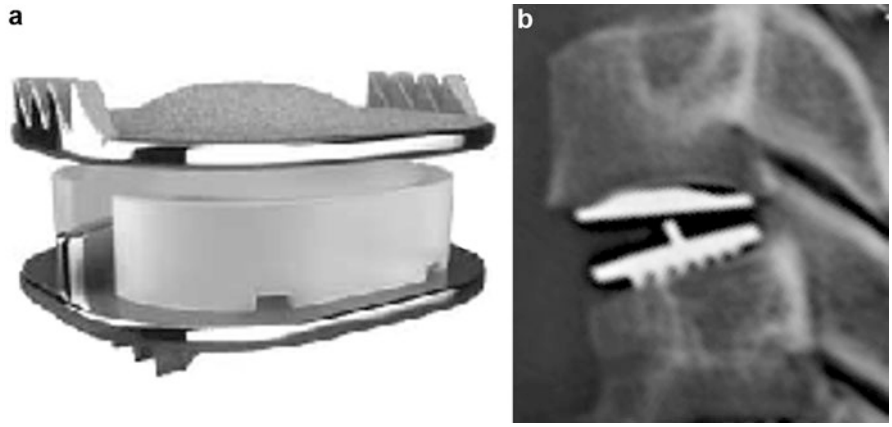

Fig. 7 Mobi-C cervical disc: (**a**) device; (**b**) lateral X-ray after implantation

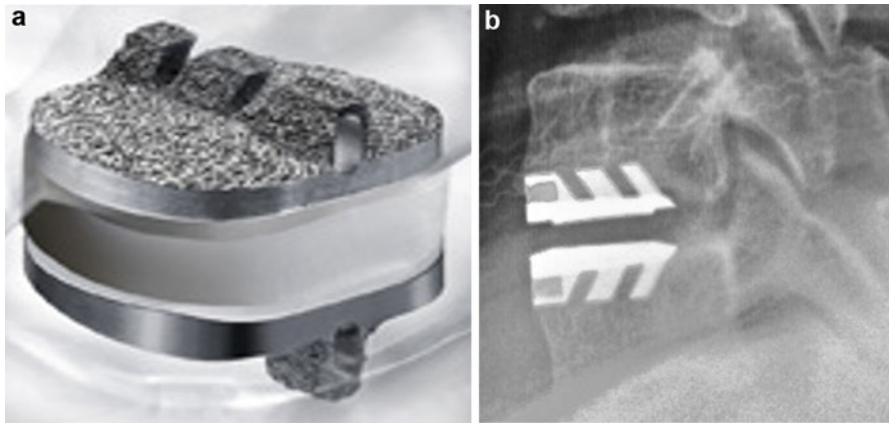

Fig. 8 Secure-C cervical disc: (**a**) device; (**b**) lateral X-ray after implantation

major complications. Range of motion was maintained with Mobi-C through 60 months. Device-related subsequent surgeries (Mobi-C 3.0%, ACDF 11.1%) and adjacent segment degeneration at the superior level (Mobi-C 37.1%, ACDF 54.7%) were significantly lower for Mobi-C cohort. They concluded that total disc replacement with Mobi-C is a viable alternative to single-level ACDF (Hisey et al. 2016).

Secure-C Cervical Disc

Device Description

The Secure-C device is a selectively constrained anterior articulating intervertebral device comprised of two end plates and a central core. The superior and inferior cobalt-chrome alloy end plates have multiple serrated keels for short-term fixation and titanium plasma spray coating on bone contacting surfaces for long-term bony ingrowth. The sliding central core is composed of ultrahigh molecular weight polyethylene, with a spherical superior interface (Fig. 8).

Outcomes

Vaccaro et al. published results of a prospective, multicenter, randomized controlled IDE trial to compare the clinical safety and effectiveness of the Secure-C device versus ACDF. A total of 380 patients from 18 investigational sites were randomized and evaluated. Overall, the study

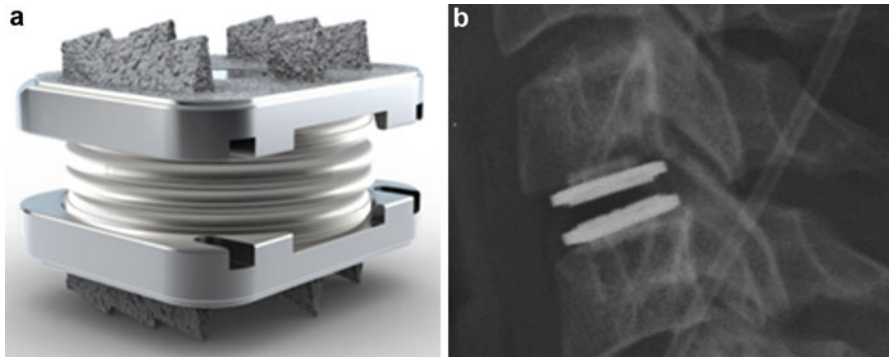

Fig. 9 M6-C artificial disc: (**a**) device; (**b**) lateral X-ray after implantation

demonstrated the statistical superiority of the Secure-C group compared with the ACDF group at 24 months. At 24 months, the Secure-C cohort demonstrated clinically significant improvement in pain and function in terms of NDI scores, VAS scores, and 36-Item Short Form Health Survey. At 24 months, the percentage of patients experiencing secondary surgical interventions at the index level was statistically lower for the Secure-C group (2.5%) than the ACDF group (9.7%). This type of disc has also proven to be a viable alternative to ACDF in appropriately selected patients (Vaccaro et al. 2013).

M6-C Artificial Cervical Disc

Device Description

The M6-C disc is an unconstrained disc with a polyethylene weave (designed to mimic the annulus fibrosus) which houses a compressible viscoelastic polyurethane core (designed to mimic the nucleus pulposus). The end plates are titanium with a plasma spray coating, and fixation is achieved with three rows of "fins" on the upper and lower end plates (Fig. 9).

Outcomes

Lauryssen et al. published results of a prospective, multicenter, non-controlled IDE pilot study to evaluate the clinical safety and effectiveness of the M6-C disc. A total of 30 patients from 3 investigational sites were evaluated and demonstrated significantly improved clinical outcomes (NDI, VAS neck and arm scores) compared to baseline at 2-year follow-up (Lauryssen et al. 2012).

Conclusion

Eight cervical artificial disc devices have been approved by the FDA dating back to 2006. These devices have a sound evidence basis as safe and viable alternatives to ACDF in properly selected patients. Patient selection is key to ensure appropriate patient outcomes as seen in these FDA IDE studies. Further long-term investigations will be necessary to ensure the longevity of these devices.

Abstract

Cervical disc arthroplasty techniques were developed as an alternative to fusion in order to preserve natural motion and reduce the risk of adjacent segment degeneration in the appropriately selected patients with cervical myeloradiculopathy. These arthroplasty implants must provide stability, preserve physiologic motion, and replicate the kinematic signature of the natural disc. There are currently eight cervical arthroplasty implants approved by the Food and Drug Administration (FDA) for use in the United States. The majority of approved

implants follow a metal on polyethylene ball-in-socket or saddle-type design. Over the past decade, there has been an explosion of cervical arthroplasty implant designs each with their own advantages and disadvantages. The purpose of this chapter is to review the biomechanics and kinematics of the natural cervical disc. We will also review available in vivo and ex vivo literature on novel elastomeric compression, hydraulic, and next-generation ball-in-socket cervical arthroplasty designs.

Keywords

Cervical spondylosis · Arthroplasty · Radiculopathy · Myelopathy · Novel implants

Introduction

Motion-preserving cervical disc arthroplasty implants were developed as an alternative to fusion in order to preserve natural motion and cervical biomechanics and reduce the risk of adjacent segment disease for patients with cervical radiculopathy or myelopathy (Hilibrand et al. 1999). The goals of cervical disc arthroplasty are to restore disc and foraminal height, preserve physiologic motion, and provide long-term stability (Cepoiu-Martin et al. 2011; McAfee 2004; Mummaneni et al. 2007). There are currently eight cervical arthroplasty implants approved by the Food and Drug Administration (FDA) for clinical use. These include the Prestige ST and LP (Medtronic), Bryan (Medtronic), ProDisc-C (Centinel Spine), SECURE-C (Globus Medical), Porous Coated Motion (PCM) (NuVasive), Mobi-C (LDR), and the recently approved M6-C Artificial Cervical Disc (Orthofix). The majority of currently approved designs involve a bi-articulating ball-in-socket type design with a polyethylene core and metal (titanium or cobalt chrome) endplate. Most endplate designs include a keel for initial stability and textured surface to promote long-term bony ingrowth (Staudt et al. 2018).

Physiologic Kinematics

A healthy cervical intervertebral disc is viscoelastic and allows for three-dimensional motion in sagittal, coronal, and axial planes. Physiologic motion of a normal cervical segment allows for 15° of flexion-extension, 4° of lateral bending, and 5° of axial rotation in each direction (Holmes et al. 1994; Iai et al. 1994; Ishii et al. 2006). Additionally, there is a linear coupling of ipsilateral lateral bending and axial rotation resulting from facet and uncinate process orientation in each cervical segment (Bogduk and Mercer 2000; Patwardhan et al. 2012; Senouci et al. 2007). The physiologic sagittal center of rotation (COR) varies by cervical segment. The flexion-extension COR at the C5–C6 segment occurs at the midpoint of the superior endplate of the C6 vertebrae. The COR occurs at a point more caudad and dorsal in upper cervical segments and more cephalad in lower segments (Bogduk and Mercer 2000; Hwang et al. 2008; Patwardhan et al. 2012). An arthroplasty device should replicate both physiologic range of motion (ROM) and maintain a natural COR. An arthroplasty device that alters segments of physiologic COR may result in abnormal translations of the adjacent vertebrae during motion, unnatural forces across the segment including the facet joints and uncinate impingement. These abnormal forces may result in limited motion, pain, or ultimately facet joint or adjacent segment degeneration (Bogduk and Mercer 2000; Patwardhan et al. 2012; Pickett et al. 2006).

The viscoelastic cervical disc demonstrates nonlinear flexion-extension load-displacement curve. This characteristic allows for motion with minimal energy expenditure around the neutral zone, termed high flexibility zone. Increasing stiffness outside this high flexibility zone prevents damaging motion beyond the physiologic range. This graded resistance to angular motion also allows for energy dissipation, thereby reducing forces across index and adjacent segments under physiologic load (Panjabi 1992; Patwardhan et al. 2012). Additionally, the viscoelastic nature of the nucleus pulposus allows the disc to conform under compressive loads and act as a shock absorber, thereby reducing force across adjacent

segments and facets (Lazennec et al. 2016). The ideal cervical arthroplasty implant allows for compressibility and graded resistance to motion. Replicating this kinematic signature will reduce shear stresses across the facet joints and adjacent segments and improve implant longevity. First-generation ball-in-socket designs do not allow for compressibility or graded resistance to motion. Elastomeric cervical disc implants were developed as an alternative with these physiologic biomechanical characteristics in mind. Elastomeric compression devices are primarily designed with a polyurethane core that theoretically allows for motion under compression and graded resistance mimicking that of the native disc. To date, there are only a few cervical disc replacement designs that claim to fit this description. These include the M6-C Artificial Cervical Disc (Orthofix), Freedom Cervical Disc (FCD, AxioMed LLC), Cadisc-C (Rainier), and CP-ESP (FH Orthopedics) (Chin et al. 2017; Staudt et al. 2018).

Design Considerations

Multiple characteristics should be considered when designing and evaluating cervical arthroplasty devices. These include articulating surface design, mono or multipiece implant, constraint, materials, and fixation methods. The majority of cervical devices contain a mono or bi-articulating surface. First-generation implants use a ball-in-socket or saddle articulation design. Next-generation implants take advantage of these traditional designs but also include elastomeric and hydraulic-type designs. Implants may exist as a single monoblock or multipiece design. Experience with hip and knee arthroplasty would suggest that monoblock designs may predispose to increase stress across the implant/bone interface leading to early failure. Modular multipiece implants may reduce stress across adjacent interfaces and provide flexibility with sizing, though multipiece implants with more articulating surfaces inherently have more methods of failure. Certain first-generation ball-in-socket designs have highly congruent articulations with a resulting fixed COR. As a result, precise implant position is necessary for restoration of physiologic COR, which varies by cervical segment (Bogduk and Mercer 2000; Hwang et al. 2008; Patwardhan et al. 2012). Other designs that allow for some translation will have a mobile COR and theoretical flexibility in implant position and may accommodate segmental differences. Constraint is defined by the amount of motion in all directions allowed by the implant. Implants may be constrained, unconstrained, or semiconstrained. Constrained designs provide greater stability but may prevent physiologic motion thereby increasing stress on the implant/bone interface, adjacent segments, and facet joints. On the other hand, unconstrained designs may be unstable under physiologic loads. The majority of cervical arthroplasty designs are semiconstrained providing stability with physiologic motion.

Most currently approved cervical arthroplasty implants are made of a metal endplate (titanium, chrome/cobalt, stainless steel) with a polyethylene or polyurethane center. This basic design was born from hip and knee arthroplasty experience, providing a low-friction bearing surface with stable bone interface. Endplate metals offer different advantages and disadvantages based on modulus, stress shielding, biocompatibility, corrosion resistance, and advanced imaging metal artifact. Newer designs are taking advantage of polyetheretherketone (PEEK) and ceramic materials thereby improving MRI compatibility. Articulating surfaces, whether they are metal on metal, metal on polyethylene, or metal on polyurethane, have different wear debris profiles. Wear debris may result in osteolysis, bone loss, loosening, and ultimate implant failure as seen in hip and knee arthroplasty. Metal on metal articulations have been largely abandoned due to concerns for metal wear debris. Overall, the long-term wear profiles of polyethylene and polyurethane devices in the cervical spine are largely unknown. Finally, the majority of devices contain metal spikes or keels for initial fixation into the adjacent vertebral endplates. Long-term fixation is achieved by bony ingrowth into porous-coated (calcium phosphate, hydroxyapatite, and plasma-sprayed titanium) surfaces (Staudt et al. 2018).

Elastomeric Implants

M6-C Artificial Cervical Disc

The M6-C Artificial Cervical Disc Implant (Orthofix) is a next-generation non-constrained viscoelastic compression-type implant. The nucleus core is made of viscoelastic polyurethane surrounded by ultrahigh-molecular weight polyethylene fiber designed to mimic the nucleus and annulus, respectively, and mimic the physiologic properties of the natural disc (Fig. 1). This physiologic core is attached to two titanium endplates and surrounded by a sheath to prevent wear debris elution and tissue ingrowth. Both titanium endplates contain three fins for provisional fixation and titanium plasma spray coating to promote bony ingrowth. Biomechanical analysis of the M6-C design has demonstrated physiologic ROM, COR, and stability in cadaveric specimens. Patwardhan et al. evaluated the biomechanics of an implanted the M6-C artificial disc at the C5–C6 segment in 12 cadaveric specimens. ROM in flexion-extension, lateral bending, axial rotation, coupled motion, stiffness, and COR was evaluated using digital video fluoroscopic images under 1.5 Nm force moments and compared to control segments. They demonstrated implantation of the M6-C prosthesis within 1 mm of the disc-space midline closely replicated control segment COR and ROM in flexion-extension. Additionally, implantation in a more posterior position did not significantly affect ROM, coupling, or stiffness, suggesting an advantage to and flexibility of implant insertion associated with this novel elastomeric implant (Patwardhan et al. 2012). An initial multicenter FDA-regulated feasibility study evaluated 24-month clinical and radiographic outcomes of 30 patients undergoing one- or two-level M6-C prosthesis implantation with 24-month follow-up. They demonstrated improvement in Neck Disability Index (NDI) and Visual Analog Scale (VAS) neck and arm scores at all time points. No patients experienced surgical or neurologic complication. Radiographic disc height increased in all patients, while global and segment ROM in flexion-extension and lateral bending was maintained (Lauryssen et al. 2012). The results of the feasibility study suggested that the M6-C produces excellent results similar to current approved implants and suggested further prospective studies are necessary to determine the motion provided by the elastomeric compression design improves long-term clinical outcomes and reduces adjacent segment disease (Lauryssen et al. 2012). A recent retrospective study by Thomas et al. in Belgium evaluated clinical outcomes of 33 patients who underwent M6-C arthroplasty for spondylotic radiculopathy or myelopathy with mean 17.1-month follow-up. All patients demonstrated improvement in NDI, VAS arm and back, and

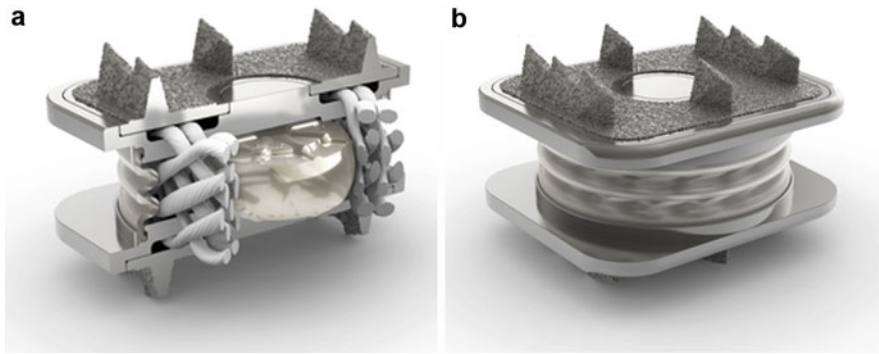

Fig. 1 (**a**) Cutaway schematic of the M6-C Artificial Cervical Disc Implant. It demonstrates viscoelastic polyurethane nucleus core surrounded by ultrahigh-molecular weight polyethylene fiber mimicking the nucleus and annulus of the natural disc. (**b**) Exterior schematic of M6-C Artificial Cervical Disc Implant demonstrating physiologic core attached to two titanium endplates. The core is surrounded by an external sheath to prevent tissue ingrowth and elution of wear debris. Each titanium endplate contains three fins for provisional fixation and titanium plasma spray coating to promote bony ingrowth

SF-36 scores. Four patients experienced device-related complications, two with endplate subsidence, one with implant loosening after motor vehicle collision, and one with immobility due to heterotopic ossification. All four of these patients had a history of previous cervical surgery. They concluded that the M6-C prosthesis is a good addition to the cervical arthroplasty options, though should be avoided in patients with history of previous cervical surgery (Thomas et al. 2016). Early reports on the FDA Investigational Device Exemption (IDE) outcomes data demonstrated favorable outcomes of 83 patients who underwent M6-C implantation at 12 (Phillips et al. 2017) and 24 months (Sasso et al. 2018) follow-up. There was significant improvement in the mean VAS neck and arm scores and index level lordosis. Mean index level ROM increased slightly from 7.8° preoperatively to 8.1 at 2 years. There was radiographic evidence of subsidence in three cases, no evidence of migration, and no revision procedures in the follow-up period (Phillips et al. 2017; Sasso et al. 2018). Further long-term studies with larger patient cohorts are needed to determine the effects on development of adjacent segment disease and long-term wear properties. The M6-C implant has recently received FDA approval for use.

Freedom Cervical Disc

The Freedom Cervical Disc (AxioMed) is a monoblock viscoelastic design consisting of an elastomeric core fixed to two titanium plates. The elastomeric polymer core consists of a silicone polycarbonate urethane copolymer. This polymer is molded and bonded to two titanium-retaining plates. Both titanium plates have a porous bead coating designed to engage and allow for bony ingrowth between the cephalad and caudad endplates. The Freedom Cervical disc is created with 8 degrees of lordosis and available in heights ranging from 5.7 to 6.9 mm. The prosthesis is designed to mimic a normal physiologic cervical disc by establishing appropriate alignment and lordosis, viscoelasticity to mimic load sharing, and stable range of motion in flexion, extension, lateral bending, and rotation. Surprisingly there are no biomechanical studies published to confirm the kinematic features claimed by the manufacturer. Specifically, there is no data regarding the stiffness of this monoblock polymer prosthesis and concerns for resultant high bone-implant forces.

The Freedom Cervical disc has undergone previous pilot studies outside the United States but is not currently approved for use within the United States (Chin et al. 2017; Staudt et al. 2018). One study by Chin et al. reported on the 2-year post market clinical outcomes of the Freedom Cervical Disc in Europe. A total of 39 patients with cervical radiculopathy at 5 institutions underwent one- or two-level cervical disc arthroplasty using the Freedom Cervical Disc. At 2 years clinical follow-up, all patients demonstrated improvement in NDI and VAS neck and arm pain scores. There were no new neurologic symptoms or device-related complications. ROM was surprisingly not evaluated in this study. They concluded that the Freedom Cervical Disc performed as expected in the appropriately selected patients with one- and two-level degenerative disc disease (Chin et al. 2017). This single study is limited by the number of patients and lack of long-term follow-up. Criticisms of this implant design include concerns regarding a single polymer of unknown compressibility matching physiologic properties of the native disc (Staudt et al. 2018).

CP-ESP Cervical Disc

A similar design, the CP-ESP cervical disc prosthesis (FH Orthopedics) is an evolution of the LP ESP lumbar prosthesis that has been implanted in Europe for over 10 years. The CP-ESP disc is a monoblock elastomeric implant with a central polycarbonate urethane (PCU) core fixed to two titanium endplates. Both endplates contain anchoring pegs, textured titanium, and hydroxyapatite layers to provide preliminary fixation and allow for bony ingrowth. The PCU core demonstrates resistance to oxidation both in vivo and ex vivo (Kurtz et al. 2007; Lazennec et al. 2016). The core is attached to the endplates via adhesion molding with peg and groove design without the

use of adhesives avoiding the risk of fluid infiltration and fatigue fractures. This design also allows the implant to replicate the anisotropy of a healthy disc, allowing for controlled compression while avoiding shear in flexion and extension. Mechanical analysis demonstrates a physiologic flexion/extension arc of 14°, lateral bending of 12°, and rotation of 8°. The CP-ESP implant is available in 5, 6, and 7 mm heights with various anterior-posterior and lateral dimensions.

A biomechanical assessment of wear debris and fatigue measured using a three-axis motion simulator over the course of ten million cycles demonstrated loss of height ranging from 0.02 to 0.12 mm and no detectable wear debris. Lazennec et al. prospectively evaluated 1- and 2-year clinical and radiographic outcomes of 62 patients who underwent one- or two-level cervical disc arthroplasty using the CP-ESP prosthesis. At both time points, all patients demonstrated improvement in NDI and VAS neck and arm scores. They also demonstrated improved radiographic range of motion at the index levels. No patients experienced implant-related complications or revision procedures during follow-up (Lazennec et al. 2016). Though this design is available for use in Europe, it is not currently under FDA review (Staudt et al. 2018).

Cadisc-C

The Cadisc-C (Ranier Technology) is an evolution of the Cadisc-L design for lumbar disc disease. This unique monoblock elastomeric design consists of polycarbonate-polyurethane nucleus with calcium phosphate coating without an associated metal endplate. The polycarbonate-polyurethane implant contains a lower modulus "nucleus" integrated into a surrounding higher modulus "annulus" allowing it to more accurately mimic the biomechanics of the natural intervertebral disc (McNally et al. 2012; Rieger 2014). The lack of metallic endplate and articulating surfaces is theorized to reduce potential for wear debris (McNally et al. 2012). Though, concern exists regarding the all polymer monoblock design lack of fixation and potential for migration. There is also no published data regarding wear debris profile of this design (Staudt et al. 2018). Currently, prospective trials are underway evaluating clinical outcomes of the Cadisc-C design in Germany (Rieger 2014).

Next-Generation Pivot/Ball Type Artificial Discs

Synergy Cervical Disc

The Synergy (Synergy Disc Replacement) Cervical Disc prosthesis is a next-generation ball-in-socket cervical disc comprised of bi-articulating titanium endplates with an ultrahigh-molecular weight polyethylene core. Bony fixation is augmented by six plasma-sprayed titanium "teels" (a combination of teeth and keels) on each articulating surface. Its three-piece design is MRI compatible and is available in 5 or 6 mm height options. The Synergy device also has a proprietary geometry which incorporates 0° or 6° of cervical lordosis (Staudt et al. 2018). Synergy was compared to two similar constrained ball and pivot arthroplasty designs (Bryan and ProDisc-C) in a retrospective study of 60 patients undergoing single-level cervical disc arthroplasty for cervical radiculopathy. Pre- and postoperative ROM along with dynamic lateral cervical spine imaging were assessed for each group. The Synergy cohort showed the least variability in change of sagittal alignment, achieving six degrees of lordosis on average with maintenance of cervical ROM achieved in all groups (Lazaro et al. 2010). A recent retrospective cohort study compared both the clinical outcomes and postoperative sagittal alignment of patients undergoing single-level surgery for cervical radiculopathy or myelopathy. Forty patients in the arthroplasty group were compared to 33 patients in the single-level fusion group with a minimum follow-up of 24 months. Both the arthroplasty and ACDF groups showed significant improvement in NDI and VAS neck and arm scores. The arthroplasty group maintained an average cervical lordosis of 6 +/− 2.7°, while the ACDF group demonstrated an

average of 4 +/− 2.4° of lordosis. The authors concluded that the Synergy system demonstrated comparable outcomes and improved sagittal alignment in comparison to cervical fusion (Yucesoy and Yuksel 2017). While it has undergone various stages of testing and pilot studies, the Synergy arthroplasty system lacks FDA approval and is not currently available in the US market.

Baguera C

The Baguera C (Spineart) is a novel ball-in-socket implant with a mobile core designed as a shock absorber. The mobile core is made of ultrahigh-molecular weight polyethylene (UHMWPE) nucleus that articulates with two titanium endplate components. The titanium endplates contain a bioceramic internal coating in contact with the UHMWPE nucleus and a porous titanium exterior intended for endplate ingrowth. Each endplate contains three fins intended to provide initial stability. The nucleus allows to 0.3 mm anterior to posterior translation, 2° rotation, and 0.15 mm elastic deformation mimicking that of the physiologic disc. One biomechanical analysis demonstrated reduced core contact pressures and liftoff throughout ROM compared to ProDisc-C (Centinel Spine) and Discocerv (Alphatec) using a cervical spine finite element model (Lee et al. 2016). Fransen et al. performed a retrospective registry analysis of 99 patients at 5 European investigational centers undergoing one- or two-level cervical arthroplasty for radiculopathy or myelopathy using the Baguera C implant. They demonstrated a decreased range of motion from 10.2° preoperatively to 8.7° for single-level procedures and from 9.8° to 9.1° for two levels at 2 years radiographic follow-up. They also demonstrated evidence of heterotopic ossification in 54% of patients. None demonstrated radiographic evidence of subsidence, kyphosis, or degeneration of the adjacent disc (Fransen 2016). While lack of radiographic evidence of adjacent segment disease is encouraging, larger long-term studies are needed to determine the efficacy of the implant. Additionally, the mobile nucleus design may theoretically predispose to long-term wear debris and potential for osteolysis as seen in hip and knee arthroplasty.

Simplify Cervical Disc

The Simplify disc has completed one- and two-level IDE study but is not yet received FDA approval. It is a semiconstrained design with titanium plasma-sprayed PEEK endplates with a retention ring housing a mobile ceramic core. Simplify is a modern generation disc with novel biomaterials (PEEK and ceramic) which provide for positive imaging characteristics.

Conclusions

The goal of motion-preserving cervical arthroplasty devices is to restore natural kinematics and motion under physiologic load and prevent degeneration of adjacent segments. Traditional, first-generation cervical arthroplasty devices contain ball-in-socket type designs and do not allow for physiologic coupled motion and compressible graded resistance. As a result, these designs may predispose to adjacent segment and facet stress predisposing to facet degeneration, pain, reduced motion, and degeneration. Early biomechanical evidence suggests that next-generation elastomeric compression devices may better replicate physiologic coupled motion and graded resistance. Further studies are necessary to determine the wear properties, durability, and long-term outcomes of these novel implants.

Abstract

Anterior cervical decompression and fusion has long been the gold standard for cervical degenerative disc disease, but concerns about the deleterious effects of fusion on adjacent segments have led to the development of cervical total disc replacement (TDR). While many TDR designs have been evaluated, metal-on-polymer and metal-on-metal designs are the most commonly used today. Different types of metals and surface modification have been introduced in attempt to improve osseous integration and decrease failure of implant. Correct positioning, adequate exposure, and thorough decompression and end plate preparation are necessary to ensure proper disc placement. Patients benefit in the postoperative period from early mobilization, improved range of motion, and often return to work earlier, with a lower risk of reoperations than with fusion. Long-term outcomes from many of the IDE trials consistently demonstrate to be comparable and even superior to fusion with cost-effective analysis further supporting financial feasibility.

Introduction

Joint arthroplasty has been an evolving treatment modality for degenerative joint disease for decades. Its evolution has permitted improved prostheses, better outcomes, and the inception of arthroplasty being used in numerous areas of the body. Utilization of arthroplasty for cervical spine pathology has been a topic of recent discussion. While prior treatment has been centered on hip and knee arthrodesis, cervical total disc replacement (TDR) displays promise for the maintenance of native spine biomechanics and kinematics while minimizing the progression of adjacent segment disease seen in arthrodesis.

Currently, the most commonly used treatment of cervical spine spondylosis and disc disease centers on Smith-Robinson, who pioneered the widely known and used anterior cervical decompression and fusion (ACDF) surgery in the 1950s with multiple studies reporting remarkably good success with this procedure (Bohlman et al. 1993). However, adjacent segment degeneration, or the appearance of degenerative changes at a level above or below a fused segment, has been seen during long-term follow-up, and efforts toward artificial joint prostheses became a potential alternative. Symptomatic adjacent segment disease (ASD) affects approximately a quarter of all patients who undergo an ACDF by 10 years with more than two-thirds of patient failing nonoperative therapy and requiring addition operative interventions (Hilibrand et al. 1999).

The first attempt to create an artificial intervertebral replacement appeared in the 1960s under Ulf Fernström. The initial implant utilized was a stainless steel ball bearing prosthesis trialed in both the cervical and lumbar spine (Baaj et al. 2009). Unfortunately, little success was obtained, and nearly 90% of the cases demonstrated implant migration and subsidence of the

prosthesis (Fernström 1966). Its failure briefly dampened enthusiasm for TDR and shifted the focus back to ACDF procedures. However, B. H. Cummins developed the first modern model of the cervical disc prosthesis in 1989 at the Frenchay Hospital in Bristol. This new device was a metal-on-metal ball-and-socket design with screws anchoring anteriorly, fixing it to the vertebral body. Again, early implants demonstrated a high degree of screw cut out, dysphagia, and implant mobilization (Cummins et al. 1998). Attempting to avoid this complication, Cummins developed a second-generation device where the anterior portion of the device, articulating surface, and locking screw device were all redesigned. This device became known as the Prestige I Disc, which was continually modified to a fifth-generation product ultimately called the Prestige LP made of a titanium-ceramic composite that could be more aggressively anchored to the vertebral body (Nasto and Logroscino 2016). In July 2007, the Prestige ST disc was approved by the FDA. Since then numerous models or varying materials were to follow such as the Bryan, which consists of two titanium alloy end plates articulating with a polyurethane core. This device is fixed to the bone by a porous titanium layer that maintains a tight fit between the vertebrae. The ProDisc-C with cobalt-chrome-molybdenum end plates and a polyethylene articulating surface is a ball-and-socket constrained prosthesis that has a central keel for initial fixation to the bone (Smucker and Sasso 2011).

Over the past 30 years, there have been increased efforts toward the development of TDR. While currently not widely accepted as a substitute for ACDF, the concept of joint arthroplasty in the spine remains in clinical practice and as a topic of evolving research. In a recent international survey of spine surgeons, only 7% used TDR as a standard treatment, while 84% used ACDF (Chin-See-Chong et al. 2017). The development of TDR has the potential to not only minimize adjacent segment disease but to ultimately mimic healthy spine kinematics and biomechanics. Additional studies are required to help gain insight into the better use of these prostheses.

Biomechanics

The goal of cervical total disc replacement is to restore native cervical spine biomechanics. While ACDF remains the standard for many cervical spine pathologies, numerous studies have found that it decreases motion at fused levels and transfers increased motion and stresses to adjacent levels, creating higher intradiscal pressure and ultimately increasing the incidence of adjacent level disease when compared to arthroplasty (Smucker and Sasso 2011; Dmitriev et al. 2004).

Constraint

The different types of movements in the cervical spine can be grouped into rotational and translational. They occur in the sagittal, coronal, and axial planes, making up the six degrees of freedom. When one degree of freedom is limited, that movement is constrained, and a fully constrained device would indicate no movement at all in the six degrees of freedom. There is a lack of consistency in the literature when defining and classifying a device based on constraint, but they have been described as unconstrained, semi-constrained, and fully constrained. The degree of constraint typically refers to translational movements since rotation is unconstrained in all devices; otherwise a fully constrained device would technically be a fusion. An unconstrained prosthesis allows for more motion, but does not resist shearing forces which are shifted on to the facet joints. A more constrained prosthesis limits motion but assumes more of the shearing forces, thus relieving the facet joints.

Kinematic studies of the cervical spine after artificial disc implantation have shown promising results in retaining native biomechanics. TDR has demonstrated preserved postoperative sagittal rotation, translation, center of rotation, and disc heights when compared to preoperative measurements (Pickett et al. 2005). When comparing biomechanical data of different implants in vivo and in vitro, DiAngelo et al. reviewed the biomechanics of different devices and noted the motion of two different prostheses in cadaveric models.

The designs in question were a semiconstrained device allowing anterior-posterior translation and a constrained device with minimal to no anterior-posterior translation. The semiconstrained device, the Prestige ST disc, more closely replicated native cervical spine kinematics at all ranges of motion, whereas the constrained disc, ProDisc-C, failed to reproduce native motion (DiAngelo et al. 2003, 2004).

Anatomical Considerations

The anatomical relationships in the cervical spine are complex, and correct alignment is essential for efficient biomechanics. Relevant bony anatomy with regard to cervical biomechanics includes intervertebral disc, uncovertebral joints, and the facet joints. Each plays a role in the overall range of motion and stability of the spine through the range of motion. During flexion, the center of rotation is located in the anterior region of the inferior vertebra, and forces are relieved off the facets, where as in extension the facets and spinous process are engaged. The two uncovertebral joints aid in lateral bending by providing resistance to shear forces. The significant changes in stability after uncovertebral joint resection highlight the importance of preserving them during decompression (Kotani et al. 1998). During lateral bending, the center of rotation moves to the superior vertebral body, and the lateral uncovertebral joints are engaged like a rail to limit translation.

Sasso et al. further evaluated the biomechanical properties of the BryanTDR versus ACDF preoperatively and postoperatively. After 24 months, TDR slightly improved flexion and extension range of motion from 6.4 to 8° without implant complication. Meanwhile, ACDF only retained about 1° of flexion and extension, which gradually decreased over a 24-month period (Nasto and Logroscino 2016; Sasso et al. 2008). Janssen et al. reported significantly higher flexion-extension range of motion after disc replacement with the ProDisc-C compared to the ACDF group at 7 years follow-up (Janssen et al. 2015). Similarly, Hisey et al. reported no loss of segmental range of motion in the disc replacement group but did note an increase in overall flexion-extension range of motion at the 5-year follow-up (Hisey et al. 2016). Conversely, others have also reported no difference in cervical range of motion between ACDF and TDR at long-term follow-up, but in general range of motion is maintained or improved with TDR (Radcliff et al. 2016b).

Biomaterials

An ideal arthroplasty device is one that is biocompatible, has superior biomechanical properties, produces minimal wear debris, and can achieve strong fixation. Immediate fixation and stability are based on screw fixation or physical stops, while long-term fixation relies on osseous integration between the prosthesis and vertebral body. Another important consideration is the wear properties of the different materials since the generated particles create an inflammatory response, resulting in osteolysis and eventually failure of implant. To address several of these factors, different materials have been used for the implant design including titanium alloy, stainless steel, and cobalt-chrome (CoCr) alloy. Also, polymers such as ultrahigh molecular weight polyethylene (UHMWPE) and polyurethane (PU) are used as articular surfaces.

End Plate Materials

Titanium alloy is a biocompatible metal that contains titanium, vanadium, and aluminum. Its modulus of elasticity is closer to cortical bone than steel allowing for better osseous integration. This property has led to the use of titanium as part of a porous coating on the outer surface of cervical implants to improve fixation at the implant-bone interface. Calcium phosphate has also been added to titanium resulting in increased osseointegration (Cunningham et al. 2009). Titanium is also inert and forms an oxide film making it highly resistant to corrosion. It also produces less imaging artifact than steel or cobalt-chrome, and both the index

and adjacent levels can be easily visualized on MRI (Fayyazi et al. 2015). However, its poor wear properties and propensity to generate more wear debris make it less useful as a bearing surface.

Stainless steel is primarily an iron-carbon alloy that can be combined with other metals to alter its properties. It is a widely available and inexpensive metal that is strong, stiff, and resistant to fatigue. However, its high elasticity modulus leads to stress shielding of bone. It also tends to be more corrosive than other metals, but when used in combination with chromium, it is less susceptible to corrosion. The biggest limitation with stainless steel is the artifact produced with MRI which does not allow for visualization of either the index or adjacent levels such as with Prestige ST (stainless steel end plates) (Fayyazi et al. 2015).

Cobalt-chrome is a strong alloy that is biocompatible and resistant to corrosion. It has demonstrated superior wear characteristics making it a more reliable metal for bearing surfaces. It also produces less debris compared to titanium alloy and is relatively resistant to fatigue. All these properties together have made cobalt-chrome a popular choice for cervical arthroplasty devices. Cobalt-chrome devices are MRI compatible, but imaging artifact lies somewhere in between that of stainless and titanium where adjacent levels can be visualized but the index level is typically obscured.

Until recently, implant designs have been solely evaluated based on the mechanical properties of the materials used, but now the focus has shifted to surface topography. The three most commonly used surface modifications in TDR include titanium spray coating, hydroxyapatite (HA) coating, and porous surfaces. Titanium spray coating has been shown to improve osseous integration on Co-Cr implants through enhanced cellular attachment, proliferation, and differentiation (Pham 2014). Hydroxyapatite accounts for a majority of inorganic bone, and HA coatings provide an osteoconductive environment. Surface porosity is another technique that is often utilized in multiple orthopedic implants due to its ability to promote bony ingrowth and stable interlocking fixation while reducing stress shielding of metals by lowering the modulus of elasticity (Dabrowski et al. 2010). These techniques function in different ways but ultimately work to enhance the osseous integration at the bony-implant interface in an attempt to achieve long-term fixation.

Bearing Designs

The most commonly used bearing surfaces are metal on metal and metal on polymer. Despite ceramics superior wear and corrosion properties, its brittleness, inability to absorb shock, and potential for catastrophic implant failure have limited its use in arthroplasty.

Metal-on-metal articulations were the initial design for total hip replacements. This was in large part due to in vitro studies that showed lower wear rates compared to polymer and clinical studies which showed a low mechanical failure rate and no osteolysis at long-term follow-up (Walter 1992; Dorr et al. 2000). The wear rates in simulator testing of metal-on-metal cervical arthroplasty have lower rates than that of metal-on-metal or metal-on-polymer total hip arthroplasty (Traynelis 2004). However, studies using metal on metal begun to show elevated levels of metal ions in urine, serum, and several organs (Jacobs et al. 1996; Urban et al. 2000). Concerns about ion toxicity and metal hypersensitivity began to mount, and the design lost some of its initial traction.

The metal on polymer design is similar in principle to modern total hip replacement devices. It is composed of two metallic vertebral end plates along with a core polymer. This was introduced as an alternative to metal on metal designs, due to concerns about systemic toxicity. UHMWPE is a thermoplastic polyethylene polymer with extremely long hydrocarbon chains. The long chains allow for more efficient load transfer giving it a high-impact strength. Cobalt-chromium on UHMWPE has a long track record of success in THA, but osteolysis is a known issue with this combination.

A new alternative currently under investigation is a PEEK-on-ceramic bearing. One of the advantages of this design is the absence of artifact

produced on imagining as well as MRI compatibility. This allows for accurate postoperative radiographic monitoring and reduces the exposure to ionizing radiation from CT scans which is often utilized with metallic TDR. Also, the wear rates, particle size, and morphology produced by a PEEK-on-ceramic bearing indicate a potential alternative to the commonly utilized CoCr-on-polyethylene and metal-on-metal bearings (Siskey et al. 2016).

Surgical Procedure and Technical Pearls

Indications and Contraindications

Well-defined patient selection criteria are critical for successful outcomes. Indications for cervical total disc replacement include radiculopathy or myelopathy resulting from one- or two-level disease, primarily anterior or disk-related pathology, preserved segmental motion, preserved disc space height, minimal facet arthropathy, and maintained sagittal alignment. Contraindications to performing TDR are tumor, trauma, infection, known allergy to implant metal, segmental instability, osteoporosis, collapsed disk space, circumferential pathology, severe cervical spondylosis, and prior cervical spine surgery at targeted level. Only about 40% of patients with symptomatic single-level cervical radiculopathy will be candidates for TDR (Auerbach et al. 2008).

Positioning

First, the patient is placed under general anesthesia and positioned supine on a radiolucent table. A bolster is placed between the shoulders and the neck is placed in neutral position. In contrast, for ACDF, the neck is often hyperextended. Tape is placed across the forehead to prevent rotation of the head intraoperatively. The arms are placed along the patient's side and taped with gentle traction, allowing for better access to the lower cervical spine. All bony protuberances should be well padded. The patient is then prepped and draped in the typical sterile fashion. Fluoroscopy should be utilized for intraoperative guidance. Rotational alignment can be assessed on AP fluoroscopy by confirming that the spinous process bisects the pedicles. The use of head weights is not recommended as this will cause a false impression of disc height through distraction of adjacent levels.

Pearls

- Poor head positioning can lead to sagittal malalignment and incorrect implant placement (Buchowski et al. 2009).
- Hyperextension leads to excessive removal of the posterior end plates, resulting in kyphosis.
- Hyperflexion leads to excessive removal of the anterior end plates, resulting in excessive lordosis.

Exposure

Prior to skin incision, fluoroscopy is used to confirm the approximate level of the incision. A standard Smith-Robinson approach is performed to access the anterior cervical spine. First, a transverse incision is made on the neck, either right- or left-sided, and sharp dissection is used down to the platysma. The platysma is dissected from the underlying fascia bluntly and split with electrocautery. Then the interval between medial portion of the sternocleidomastoid muscle (SCM) and the strap muscles is bluntly dissected. The carotid pulse should be palpated to locate the artery. Blunt dissection is continued medially to the SCM and carotid sheath. This is carried down through the pretracheal fascia and into the retropharyngeal space. Overlying the spine are the prevertebral fascia, anterior longitudinal ligament, and longus colli muscle. The longus colli is elevated in a subperiosteal manner. Retractors are then inserted and exposure of the anterior cervical spine is complete. The targeted intervertebral disc is confirmed on lateral fluoroscopy. The midline is located halfway between both uncinate processes, and a mark is made both in the superior and inferior vertebral bodies for implantation.

Fig. 1 AP fluoroscopy demonstrating midline placement of Caspar pin to avoid axial rotation

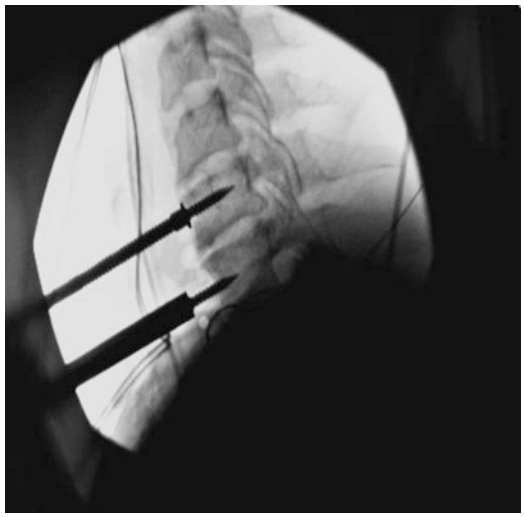

Fig. 2 Lateral fluoroscopy showing placement of Caspar pins parallel to vertebral end plates

Pearl

- Expose the lateral boundaries of the uncinate processes so they can be visually identified in order to ensure the implant is properly centered in the coronal plane.

Technique

After confirming the intervertebral disc, distraction pins are inserted midline in the superior and inferior vertebral bodies (Fig. 1).

Pearls

- Place the distractor pins parallel to the vertebral end plates so that the disc is symmetrically opened (Fig. 2).
- Ensure that the distractor pins are parallel to the true sagittal plane and do not deviate in the axial plane. Otherwise, a rotational displacement will be created once the pins are distracted.
- Use a Cobb elevator to carefully distract the disc space by levering on the end plates. Use the distractor pins to maintain the amount of distraction achieved from end plate leverage. Do not spread the vertebral bodies apart directly with the distractor pins.
- Take a preoperative X-ray to identify the facet joint height prior to distraction.

Depending on the implant used, this part of the procedure may sometimes follow the discectomy. Lateral fluoroscopy is used to confirm pin placement is parallel to the disc space. A locking distractor is attached to the pins and a Cobb elevator, and distracting forces are applied (Figs. 3 and 4). An annulotomy and discectomy are carried out using curettes and rongeurs.

Pearl

- Perform a wide, symmetric annulotomy.

This is completed between uncinate processes and from ventral to dorsal while using progressively smaller curettes. For complete decompression, meticulous removal of all osteophytes is critical. We recommend minimal use of a high-speed burr. However, if a one is used, copious amounts of irrigation and bone wax should be applied to reduce the risk of heterotopic ossification. When preparing the end plates, only the cartilaginous portion should be removed. Special attention should be paid to osteophytes located by

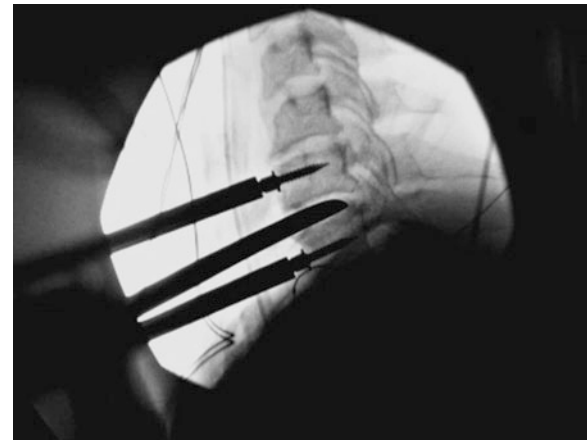

Fig. 3 Lateral image of same patient as Fig. 2 showing use of a Cobb to distract disc space

Fig. 4 Lateral image after use of Cobb and distraction forces applied to distract disc space

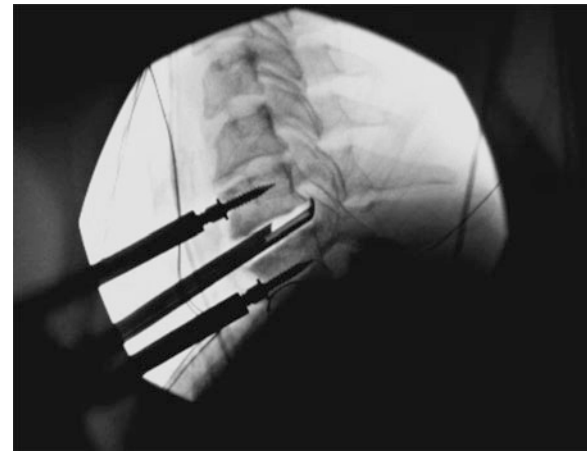

Fig. 5 Lateral fluoroscopy showing use of a Kerrison rongeur to remove posterior osteophytes for a complete decompression

the uncinate process or posterior vertebral body (Fig. 5). Partial resection of the uncinate process can be performed if necessary, but complete resection should be avoided as this could lead to cervical instability. If resection of the uncinates is necessary, try to perform bilateral symmetric

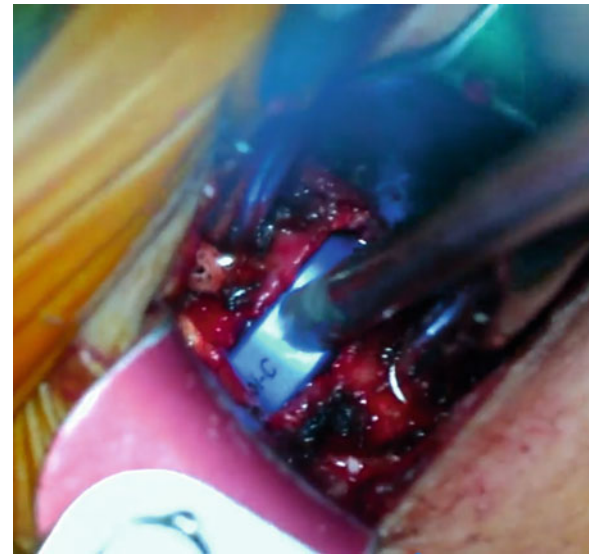

Fig. 6 Trial implant placed following decompression

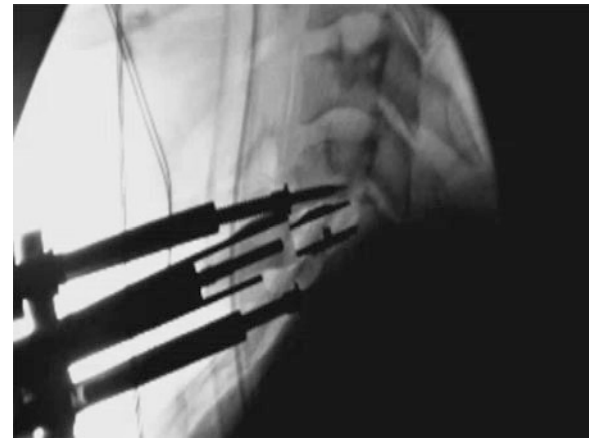

Fig. 7 Lateral image showing compression of the Caspar pins onto the disc replacement. Notice that facets are not distracted compared to other disc levels

resection. Bilateral neuroforaminal decompression is performed with rongeurs. Once the decompression has been completed, trial implants and fluoroscopy are used to determine the optimal implant size and position (Fig. 6).

Pearls

- Ensure that the trial implant is as far posterior as possible as the center of rotation of the cervical spine is near the posterior vertebral body border.
- Select as wide of a trial as possible to ensure maximal medial-lateral surface area coverage and reduce surface stresses.
- Select as deep of a trial as possible to ensure maximal anterior-posterior surface area coverage and reduce surface stresses.
- Study the adjacent level facet joints when trialing and after disc replacement is placed to ensure that you are not over distracting the segment (Fig. 7).
- Remove all distraction while trialing.
- After trialing, cover all cut bone surfaces (e.g., uncovertebral joints) with bone wax to reduce the rate of heterotopic ossification.
- The trial should fit snugly into the disc space, but ideally some cranial-caudal toggle motion

Fig. 8 Final placement of disc replacement with distractor pins removed

of the trial handle should occur to indicate that the disc is not overstuffed.
- If the surgeon is having difficulty visualizing the precise posterior vertebral body margin, then take a lateral fluoroscopy shot with a nerve hook behind the vertebral body.
- For devices with a keel, ensure that the keel cut goes as far posteriorly as the intended implant. Otherwise, the implant could fracture a piece of posterior vertebral body cortex if it is attempted to be placed more posteriorly than the extent of keel cut.

The device is then inserted according to manufacturer's standards while confirming placement visually (Fig. 8) and radiographically in the coronal and sagittal planes.

Pearls
- Occasionally, the cranial and caudal end plates will not advance uniformly. If you notice that one end plate is more anterior than the other end plate, use the single end plate tamp. Otherwise, the implant will have a kyphotic appearance.
- Performing a thorough discectomy, decompression and preparation of the end plates are critical for proper implant placement and to optimize postoperative range of motion. Care should be taken to not violate the vertebral end plates when using the high-speed burr as this could result in implant subsidence.
- Use bone wax on all cut bone surfaces (e.g., anterior osteophytes, distractor pin holes) to prevent the egress of marrow and reduce the rate of heterotopic ossification.

Postoperative Course

Patients are routinely discharged same day for single-level arthroplasty and on postoperative day 1 or 2 for multilevel disc arthroplasty. Postoperatively, a soft collar is not generally used. Instead, the patient should be mobilized out of bed on postoperative day 0 and can immediately start gentle neck range of motion, but extremes should be avoided. Follow-up radiographs are useful to assess for postoperative kyphosis, implant subsidence, and early and delayed fusion. However, imaging artifact may limit radiographic accuracy. Physical therapy should be instituted as tolerated, generally 2–6 weeks postoperative. One of the early touted benefits of TDR is the restoration of motion at the diseased segment and less strain on adjacent levels. This has clinically manifested in improved postoperative range of motion and earlier return to work (Burkus et al. 2014; Zhu et al. 2016a).

Complications

Complications associated with cervical total disc replacement is one of the main reasons cited for not offering it as an option to patients in a survey of spine surgeons (Chin-See-Chong et al. 2017) However, a recent meta-analysis comparing

the adverse events between ACDF and TDR indicated no difference in terms of dysphagia/dysphonia, hardware-related complications, heterotopic ossification, neurological deterioration, overall neurologic adverse events, or mortality. There were three types of adverse events that did show a significant difference. First, there was a small increase in minor wound-related adverse events for TDR, but none required a second procedure for deep wound infection or removal of infected implant. There was a high variation in rates of infection among the different studies, and this was attributed to inclusion of a general category of infection instead of specifying wound-related infections in some studies. Also, ACDF was associated with a higher incidence in surgical-related neurologic adverse events and secondary surgeries which generally occurred late. The definition of neurologic adverse events was not consistent and leads to variable rates from 2.8% to 73.8%. Overall, there does not appear to be a major difference in complication rates between TDR and ACDF, but future studies will need to use uniform definitions in order to make accurate comparison.

Anterior Approach

Cervical total disc replacement shares some of the same complications that are associated with an ACDF by virtue of a similar anterior approach. The anterior approach can be associated with dysphagia due to injury to the esophagus or surrounding nerve plexus. Transient dysphonia or dysarthria can result from injury to recurrent laryngeal, superior laryngeal, and hypoglossal nerve. Periodic release of retractors and a good understanding of the anatomy can reduce the risk of these injuries. Postoperative hematoma should be closely monitored for as it could compromise the airway. Kato and colleagues conducted a propensity score matching analysis of a cohort of CSM patients which showed that there is no difference in outcomes or overall complication rates between anterior and posterior cervical approaches (Kato et al. 2017). However, dysphagia and dysphonia were more common in an anterior approach, while surgical site infections and C5 palsy are more common with a posterior approach.

Heterotopic Ossification

Heterotopic ossification (Fig. 9) is an abnormal deposition of the bone in soft tissue and was first described in total joint arthroplasty procedures. One of the main advantages of a TDR over fusion is its ability to preserve motion, and HO could hamper this by restricting range of motion and potentially affect outcomes. The clinical significance of HO remains questionable. Several predisposing factors have been identified including age, gender, degree of preoperative spondylosis, and implant type. Heterotopic ossification has

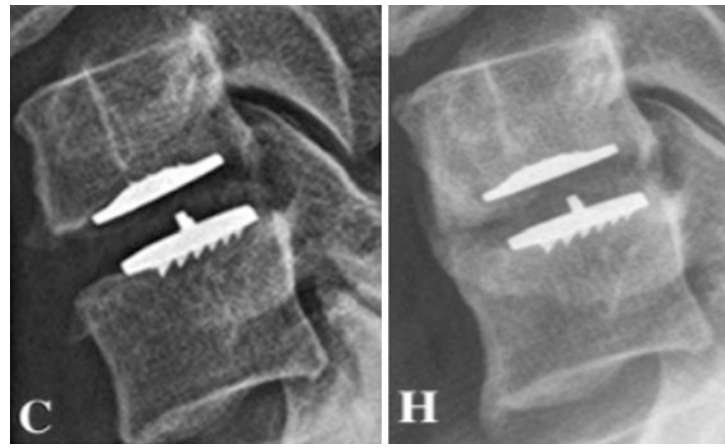

Fig. 9 Normal postoperative X-ray following cervical disc replacement (C) versus same patient after developing heterotopic ossification (H). (Lee et al. 2012)

been found to be more common in two-level TDR compared to single-level TDR (Wu et al. 2012). The incidence of HO is highly variable, ranging from 17.8% to 77.3%, and was proportional to the duration of follow-up (Leung et al. 2005; Lee et al. 2012). Although Lee et al. showed that cervical range of motion was limited by high-grade HO, it has not been found to affect clinical outcomes following TDR (Wu et al. 2012). Treatment of HO with NSAIDs is largely based on literature from total joint arthroplasty, but strong evidence to support its use is lacking. Additionally, in order to attempt to reduce the rate of HO, it is recommended to bone wax all cut bone surfaces (e.g., anterior osteophytes, distractor pin holes) to minimize the exposure of marrow.

Adjacent Segment Disease

Adjacent segment disease is a broad term that includes the degenerative changes at vertebral levels neighboring surgically treated segments (Fig. 10) and is associated with signs and symptoms such as radiculopathy, myelopathy, or instability. ASD is one of the major influences that promoted further investigations of TDR. The motion-preserving properties could theoretically reduce the risk of ASD and subsequent reoperations. A meta-analysis of 14 randomized controlled trials comparing TDR and ACDF confirmed that TDR was associated with a lower rate of ASD and fewer adjacent segment reoperations (Zhu et al. 2016b). The use of TDR for ASD following fusion is controversial with only smaller studies indicating it is potentially a safe option (Rajakumar et al. 2017) (Fig. 11).

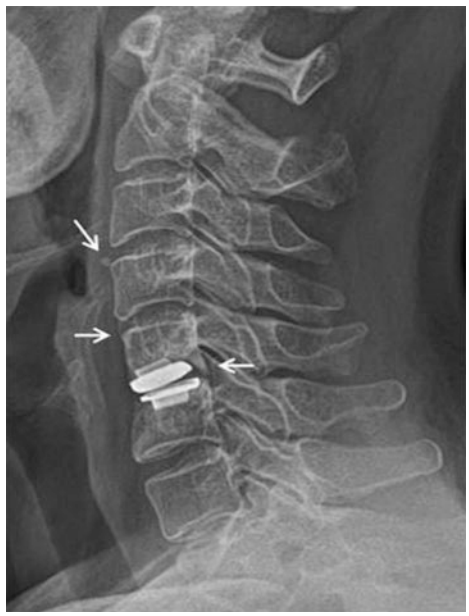

Fig. 10 Adjacent segment degeneration superior and inferior to disc replacement, as well as posterior osteophyte at index level (Kim et al. 2016)

Postoperative Sagittal Imbalance

One of the relative contraindications for TDR is the presence kyphosis or positive cervical sagittal balance (Johnson et al. 2004). Sagittal balance determines the load distribution on the device, and any imbalance could lead to abnormal wear and worsening kyphosis. The clinical significance of segmental kyphosis can be profound, resulting in segmental instability, adjacent segment degeneration, axial neck pain, early hardware failure, and poorer functional outcomes (Cao et al. 2011). However, different techniques have been developed to prevent kyphosis, but caution should be used. Some techniques can lead to overcorrection of lordosis, anterior migration of prosthesis, restricted range of motion, and neck pain (Lei et al. 2017).

Implant Migration and Subsidence

Migration and subsidence are generally uncommon. Goffin et al. reported a single case of both migration and subsidence (Goffin 2006; Goffin et al. 2003). He proposed techniques such as maintaining the integrity of the end plates, using the widest possible device to improve load distribution, and avoiding TDR in patients with poor bone quality (i.e., osteoporosis, metabolic bone disorders). Also, the addition of a keel to the arthroplasty device, which lies up against the anterior vertebral body, has been utilized by some devices to reduce the risk of posterior migration.

Evidence

Single-Level Disc Arthroplasty Outcomes

Several long-term randomized prospective trials have been conducted to evaluate patients undergoing cervical total disc replacement. A meta-analysis comparing TDR versus fusion for single-level cervical disc disease concluded that TDR improved neck and arm pain and had a higher neurological and overall success rate (Xing et al. 2013). Later studies have continued to demonstrate comparable and even superior clinical and radiographic outcomes (Janssen et al. 2015; Rožanković et al. 2017).

In a study with longest follow-up to date, Dejaegher et al. reported a 10-year follow-up on patients undergoing disc replacement with the Bryan prosthesis (Dejaegher et al. 2017). Eighty-nine patients underwent single-level disc replacement, and patients were assessed every 2 years. Neurologic success was achieved in more than 80% of patients, and they saw significant improvement in terms of level of disability, neck and arm pain, and functional status. Twenty-four percent of patients developed new or recurrent neurologic symptoms, similar to previously published rates for ACDF.

Multilevel Disc Arthroplasty Outcomes

Similar studies have investigated outcomes for patients who underwent multilevel TDR, which have been largely limited to two and three levels. Gornet et al. investigated outcomes for those patients undergoing adjacent level disc replacement with a Prestige LP device in comparison to ACDF with cortical ring allograft and anterior plating (Gornet et al. 2017). Success for this study was defined by four criteria: Neck Disability Index (NDI) score improvement of $\geq$15 points, maintenance or improvement in neurological status, number of serious adverse events caused by the implant or surgery, and need for additional surgeries. Results showed that patients had better success with multilevel disc replacement compared to a multilevel fusion (81% vs. 69%).

Radcliff et al reported results from a 5-year study comparing two-level TDR to fusion. Patients undergoing disc replacement demonstrated significantly improved Neck Disability Index scores compared to the fusion group (Radcliff et al. 2016b). Similarly, Lanman et al. reported greater overall success of the Prestige LP TDR over fusion at 84-month follow-up (Lanman et al. 2017). Patients undergoing disc replacement also demonstrated improved NDI scores and higher neurological success when compared to fusion.

In comparison to single-level TDR, Huppert and colleagues showed that multilevel TDR had similar levels of improvement in outcomes, satisfaction, and range of motion compared to single-level TDR (Huppert et al. 2011). Although the multilevel cohort had a higher rate of dysphagia and dysphonia, all but one resolved spontaneously. In addition, there was no significant difference in the number complications or reoperations. Likewise, a meta-analysis comparing single- and multilevel TDR revealed no differences in outcomes, functional recovery, or reoperation rates (Zhao et al. 2014).

Several studies have compared multilevel ACDF and TDR, and a recent meta-analysis concluded that both groups had similar clinical outcomes (Wu et al. 2017). However, patients who underwent TDR did experience lower rates of ASD and complications while achieving greater overall range of motion. Altogether multilevel TDR appears to be as effective as single-level TDR and multilevel ACDF.

Reoperations

There are several reasons why patients have to undergo additional surgery after their index cervical total disc replacement. The most common reasons included removal of device with conversion to fusion, recurrence of symptoms, and procedures to address ASD.

Janssen et al. reported that after 7 years, 18% of ACDF patients underwent secondary procedures, while only 7% of the ProDisc-C group needed additional procedures (Janssen et al. 2015). The risk for secondary surgery was approximately 3.7 times higher for single-level ACDF. Mostly reoperations were performed at the index level for both groups; however, adjacent level procedures were more commonly done in the ACDF group. Hisey and colleagues reported similar trends, with the Mobi-C group requiring a higher number of additional procedures compared to the ACDF group (Hisey et al. 2016).

For multilevel disc replacements, Radcliff et al. found that the disc replacement cohort underwent fewer secondary surgeries and adjacent level procedures than the fusion group (Radcliff et al. 2016b). The reasons for reoperations for the Mobi-C group included neck pain and radiculopathy (most common), hematoma, poor device attachment, and inferior level end plate migration. For the Prestige LP, Lanman et al. reported a reoperation rate of 4.2% through 84 months, compared to 14.7% for the ACDF group (Lanman et al. 2017). In this study patients had their device removed mostly due to radicular arm pain, cervical kyphosis and sagittal imbalance, foraminal stenosis and other degenerative changes, "failed arthroplasty," and loosening of hardware. Likewise, Gornet et al. reported on the Prestige LP device, showing reoperation rates of 2.4% compared to 8% with ACDF (Gornet et al. 2017).

Overall, all of these studies and even a meta-analysis have demonstrated that TDR has a superior advantage in regard to reoperations rates (Gao et al. 2015). Reoperation rates for TDR have been consistently lower than 10%. This is particularly important due to the heavy burden that reoperations place on the cost-effectiveness, outcomes, and patient satisfaction.

Cost-Effectiveness

Due to the rapid expansion of spine surgery and increasing healthcare expenditure, the costs of a procedure are an important consideration. In addition, due to the similar outcomes between ACDF and TDR, a cost-effective analysis can offer an economic perspective and potentially shed light on which procedure is superior. Numerous studies have analyzed the cost-effectiveness of the two procedures with some studies indicating no difference (Overley et al. 2017) and others indicating that TDR is more cost-effective (Ament et al. 2016). Clinical outcomes are typically converted to health state utility when performing a cost-effective analysis. In general, utility scores for TDR are either similar (Qureshi et al. 2013) or superior to ACDF (Ament et al. 2015). However, cost has been more variable with some studies indicating lower cost with TDR (Radcliff et al. 2015, 2016a) and others showing

higher costs when compared to ACDF (Overley et al. 2017). In comparison to the often-cited willingness-to-pay threshold of $50,000, TDR is a cost-effective procedure in its own right and is comparable to ACDF.

Patient Satisfaction

With a growing emphasis on improving patient satisfaction and linking it to reimbursements, many of the IDE trials have incorporated it into their studies. Overall patient satisfaction is very high for TDR and is comparable to fusion with a more recent meta-analysis indicating that it is higher for TDR (Hu et al. 2016).

Murrey and colleagues asked patients whether or not they would undergo the same surgery again. Results demonstrated that 96% of ProDisc-C patients would choose to have another disc replacement, which was similar to patients who were fused (Murrey et al. 2009). Similarly, Hisey et al. reported high levels of satisfaction among the Mobi-C and ACDF groups at all time points up to a 5-year follow-up (Hisey et al. 2016). Of note, 97.1% of patients stated they would recommend the Mobi-C single-level disc replacement to a friend, compared to 91.1% for patients who had an ACDF.

For multilevel cervical disc replacement, Radcliff et al. reported 96% satisfaction rate at 5 years with the Mobi-C device versus 89.5% satisfaction for the ACDF group. Ninety-five percent of patients receiving the Mobi-C device stated that they would recommend the surgery to a friend, while only 84% of patients in the ACDF group would recommend it (Radcliff et al. 2016b). For the Prestige LP, 95% of patients receiving the disc replacement stated they were "definitely" or "mostly" satisfied, and the same percentage of patients stated they would undergo the procedure again (Lanman et al. 2017). Gornet et al. surveyed patient's responses and reported three findings: (1) patient satisfaction was greater with TDR (94.5% vs. 89%), (2) more TDR patients felt they were helped by their surgery (94% vs. 85.5%), and (3) a larger percent of TDR patients were willing to have the surgery again (93% vs. 89%) (Gornet et al. 2017).

Pain Medication Usage

Due to widespread concerns about narcotic abuse, the impact on cost of care, and the fact that pain medication acts as a surrogate for pain control, the amount of pain medication used is another factor that has been monitored. Janssen et al. reported that the use of narcotic pain medications and muscle relaxants for TDR and ACDF was similar preoperatively and postoperatively (Janssen et al. 2015). However, Murrey et al. found that at 24 months a lower percentage of TDR patients used narcotics and muscle relaxants compared to those who had an ACDF (Murrey et al. 2009).

Return to Work

The ability to return to work is a reflection on functional outcomes and influences patient satisfaction and cost-effectiveness. One of the initially proposed advantages of TDR over fusion was that early mobilization and maintenance of normal cervical kinematics could result in earlier return to work. A systematic review comparing TDR and ACDF indicated that an equivalent rate of patients ultimately returned to work at 6 months, but those who underwent TDR resumed work sooner (Traynelis et al. 2012).

In two separate studies, Gornet and colleagues evaluated return to work following single-level and two-level TDR compared to ACDF (Gornet et al. 2015, 2017). Preoperatively, 67% of single-level and 70% of two-level disc replacement were working, and after 2 years both groups had a return-to-work rate of 73%, indicating they retained their preoperative work status well. For single-level procedures, they found that TDR returned to work on average 20 days earlier than the ACDF group even after adjusting for preoperative work status and propensity scores. With regard to two-level TDR, there was a trend to earlier return, but no statistical difference was noted. Similarly, Malham et al. reported a return to work rate of 74% after 2-year follow-up for patients undergoing disc replacement, with a median return to work time of 39 days.

In general, patients who undergo a TDR maintain their preoperative work status well, have similar return-to-work rates compared to fusion, and do appear to allow for earlier return to work. Return-to-work rates also appear to be roughly similar between the different TDR devices with most returning around 40–50 days after surgery, but no direct comparisons have been made.

Conclusion

The advent of joint arthroplasty has created many avenues in the management of degenerative joint disease; in particular, TDR has challenged the most commonly used treatment modality for cervical spine disease. While ACDF has proven to be an effective and reliable procedure, long-term data demonstrates an inevitably high incidence of adjacent segment disease. In contrast, treatment with TDR aims to eliminate strain on adjacent levels through its ability to recreate cervical spine biomechanics and preserve motion. Many biomaterials including titanium, cobalt-chromium, stainless steel, and polymers have been explored, along with different surface topographic modifications, but the ideal construct has yet to be perfected.

TDR has demonstrated many attractive advantages. It permits patients the ability to initiate range of motion immediately in the postoperative period. This eliminates periods of immobilization and permits quicker recovery to baseline status. Patients who underwent TDR have consistently expressed a very high level of satisfaction. Additionally, in comparison to ACDF, TDR has similar or even superior clinical outcomes, cost-effectiveness, and time to return to work, along with a decreased need for pain medication and lower reoperations rates. However, most of the data has resulted from the initial IDE trials which raises concerns about publication bias, external validity, confirmation bias, and financial conflict of interest (Radcliff et al. 2017). Results have been promising, but future independent research efforts are needed if TDR is to gain acceptance as a reliable alternative to ACDF.

Cervical Total Disc Replacement: Biomechanics

42

Joseph D. Smucker and Rick C. Sasso

Contents

Abstract

Cervical disc arthroplasty is an evolving surgical concept designed to treat certain pathological conditions of the cervical spine. The introduction of arthroplasty devices has stimulated novel studies aimed at understanding motion in the cervical spine and has also driven investigators to examine the consequences that result from surgical alteration of pathological structures. The study of cervical "biomechanics" and "kinematics" has evolved from basic analysis of flexion/extension radiographs to complex, computer-assisted modeling that aides investigators in understanding concepts such as center of rotation (COR), functional spinal unit (FSU)

Introduction

The design of arthroplasty devices for the human cervical disc has brought about a renewed interest in the biomechanics of the cervical spine. Modern techniques of assessment and measurement are currently being employed parallel to traditional outcome measurements in the hope that such information may advance the collective understanding of disc arthroplasty on cervical motion.

Concepts of cervical arthroplasty have undergone a dramatic evolution since the development of the original Bristol/Cummins disc arthroplasty device. At a basic level, motion retention/preservation is a primary kinematic measure of device success in this procedure, though the current indications for the procedure are typically of neurological origin. Retention of motion or "motion sparing" in cervical arthroplasty has quickly evolved in device design over the past 20–30 years. Materials used in disc arthroplasty have also changed. The evolution of metal-on-metal implants has occurred in parallel with the development of novel bearing concepts incorporating metal alloys, polyethylene, and ceramics.

Currently the term "cervical arthroplasty" is applied to the procedure of "disc arthroplasty" or "disc replacement." A number of these devices are in the process of early use or are involved in US Food and Drug Administration (FDA) trials. While the early data from clinical trials is encouraging, there remains a need to demonstrate the biomechanical properties of these devices and techniques in the intermediate and long term. Cervical arthroplasty of the disc alone is not intended to address the posterior elements at the index surgical level – leaving open the option for future modifications of the concept of cervical arthroplasty and kinematic motion sparing.

Background

The cervical spine consists of vertebral bodies with intervening discs and soft tissue structures that support motion and protect the neural and vascular elements. From a biomechanical perspective, these discs and their corresponding facets function in load bearing and motion transfer allowing for flexion/extension, lateral bending, and rotation as well as complex coupled motions. In addition to its biomechanical functions in motion, the cervical spine serves as the protective passage for the spinal cord and vertebral arteries.

Cervical spondylosis is the process by which the cervical spine most frequently loses motion and is occasionally to blame for ensuing neurological phenomena which have been the traditional indication for surgical interventions. Disc degeneration is well documented as the transition from mild degenerative disc disease to multilevel cervical spondylosis progresses. For many years, the surgical treatment for pathology in the cervical intervertebral disc has been limited to procedures which remove pathologic disc material and address the bony and neurologic pathology in the region of the excised disc.

Anterior cervical discectomy and fusion (ACDF) is a proven intervention for patients with radiculopathy and myelopathy (Bohlman et al. 1993). It has served as the standard by which other cervical and spinal disorders may be judged as the result of its high rate of success. The success of this technique is often judged based upon its consistent ability to relieve symptoms related to neurological dysfunction. In this sense, the clinical results with regard to the patient's index complaint are outstanding. The radiographic results of this technique are also initially predictable with a high rate of fusion. Plating techniques have diminished the need for postoperative immobilization or eliminated them entirely (Campbell et al. 2009). However,

because of limitations specific to this procedure, investigators have developed surgical alternatives to fusion that attempt to address the kinematic and biomechanical issues inherent in it.

A major concern related to the treatment of cervical degenerative disc disease (DDD) and spondylosis with ACDF are the issues of adjacent segment degeneration and adjacent segment disease (ASD). Adjacent segment degeneration is manifest as the radiographic appearance of degenerative change at a level directly above or below a level treated with a surgical intervention – typically being associated with degeneration of a level adjacent to a fused level. Adjacent segment disease (ASD) is defined as adjacent segment degeneration causative of clinical symptoms (pain and/or neurological disorders) severe enough to lead to patient complaint and/or require operative intervention (Hilibrand et al. 1999). Adjacent segment degenerative change has been reported to be as high as 92% by Goffin et al. who wrote a long-term follow-up on patients after treatment with anterior interbody fusion (2004). While there remains some debate as to the causation of adjacent segment degeneration – with a mix of postsurgical (altered biomechanics) and naturally determined aging (genetics) cited as root causes – there is little debate as to the existence of this phenomenon. A number of studies have made a consistent point of distinguishing between radiographic "degeneration" and symptomatic "disease" (Goffin et al. 2004; Robertson et al. 2005).

There is clinical evidence to support the postsurgical nature of ASD with respect to kinematics. In patients previously treated with fusion, adjacent segment disease has been documented at a rate of 2.9% of patients per annum by Hilibrand et al., and 25% of patients undergoing cervical fusion will have new onset of symptoms within 10 years of that fusion (Hilibrand et al. 1999). This study has received a great deal of attention and has led to further investigations as to kinematic and biomechanical causation. Other reports have focused on the recurrence of neurological symptoms and degenerative changes adjacent to fused cervical levels (Goffin et al. 1995, 2004). The concept that adjacent levels need to kinematically compensate for loss of motion in the fused segment may also be valid. Segments adjacent to a fusion have an increased range of motion and increased intradiscal pressures (Eck et al. 2002; Fuller et al. 1998).

Total intervertebral disc replacement (TDR) is intended to preserve motion, minimize limitations of fusion, and may allow patients to quickly return to routine activities. The primary goals of the procedure in the cervical spine are to restore disc height and segmental motion after removing local pathology that is deemed to be the source of a patient's index complaint. A secondary intention is the preservation of normal kinematics at adjacent cervical levels, which may be theorized to prevent later adjacent level degeneration. Cervical TDR avoids the morbidity of bone graft harvest (Silber et al. 2003; St. John et al. 2003). It also may avoid complications such as pseudarthrosis, issues caused by anterior cervical plating, and cervical immobilization side effects.

General Cervical Spine Biomechanics

Motion in the cervical spine implies a direct interaction between two or more cervical vertebrae and their supporting structures. A motion segment of the cervical spine, often analyzed as a functional spinal unit (FSU), is complex. The cervical spine is much more than a single FSU, and investigators have found that much more complex kinematic relationships exist as they seek to understand not only the effects of various treatments on a single ("index") FSU but also the effects of that same treatment on adjacent or remote FSUs.

Each FSU consists of three compartments (the disc and two facets) and multiple supporting ligamentous and soft tissue structures. The normal cervical spine exhibits complex coupled motions in addition to the traditionally understood independent kinematic motions such as anterior-posterior translation during flexion and extension. An implant designed to replace the cervical disc should consider the effect of all three compartments and the multiple ligamentous and soft tissue structures present in this complex environment.

One of the primary goals of cervical disc replacement is to reproduce "normal kinematics" after implantation. Fortunately, numerous kinematic studies of various designs have been undertaken parallel to US FDA (IDE) studies. Collectively, these studies may be classified by device and/or study design criteria. Some investigators have taken advantage of novel finite element (FE)-based techniques, while others have used more traditional in vivo or in vitro means. Review of these studies is instructive in understanding the current state of kinematic knowledge with regard to cervical TDR. Over time, similar studies may suggest which type of implant design will provide "kinematically accurate" motion.

Early device designs made use of ball-in-socket articulations within the device. A ball-in-socket (constrained design) does not allow for natural translation. The complexity of the cervical spine requires a "balance" of all the significant structures including facets and ligaments. A ball-in-socket, by its design, dictates the kinematics of motion irrespective of traditional FSU behaviors and eliminates the normal anterior/posterior translation that the facets provide. A number of studies describe the increased forces born by these facets – a phenomenon sometimes described as "kinematic conflict."

The most significant effect of this change in facet loading is in extension. During flexion the facets "un-shingle" and reduce their involvement in constraining the motion of the functional spine unit. However, when the spine goes into extension, the facets "shingle" and become more involved in constraining the motion. Thus, with a constrained facet joint and a constrained arthroplasty device, one would expect to see binding or limited motion as one joint works against the other in the FSU. For this reason device designers have introduced less constraint in more recently designed devices.

There are a number of methods by which kinematic data may be derived. In vivo measurements in the human are often made through review of flexion and extension radiographs that are digitized and subsequently measured with software packages (Sasso and Best 2008) (Figs. 1 and 2). Alternatively, nonhuman in vivo measurements may occur in translational projects wherein the spine is tested via histological and radiographic means as well as benchtop environments with mechanical loading devices, optical tracking (Fig. 3), and pressure sensors. In vitro testing of human cadaveric specimens occurs via similar benchtop testing protocols with the obvious exclusion of histological means (Figs. 3 and 4).

Computer-assisted finite element (FE) modeling is a technique by which a computer-generated

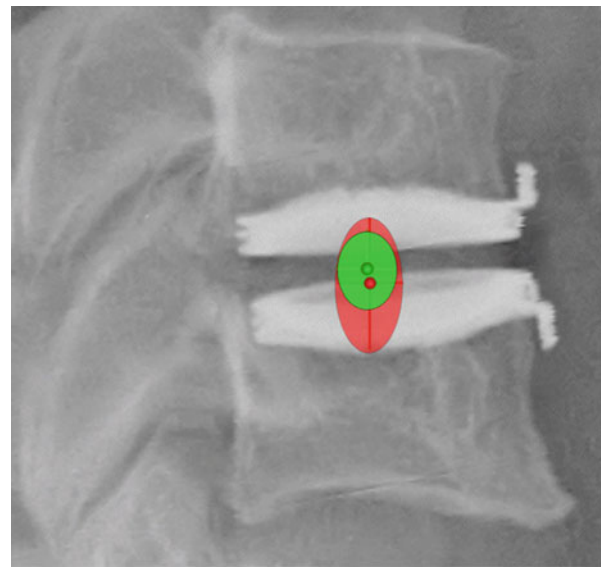

Fig. 1 The BRYAN® Cervical Disc Prosthesis is demonstrated in vivo in this lateral cervical radiograph. The center of rotation (COR) has been calculated pre- and post-placement of the arthroplasty prosthesis at the index surgical level. Software allows for in vivo analysis of kinematic changes in humans via radiographic means over time. Changes in COR may correlate to long-term kinematic outcomes, device survival, and adjacent level changes. (© Courtesy of Rick Sasso, Indianapolis, IN)

Fig. 3 Explanted spinal specimens may be tested in a number of ways. Optical tracking allows for real-time tracking of motion and is commonly used in conjunction with forces applied to the cervical spine in a controlled, monitored environment. Cameras on this OptiTrack™ Device (NaturalPoint® Inc., Corvallis, Oregon) follow the motion of rigid bodies. (© Courtesy Nicole Grosland, PhD and Joseph D. Smucker, MD – The University of Iowa and Indiana Spine Group)

model of the cervical spine is modified to include surgical procedures such as ACDF or arthroplasty techniques and principles (Ahn and DiAngelo 2008; Kallemeyn et al. 2009). Specimen-specific modeling is a more refined method of testing such principles (Kallemeyn et al. 2009) (Fig. 5). FE modeling has the potential advantage of providing investigators with a more flexible testing environment given the assumption of model-specific limitations.

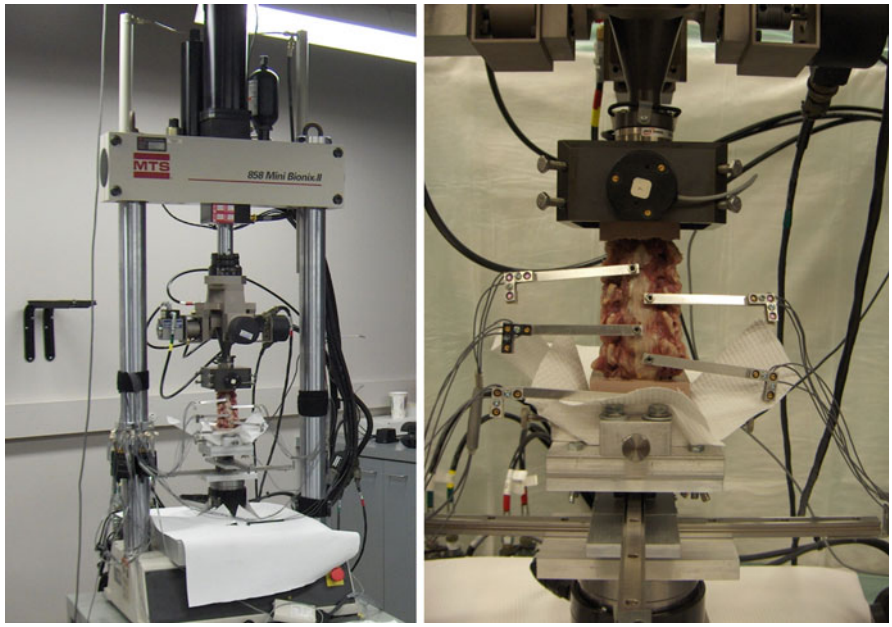

Fig. 4 Controlled application of force within the defined degrees of freedom in the cervical spine is applied to create motion in an ex vivo environment. This MTS™ 858 Mini Bionix II system (MTS Systems Corp., Eden Prairie, MN) applies precise force via computer-controlled hydraulic mechanisms. Optical tracking via the OptiTrack™ system is combined with this controlled application of force to track and analyze simple and coupled motions created in this multi-FSU spinal specimen – allowing for real-time tracking of motion. History of Disc Arthroplasty Design Kinematics

An understanding of the evolution of cervical TDR serves as an important lesson in the concepts of kinematic device design properties and articular constraint. In the late 1980s, Cummins et al. (1998) developed a metal-on-metal ball-and-socket cervical disc replacement comprised of 316 L stainless steel. With the acquisition of this technology and the later development of new metal-on-metal devices, a rapid transition evolved to the most recent device, the PRESTIGE® LP (Medtronic Sofamor Danek, Memphis, TN). A predecessor of this device, the PRESTIGE® ST (Medtronic Sofamor Danek, Memphis, TN), is currently approved for human use by the US FDA.

A number of devices have evolved parallel to the metal-on-metal implants and include the BRYAN® Disc (Medtronic Sofamor Danek, Memphis, TN), the Porous Coated Motion Prosthesis (PCM®, NuVasive, San Diego, CA), the SECURE-C® (Globus Medical, Audobon, PA), and the MOBI-C® (Zimmer Biomet, Parsippany, NJ). To date, several such devices have obtained approval for use in the US market: the PRODISC-C® (Centinel Spine, West Chester, PA) and the BRYAN® Disc. Each of the other devices is in the process of limited human trials and/or US FDA-IDE submission and represents an alternative to metal-on-metal bearing surfaces which have the potential for metal debris and systemic concentration of metal ions.

While the ideas of bearing surfaces, wear debris, and constraint are not new to discussions with regard to arthroplasty in general, they are relatively young in the spine. In fact, a full understanding of the term "constraint" with regard to cervical kinematics post-disc arthroplasty has not been agreed upon – as constraint may arise within the device or as a result of the local anatomy

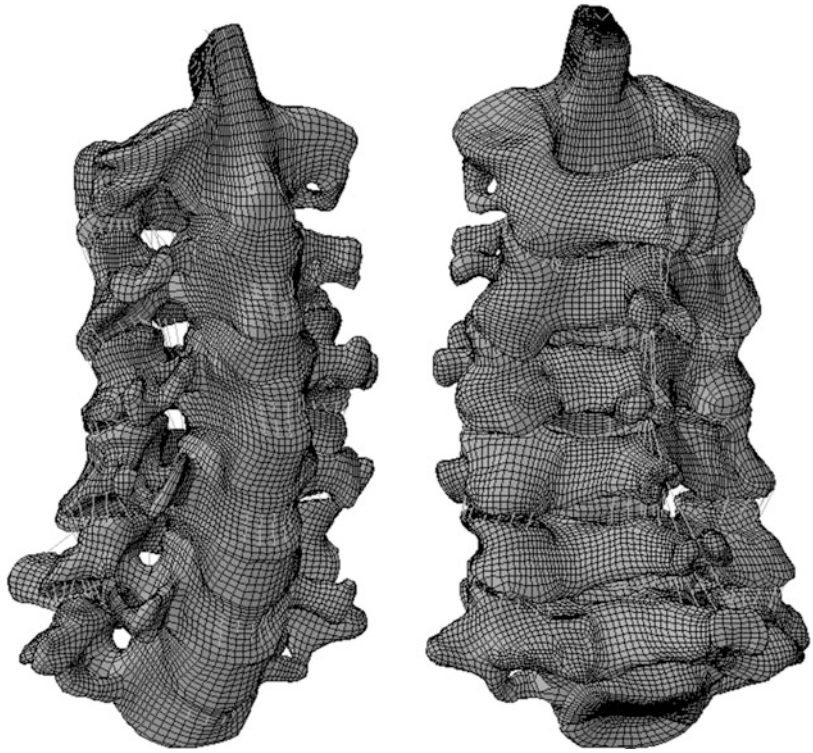

Fig. 5 Dorsal and ventral views of a finite element (FE) model of the human cervical spine (C2-C7) are presented. Multiblock analysis occurs after biomechanical properties are assigned to bony and soft tissue structures. Initial specimen-specific models are created from computed tomograpic (CT) analysis of the human cervical spine. The specimen may then be analyzed in a computer environment with simulation of motion via computer applied forces to the model. The model may be further modified via implantation of spinal devices such as disc arthroplasty devices. Facet forces, intradiscal forces, and other kinematic measurements such as COR may be calculated. (© Courtesy Nicole Grosland, PhD and Joseph D. Smucker, MD – The University of Iowa and Indiana Spine Group)

(facets, PLL, etc.). As the knowledge base in spine TDR increases, intelligent investigations and discussions will include many of these concepts and may redefine our understanding of them.

It is relevant to understand that the load born by devices in the cervical spine is dissimilar to that born in the lumbar spine. The biomechanical environment of the cervical spine has been taken into account in the design of the current generation of these devices. As intermediate- and long-term studies on individual devices become available, the design concepts of these initial devices will have the opportunity for continued examination in their in vivo environment.

Current Kinematic Studies

The BRYAN® Disc

Galbusera et al. published their review in March 2006 of the biomechanics and kinematics at the C5–C6 spinal unit both before and after placement of a BRYAN® Cervical Prosthesis (Galbusera et al. 2006). In this study, the authors produced a finite element (FE) model of the functional spinal unit at C5–C6. The model employed reconstruction of both the vertebral bodies at C5 and C6 and representations of the vertebra, ligaments, and

discs at this level. The authors applied motion through the intact FSU to assess several kinematic measures with a compression preload. The kinematic measures studied included flexion/extension moments, pure lateral bending moments, and a pure torsion moment. They reviewed their results comparing this to known data from prior publications. The FE model was then modified to include the placement of the BRYAN® Arthroplasty Device with repeat stimulations.

The authors noted that they were able to calculate the instantaneous center of rotation of C5 with respect to C6 throughout flexion/extension. In general, FSU rotation curves post-arthroplasty were comparable to those obtained from the intact FSU with the exception of a slightly greater stiffness that was noted to be "induced by the artificial disc" (Galbusera et al. 2006). Pre- and post-arthroplasty data suggested that the position of the instantaneous center of rotation was similar in both models and was stable throughout flexion and extension – being confined to a small area "corresponding to the physiological region in both models" (Galbusera et al. 2006).

Galbusera et al. later published a more detailed finite element model from C4 to C7 expanding upon their 2006 study (Galbusera et al. 2008). In this study the group produced a finite element model including functional spinal units and appropriate soft tissue structures from C4 to C7 for kinematic testing in flexion and extension. Once again, a BRYAN® Disc Prosthesis was inserted at the C5–C6 level. Pre- and post-placement motions were analyzed. Once again, in both flexion and extension, placement of the BRYAN® Disc Prosthesis showed that there was a "general preservation of the forces transmitted through the facet joints" and that "calculated segmental motion was preserved after disc arthroplasty" (Galbusera et al. 2008). Similar to the prior study, the instantaneous centers of rotation (ICR) in flexion and extension showed preservation pre- and post-placement of the BRYAN® Disc.

This study did suggest some post-placement asymmetry in flexion and extension that the authors summarized may be secondary to lack of the anterior longitudinal ligament post-prosthesis placement. However, they were able to conclude that disc arthroplasty with the BRYAN® Disc in this multi-FSU model reproduced "near physiological motion" at the C5–C6 level (Galbusera et al. 2008).

Pickett et al. have also described the kinematics of the cervical spine following implantation of the BRYAN® Cervical Disc (Pickett et al. 2005). In this prospective cohort study, the authors described a total of 20 patients who underwent single- or two-level implantation of the BRYAN® Disc. Each of these patients was treated per protocol for a degenerative condition of the cervical discs that was producing neurologic symptoms including radiculopathy and/or myelopathy. From a kinematic standpoint, this study examined pre- and postsurgical plain radiographs including neutral lateral as well as flexion and extension radiographs at prescribed intervals. Kinematic parameters including rotation, horizontal translation, change in disc height, and center of rotation at each spinal level were evaluated using quantitative motion analysis software produced by Medical Metrics Corporation (Houston, Texas).

The authors demonstrated a postsurgical preservation of range of motion at the operated spinal segment with a mean postsurgical range of motion of 7.8° at the 24-month postsurgical follow-up. They noted that disc placement "either placed at C5–6 or C6–7" seemed to change the "relative contribution of each spinal segment to overall sagittal rotation (DiAngelo et al. 2004)." They also noted that total overall cervical motion as measured from C2 to C7 was increased at late follow-up intervals. There were no significant changes in sagittal rotation, anterior-posterior disc height, translation, or center of rotation following placement of the BRYAN® Arthroplasty Device at the follow-up intervals. The authors concluded that placement of BRYAN® Artificial Disc for cervical radiculopathy and or myelopathy appears to "reproduce the preoperative kinematics of the spondylotic disc (Pickett et al. 2005)." This in vivo study tends to support the finite element studies noted earlier as published by Galbusera et al. (2006, 2008).

Rick Sasso and Natalie Best published a novel BRYAN® Disc article in February 2008 analyzing

radiographic data from patients who had undergone either ACDF with allograft and plating or placement of a single-level BRYAN® Cervical Disc (Sasso and Best 2008). In this single-level study, all patients had radiographic follow-ups immediately preoperatively as well as postoperatively at regular intervals up to a 24-month endpoint. The study represents data from a subset of patients involved in the randomized prospective BRYAN® Cervical Disc Arthroplasty study for the US FDA. The authors evaluated flexion/extension and neutral lateral radiographs at the prescribed intervals and analyzed motion using Medical Metrics software similar to that described in the prior chapter by Pickett et al. (2005). They quantified functional spinal unit motion, translation, and center of rotation.

As expected, there was significantly more motion in flexion and extension in the disc replacement group than in the fusion group at the index surgical level. In this study, the arthroplasty FSUs were able to retain an average range of motion of 6.7° at the 24-month follow-up interval. This was in contrast to the range of motion of the fusion group which was initially 2.0° at the 3-month follow-up, decreasing overtime to 0.6° at the final 24-month follow-up. The authors also noted that flexion/extension both above and below the operative level was not statistically different in those groups having undergone cervical arthroplasty versus fusion. An interesting finding, however, is that mobility overall increased for both groups over time. At levels above the fusion, there was an increase in translation in comparison to the arthroplasty device which showed no evidence of an increase in translation at the adjacent level. The finding of increased translation was only statistically significant at the 6-month follow-up interval. The authors concluded that the BRYAN® Disc appeared to preserve preoperative kinematics at adjacent levels in comparison to fusion which showed some changes overall in the kinematics (Sasso and Best 2008). This did support the postulation that arthroplasty has the potential to preserve cervical kinematics at adjacent levels postoperatively.

Sasso et al. also reported upon the motion analysis/kinematic properties of all patients enrolled in a prospective randomized multicenter trial for the BRYAN® Cervical Artificial Disc Prosthesis (Sasso et al. 2008). Their overall objective in this study was to analyze the entire set of patients in a prospective fashion similar to the subset which was previously reported (Sasso and Best 2008). In this study, all patients received either a single-level ACDF or a single-level disc arthroplasty with the BRYAN® Cervical Disc Prosthesis. A total of 221 patients received fusion, whereas 242 received a single-level arthroplasty. Operative segments could include the C3–4 disc space down to the C6–7 disc space. Similar to the previous subset, the authors analyzed flexion/extension and neutral lateral radiographs obtained at prescribed intervals postoperatively in comparison to the preoperative interval. This study examined patients up to and including the 24-month interval. Medical Metrics software was once again used to track the cervical vertebral bodies at the index FSU looking at flexion and extension range of motion as well as translation.

Similar to the prior subset, the arthroplasty group retained statistically significant increases in motion at the index FSU in comparison to the ACDF group. The arthroplasty group had an average of 7.95° of motion at the 24-month follow-up. The preoperative range of motion at the same FSUs was 6.43° with no significant evidence of degeneration of motion at the same FSU following arthroplasty at the 24-month interval. As expected, average range of motion in the fusion group slowly diminished to the point of being 0.87° at 24 months. Preoperatively this group had a range of motion of 8.39°. Also noted was no evidence of BRYAN® Disc migration or subsidence at the 24-month follow-up – suggesting that the arthroplasty device was functioning as designed at this early follow-up interval and reproducing the kinematics of the degenerative disc space at the index FSU in comparison to fusion of those same levels.

The PRODISC-C®

DiAngelo et al. have examined the in vitro biomechanics of the PRODISC-C (DiAngelo et al. 2004). Their study was designed to compare disc

arthroplasty to ACDF in cervical spine biomechanics in a multilevel human cadaveric model. This study employed three spinal conditions: intact harvested specimens alone, single-level arthroplasty specimens, and single-level fusion specimens. The study incorporated a total of six fresh human cadaveric specimens harvested from C2 to T1. All specimens were treated according to the group assigned at the C5–6 level following testing in their intact condition. This study simulated fusion in a unique way. Fusion was accomplished across the treated spinal level via custom designed fixtures similar to an external fixation system. Following surgical treatment according to protocols, kinematic principals were tested under biomechanical loading devices. This was done with a programmable testing apparatus that "replicated physiologic flexion/extension, lateral bending, and axial rotation (DiAngelo et al. 2004)." The authors then measured vertebral motion via applied load and bending moments.

As expected, the simulated fusion was successfully able to diminish motion at the treated level relative to the harvested untreated as well as disc arthroplasty conditions. The authors noted that adjacent segment motion increased in those specimens following the reduction of motion at the simulated fusion segment. This study noted that in all modes of testing, the PRODISC-C arthroplasty device "did not alter the motion patterns at either the instrumented level or adjacent segments compared with the harvested condition except in extension (DiAngelo et al. 2004)."

Puttlitz et al. have examined post-disc arthroplasty kinematics using the PRODISC-C in a human cadaveric model (Puttlitz et al. 2004). This study utilized a total of six fresh frozen human cadaveric spines to evaluate two different spinal conditions including both the intact and post-disc arthroplasty condition at the C4–C5 level. Prior to testing, compression and a follower load were applied, as well as pure moment loading to the specimens to evaluate treatment kinematics and pretreatment kinematics. Range of motion (ROM) kinematics was then measured using an optical tracking system, and data was reported.

The results of this limited cadaveric study suggest that the PRODISC-C was able to retain "approximate" intact motion in all three rotation planes "flexion/extension, rotation, and lateral bending (Puttlitz et al. 2004)." They also examined coupled rotations including lateral bending during axial rotation and axial rotation during lateral bending – noting no significant difference in these two tested conditions following arthroplasty. They concluded that ball-and-socket devices such as the PRODISC-C can "replicate physiologic motion at the affected and adjacent levels (Puttlitz et al. 2004)." This is the only study on the PRODISC-C that examines a motion coupling from a kinematic standpoint and suggests maintenance of the coupled motions following cervical arthroplasty. It is possible that a larger in vitro study could provide further insight into the coupling motions examined in this study that were novel to it.

Combined PRODISC-C®/PRESTIGE® ST/LP Studies

Chang et al. have looked at both the PRODISC-C® and PRESTIGE® Artificial Devices compared with ACDF in a cadaveric model (Chang et al. 2007a). The object of the authors' investigation was to examine cervical kinematics at surgically treated levels as well as adjacent segments in a cadaveric model – evaluating two different types of cervical artificial disc devices in comparison to the intact spine and a fusion model. For the purposes of this study, a total of 18 cadaveric human spines were tested in their intact state with kinematic modes including flexion/extension, axial rotation, and lateral bending. These three groups of specimens were then subjected to a surgical intervention including placement of a PRODISC-C®, a PRESTIGE II® Artificial Disc, or ACDF. All specimens were operated at the C6–7 level. This study simulated ACDF with placement of a 7 mm tapered cortical allograft followed by placement of a rigid anterior cervical plate and screws "to maintain lordosis at the treated level (Chang et al. 2007a)." Placement of either the PRESTIGE® or the PRODISC®

device was performed according to the manufacturers' recommended surgical technique at the C6–7 level.

Range of motion was noted to increase after arthroplasty in comparison with the intact spine in extension in both the PRODISC-C® and PRESTIGE® groups as well as in flexion in both arthroplasty groups. With respect to bending, the post-arthroplasty ROMs were greater than those of the intact spine in both arthroplasty groups; this was also similar for rotation. Adjacent level ROM was noted to decrease in all specimens that underwent implantation of a cervical arthroplasty device for all tested kinematic modes. With respect to ROM adjacent to the fusion-treated spines, it was noted to diminish in all motion modes at the treated level but increase at all adjacent levels with a reported range of 3–20%. Adjacent level range of motion diminished in all modes post-arthroplasty with the exception of extension in those patients who underwent a total disc arthroplasty.

This study lends additional credence to the idea of adjacent level disease as a result of surgery as noted by the increased range of motion kinematics at adjacent levels in those cadaveric specimens undergoing ACDF in comparison to the diminished range of motion noted in those patients undergoing cervical disc arthroplasty.

Chang et al. have also evaluated adjacent level disc pressure and facet joint forces after cervical arthroplasty with the PRODISC-C®/PRESTIGE® devices in comparison to ACDF in an in vitro human cadaveric model (Chang et al. 2007b). In this study, the authors examined intradiscal pressures at adjacent levels, as well as facet joint stress following both arthroplasty and cervical spine fusion in 24 human cadaveric spines obtained from C3 to T2. This study examined a surgical intervention at C6–7 in 18 of these specimens. Six specimens were excluded from the original 24 in the study based upon pre-procedural radiographic studies suggesting bone abnormalities. This study examined intradiscal pressures with pressure transducer needles. The forces in the facets, however, were indirectly measured.

The specimens were then divided into three groups with six specimens per group – each receiving either an artificial disc implantation (PRODISC-C® or PRESTIGE®) or in the case of the third group an ACDF. With respect to the PRODISC-C® group, a 7 mm height disc was chosen, and with respect to the PRESTIGE® group, an 8 mm height disc was chosen. These were determined to be "adequate for the cadaveric specimens (Chang et al. 2007b)." The fusion groups, as per a previous study reported by Chang et al. (Rousseau et al. 2008), underwent fusion with a 7 mm lordotic tapered allograft fixed with a rigid plate and screw.

Biomechanical testing ensued with flexion/extension, lateral bending, and axial rotation modes measured. In the arthroplasty-treated specimens, the intradiscal pressure was not significantly different in comparison to the intact spine at adjacent levels proximal and distal to the arthroplasty FSU. However, in those specimens treated with fusions, the intradiscal pressures increased at the location of the posterior annulus fibrosus in extension and at the location of anterior annulus in flexion at the cranial adjacent level. At the caudal adjacent level intradiscal pressure change was not noted to be significant. Indirect measurements of facet forces were computed in this study and were noted to be minimal in flexion, bending, and rotation modes in both arthroplasty- and fusion-treated spines. In extension the arthroplasty models exhibited an increase in facet forces at the treated FSUs in comparison to the fusion model where the facet forces decreased at the treated FSU and increased at the adjacent segments (Chang et al. 2007b).

Rousseau et al. undertook an in vivo analysis of two types of ball-and-socket cervical disc devices which they classified as "two-piece implants (Rousseau et al. 2008)." The authors of this study considered three-piece implants to be those with a mobile nucleus between two metal implants. They examined a total of 26 patients who had been implanted with the PRESTIGE® LP Device and compared them to 25 patients who had been implanted with the PRODISC-C® Device. Investigational specimens were then referenced against the measurements of 200 healthy cervical discs in vivo. Spineview™ software (Surgiview, Paris, France) was used to

calculate the intervertebral range of motion and the mean center of rotation kinematic variables. The authors also calculated the center of rotation between full flexion and extension for range of motion.

In comparison to the normal non-implanted vertebral discs, the range of motion kinematics in flexion and extension were noted to be significantly reduced with both types of arthroplasty. Comparing the two arthroplasty groups head to head, range of motion was similar, and the location of the center of rotation with full flexion and extension appeared to be "influenced by the type of intervertebral disc despite interindividual variability (Rousseau et al. 2008)." Specifically, the authors noted that there was a trend toward a "more anterior and superior" location of the center of rotation in full flexion and extension with the prosthetic devices then observed in normal nonoperated control discs (Rousseau et al. 2008). This comparison of two-piece ball-and-socket-type prosthesis was notable for the fact that neither cranial nor caudal types of device designs were able to fully restore flexion and extension kinematics to normal mobility in the kinematic measurements described in the study including range of motion and center of rotation.

The PRESTIGE® Disc

DiAngelo et al. have described an in vitro biomechanical study comparing non-fusion (intact specimen) to ACDF and cervical arthroplasty in a multilevel human cadaveric model (DiAngelo et al. 2003). The study was conducted using a programmable testing apparatus that allowed for replication of physiologic flexion/extension and lateral bending. The authors measured vertebral motion applied load and bending moments. The authors used the PRESTIGE® ST cervical joint for arthroplasty and an Orion® (Medtronic Sofamor Danek, Memphis, TN) plate to simulate fusion in this small cadaveric study. Included were a total of four fresh human cadaveric specimens harvested to include C2–T1.

Following their measurements, they reported findings. The application of an anterior cervical plate significantly decreased the motion across the fusion site relative to the native or artificial joint conditions. The placement of a PRESTIGE® artificial cervical joint "did not alter the motion patterns at either the instrumented level or the adjacent segments compared with the harvested condition (DiAngelo et al. 2003)." This study of kinematics is novel not only in the maintenance of normal range of motion at the implanted FSU but also with regard to maintenance of normal motion at all segments of the spine status post-placement of a PRESTIGE® cervical disc prosthesis. Unfortunately, this small in vitro study did not have the power ability to make large in vitro analyses.

The PCM® Disc

Several novel kinematic studies have been performed with regard to the PCM® Device. The device has undergone basic testing from a kinematic standpoint (Hu et al. 2006) in addition to studies that add to the basic kinematic studies in novel ways (McAfee et al. 2003; Dmitriev et al. 2005). These have included studies that examine the role of the posterior longitudinal ligament (PLL) and those that measure adjacent level intradiscal pressures following placement of the PCM® Device (Hu et al. 2006; McAfee et al. 2003; Dmitriev et al. 2005).

Hu et al. have examined the PCM® arthroplasty device, evaluating biomechanical as well as other factors, in a caprine animal model (Hu et al. 2006). The PCM® Disc was tested in vivo and ex vivo in 12 goats divided into 2 distinct groups. These two groups differed in their survival periods – 6 and 12 months, respectively. Each specimen underwent an anterior discectomy at the level C3–C4 followed by implantation of the PCM® Device. Outcomes of the study were based upon examination of the prosthesis by computerized tomography, multidirectional post-sacrifice flexibility testing, decalcified histology, and histomorphometric and immunochemical analyses.

With regard to postoperative survival, there was no evidence of prosthesis loosening at the

two examined survival periods. Multidirectional flexibility testing from a kinematic standpoint was performed in all standard measures. Under axial rotation and lateral bending, there was no significant difference in the range of motion of the operated FSU in comparison to nonoperative controls. The authors concluded that intervertebral range of motion was preserved under axial rotation and lateral bending at the two examined postsurgical time frames in this animal mode (Hu et al. 2006).

McAfee et al. established that the posterior longitudinal ligament (PLL) may provide a stabilizing influence to the cervical spinal segment (McAfee et al. 2003). Biomechanical testing was performed using human cadaveric spines and a six-degree-of-freedom spine simulator with additional optoelectronic motion measurement. The major finding was that biomechanical stability may be restored following complete anterior cervical discectomy with resection of the PLL via implantation of an arthroplasty device such as the PCM® Device.

Dmitriev et al. have looked at intradiscal pressure and segmental kinematics following cervical disc arthroplasty with a PCM® Device (Dmitriev et al. 2005). This in vitro human cadaveric study examined a total of ten spines. Each spine underwent intact analysis with subsequent reconstruction at C5–C6 with a total disc replacement, an allograft dowel, or an allograft dowel and an anterior cervical plate. The authors then tested the specimens in displacement control under axial rotation, flexion/extension, and lateral bending kinematic modes. They recorded intradiscal pressure at levels adjacent to the C5–6 space including C4–5 and C6–7 FSUs. Range of motion was monitored at the operative FSU (C5–C6).

The authors noted that the intradiscal pressures recorded at adjacent levels were similar to the intact (nonoperated) condition in those patients who had undergone a total disc replacement with the PCM® Device. However, the intradiscal pressures at C4–5 in flexion/extension for both types of simulated fusions were noted to be significantly higher than the mean intradiscal pressures measured at these same levels in the intact and disc replacement groups. Similar findings were noted at C6–7, where significantly increased intradiscal pressures were achieved in all three loading methods including axial rotation, flexion/extension, and lateral bending. As expected, both types of simulated fusions at C5–6 produced a significantly diminished range of motion during flexion/extension testing. The authors concluded that the PCM® Disc has the ability to maintain adjacent level intradiscal pressure in comparison to increased intradiscal adjacent level pressures noted with simulated fusions. This study lends some support to the concept of adjacent level disease as a result of the modified kinematic environment adjacent to a fusion.

Computer Simulation and Finite Element (FE) Modeling Studies

In addition to numerous disc-specific kinematic studies that have been published in recent years, several authors have contributed to the collective understanding of finite element (FE) modeling with respect to artificial cervical disc replacements. Ahn et al. published such a study, noting as background that there was a need for further simulation studies to understand common design themes for restoration of motion as the result of numerous types of cervical disc designs (Ahn and DiAngelo 2008). They cited the numerous examples of both constrained and semi-constrained devices. The study proposed to expand upon the limited number of in vitro studies previously discussed herein.

The study incorporated a three-dimensional graphics-based computer model of the subaxial cervical spine that had previously been developed. This model was used to study the kinematics and mechanics of an arthroplasty device placed at the C5–6 disc space – the validation for which had been described in a previous study by the same group (Ahn and DiAngelo 2008). The basic computer model incorporated the geometry of cervical vertebrae as established from the computer tomographic images of a 59-year-old woman, linking the adjacent vertebrae at C5 and C6 as a “triple joint complex

comprised of the intervertebral disc joints in the anterior region and 2 facet joints in the posterior region and the surrounding ligament structure (Ahn and DiAngelo 2008)."

The authors modeled intervertebral discs as nonlinear elements having a total of six degrees of freedom. With this model, they studied three different theoretical prosthetic disc devices. The first device tested was a disc with the center of rotation of a spherical joint located in the midportion of the C5–6 disc, the second device being with the center of rotation of the cervical joint located 6.5 mm below the midportion of the C5–6 disc, and the third being the center of rotation of the cervical joint in a plane located at the C5–6 disc level. The authors simulated removal of the anterior longitudinal ligament and the anterior portion of the annulus as well as the nucleus pulposus for placement of the disc prosthesis. They then tested the three disc implantation designs throughout the six degrees of freedom allowed by the computer model.

With the three types of disc devices, the authors noted that a constrained spherical joint (device design #1 with the joint placed at the midportion of the disc) significantly increased facet loads during cervical spine extension kinematics. Tested design #2 lowered the rotational axis of the spherical joint toward the subjacent body, and this was noted to kinematically cause a "marginal increase in facet loading during flexion, extension, and lateral bending (Ahn and DiAngelo 2008)." Unconstraining the device (device design #3) minimized facet loading buildup during all loading modes by placing the center of rotation of the spherical joint in a plane located at the C5–6 disc level.

The authors concluded that a finite element model was able to demonstrate simple design changes that may have effects on the kinematic behavior of cervical discs placed in human spines at the C5–6 disc space. They were able to predict facet loads calculated from their computer model but noted that the computer model still needs to have validation with regard to in vitro experimental studies. This model does add credence to kinematic principles of device design and goes one step beyond some of the in vitro research in its theoretical device design principles.

Liu et al. have described a fluoroscopic kinematic study looking at the kinematics of the anterior cervical discectomy fusion versus cervical artificial disc replacement at the C5–6 joint (Liu et al. 2007). In this novel study, the investigators used a controlled group of ten normal subjects as well as ten patients treated with ACDF in comparison to ten patients treated with cervical artificial disc replacement. Both types of surgical procedures were performed at the C5–6 level. Radiographic data was collected with the patient performing a full flexion and extension motion under fluoroscopy surveillance with kinematic data collection obtained from these fluoroscopic images. The data were derived based on the "inverse dynamic model of the entire cervical spine (Liu et al. 2007)." This custom model was created based on "KANE'S Dynamics and the Reduction Modeling Technique (Liu et al. 2007)." The authors then calculated kinematic data using software and reported the results.

The ACDF group had notable increases in intersegmental rotation at adjacent disc spaces (C6–7 and C4–5 levels) in comparison to the intact normal specimen. Also notable was the fact that the intact spine (no surgical intervention) had a greater range of motion than that observed in ACDF despite these increases of adjacent segment rotations in the ACDF population. The authors noted that the kinematic measurements in the cervical arthroplasty group were similar to those in the normal group and postulated (by their measurement principles) that cervical artificial disc arthroplasty has the potential to restore "normal dynamic motion of the cervical spine (Liu et al. 2007)."

This study provides a novel approach for analysis of in vivo contact forces and expands upon basic kinematic measurements that have been reported in disc arthroplasty studies. It also suggests that cervical arthroplasty has the potential to maintain adjacent segment kinematics, although it is difficult to make predictions with respect to adjacent segment degeneration as a result of this motion analysis study.

Multidisc Studies

Lin et al. created a novel in vivo study to evaluate bone/implant stresses at the C5–6 disc space with placement of BRYAN®, PRESTIGE® LP, and PRODISC® Cervical Disc prostheses (Lin et al. 2009). Their image-based finite element modeling technique was designed to predict stress patterns at the interface between the prosthesis and the lower vertebral endplate – an effort to elucidate possible mechanisms of subsidence and describe load transfers of disc designs. The group built a three-dimensional finite element model of the C5–6 functional spinal unit based on computed tomographic (CT) images acquired from a patient who had previously been identified as a candidate for cervical disc arthroplasty.

The modeling process included facet joints, uncovertebral joints, and specific artificial disc designs that could be placed within the intervertebral disc space. The authors evaluated the discs and endplates in flexion/extension and lateral bending with compression applied. The authors noted that the PRODISC-C® and PRESTIGE® LP Discs caused "high stress concentrations around their central fins or teeth, which may initiate bone absorption (Lin et al. 2009)." With respect to the BRYAN® Disc, the prosthesis appeared to recover the highest range of motion secondary to what the authors described as the "high elastic nucleus" which was notable for diminishing the stresses at the superior endplate of C6 (Lin et al. 2009). The authors also noted that the PRESTIGE® LP Disc, with its rear positioned metal-metal joint, may be a concern for a mechanism of possible subsidence in the posterior aspect of this arthroplasty device.

The authors concluded that the rigidity of the nucleus/core in both the PRESTIGE® LP and the PRODISC-C® prostheses is capable of maintaining initial disc height at the consequence of high contract stresses at the bone endplate interface with either "improper placement or under sizing (Lin et al. 2009)." The BRYAN® Device differs in its core rigidity creating a much larger displacement during motion allowing for "more variation in disc height that may theoretically increase the load sharing of facet and uncovertebral joints compared to more rigid artificial disks (Lin et al. 2009)." This in vivo finite element study goes beyond typical center of rotation and flexion/extension

kinematics in looking at one of the major causes for implant failure, subsidence. The study is only predictive of the stresses caused by device design and does not predict ultimate subsidence mechanisms. It goes beyond prior studies in elucidating possible areas of increased device/endplate mechanical stresses that are the result of normal device kinematics.

Future Kinematic Design Principles

With respect to basic device design principles, kinematic modeling will likely have an effect on patient outcomes and adjacent segment disease in the long-term. Future design work will continue to make heavy use of preclinical modeling, FE modeling, biomechanical testing, and translational nonhuman testing. Currently implanted cohorts from US FDA trials will alter our understanding of device kinematics over the intermediate and long-term. At the time of this writing, US follow-up of these devices has been published up to 10 years (Sasso et al. 2017). Wear debris caused by device design and kinematic conflicts may play a role in device construction materials and constraint properties as we understand long-term outcomes beyond this interval. Postoperative imaging limitations will also affect future device design as in vivo human studies will continue to make heavy use of imaging techniques and measurements in lieu of biomechanical and histological techniques (Figs. 6 and 7).

Current arthroplasty designs restore only the anterior and middle columns of the cervical spine. They rely on posterior column preservation at the index surgery and over time. Future device designs may include techniques that modify not only structures at the level of the disc but also facets.

Conclusions

We sought to review the basic cervical kinematics that exist and correlate the early data reported from in vivo, in vitro, and finite element (computer-based) studies on disc arthroplasty. Device design with respect to the modified center of rotation at an FSU, device fixation to the vertebral endplates, and flexibility of the articulating nucleus all appear to play a role in reproduction of normal cervical kinematics after cervical disc arthroplasty. A number of these studies also begin to suggest kinematic means of surgical contribution to adjacent level degeneration. It is extremely encouraging to see that many kinematic studies that have been undertaken coincide with the results of US FDA-IDE trials of these devices.

Little data currently exists on how reproduction (or lack of reproduction) of normal kinematics affects intermediate- and long-term patient outcomes and adjacent segment degeneration. Abnormal kinematics may contribute to early

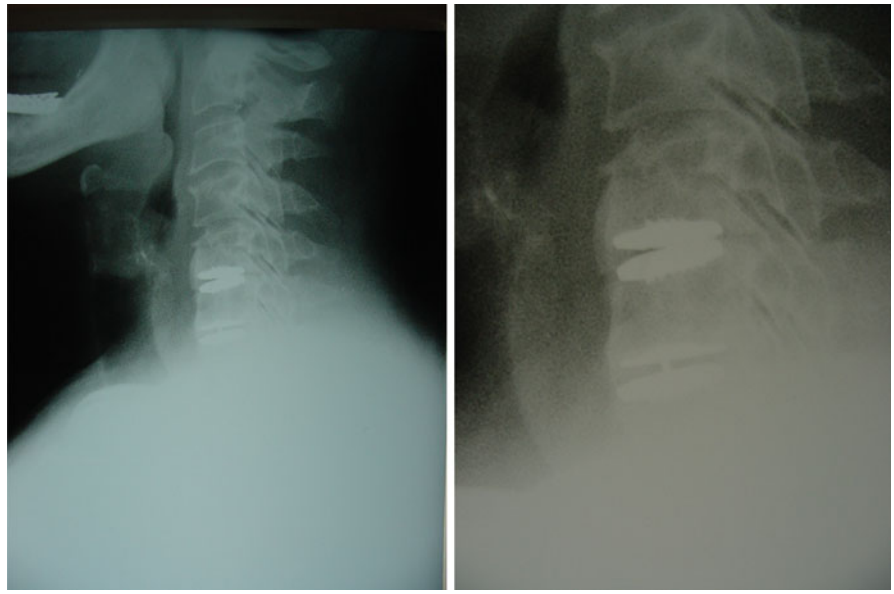

Fig. 8 The MOBI-C® is visualized on these lateral radiographic views of the cervical spine. This patient presented with loss of motion and radiographic evidence of heterotopic ossification at the index surgical levels (C5-C6 and C6-C7). subsidence in some of these devices; however, other than descriptive subsidence complications in a number of clinical series, the abnormal kinematics of the devices themselves have not clearly been suggested to be at fault for such events. Several studies have suggested that cervical disc arthroplasty causes an early-term risk of heterotopic ossification (Mehren et al. 2006; Leung et al. 2005; Heidecke et al. 2008) (Fig. 8). The authors of this publication are not aware of any current kinematic studies that demonstrate or further elucidate either the biomechanical or kinematic mechanisms that may result in heterotopic ossification. Indeed, it may be that device placement/implantation techniques place patients at more risk of heterotopic ossification than properties intrinsic to the arthroplasty devices. This is supported by indirect experiential evidence of a diminished rated of heterotopic ossification in patients who have been treated with NSAIDS in some randomized prospective studies (Sasso et al. 2007a, b; Heller et al. 2009).

As cervical device design continues to proceed, it will be critical for both device designers and study investigators to understand the kinematics in the short-, intermediate-, and long-term phases of the various devices. Modified kinematics as the result of improper placement of arthroplasty devices must also be investigated. Such understanding will likely contribute to increased knowledge with respect to the long-term wear and survival of the devices and may possibly alter the patient outcomes in a positive manner.

Abstract

Anterior cervical discectomy and fusion (ACDF) is still considered the gold standard for surgical management of cervical spondylosis. The discovery of the impact of fusion on other functional spinal units in the form of adjacent segment disease has led to the development of motion-sparing techniques in cervical spine surgery, such as cervical arthroplasty. A substantial number of different cervical artificial disc implants have been approved for clinical use, some with long-term follow-up data demonstrating the safety and efficacy of the implants in maintaining motion of the index level. However, a significant number of prostheses failed to retain the desired mobility, mostly due to heterotopic ossification and unintentional fusion. Choosing the appropriate implant design, along with meticulous surgical technique, is the most important prerequisite for good surgical results and longevity of implant integrity and function. In this chapter we discuss the evolution of key characteristics of implant design crucial for successful surgery, as well as surgical tips and techniques related to cervical arthroplasty.

Cervical arthroplasty · Total disc replacement · ACDF · History · Adjacent segment · Implant design · Implant selection · Discectomy · End plate preparation · Heterotopic ossification

Introduction

Since its introduction in the mid-1950s, anterior cervical discectomy and fusion (ACDF), as first described by Robinson and Smith (1955) and Smith and Robinson (1958), has become the gold standard for the treatment of single- and multilevel cervical disc disease and cervical spondylosis. Although many different additions and minor changes have modified the ACDF approach over time, such as by Cloward (1958), the approach itself and the basic surgical technique implied have conceptually remained the same, testimony to the rationale and technical simplicity of this approach. ACDF is still justifying its position as a straightforward technique that yields unequivocally excellent clinical results.

It was not until the late 1980s and 1990s that awareness emerged of the impact of fusion of diseased cervical segments on adjacent functional spinal units in a clinically significant proportion of patients. Although the existence of adjacent segment degeneration has been reported before, it was only after the landmark paper by Hilibrand et al. (1999) in which the authors reported on a small percentage (2.9%) of new-onset adjacent segment symptomatic radiculopathy cases per year, but a significant cumulative rate of 25% in a 10-year period after the index ACDF surgery that cervical spine motion preservation techniques have come again under focus by the spine surgical community. The purported mechanism for the non-negligible incidence of adjacent segment disease following ACDF has been speculated to be a higher, nonphysiological degree of stress imposed upon functional spinal units next to the fused segments, leading to their accelerated degeneration. Various reports have shown that intradiscal pressure in segments adjacent to those fused by surgery increased after surgical immobilization. This begs the question of whether the incidence of adjacent segment disease could be lowered by preservation of motion in the operated segment after surgical decompression.

History of Cervical Arthroplasty

The idea of arthroplasty as opposed to arthrodesis has a long history in orthopedic surgery, specifically in the field of hip and knee surgery (Wiles 1958; McKee and Watson-Farrar 1966).

While loss of function of a hip or knee joint creates a debilitating condition for the individual, the fusion and loss of function of a single functional spinal unit, or even multiple segments in the cervical spine, are surprisingly well tolerated. Nevertheless attempts to retain mobility in operated cervical levels have also a long history dating from the 1960s, with the first reported implantation of a cervical

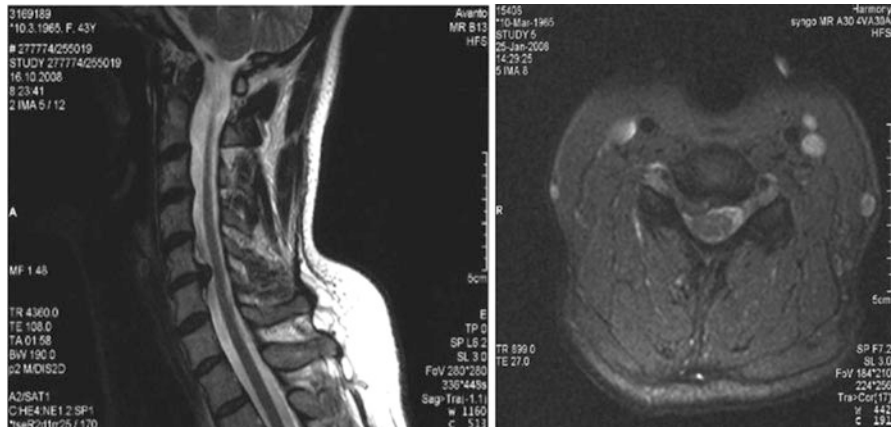

Fig. 1 MRI showing a typical indication for cervical disc arthroplasty – a single level soft disc herniation causing radiculopathy refractory to conservative treatment

arthroplasty device by Fernström (1966). These implants consisted of a stainless steel ball implanted in the intervertebral space after discectomy. Because of a high proportion of implant subsidence and implant migration, the placement of these devices was quickly abandoned.

Spinal arthroplasty for arthrodesis fell out of favor until the newly emerged success of lumbar arthroplasty in the 1980s. It was the invention of the SB Charité lumbar disc prosthesis with excellent results in trials that renewed interest in spinal arthroplasty (Cinotti et al. 1996; Lemaire et al. 1997; Zeegers et al. 1999; Guyer and Ohnmeiss 2003). Different other lumbar devices, such as the ProDisc, have been widely implanted, and all of these have survived to see different design changes and improvements. Because of this trend, renewed interest in cervical spine arthroplasty also reemerged.

Rationale for Cervical Disc Arthroplasty

With the introduction of modern cervical total disc replacement devices, the initial indications for surgery included patients with cervical degenerative disc disease confined to one level causing radiculopathy and/or myelopathy with radiological evidence of only soft disc herniation or mild spondylosis. Cervical arthroplasty was therefore considered only for a selected subgroup of patients with single-level disease between C3 and C7 with no evidence of pathological changes to facet joints and posterior elements of the spine (Fig. 1). Intuitively, this raises questions regarding possible selection bias with regard to surgical outcome. Counterintuitively, and interestingly enough, in the paper by Hilibrand et al., a negative correlation between the number of levels included in the ACDF construct and onset of adjacent segment disease was reported. Two- and three-level ACDF somehow appear to be correlated with a lower incidence of adjacent segment disease than single-level arthrodesis.

After initial reports (Cummins et al. 1998; Goffin et al. 2002), mainly case series in Europe followed by the reports of US Food and Drug Administration (FDA) investigational device exemption (IDE) studies that the spectrum of indications for cervical arthroplasty has expanded. The indications beyond radiculopathy due to soft disc herniations include axial neck pain, myelopathy and foraminal stenosis, and nerve root entrapment due to narrowed disc space.

In contrast to the initial limitation to single-level disease, the indications now are widely accepted for two-level disease (Fig. 2) and in cases where a symptomatic degenerative disc disease (DDD) is addressed in conjunction with an adjacent level to a previously fused level (Fig. 3).

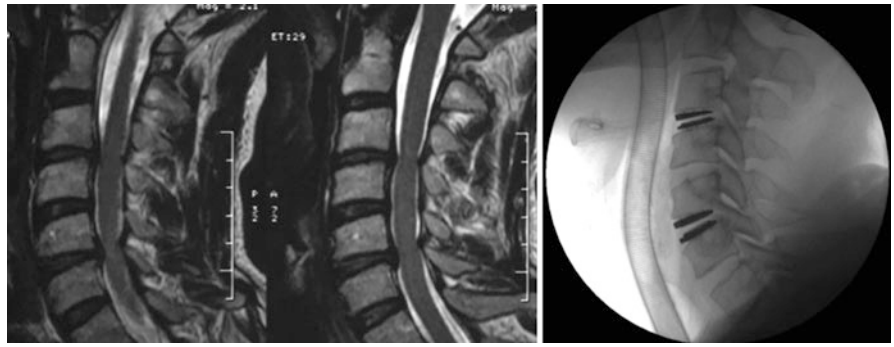

Fig. 2 Extended indication for cervical TDR – two-segment disease

Fig. 3 Extended indication for cervical TDR – arthroplasty adjacent to previous fusion

Patients in whom a cervical arthroplasty procedure is considered must have failed a course of conservative treatment of at least 6–8 weeks.

Contraindications, Disadvantages, and Specific Complications Related to Cervical Total Disc Replacement (TDR)

A number of spinal conditions strongly preclude the use of cervical TDR devices. These include conditions with predominantly posterior compression of neural elements, such as cases with facet joint or yellow ligament hypertrophy and cases of congenitally narrow spinal canal that cannot be adequately addressed only from anteriorly. These also include cases where there is no motion preserved in the index level, such as cases of ossification of the posterior longitudinal ligament (OPLL), for instance. A vast number of metabolic conditions including osteoporosis or severe osteopenia and bone metabolic diseases (such as Paget's) are a contraindication.

When comparing the indications, surgical goals, and expectations in the long run for the two procedures (ACDF vs TDR), different factors come into play with respect to the surgical procedure undertaken. The main goal of both ADCF and TDR is the adequate surgical decompression of neural structures from an anterior approach. In the case of ACDF, the secondary goal after decompression is the solid fusion and restoration of ideal vertebral body alignment. This is achieved by proper end plate preparation and

implantation of adequate allograft material with or without an anterior plating system. After achievement of bony fusion, further formation of bony spurs toward the spinal canal in the operated segment(s) is prevented, and sometimes the resorption of previously formed ones can be detected. Basically, outpatient follow-up of these patients in the majority of cases comes to an end, or patients tend to be lost to follow up after achievement of bony fusion because they are no longer symptomatic.

The goals of arthroplasty somewhat differ in that after surgical decompression a different milieu is set up. The surgeon must take into account the need for adequate end plate preparation, which differs depending on the prosthesis to be implanted, but also be minimally disruptive to adjacent tissues. It has been shown that meticulous surgical technique is of paramount importance for the long-lasting success of cervical arthroplasty, both in optimizing clinical results and in complication avoidance. This of course also true with ACDF, but in TDR the impact of surgical technique is even more pronounced. For example, trauma to the longus colli muscle has been connected to the formation of heterotopic ossification, a new complication specific for artificial disc surgery. Unlike with the ACDF procedure, there is no termination to follow-up of these patients since there is a need to follow the functionality of the prosthesis itself.

Principles of Artificial Cervical Disc Designs

A vast number of different artificial cervical disc prostheses are available on the market worldwide. However, some crucial key points of design, biomechanical parameters, construction elements, and materials differentiate these various TDR designs. Although there may not be an ideal artificial disc implant, and due to the variability of individual anatomy and pathology, a single ideal implant likely cannot exist, and the history of implant development has brought to light some features that are clear improvements. An artificial disc has to be easy to implant, available in different sizes in terms both of height and footprint size (endplate coverage), and to have an incorporated lordotic angle of approximately 7°. Ideally, it should be MRI compatible with as few MRI-related artifacts as possible and has to have radiopaque markers for safe implantation. It also needs to be able to resist the stress imposed by millions of cycles of movement without mechanical failure and at the same time produce virtually no shear material debris. A key function is to have an adequate instantaneous axis of rotation, unrestrained near-to-physiological range of motion in all directions coupled with a small but crucial amount of translation while at the same time allowing for some degree of motion present in the facet joints. Ideally, the prosthesis must be confined to the intervertebral space to minimize dysphagia, while at the same time precluding prosthesis migration and subsidence. And lastly, revision surgery, if required, must not be complicated.

As one can see from the list of characteristics, these implants are subjected to a very rigorous group of requirements. From the history of the evolution of their design, one can also see the evolution of our understanding of the requirements of a functional cervical arthroplasty device.

Prestige Cervical Disc System (Medtronic, Memphis, TN, USA)

The first modern cervical artificial disc device was designed by B. H. Cummins in the Department of Medical Engineering at the Frenchay Hospital in Bristol, UK, in 1989 (Cummins et al. 1998). The first design was a stainless steel two-piece metal-on-metal, ball-on-socket device with anteriorly placed anchoring screws. This so-called Bristol-Cummins artificial cervical joint has subsequently experienced several design improvements. Later on named the Frenchay cervical disc, the device was eventually bought by Medtronic and redesigned to “Prestige” in 1998. The major design improvement was a change of the concave articulating surface from a

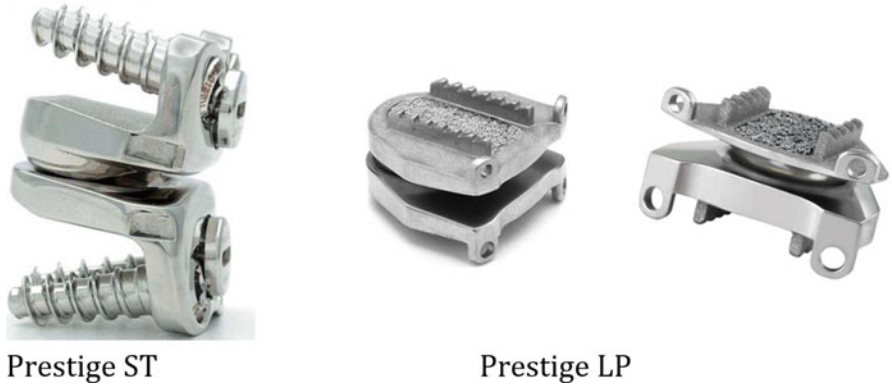

Fig. 4 The Prestige ST and Prestige LP artificial discs

Fig. 5 The Bryan disc

hemispheric cup to a more ellipsoid saucer, allowing for additional freedom of movement, in particular a small amount of anteroposterior translation coupled with flexion and extension. The screw locking mechanism was also changed to a lower profile with a locking mechanism designed to prevent screw pullout. With the fifth generation called the Prestige LP, it has become one of the most widely and extensively studied artificial discs. It has evolved from a stainless steel ball-on-socket device with anterior plate/screw fixation to a titanium ceramic composite using two small keels for low-profile fixation (Fig. 4).

Bryan Cervical Disc (Medtronic, Memphis, TN, USA)

Contrary to the Prestige artificial disc, the Bryan cervical disc (Fig. 5) that was invented in the late 1990s by Vincent Bryan was initially designed as a composite metal-on-plastic design. More adherent to low-friction principles of tribology, it consists of a polyurethane core between two titanium alloy shells, allowing for unrestrained motion and shock absorption. The titanium shells are covered by a porous surface that promotes bony ingrowth. The whole implant is contained in a polyurethane membrane designed to prevent shedding of wear debris. Specific to the Bryan system is the surgical implantation technique that necessitates a specific milling of vertebral end plates that guarantees initial implant stability. As with the Prestige disc system, substantial clinical data with the use of the Bryan disc are available due to the large number of devices implanted and long follow-up (Goffin et al. 2003; Anderson et al. 2004.).

ProDisc-C (Centinel Spine, USA)

Analogous to the lumbar ProDisc-L, the ProDisc-C (Fig. 6) is a uniarticulating ultrahigh-molecular-weight polyethylene (UHMWPE)-on-cobalt chrome ball-in-socket design. Short-term fixation stability is achieved by a protruding midline keel on the end plate surfaces of the device.

Fig. 6 The ProDisc-C disc

Fig. 7 The PCM disc

Porous Coated Motion (PCM) (Nuvasive, San Diego, CA, USA)

Different from the previous designs, the PCM (Fig. 7) is a uniarticulating two-piece non-constrained device. The initial fixation to the vertebrae is achieved by the curved design and serrations of the implant end plates, while long-term fixation is provided by bony ingrowth into its titanium and calcium phosphate surface. The articulation of this implant is UHMWPE-CoCr combination. Specific to this device is the lack of inherent range of motion limitations due to its design which relies on gliding motion. The motion limitation of this unconstrained device is dependent upon the surrounding soft tissues and facet joints.

Mobi-C Cervical Disc (Zimmer, USA)

The Mobi-C cervical disc (Fig. 8) is a combination of two titanium end plates and a polyethylene core in a semi-constrained design. The specific characteristic of this device is the presence of two peripheral stops incorporated in the construct of the inferior titanium plate that limits the mobility of the polyurethane insert.

Discover (Centinel Spine, USA)

The Discover artificial cervical disc (Fig. 9) has a fixed core ball-in-socket joint with articulating surfaces of titanium alloy and a cross-linked UHMWPE core. It offers an inherent 7° of structural lordosis. The immediate fixation is provided by six 1mm fixation teeth, while the titanium plasma and hydroxyapatite coating provides for better bony ingrowth and long-term fixation of the device.

Preoperative Planning

Irrespective of the device to be used, and consistent with good surgical practice, a thorough history and clinical examination and preoperative assessment of the patient's symptoms and signs, as well as a preoperative radiological work-up, must be undertaken. In preparation for cervical arthroplasty surgery, apart from standard C-spine X-rays showing the patient in the neutral standing position (particularly potentially useful during the operative procedure – described below) and MRI scans delineating the localization and characteristics of pathology as well as of neural structures, flexion and extension X-rays are necessary. If available, a CT scan is of use for evaluation of facet joint degenerative changes.

Knowledge of the normal lordotic curvature of the patient's cervical spine, as assessed by the preoperative neutral standing lateral X-ray, is of paramount importance when positioning the patient on the operating table. Failure to position the patient correctly with insufficient extension or overextension of the neck is a crucial mistake that

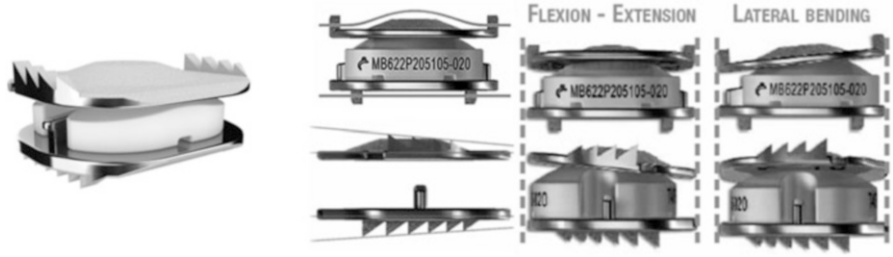

Fig. 8 The Mobi-C cervical disc

Fig. 9 The Discover disc

can occur even before initiating the surgical procedure itself. Measuring the purported implant size on preoperative X-rays can give the surgeon an idea of whether adequate end plate preparation has been made at the completion of neural decompression.

Surgical Technique

Positioning

Since indications for artificial disc replacement surgery differ from the standard ACDF indications that encompass a much larger spectrum of cervical spine degenerative diseases, the surgical nuances that differ are numerous and present in each step of the procedure starting with patient positioning. When planning total disc replacement surgery, it is absolutely mandatory to try and achieve as neutral a position as possible to maintain a midline position and natural lordotic curvature. Midline position is required for accurate coronal alignment and midline placement of the implant in order to minimize adjacent segment stresses and guarantee maximum duration of implant function. The head of the patient must not be rotated to either side. One way of assessing the degree of flexion/extension is to superimpose the preoperative X-ray of the patient taken when standing to the one taken intraoperatively during positioning. Hyperextension during surgery, for example, can lead to unintended AP translation inside the device resulting in suboptimal postoperative implant range of motion.

The head is maintained in the desired position by a self-retaining tape placed over the patient's forehead with care taken not to leave the eyes unprotected (avoided by applying ointment) should they unintentionally open under the drapes during surgery. The neck must not be left unsupported; usually an appropriate pad or a roll of cotton compresses is put under the neck to match its curvature, thus offering support during surgery (Fig. 10).

Positioning Pearls

- Ensuring a centered head position and midline cervical spine alignment is crucial for successful arthroplasty device implantation.
- The head should be taped to the surgical table to prevent any movement during surgery.
- Final positioning before draping can be checked by X-ray to ensure optimal alignment and lordotic curvature have been achieved.

Positioning Pitfalls

- Inadvertent rotation of the cervical spine during surgery can lead to improper implant

Fig. 10 Proper patient positioning for performing cervical disc arthroplasty. Note the placement of the mechanical ventilation tube in the opposite corner of the mouth, the position of the tape used to immobilize the head, and the roll of cotton pads that provide support for the neck in a neutral position

positioning and incorrect stress on the device resulting in possible suboptimal functionality of the prosthesis, neck pain, and even implant migration.

Approach

Depending upon the implant used, different dedicated sets of surgical instruments are present.

As with classical ACDF, the side of approach depends on the preference of the surgeon but also upon patient characteristics. A classical anterolateral approach to the cervical spine is undertaken. Since the vast majority of arthroplasty surgeries performed are for single-level disc disease, a classical approach through a horizontal incision concealed in a skin crease at the level of the conic ligament is undertaken. Care must be taken to minimize any unnecessary tissue trauma and bleeding, especially in the plane of the prevertebral fascia in order to minimize formation of heterotopic ossification. Instead, only mobilization of the medial margins of the longus colli muscle is undertaken with a Penfield No. 4 instrument or a similar dissector in order to visualize the uncovertebral joints and establish the midline. A marker is inserted into the disc, and fluoroscopy is performed to confirm the surgical level.

Approach Pearls

- For patients with short neck and for surgery on lower levels (C6–C7), shoulders should be gently pulled down and taped to the surgical table in a craniocaudal direction to ensure operative level X-ray visualization.
- The skin incision should be made using natural skin crests if visible, to ensure a better cosmetic outcome.

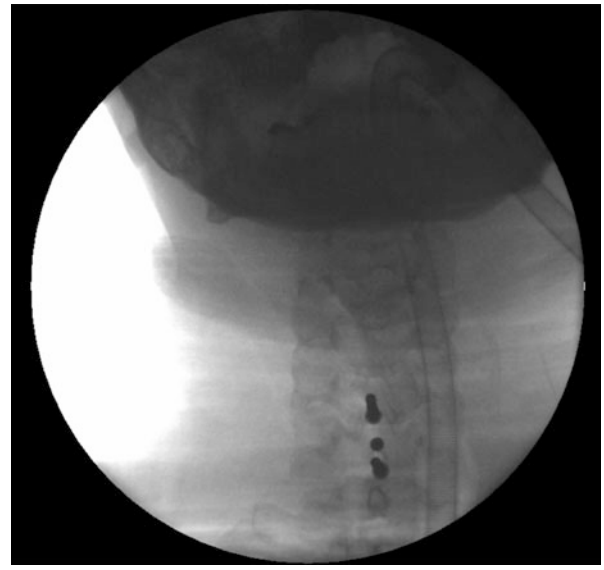

Fig. 11 Diagram and intraoperative fluoroscopy showing the placement of midline pin(s). Placement of the midline pin either in the disc or vertebra should be done equidistant from both uncovertebral joints. Radiographic confirmation of this position is mandatory

- Deep cervical fascia should be widely dissected in respect to the craniocaudal direction to minimize retractor compression to adjacent structures.
- Meticulous hemostasis must be achieved at all steps during surgery to avoid placement of drainage at the time of closure.

Approach Pitfalls

- Extensive electrocautery of the longus colli muscle must be avoided in order to minimize tissue trauma and scar formation, which can predispose to heterotopic ossification.

Midline Determination

Irrespective of the implant type, establishing the midline is of crucial importance for the long-term success of surgery. As previously stated, this is done by identifying the middle of the distance from the two uncovertebral joints while inflicting minimal trauma to surrounding soft tissue. Radiographic verification of the midline position of pins on adjacent vertebrae is performed by fluoroscopy after positioning a midline pin either in the disc itself or in the body of the adjacent vertebrae. Care must be taken not to misinterpret the midline alignment on fluoroscopy, and this is verified when both the pin and spinous process are aligned in a projection perpendicular to the intervertebral space (Fig. 11).

Midline Determination Pearls

- Longus colli muscle dissection should be performed with the use of a dissector to the level where both uncovertebral joints are fully visible, facilitating the determination of the true midline.
- When assessing the midline position of pins by fluoroscopy, it is necessary for the pins to be in line with the superimposed spinous processes of the corresponding vertebrae.

Placement of Pins

Retractor pins are then placed in the adjacent vertebral bodies (Fig. 12). This can be done with the aid of a guiding system. In this manner parallel placement and therefore an even and parallel retraction of both distractor pins are facilitated. If a dedicated guidance system is not available, care of must be taken to assure the placement of the vertebral body pins as close as parallel to one another as possible.

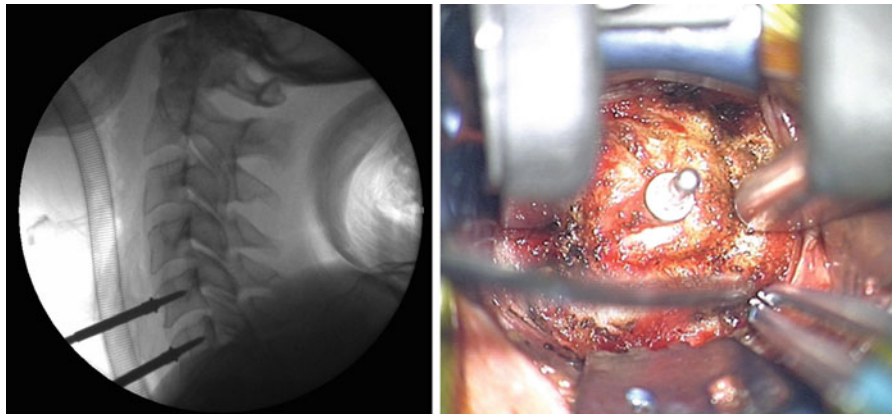

Fig. 12 Intraoperative fluoroscopy and intraoperative photograph showing positioning of the distractor pins

Pin Placement Pearls

- Parallel placement of pins will ensure equal distraction forces to be applied on both vertebrae.
- Both pins must be of same length and diameter.
- Pins must be placed in the mid-portion of the vertebral bodies, parallel to the end plates.

Pin Placement Pitfalls

- It is important not to overdistract, because overdistraction can put additional stress on facet joints leading to either postoperative neck pain or possible degeneration of the facets which at the end can diminish functioning of the prosthesis.

Discectomy

Initial partial discectomy is performed with the pins in place and before their distraction. The discectomy is then finished in a stepwise fashion, with minimal increments in vertebral body distractions over the pins as the discectomy is completed. Overdistraction must be avoided, since this can lead to implantation of an oversized device, leading to excessive distractive stress on the facet joints and postoperative pain and failure of motion preservation.

It is important to remove all residual disc material to the posterior longitudinal ligament and laterally to both uncovertebral joints. Removal of the posterior longitudinal ligament is always necessary, as well as removal of any osteophytes protruding into the spinal canal. However, all unnecessary bone drilling should be avoided and the operative field thoroughly rinsed with saline in order to flush away any bone debris.

Discectomy Pearls

- Removal of the posterior longitudinal ligament is necessary, in order to visualize adequately the decompression of neural structures.
- Additional foraminotomy is usually not required because most cases are limited to soft disc herniation; however, it is crucial to see the entire foramen and the nerve within it and to check for any residual compression using a probe or a nerve hook.

End Plate Preparation

Nuances of end plate preparation differ based on the type of implant used, and manufacturers' advice should be followed. Generally, the end plates should be prepared flat and shaped to match as closely as possible the curvature or angulation of the implant end plate geometry. Implants using keels as means for immediate anchoring have the inherent risk of provoking vertebral body fractures especially in the setting of performing arthroplasty surgery on two adjacent levels or next to a previous fused segment,

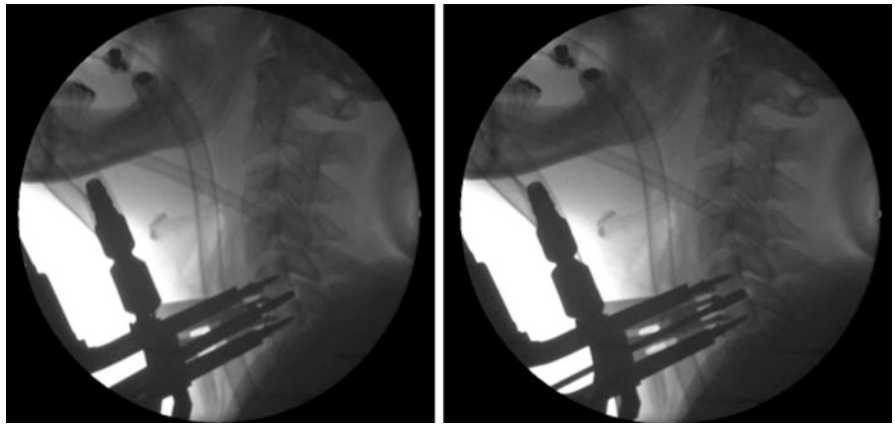

Fig. 13 Intraoperative fluoroscopic visualization when choosing the appropriate footprint size

so care must be taken not to be overly aggressive in preparation for their positioning. Newer generation devices use small spurs or teeth for immediate implant fixation which is generally less traumatic to the bony end plates.

Final end plate preparation is achieved with the use of appropriately sized rasps, with which any residual cartilaginous tissue impeding bony ingrowth into the implant end plates can be removed. Care must be taken not to impose injury to the subchondral bone. The superior end plate usually is concavely shaped, and this surface can be carefully flattened both anteriorly and posteriorly in order to accommodate the implant surface. The end plate of the lower vertebra should be usually flattened only posteriorly. At the end of the endplate preparation phase, both vertebral surfaces should be parallel to one another. A thorough irrigation is performed again.

End Plate Preparation Pearls

- When using prosthesis featuring a predetermined lordotic angle, achieving absolute parallelism during end plate preparation is mandatory; failure to do so may lead to loss of lordotic shape of the prosthesis.

Footprint Size

Choosing the right size of the implant in terms of endplate coverage is the best way to avoid implant subsidence as well as heterotopic ossification. The greater the coverage area, the lesser the chance that the implant will injure the adjacent bone and migrate. In the setting of various implant sizes available, the largest implant that still fits into the intervertebral space without protruding should be used.

Footprint Size Pearls

- Checking the appropriate footprint size is done exclusively under fluoroscopy (Fig. 13).
- The largest footprint size that does not enter the uncovertebral joints is to be chosen.
- When checking for footprint size, the template itself must be positioned parallel to the distraction pins (Fig. 14).

Disc Trial

To further optimize disc implant selection, several sets include disc trials that mimic the final disc implant and can be assessed under fluoroscopy in terms of height, coverage, and positioning.

Disc Trial Pearls

- It is of primary importance that the midline of the trial prosthesis matches the midline of the vertebral body, because this in the end will affect the center of rotation of the implant; again, this can be achieved only by fluoroscopic guidance.

Fig. 14 Intraoperative image showing the proper position of the probe when checking adequacy of footprint size

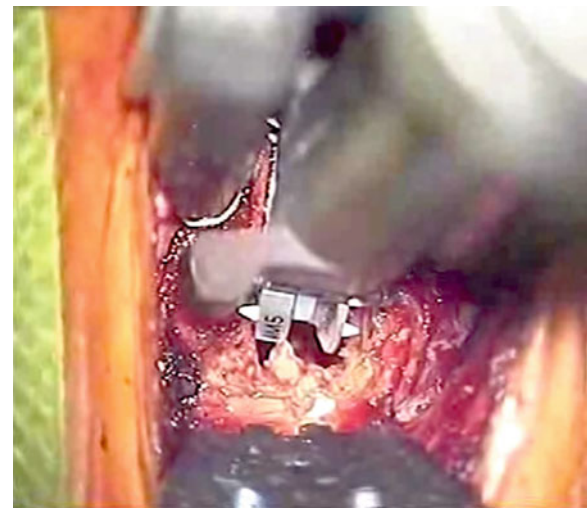

Fig. 15 Intraoperative photograph showing implantation of the Discover disc

Implant Insertion

Implant placement (Fig. 15) steps must be followed as described by the manufacturer. Any unnecessary manipulation of the implant should be avoided. Also, the simultaneous use of a burr and any metallic suction devices or similar metallic instruments during any surgical step should be performed with care. Contact of the burr with such an instrument can provoke formation of metal debris which can over the course of years lead to implant scratching and accelerated wear.

Final position (Fig. 16) must be checked by AP and LL fluoroscopy and any further positioning adjustment made accordingly. Since these implants are designed to last for millions of cycles of flexion and extension, translational movement, and rotation, any suboptimal placement should not be tolerated.

Implant Insertion Pearls

- Malpositioning of the prosthesis leads to prosthesis malfunction, and should such a malpositioning be verified at implantation, a reinsertion should be undertaken. For prosthesis using keels, this often cannot be done without significant injury to the cortical bone. Therefore prostheses using lower profile anchoring features, such as teeth or spurs, are advantageous, particularly for surgeons with less experience in cervical arthroplasty.

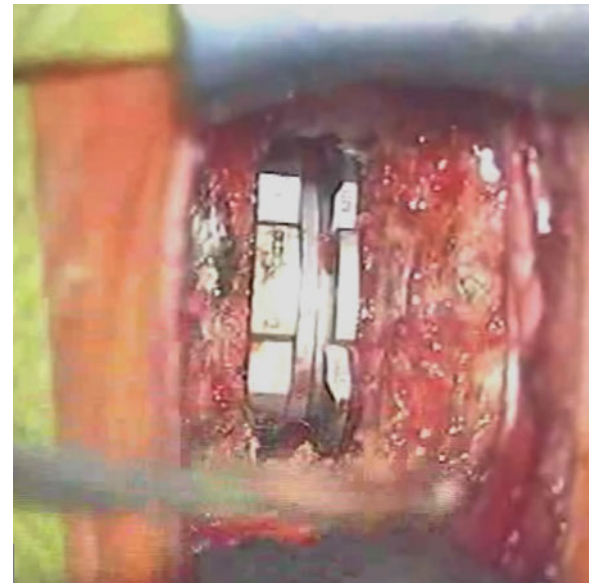

Fig. 16 Intraoperative photograph showing final position of the Discover disc

Wound Closure

After the device insertion is completed, all pins and retractors should be removed and fluoroscopy undertaken to check the final implant positioning. If the implant position is optimal, the wound can be irrigated and inspected for any bleeding. Hemostasis should be meticulously performed, and drainage for one-level surgery is usually not required. Only the platysma is sutured, as well as the subcutaneous layer using a 4–0 resorbable suture. Dermabond is applied on the skin, so that no particular restrictions regarding the skin incision site are necessary.

Postoperative Care and Follow-Up

Patients are encouraged to be upright and walk 3–4 h after surgery and are usually discharged the same or the following day. Administering pain medication as needed as well as NSAIDs for 1–2 weeks after surgery is advised. Wearing of a cervical collar is not recommended.

Follow-up in our practice is usually scheduled at 3, 6, and 12 months after surgery, with dynamic X-rays only.

Patients are also advised to come for further postoperative follow-up 24, 48, 72, and 96 months. The purpose is to check for possible heterotopic ossification that may occur during the patient's postoperative course and to follow and understand long-term outcome of both the patient and the device.

Conclusions

Modern cervical disc arthroplasty surgery started in 2001 in Belgium with the work of Goffin. Since then, cervical disc arthroplasty (CDA) has become a standard procedure in many orthopedic and neurosurgical departments all over the world. Several meta-analyses and randomized control trials showed that CDA is an effective and safe surgical procedure for the treatment of single-level cervical disc disease. Furthermore, in some studies, CDA was found to be superior to ACDF in terms of neck and arm pain, neurological success, and range of motion at the operated level and when assessing for secondary surgical procedures.

CDA is a procedure that has its own history in terms of both technological and surgical

development. It has a significant role in our present spinal surgery armamentarium and hopefully a bright future. Evaluation of new technology is an ongoing process, and we have to be careful and prudent in its implementation, but we also have a reason to be optimistic.

Cervical Total Disc Replacement: Expanded Indications

44

Pierce D. Nunley

Contents

Abstract

Cervical total disc replacement (cTDR) was first used in the 1960s with little success. Widespread use began in the early 2000s, with multiple devices approved in the United States (US) and outside the US (OUS). The US regulatory process, the Investigational Device Exemption (IDE) trial, slows the adoption of some technology in the USA including cTDR. The design, including strict inclusion/exclusion, of IDE trials results in the most compelling, and highest level of evidence data in support of cTDR. The strict patient selection for the IDE trials continues to impact clinical use, as the US indications for use of cTDR remain restrictive compared to OUS. Literature supporting expanded indications of cTDR is limited to low level of evidence and small patient populations from mostly OUS sources. OUS surgeons have many years (10+) of experience with expanded indications, so we will also explore their experiences with cTDR. The reality in the USA is that approval of expanded indications will likely not occur without another IDE trial. What evidence is necessary for US surgeons to adopt expanded indications in their practice?

Cervical total disc replacement · Cervical arthroplasty · Cervical indications

Brief Worldwide History of cTDR

The first cervical total disc replacement (cTDR) was implanted in 1966 by the Swedish surgeon, Ulf Fernstom. The stainless steel ball bearing, known as the Fernstrom ball, was plagued with high failure rates, so approximately 75 were implanted before use was discontinued (Fernström 1966; Fisahn et al. 2017). In 1989, Cummins (Bristol, UK) developed a stainless-steel artificial disc consisting of metal on metal ball and socket device with anchoring screws. One more redesign, following high failure rates of the original Cummins design, produced the Frenchay cervical disc. The first with promising clinical outcomes, the Frenchay disc, was purchased by Medtronic (Medtronic, Minneapolis, MN, USA) and became the Prestige ST cervical disc (Cummins et al. 1998; Wigfield et al. 2002). The Bryan disc was designed in the USA by Vincent Bryan in 1992. The Bryan disc design was markedly different than Prestige, with two titanium alloy endplates and a polyurethane core filled with saline (Basho and Hood 2012). During this time period, another disc, ProDisc-C, was designed by a French surgeon, Dr. Thierry Marnay. ProDisc-C brought a third unique design to the cTDR market. The device was composed of cobalt-chromium-molybdenum and ultra-high molecular weight polyethylene (UHMWPE) articulating surface, with two keels to facilitate anchoring to the vertebral endplates (Baaj et al. 2009).

The 1990s and early 2000s experienced gaining momentum for design of new cTDR devices, but design was only a beginning for cTDR technology. Regulatory approval is required for cTDR devices in the country of distribution, although these approval requirements vary widely. In addition to approval of the device, many regulatory agencies will also approve the specific indications for use of the device.

Development of Indications

The development of medical device patient indications differs widely throughout the world. We will address the US indications and the OUS indications separately.

The USA

In the USA, the FDA regulates cTDR as a Class III medical device, requiring a large-scale (multicenter, prospective, controlled, and randomized) investigational device exemption (IDE) clinical trial for approval. The high-quality, controlled nature of these trials renders level 1 evidence comparing cTDR to anterior cervical discectomy and fusion (ACDF). During these trials, patient eligibility criteria are strict. Upon approval the manufacturer in conjunction with the FDA issues a document, "Instructions for Use" (IFU) that includes indications, contraindications, warnings, and precautions specific to the cTDR device. For purposes of this chapter, we will refer to indications, contraindications, warnings, and precautions, simply as "indications." The basis for the cTDR indications is the patient population included in the clinical trial, supported as level 1 evidence. Among the seven approved cTDR devices in the USA, the study populations and therefore the indications remain relatively homogeneous. In the USA, surgeons are allowed to operate on patients "off-label" (outside of the indications), but many surgeons choose to respect the indications based on the extensive data and high level of evidence that supports them. Additionally, US reimbursement remains a challenge even for on-label use of cTDR, so insurance approval of off-label use is rare.

OUS

OUS the regulatory approval process varies between countries, but largely these do not require highly controlled or high level of evidence trials for approval. Therefore, post-approval indications are at the discretion of the surgeon and tend to be

more expansive. In general, the OUS reimbursement landscape is also less restrictive, allowing the surgeon and patient to determine the best treatment option without coverage as a factor.

The focus of this chapter will be the current US indications and what evidence exists to expand these indications. Many countries OUS already accept broader indications for cTDR, but should and will the USA adopt these expanded indications?

US Current Indications

US cTDR patient indications remain narrow, but highly supported with level 1 evidence. While each cTDR device has slight variation in the approved indications, the following are common among the cTDR devices:

- Single or two contiguous levels between C3 and C7 for conditions
  - Intractable radiculopathy (with or without neck pain)
  - or myelopathy
  - and at least one of the following:
    herniated nucleus pulposus
    spondylosis (defined by osteophytes)
    visible loss of disc height compared to adjacent levels
- Failure of 6 weeks of conservative therapy
- Skeletally mature patients

Additionally, the following relevant (not fully inclusive listing) contraindications and/or warnings and precautions exist for guidelines against the use of cTDR:

- Prior cervical spine surgery, including prior surgery at the index level
- More than two disease levels requiring surgery
- Severe facet joint degeneration
- Segmental instability (translation >3.5 mm and/or $>11^\circ$ angular difference to that of either adjacent level)
- Disc height less than 3 mm measured from the center
- Significant kyphotic deformity or significant reversal of lordosis
- Neck pain alone

The US data and indications exclude large subsets of the population, and the most heavily debated include hybrid treatment (adjacent to a prior or concurrent fusion) and treatment for greater than two levels.

Evidence to Expand US Indications

For the FDA to officially expand US indications, level 1 evidence collected as part of an IDE would be required with the current regulatory cTDR classification. But for surgeons, what evidence is compelling enough to expand indications within your practice?

The published literature on expanded indications is a lessor level of evidence than the data published from the IDE studies. However, several of these studies are robust and provide valuable insight into expanded use of cTDR.

An analysis conducted by Auerbach used the US indications/contraindications of cTDR for Prestige, ProDisc-C, PCM, and Bryan to group patients requiring cervical spine surgery. Patients were grouped into three categories: (1) patients with direct contraindications, (2) qualified cTDR patients, and (3) qualified patient if indications were expanded to include clinical adjacent segment pathology (CASP). Of 167 patients, 95 were contraindicated, with 7/95 that would have qualified if CASP were included. It is noteworthy that the most common exclusion criteria were greater than two operative levels requiring surgery (47 patients). Only the remaining 72/167 patients were qualified to receive a cTDR (Auerbach et al. 2008). Adjacent to a previous fusion and required surgical levels greater than 2, remain a contraindication in the USA, and it could impact over 50% of patients presenting for cervical spine surgery.

Twenty patients were prospectively enrolled in a study in China for treatment at one or two levels with Bryan cTDR. Unlike in the US trials, the two-level treatment was not restricted to

contiguous levels. Clinical outcomes were favorable through 4 years, with no reported serious complications (Zhang et al. 2013). Another Chinese study prospectively enrolled 48 patients treated with Bryan at one, two, and three levels. Clinical outcomes remain favorable through 10 years, although reported heterotopic ossification (HO) rates are high, 69.0%. These HO rates are not categorized into grades, as is typically in the USA, so the true magnitude and impact are unclear (Zhao et al. 2016).

PCM cTDR has been analyzed and reported with expanded indications in several Brazilian studies. A 2007 study included patients treated at one ($n = 72$), two ($n = 53$), three ($n = 12$), and four ($n = 4$) cervical levels (not required to be contiguous) between C3 and T1. There was no exclusion for prior cervical fusion, resulting in 11 one-level and 9 multilevel patients treated with PCM as a revision to a failed fusion, and 12 one-level patients and 9 multilevel patients were treated with PCM adjacent to a prior fusion. Results were significantly improved for both groups, with significantly more improvement in the multilevel cohort (Pimenta et al. 2007). The authors found that the incidence of HO in this population was low, 7.7% through 6 years. While higher HO did correlate to loss of motion, clinical outcomes were not impacted (Pimenta et al. 2013).

A similar study in Brazil used CT results to analyze facet degeneration through 5 years postoperatively. Study enrollment criteria were similar to the previous study, prior fusions were not excluded, and patients were operated at one ($n = 72$), two ($n = 67$), three ($n = 17$), and four ($n = 6$) cervical levels (not required to be contiguous) between C3 and T1. Results indicate there is facet joint degeneration, although minimal, 14% with grade 3 or 4 degeneration (Oliveira et al. 2011).

In France, Mobi-C cTDR has been studied in a large prospective, non-controlled population using expanded indications. Patients were treated at one ($n = 175$), two ($n = 51$), three ($n = 4$), and four ($n = 1$) levels from C3 to T1 with outcomes reported through 2 years. Similar to the PCM studies, prior fusions, even at the index level, were not excluded. Of one-level patients, 21 (with 28 fused levels) had prior cervical fusions, with 18 of these adjacent to the index level. Of multilevel patients (2, 3, and 4 levels) 5 (with 5 fused levels) had prior cervical fusions, with 3 adjacent to the index level and 2 at the index level. Outcomes for both groups were favorable, with no significant difference between the one-level and multilevel groups (Huppert et al. 2011).

Forty-eight patients treated with Bryan cTDR at one-level were retrospectively reviewed in Korea. Twelve of the 48 patients were treated with Bryan adjacent to a fusion (hybrid). Although postoperative kyphotic changes were noted radiographically, the differences were not significant and clinical outcomes remain improved through the 11.8 month mean follow-up (Yoon et al. 2006).

The literature on expanded indications, while compelling, is of lessor evidence than the robust and highly controlled trials that are more common in the USA.

The evidence to expand US indications is not all based on published literature; it is also based upon surgeon experience. Many OUS and some US surgeons are regularly performing cTDR operations outside of the US indications including patients older than 75, greater than two operative levels, replacement of a failed fusion, adjacent to a fusion, and noncontiguous or "skip" levels.

Conclusions

The use of cTDR as an alternative to cervical fusion has gained momentum since the early 2000s and has seen even more widespread support in the last 10 years. Although still considered a novel technology, the number of implantations and supporting literature is abundant. However, the worldwide indications for use of cTDR differ widely. The typical US surgeon remains conservative in patient selection for cTDR, while OUS surgeons commonly expand the patient selection to include more conditions. Continued research, particularly level 1 and 2 evidence studies,

focused on expanded indications will help to appropriately advance cTDR, in an evidence-based fashion.

Cervical Total Disc Replacement: Heterotopic Ossification and Complications

45

Michael Paci and Michael Y. Wang

Contents

Abstract

Cervical total disc replacement (CTDR) can be complicated by the occurrence of heterotopic ossification (HO). HO occurs when bone formation happens in tissues where it is not normally present. It is graded radiographically and develops on a spectrum, from ossification anterior to the cervical spine to ossification involving the articulating surfaces and causing an effective fusion. The true incidence of HO after CTDR is still under debate, with rates reported in the literature varying from approximately 20–90% of patients. The exact causes of HO are still unknown, but associations have been found with male gender, older age, type of prosthesis used, multilevel surgery, and surgical technique. The presence of HO after CTDR has not been correlated with worse clinical outcomes. There is no evidence to date to support a specific strategy to prevent HO, but prescribing a short course of nonsteroidal

anti-inflammatory drugs (NSAIDs) is often done. CTDR is also associated with other complications, including complications that can occur during the anterior approach to the cervical spine, complications related to the prosthesis used and adjacent segment disease.

Keywords

Cervical disc replacement · Heterotopic calcification · Anterior cervical approach · Prosthesis-related complication · Adjacent segment disease

Introduction

Cervical total disc replacement (CTDR) has become a procedure of choice in select patients with one-level and two-level, symptomatic cervical spondylosis for whom motion preservation is an important goal. As detailed elsewhere in this book, this procedure has been shown to have benefits when compared to the more traditional anterior cervical discectomy and fusion (ACDF). It also carries some risks and these will be explored in the current chapter. In particular, we will discuss heterotopic ossification (HO), including its definition, its grading, prevalence after CTDR, risk factors for developing it, and methods to prevent it. We will also discuss more general risks associated with the anterior approach needed to perform a CTDR, as well as specific risks related to the different types of implants use in CTDR.

Heterotopic Ossification

Definition

Heterotopic ossification is a process by which bone and calcifications are deposited in tissues in which they are normally not present. This is known to occur in the context of trauma (such as brain trauma and spinal cord injury), as well as in the setting of arthroplasty, including hip replacement and CTDR (Shehab et al. 2002). In the setting of arthroplasty, the amount of bone formed and its location in relation to the articulating surfaces can threaten the range of motion of the joint involved. The exact pathophysiology of HO is still not well understood. It is clear however that a process of bone deposition can be triggered when bony fragments or shavings fall into contact with certain mesenchymal tissues such as muscle or fascia. It is thought that the presence of bony fragments in such tissues, with their accompanying osteoblasts and bone morphogenic proteins, can lead to the abnormal differentiation of mesenchymal cells into osteoblasts (Balboni et al. 2006). This in turn can lead to new bone formation.

Grading

A well-known grading system for heterotopic ossification following hip arthroplasty was classified in 1973 by Brooker et al. This system was based on the radiographic appearance of HO in relation to the hip joint. McAfee et al. (2003) adapted this grading system for HO in the setting of lumbar disc replacement. Mehren et al. (2006) further adapted this classification for HO in the setting of CTDR.

HO in CTDR is classified based on its radiographic appearance and the extent to which it involves the disc space and its movement (Mehren et al. 2006). Grade 0 is given when no HO is visible. Grade 1 is given when some HO is seen anterior to the vertebral column but not in the disc space. Grade 2 is given when HO starts to appear within the disc space, but no bridging osteophytes are visible yet. Grade 3 is given when bridging osteophytes have formed across the disc space, but some movement is still possible. Finally, grade 4 is given when the level treated by CTDR is entirely fused because of HO, and no movement is possible.

Occurrence of HO After CTDR

The exact incidence of HO after CTDR is still not well established. Different studies have presented widely varying data on this phenomenon. Leung

et al. (2005) observed a cohort of 90 patients who underwent CTDR. They found that 17.8% of patients developed HO at 12 months postoperatively, with 6.7% showing grade 3 or 4 HO. Heidecke et al. (2008) presented a cohort of 54 patients treated with CTDR (59 levels treated). Of these, 29% showed evidence of HO at 2 years of follow-up. Similarly, Lee et al. (2010) present a cohort of 48 patients treated with one-level CTDR. They reported that 27.1% of patients had developed HO at a mean follow-up time of 14 months. On the other end of the spectrum, Mehren et al. (2006) showed a much higher level of HO formation after CTDR. In their group of 54 patients treated with CTDR (77 levels treated), 66.2% of levels demonstrated evidence of HO at 1 year of follow-up. Park et al. (2013) present even higher figures with a 94.1% incidence of HO at 24 months in a cohort of 75 patients treated by CTDR.

It is clear that the rates of reported HO after CTDR vary significantly. The cohort studies presented are all relatively small, and the patient populations from each group likely differ significantly from one another as well.

Interestingly, it seems that the rate of HO after CTDR may increase with time after the initial intervention. This seems intuitively logical as it mirrors the natural history of cervical spondylosis in which osteophyte formation progresses over time at a diseased segment until the segment is fused. Suchomel et al. (2010) present data that support this idea. They followed a group of 54 patients (65 levels) treated with CTDR over a period of 4 years. At 6 months, 9% of levels showed grade 3 HO, and none showed grade 4 HO. By 4 years, 45% showed grade 3 HO, and 18% showed grade 4 HO.

Risk Factors for Developing HO After CTDR

Risk factors associated with the development of HO after CTDR remain under investigation. Older age, male gender, two-level CTDR, surgical technique, and type of prosthesis have been associated with HO in various studies that have examined this phenomenon.

Yi et al. (2013) presented a cohort of 170 patients who underwent CTDR with a minimum follow-up of 12 months. They reported a 40.6% rate of HO at follow-up. They found that male gender conferred an odds ratio of 2.117 of developing HO when compared to female gender. They also found that prosthesis type was associated with HO in their cohort. Compared to patients who received a Bryan disc (Medtronic, USA), patients who received a Mobi-C (LDR Medical, France) or ProDisc-C (Synthes, USA) had a significantly increased rate of HO (odds ratios of 5.262 and 7.449).

Leung et al. (2005) also examined possible risk factors for the development of HO in their cohort. They found a significant association between the development of HO and male gender. Additionally, they reported an association between age and HO, with older patients having an odds ratio of 1.10 of developing it as compared to younger ones.

Wu et al. (2012) studied whether two-level CTDR was a risk factor for HO as compared to one-level CTDR. Their hypothesis was that patients needing treatment at two levels were more likely to have more advanced spondylosis in their cervical spine and would thus be more at risk for HO. They presented a cohort of 70 patients who were followed for an average of approximately 46 months. Forty-two patients underwent a one-level procedure, whereas 28 underwent a two-level procedure. The authors found that 75.0% of the patients treated at two level developed HO, as compared to 40.5% for those treated at one level, and this was statistically significant ($p = 0.009$). They argue that this confirms their hypothesis and that patients treated at two-levels had more advanced cervical spondylosis that continued to progress postoperatively.

As previously noted, Park et al. (2013) presented a very high rate of HO in their cohort of patients treated with CTDR (94.1%). They argue that surgical technique can play a role in the development of HO as patients in their cohort were treated by two surgeons with a slightly different technique and one was associated with a significantly higher level of HO. Indeed, one surgeon was described as using a ball-type burr,

whereas the second was described as using a diamond-tipped burr. Patients who underwent the procedure with the second surgeon had an odds ratio of 3.33 of developing HO as compared to those who were operated by the first one. The authors discuss that the differing burr types and techniques may have led to a different amount of bony exposure, thus leading to differing HO rates.

Clinical Significance of HO

Given that HO occurs in a significant proportion of patients who undergo CTDR, and that it seems to progress with time, many authors have questioned whether it defies the purpose of the procedure itself. Indeed, the choice of CTDR over a more traditional ACDF is usually made with the intent to preserve motion. However, higher grades of HO are known to restrict the implanted prosthesis' motion, thus resulting into something more akin to a fused level from an ACDF.

As previously discussed, Lee et al. (2010) presented a small cohort of 48 patients who underwent CTDR, with a rate of HO of 27.1%. They examined the clinical outcomes of patients with HO and compared them to those without. They did not find any significant differences in pain as quantified by the visual-analog scale (VAS), in function as quantified by the Oswestry Disability Index (ODI) or in range of motion (ROM) as quantified radiographically. These results are however limited by the overall short patient follow-up and the fact that they did not have any patients who presented with grade 4 HO.

Tu et al. (2011) also compared the clinical outcomes of patients with and without HO after CTDR. They present a cohort of 36 patients (52 levels treated) followed for approximately 27 months. They report a rate of HO of 50%. They did not find a significant difference in VAS scores or in Odom outcome criteria in patients who developed HO compared to those who didn't. These results are however also of limited value given the small group of patients presented, the short follow-up and that there was only one patient who developed grade 4 HO.

More studies are needed to better evaluate the effect of HO on patient outcomes. It is however not surprising that patient-reported outcomes such as the VAS score or the Odom criteria have not been shown to differ between patients with and without HO. HO usually does not lead to neural compression. The relief of arm pain achieved during surgery should therefore not be affected by HO. Further, as CTDR was shown to be as effective as ACDF for treatment of such symptoms, even patients with grade 4 HO would be expected to report overall good outcomes. It remains to be seen whether the gradual loss of motion at a CTDR level would eventually lead to clinical deterioration, in particular, in an increase of mechanical neck pain. There is no available evidence to support this at this time.

Prevention of HO

There are currently no evidence-based methods to treat or prevent HO after CTDR. The current practice in our department is to prescribe patients a 1-week course of low-dose indomethacin, discourage the use of any neck collar or brace postoperatively, and encourage a regimen of physiotherapy and light exercise.

Most studies examining possible methods to prevent HO in arthroplasty were carried out in the setting of hip arthroplasty. Radiation therapy and nonsteroidal anti-inflammatory drugs (NSAIDs) have both been shown to be effective methods of preventing HO in patients undergoing hip arthroplasty (D'Lima et al. 2001).

Given the high morbidity of radiation when it is given to the soft tissues of the neck, it is not a reasonable therapeutic option for prevention of HO after CTDR. Indomethacin, which can be contraindicated if patients are known to have a history of renal disease or peptic ulcer disease, nevertheless has a much lower-risk profile. Tu et al. (2015) present a retrospective review of a cohort of 75 patients (107 levels) treated with CTDR. Patients were followed up for a mean of approximately 38 months. The authors examined the rate of HO between those who were given NSAIDs post-op and those who were not.

Although they found a lower rate of HO in the NSAIDs taking group (47.2% vs. 68.2% for those who did not take them), this was not statistically significant. They also found a lower rate of prostheses that had undergone arthrodesis in the NSAIDs taking group (13.2% vs. 22.7% in those who did not take them), but this was not significant either. Both groups had similar VAS scores for neck and arm pain at follow-up, as well as similar Neck Disability Index (NDI) scores. This data therefore does not seem to indicate any clinical benefit from NSAIDs after CTDR. As most of the data presented in this chapter, this data comes from a small retrospective cohort, and this limits its value.

One prevention strategy which is advocated by many authors is the copious irrigation of the wound during surgery. This is done to clear out bone fragments and shavings from the surgical site in order to limit the induction of bone formation that could be triggered by such remnants. Leung et al. (2005) and Tu et al. (2011) advocate for this strategy. Although it makes sense based on our current understanding of the pathophysiology of HO, it is not supported by any evidence to date. Further, as discussed by Lee et al. (2010), most surgeons already irrigate the wound extensively to reduce the rate of infection. This step may therefore not be a factor in the development of HO.

Other Complications Related to CTDR

Complications Related to the Anterior Approach

Although there are technical differences between CTDR and ACDF, the initial approach and neural decompression are essentially the same. As such, complications related to these steps are also similar. CTDR starts with an anterior neck dissection through the natural planes between the trachea and esophagus medially and the sternocleidomastoid and the carotid sheath laterally. This dissection is taken down to the anterior surface of the cervical vertebral column, at which point the proper disc level is identified and the discectomy and neural decompression can commence.

Many structures can be injured from the time of incision to the end of the neural decompression. We usually quote a rate of serious complications (such as neural injury, paralysis, vertebral artery injury) of less than 1% and a combined rate of 3–5% for all other possible complications.

Possible complications that are regularly discussed with patients preoperatively include infection, hematoma, hoarseness from recurrent laryngeal nerve injury, dysphagia from retraction on the esophagus, soft tissue injury in the neck (including esophagus and airway), cerebrospinal fluid leak, nerve injury, paralysis, and complications from anesthesia. More unusual complications can include Horner's syndrome from a too lateral dissection, superior laryngeal nerve injuries from high cervical dissection resulting in a risk of aspiration, and vertebral artery injury. C5 nerve root palsies are also possible from an anterior approach.

In a retrospective review of a cohort of 1015 patients who underwent ACDF at their institution, Fountas et al. (2007) reported the incidence of complications relating to the anterior approach to the cervical spine. They found the overall rate of morbidity to be of 19.3%. The main postoperative complications included dysphagia (9.5%, mostly transient), hematoma (5.6%), laryngeal nerve palsy (3.1%), dural tear (0.5%), esophageal perforation (0.3%), worsening myelopathy (0.2%), wound infection (0.1%), and mortality (0.1%). These are all complications that can also be associated with CTDR.

Complications Related to the Prosthesis

Although the rate of complications associated with the implanted prosthesis in CTDR seems to be very low, several issues have been reported. As each different type of prosthesis has a different design, the issues that have been reported vary from one type to another.

In their preliminary report on CTDR using the Bryan disc (Medtronic, USA) in a group of 60 patients, Goffin et al. (2002) reported that they identified possible device migration of more

than 2 mm but less than 3 mm in two patients. In their follow-up report, the same group reported a third case of device migration (Goffin et al. 2003). The authors attributed this phenomenon to inadequate initial milling of the vertebral body endplates when inserting the device. Indeed, one of the steps to implanting a Bryan disc involves inserting a milling/drilling device between both endplates and compressing them over this drill so that they can acquire the proper concavity to accept the prosthesis. Issues with this step of the surgery can therefore lead to improper placement and subsequent migration.

Some prostheses have a metal keel that must be implanted in the vertebral body, and this has been a source of complications as well. The ProDisc-C (Synthes, USA) is composed of two articulating surfaces which are each connected to a keel that must be inserted in the vertebral bodies above and below the disc space being treated. Shim et al. (2007) report a case of CTDR during which the vertebral bodies involved both fractured posteriorly when the authors were using a chisel to prepare them to receive the device's superior and inferior keels. They identified this intraoperatively and were able to remove any bone fragments that were compressing the thecal sac. Tu et al. (2012) present a similar situation in which the superior vertebral body was found to have a sagittal split fracture after the insertion of a ProDisc-C device. The patient was treated conservatively. See Fig. 1 for an example of a keel-based prosthesis.

We found two reports of outright device failure because the hardware's material fissured or cracked. Fan et al. (2012) present a case of Bryan disc failure, in which the prosthesis itself was found to have developed a fissure 8 years after implantation. Similarly, Nguyen et al. (2011) present a case of CTDR in which a prosthesis with a ceramic surface was found to have cracked leading to recurrent symptoms.

Interestingly, we also found one report in which a patient developed an inflammatory reaction to the implant, and this was assumed to be because of intolerance or allergy to the material used. Cavanaugh et al. (2009) report that a patient who underwent a one-level CTDR returned 6 months postoperatively with recurrence of symptoms. Imaging revealed a mass behind the implant which turned out to be inflammatory tissue at reoperation. The authors conclude that the patient was likely hypersensitive to one of the components of the implant.

Fig 1 This lateral cervical radiograph demonstrates a keel-based prosthesis, the ProDisc-C (Synthes, USA). This patient did not suffer any complications during surgery and has not developed any HO

Adjacent Segment Disease

The main goal of CTDR is to preserve motion at the operated level. In theory, this preserved motion is also supposed to decrease the incidence of adjacent segment disease (ASD). This issue remains controversial, however, with differing reports of long-term outcomes when CTDR is compared to ACDF.

Robertson et al. (2005) compared the incidence of ASD at 24 months postoperatively in a group of patients who underwent CTDR to that of a group

of patients who underwent ACDF in a prospective clinical trial. This trial included 74 patients undergoing CTDR and 158 patients undergoing ACDF. The authors found that at 2 years of follow-up, the CTDR group showed a significantly lower rate of ASD compared to the ACDF group (17.5% vs. 34.6%, $p = 0.009$).

A different conclusion was however reached by the group of Nunley et al. (2012). They analyzed the data from three prospective randomized trials comparing CTDR to ACDF. Their pooled data resulted in a cohort of 113 patients who underwent ACDF and 57 patients who underwent CTDR. The authors found that at a median follow-up of 42 months, both groups showed a similar rate of ASD (14.3% vs. 16.8%, annual rate of 3.23% in the ACDF group and 3.77 in the CTDR group).

A more recent paper by Janssen et al. (2015) presents longer follow-up data of a randomized controlled trial of CTDR versus ACDF. They present data at 7 years of follow-up for 79 patients who underwent CTDR and 73 patients who underwent ACDF. The authors found that significantly more patients in the ACDF group had to undergo revision surgery for ASD than in the CTDR group (13 vs. 6 patients).

Although it remains controversial as to whether CTDR leads to lower rates of ASD than ACDF, ASD is a phenomenon that does occur with CTDR, and we believe it should be discussed with patients.

Conclusion

CTDR can be complicated by HO, as well as by issues related to the anterior approach to the cervical spine, by issues with the prosthesis used and by ASD. Nonetheless, the data presented in this chapter demonstrate that CTDR is an overall safe procedure and that HO has a limited effect on clinical outcomes. More research is needed to better delineate the exact pathophysiology of HO as well as its natural history. We believe that it is only once the phenomenon is better understood that effective strategies to prevent it will be found.

Lumbar TDR Revision Strategies

Paul C. McAfee and Mark Gonz

Contents

Abstract

At the University of Maryland St Joseph Medical Center (UMSJMC), we have become a tertiary referral center for revision anterior retroperitoneal and transperitoneal approaches. To date we have performed over 500 repeat anterior approaches and over 100 revisions for failed lumbar arthroplasty referred from Elsewhere General.

With current lumbar TDR designs, the lumbar spine is approached anteriorly for numerous reasons. These include (1) minimal morbidity allowing for short recovery times; (2) unobstructed visualization of the disc space, allowing for total discectomy and accurate implant sizing; (3) the absence of the need to enter or retract posterior neural structures in the spinal canal; and (4) the familiarity of territory for many spine and vascular surgeons. Accordingly, the approach-related risks are both predictable and relatively low. In contrast, revision approaches to the anterior lumbar spine are about six times higher risk for major bleeding or thromboembolic complications due to

adhesion formation, which prevent accurate identification of the great vessels. The anterior lumbar spine therefore remains a relatively facile approach as an index procedure but is fraught with potential complications in any revision situation. In our experience, many failures of lumbar disc replacement could have been avoided as they can be traced to surgeon-specific factors (as opposed to patient-specific factors) such as incomplete discectomy, improper device insertion, or inappropriate indications.

Our approach for revisions is to over-prepare – assume you will have suboptimal visualization between fascial planes. This means we place ureteral stents to palpate the ureters. In addition, in the event of inadvertent entering of the ureter, the stent facilitates suture repair by acting as a conduit in the early postoperative period. Occasionally for high-risk cases, we also prophylactically cannulate the femoral vessels. This allows faster intraoperative endovascular passage of balloons intraoperatively to assist hemostasis. In addition we can pass covered vascular stents up from the femoral vein and artery in an endovascular technique in the event of friable vessels with limited exposure in a deep retroperitoneal revision.

Keywords

Revision disc replacement · Spinal deformity · Spinal reconstruction

Key Points

1. Revision lumbar anterior retroperitoneal approaches are perhaps the most risky procedures in spinal surgery due to adhesions and difficult visualization of the very friable lumbar veins.
2. It behooves the spine surgeon to have a great working relationship with a vascular specialist and to over-prepare for repeat anterior retroperitoneal approaches.
3. Removal of the prosthesis requires being able to distract the disc space to gain working room between the vertebral endplates.

Introduction

One of the key considerations in approach for surgery in failed total disc replacement is to be able to differentiate between "pilot error" (suboptimal surgical technique) and inherent problems with the technology (metal-on-metal wear debris, osteolysis, poor ingrowth fixation, etc.). The best method for distinguishing inherent shortcomings of the technology is to present the immediate postoperative radiographs to a consensus group of experts – if the experts can predict the subsequent mode of failure, then one is dealing with a complication in surgical technique. However, if a consensus group of experts cannot predict the eventual mode of failure, then the complication is due to an inherent problem in the prosthetic design or biomaterials (Fig. 1).

Implant Failure: UHMWPE Core

Polyethylene core fractures, core dislocations, or implant breakage have been more common with UHMWPE implants. Instances of excessive polyethylene wear and osteolysis have been quite rare and have uniformly occurred in patients implanted before US FDA approval. David reported a case of polyethylene failure due to oxidation 9.5 years following implantation. Similarly, as reported in the largest series of TDR failures reported to date, there was one case of detectable polyethylene core wear noted 12 years postoperatively. Since 1997, an industry-wide enhancement to the sterilization process of polyethylene, whereby irradiation occurs in an inert gas such as nitrogen rather than air, has resulted in dramatically improved wear characteristics due to a reduction in the incidence of oxidation. This results in an increase in cross-linking or highly cross-linked UHMWPE – this improves wear characteristics but increases the brittleness of the core implant. This corrective preventative action of avoiding polymerization and reducing the UHMWPE wear rate was born out of the total hip implant experience on partially cross-linked UHMWPE. In contrast to the above cases, analysis of a retrieved polyethylene core from a

Fig. 1 These are the lateral (**a**) and the anteroposterior (**b**) radiographs of a 56-year-old woman who demonstrated a serum-confirmed nickel allergy shortly after implantation of this L5–S1 cobalt-chrome alloy arthroplasty. She also had undergone posterior fixation of an L5 spondylolysis with instrumentation from Elsewhere General. We performed anterior removal of the prosthesis and anterior lumbar interbody fusion at L5–S1 using allograft with buttress screws. The posterior instrumentation was revised into L5–S1 conventional pedicle instrumentation for increased stability. The lateral (**c**) and anteroposterior (**d**) radiographs demonstrate a stable 360 fusion and instrumentation. We advocate a combined front and back approach for most revisions following arthroplasty revision. The patients' metal allergy resolved

revision surgery performed for bone-implant loosening 1.6 years postoperatively in a patient implanted post-1997 demonstrated low levels of oxidation with mechanical properties that were not substantially degraded. At the time of this writing, there are only two published cases of anterior dislocation of the polyethylene inlay of a ProDisc artificial disc replacement. We have had over ten cases of posterior core dislocations presented from Elsewhere General. These are some of the most difficult revisions as the patients present with severe pain, pressure of the core on the cauda equina, and leg weakness. The key surgical step in the revision technique is to be able to insert a skeletal distraction device between the failed vertebral bodies to be able to distract the disc space. This is analogous to a Caspar distractor in the cervical spine. One has to distract the lumbar disc space to increase the working space in order to atraumatically remove the failed implant. Invariably we remove the core first and then reach vertebral endplate, in succession. With a keeled prosthesis, the loosening of the metal-bone ingrowth is achieved with a narrow osteotome.

Porous Ingrowth Failure and Loosening

Metal-bone interface complications account for the greatest number of failures of lumbar disc replacement, and the mode of failure depends on the type of device. Sagittal vertebral body

fractures can occur with keeled devices because the keel slot creates a stress riser in the bone. Two-level implantations in which keel slots are introduced into the superior and inferior aspects of the intercalated vertebra are at highest risk for this complication. To reduce this risk, the MAVERICK keel has been reduced from 11 mm to 7 mm[19]. In contrast, implants with smaller "anchors" at the bone-implant interface, such as the CHARITE, in which six 3 mm teeth engage the vertebral endplate, exhibit a greater tendency to migrate or dislodge if improperly placed. In the CHARITE US IDE study, there were 15 of 347 implantations that required removal, and none of these had been inserted in the "ideal" position[3]. Regardless of the design, TDR placement anterior to the center of rotation, especially in a hyperlordotic segment, will have a tendency to migrate or dislocate anteriorly due to excessive shear. Spondylolysis and spondylolisthesis present a biomechanically less stable environment for TDR and explain some of the early failures by migration and should be considered an absolute contraindication to lumbar TDR. Damage to the vertebral endplate during insertion, placement of a TDR in an osteoporotic spine, inaccurate positioning, and insertion of an implant that is too small are all factors that can contribute to TDR subsidence. In van Ooij and coworkers' report of 27 complications of the CHARITE device, there were 16 cases of subsidence. The cause, prevalence, or incidence of these failures could not be determined as the study was retrospective without mention of the total number of cases. Strict adherence to indications, surgeon education, and DEXA with preoperative correction of osteoporosis should theoretically reduce the incidence of this complication (Fig. 2).

Spinal instability has a greater tendency to occur in multilevel implantations. Preoperative scoliosis is a relative contraindication to TDR; however, subtle coronal and sagittal plane deformities may not be taken into account. TDR insertions in these scenarios will likely exacerbate rather than reduce any deformity because stabilizing structures such as the anterior and posterior longitudinal ligament as well as the majority of the annulus are removed during the implantation. Even in the well-aligned spine, incomplete discectomy and "off-axis" TDR placement at one level can create an "off-axis" situation at the next level (a so-called Z deformity). Thus when more than one vertebral level is to be implanted, device placement errors will tend to be compounded at sequential levels of insertion resulting in a "Z deformity." The principle concept is that cervical disc replacement adds inherent rotational stability to the cervical spine – unfortunately lumbar TDR adds to rotational instability to the lumbar spine. This is well documented by McAfee et al. in our laboratory (McAfee et al. 2006b) due to the posterior position of the lumbar facets, the relatively small cross-sectional area of the lumbar facets, and the relative importance of the anterior longitudinal ligament (ALL) in the lumbar spine body. For these three reasons, multiple levels of cervical TDR increase the cervical spine stability, whereas multilevel lumbar TDR decreases lumbar spine stability postoperatively.

Wear Debris and Cytokine Reaction: Prosthetic Inflammatory Response

Particulate debris generated from virtually any articulating biomaterial is characterized by macrophage recruitment and pro-inflammatory cytokine release. The culmination of this cascade is matrix metalloproteinase activation, which leads to bone resorption and osteolysis. Osteolysis is a well-documented complication of total joint replacement; however, most investigators agree that it will not be prevalent following TDR. One reason for the potentially reduced risk in the spine is the fact that the intervertebral disc lacks a surrounding synovial space, the key source for macrophages, and other inflammatory cells. The second reason is the relatively reduced range of motion and, hence, reduced volumetric wear in TDR compared with typical diarthrodial joint replacement. With over 20 years of global experience and over 10,000 TDR implantations worldwide, there are only anecdotal reports of osteolysis, and to our knowledge, only one has been documented histologically. Heterotopic

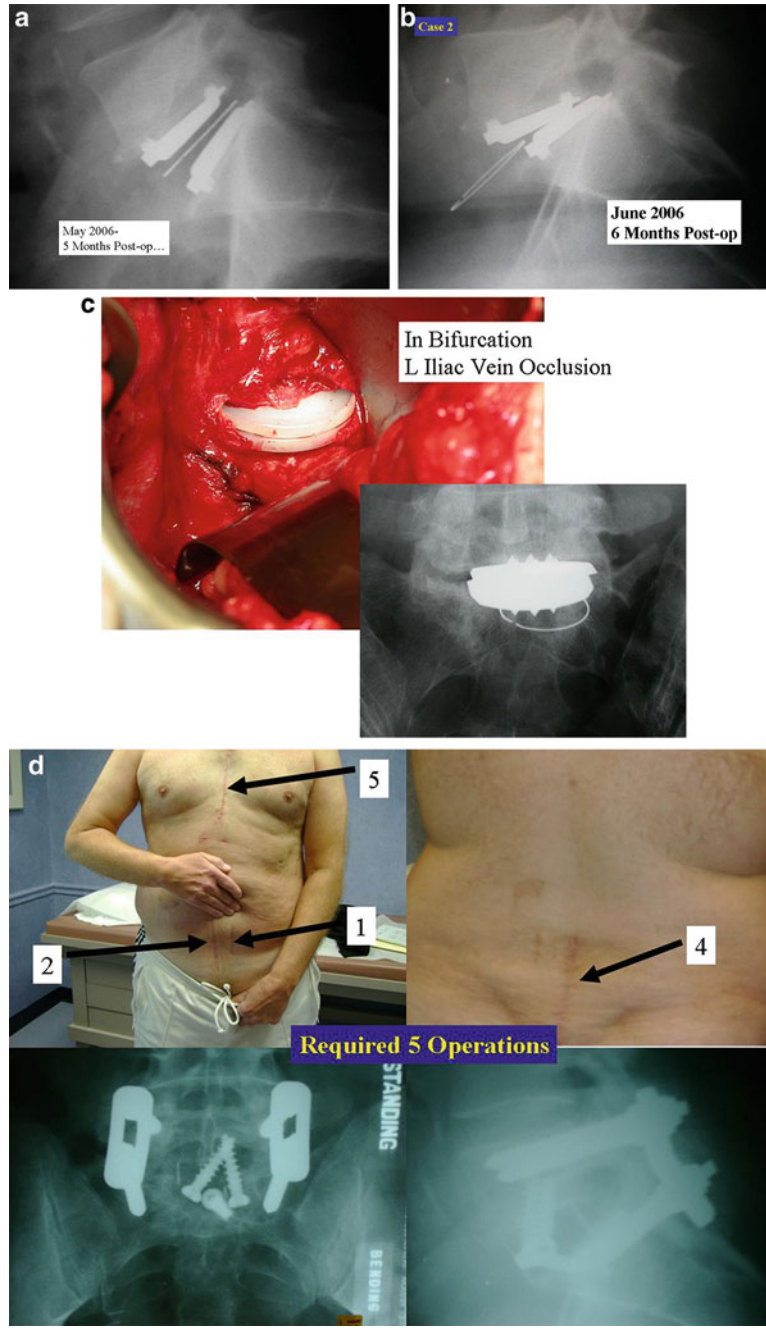

Fig. 2 (**a**) This 51-year-old executive underwent L5–S1 CHARITE disc replacement without incident. (**b**) Unfortunately 6 months following the surgery, he bent forward to pick up a heavy object, and he displaced the UHMWPE core of the prosthesis anteriorly. (**c**) A venogram was performed as part of the diagnostic workup of the anticipated revision surgical procedure. It demonstrated complete occlusion of the left iliac vein. This required insertion of an IVC umbrella at the start of the anterior revision procedure to avoid pulmonary embolism. (**d**) Following anterior and posterior arthrodesis and instrumentation at L5–S1, the patient also required CABG. In total the patient required five operative procedures. The illustration indicates no further migration of spinal instrumentation in this complicated patient requiring anticoagulation

ossification (HO) surrounding lumbar TDR implants has been classified previously by McAfee and colleagues in preparation for the CHARITE US IDE trial. In this trial, the incidence of HO was 4.3%; however, the presence of HO did not have any impact on flexion-extension range of motion or clinical outcome. We know of no other lumbar TDR trial in which the presence of HO has been systematically evaluated; however, isolated cases of periannular ossifications have been reported. To be fair, however, the imaging characteristics of the lumbar devices,

which are typically cobalt-chrome or stainless steel alloys, do not allow for identification of all but the larger amounts of periannular bone formation.

Nerve Root Compression from Implant Migration

Nerve root compression is occasionally found in cases of lumbar TDR when compared with fusion controls in prospective randomized evaluation. Most cases of revision surgery in the CHARITE US IDE trial involved reoperation with laminectomy and foraminotomy for new neurologic symptoms in the lower extremities. After any anterior discectomy and instrumentation, patients should be asked if they have any "new" pain in their legs that was not present preoperatively, and a thorough neurologic examination should be performed in the postanesthesia care unit. If there are any new neurological complaints or physical exam findings (i.e., motor or sensory loss), a CT scan with myelographic contrast should be performed to assess positioning of the implant and ensure that a hematoma, bone fragment, or disc material is not present in the spinal canal or neuroforamina. MRI is not particularly helpful postimplantation due to metal artifact obscuring the regions of greatest interest. By rapidly diagnosing the cause for new neurologic symptoms with appropriate imaging, early revision such as implant repositioning is possible. Neurologic injury without radiographic abnormalities is a complication that typically presents with left-sided leg pain in the L4 or L5 dermatome. First reported by Thalgott and *colleagues*, this complication has been thought by some to be due to excessive retraction of the lumbar plexus during the retroperitoneal exposure[26]. The lumbar plexus is at highest risk when exposing the L4–L5 disc space. To mobilize the left common iliac vein to the patient's right side, the iliolumbar vein(s) needs to be identified and ligated as it courses dorsally between the lumbar nerve roots located under the psoas muscle. Alternatively, such symptoms have been thought to be sympathetic mediated and result from the vascular exposure, as similar symptoms may be seen following non-spinal vascular dissections. In either case, whatever the etiology, the dysesthetic pain pattern typically resolves after 6–8 weeks; however, corticosteroid selective nerve root blocks may help minimize the symptoms. Notwithstanding, the burden of proof remains to demonstrate that the acquired symptoms are not due to new nerve root compression, which may be remedied with further surgery.

Biomechanical Instability

Excessive motion is a phenomenon that is not a prevalent mode of failure for TDR but likely underdiagnosed. It is defined as motion exceeding the natural motion arc in six degrees of freedom from the native motion in a specific patient's functional spinal unit. This motion results in subclinical instability that the body senses and in turn attempts to combat. This can present with postoperative muscle spasms and unexplained and chronic postoperative pain. It is a diagnosis of exclusion. The TDR is typically in excellent position without signs of dislodgement, dislocation, or subsidence. The hallmark is significant hypertrophy of the facet joints. Because the workup algorithm follows closely to ruling out spondylolysis, a CT scan can be very helpful in characterizing this hypertrophy. To determine surgical candidacy following exhaustive conservative management which typically includes long-acting narcotics, local facet blocks are the major objective tool to assess pain relief. Care must be taken to counsel the patient to give feedback following the injections to pay close attention to the duration of relief that may ensue corresponding to the half-life of Marcaine. If the patient notices a significant decrease in pain, a stabilizing procedure in the form of a posterolateral fusion with instrumentation can be discussed as an option of treatment. There is presently no way of predicting which patients will be affected by this phenomenon. Some surgeons have pointed to facet orientation as a predisposition. Especially at L5–S1, more sagittally oriented facets in conjunction with sacral inclination can predispose to increased

facet forces and this mode of failure. When diagnosed properly with facet blocks, patients have had resolution of pain and spasms and likewise weaned off of narcotics completely.

Vascular Revision Strategies

Revision total disc replacement is a potentially life-threatening procedure and should be reserved for indications that justify the increased risk.

Revision anterior exposure within 2 weeks of TDR incurs relatively little additional morbidity because adhesion formation is minimal. For this reason, surgeons should have a low threshold for revising implants that are clearly malpositioned or exhibit early migration within this 2-week time frame. If the prosthesis can be repositioned or revised to another TDR, without damage to host bone, it seems reasonable to do so. Beyond this period of time, a revision strategy must be individualized to the particular clinical situation. A posterior instrumented fusion with or without a decompressive laminectomy is currently the most effective salvage procedure. Preoperative planning is critical to a successful anterior revision. The authors analyze the cause for failure to establish individual goals for the revision. Corrections such as polyethylene replacement, size, or position changes are relatively easy to anticipate. Appropriate patient counseling regarding the increased risks, potential for changes, or need to abort the original plan for safety considerations is also critical. Reviewing the initial operative reports, clinic notes, and original indications can be particularly enlightening if a revision to a TDR is contemplated. If a patient failed to meet indications for a TDR at the index procedure, it is unlikely that they will meet indications at the revision. Patients with significant host bone loss, deformity, or instability should be revised to an interbody arthrodesis.

In our experience, major vascular injury, deep venous thrombosis, and potential ureteral injury are at particularly increased risk in the anterior revision scenario, and our operating room preparation strives to mitigate these risks (McAfee et al. 2003, 2006a, 2006b). Ureteral stenting is easily performed preoperatively and is valuable not only for intraoperative identification of the ureter but also for maintaining ureteral patency during the healing phase if an injury were to occur. Significant reduction in the somatosensory-evoked potentials of one leg may be the first indicator of excessive arterial retraction, and for this reason, we routinely utilize this form of somatosensory (SSEP) monitoring. Placing a pulse oximeter probe on the great toes is another form of monitoring that can assist in detecting excessive arterial retraction or occlusion. Often temporary relaxation of the retractors will result in normalization of the SSEP or pulse oximeter readings. We currently insert inferior vena cava (IVC) filters preoperatively as postoperative lower extremity duplex evaluations have missed a deep venous thrombosis (DVT) in the pelvic great vessels which progressed to a postoperative pulmonary embolism (PE) (Tortolani et al. 2006). Finally, we prepare the inguinal region into the operative field through which percutaneous vascular access wires are placed into the right and left femoral veins. If an injury to one of the venous great vessels occurs, balloon catheters can be inflated to tamponade and control bleeding in a timely fashion.

The specific revision surgical approach depends on the reason for failure and the original surgical approach; however, the currently available options include posterior decompression, posterior decompression and instrumented fusion, anterior TDR removal and fusion, or anterior TDR removal and reinsertion. Usually anterior TDR removal and conversion to fusion is the safest salvage strategy because gaining the exposure necessary to implant a new disc replacement is rarely possible due to adhesion formation. Our attitude is we perform anterior and posterior arthrodesis for L4–L5 revisions because we want this to be the absolute last time the great vessel dissection should ever be required. Anterior interbody fusion devices typically require less exposure and can be inserted obliquely across the disc space. This can be extremely handy when the only accessible area to the disc is to one side. Revision to a TDR is no longer a consideration in our experience in the lumbar spine.

Revision anterior exposures should always be performed with an experienced vascular access surgeon, and gaining access via a virgin territory is desired but rarely possible. At L5–S1, if a left-sided retroperitoneal approach was utilized at the index procedure, then transperitoneal or right-sided retroperitoneal approach can be considered. Conversely, if a transperitoneal approach was used at the index procedure, then a right- or left-sided retroperitoneal exposure can be considered. L4–L5 and higher is always more challenging because the left-sided retroperitoneal approach is virtually always utilized during the initial exposure. Transperitoneal and right-sided approaches are technically far more demanding at L4–L5 because of the central to right-sided position of the IVC. For this reason, anterior revisions to L4–L5 should be performed via a transperitoneal or through the same left-sided retroperitoneal approach. By identifying the left psoas muscle, one can generally palpate the lateral border of the lumbar spine, and, from this point, a subperiosteal dissection can facilitate safe exposure toward the midline and beyond. In the end, the experience and comfort level of the access surgeon will be as, if not more, important than the type of approach used during the index procedure.

Given the aforementioned technical challenges, the most common salvage procedure for failed TDR is posterior instrumented fusion with pedicle screws. This technique essentially locks the prosthesis from any further movement and allows for bone grafting in the posterolateral intertransverse region. Cunningham et al. found that pedicle screws alone combined with a lumbar disc replacement were not found to be statistically different biomechanically from pedicle screws and a femoral ring allograft. Posterior hemilaminectomy or laminotomy without fusion is an alternative for focal disc or bone displacements into the spinal canal; however, extreme care must be taken to avoid destruction of stabilizing structures like the facet joints.

Conclusions

Lumbar TDR is a safe and effective treatment option for appropriately selected patients with lumbar degenerative disc disease. Bone-implant failures can be prevented by strict adherence to FDA indications and accurate placement of the device. For at least one device, suboptimal positioning has been correlated with worse patient outcome, a finding which will likely be borne out for other TDR designs. Device failures for current designs are rare and are characterized by polyethylene fracture or dislocation. Anterior revision surgery with an experienced access surgeon and preoperative placement of ureteral stents, vena cava filters, percutaneous vascular access wires, and spinal cord monitoring can reduce the risks of major vessel injury or thrombosis.

Abstract

Motion preservation technology in the lumbar spine is not confined to lumbar disc arthroplasty. Pathology involving the posterior elements of the lumbar spine is often the source of pain generation and stenotic symptoms. Posterior-based motion preservation systems fall under two categories: facet arthroplasty and posterior dynamic stabilization (PDS). Several devices have gone through clinical trials since initial introduction in the early 1990s for PDS systems and mid-2000s for facet arthroplasty systems presenting viable alternatives to lumbar fusion. Understanding the anatomy and the biomechanical forces acted on the lumbar region has led to the creation of these devices with goals of symptomatic relief, motion preservation, and prevention of adjacent segment disease.

Introduction

There has been significant advancement in spinal implants and the treatment of spinal pathology over the last few decades, including a resurgence of motion preservation and joint arthroplasty. While we still have much to learn concerning the pain generators and correlating pathology of the lumbar spine, procedures such as total facet arthroplasty and posterior dynamic stabilization allow for additional tools in a surgeon's armamentarium.

Historically, the standard of care for degenerative pathology with instability of the lumbar spine has been fusion with or without instrumentation. Dynamic stabilization has emerged as a viable alternative to the standard of care. To begin addressing some of the concerns with fusion, posterior dynamic stabilization was introduced beginning with the development of the Graf ligament in 1989 and subsequently the Dynesys (Zimmer Spine, Minneapolis, MN) in 1994. The facet joints have also been targeted as another potential pain generator of the lumbar spine. Total facet arthroplasty has arisen as a treatment option for spinal stenosis as well as degenerative spondylolisthesis, allowing for an alternative to spinal fusion and the ability to address the facet joints as possible lumbar pain generators.

Throughout this chapter, we will review the biomechanical basis as well as clinical literature supporting the role of posterior-based dynamic stabilization (PDS).

Facet Anatomy and Biomechanics

The facet joint is critical to the proper motion of the functional spine unit which consists of the disc, the facet joints, and the ligaments. The motion at each segment is determined by the health of each of these components. Each vertebral segment interacts with the adjacent vertebral segment by means of five articulating joints; the disc and the four facet joints at each level. These components share the loads as they are transmitted through the spine. The facet joint acts like a cam with a multi-radius arc of motion that is engaged as the spine moves. This assists with proper spinal motion, protection of neurologic structures, and transferring of load through the spinal column (White and Panjabi 1978). These diarthrodial, synovial joints bear weight in both compression and shear providing functional range of motion (ROM) while limiting excessive ROM. They help to protect the lumbar disc from excessive stress. Due to this mutualistic nature of disc and associated facets, the degenerative changes in the disc lead to increased loads and progression of degeneration in the facets (Webb and Holen 2008) (Fig. 1). The loads are transferred through each component, and as the spine ages, their interaction with each other changes. The loads transferred are going to vary depending on the health of the segment.

Lumbar facets require high load transmission and therefore are significantly larger than cervical facets. ROM is limited in the lumbar segment with the focus in flexion and extension. The ability of the facets to share the load with the intervertebral disc is position dependent with a load sharing of 0% in full flexion to 33% in full extension (Panjabi et al. 1989). The facets are located more centrally with an adducted positioning to prevent hyperextension and rotational torsion (Webb and Holen 2008). The amount of sagittal angulation increases as you move caudally in the lumbar spine. In childhood, the facets are angled more posteriorly with a transition to a more sagittal position with age; this can be a factor in many of the facet-related issues (Scoles et al. 1988). The lumbar facets main function is to prevent anterior shear which has been proven to damage the intervertebral disc (Reily 2011). Resistance increases toward the endpoint of motion. This gradual increased resistance protects the joint and the adjacent structures by

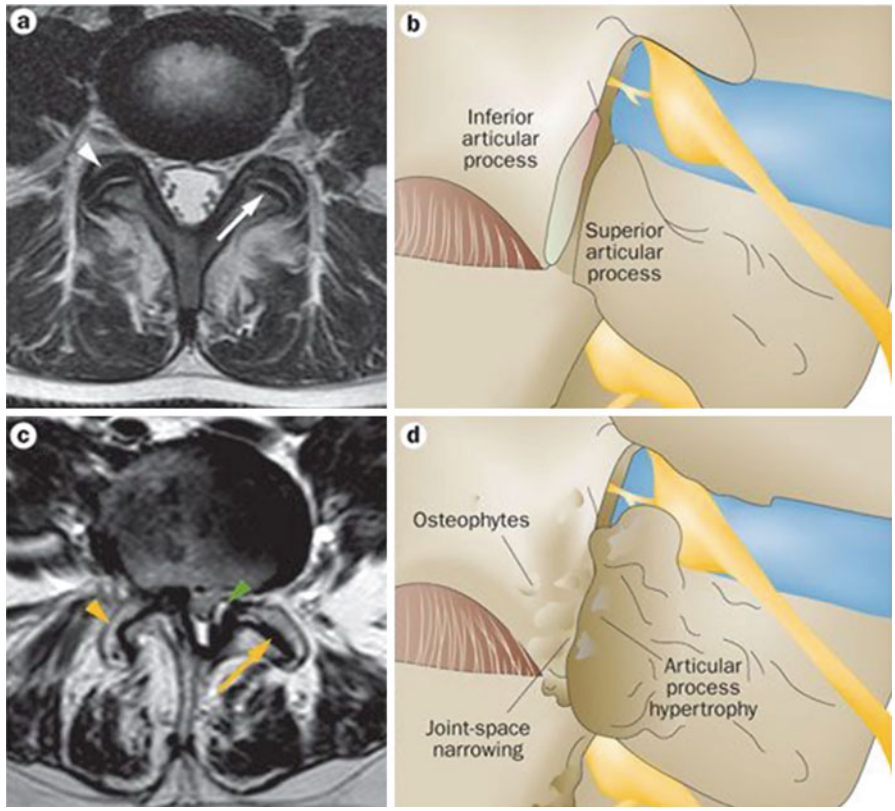

Fig. 1 Normal facet joints and advanced facet joint osteoarthritis. (**a**) T2-weighted axial MRI image of normal facet joints with no joint-space narrowing (white arrow), and no osteophytes or articular process hypertrophy (white arrowheads). (**b**) Normal facet joints. (**c**) T2-weighted axial MRI image of osteoarthritic facet joints with joint-space narrowing (yellow arrow), osteophytes and articular process hypertrophy (yellow arrowhead). Facet joint osteoarthritis, disc-bulging, and a facet joint synovial cyst (green arrowhead) in combination lead to stenosis of the central canal and lateral recesses. (**d**) Osteoarthritic "facet joints." (Gellhorn et al. 2013)

providing a soft stop. When anterior shear load is applied suddenly, the facets carry 1/3 of the load, while the disc carries 2/3 of the load; when the load is applied over time, the majority of the load is carried by the facets (White and Panjabi 1978). Nachemson (1960) used pressure transducers and determined that the facets carry approximately 15% of vertical load in the lumbar spine. Yang and King (1984) established the mechanism of facet transmission of axial load in cadaveric specimens by the use of an intervertebral load cell with results demonstrating a normal facet carrying 3–25% of the load, while an arthritic joint could carry as much as 47%.

The facets are surrounded by capsules that are innervated by type I, II, and III mechanoreceptors. This neural input allows for positional feedback for postural control. Destruction of this innervation may also be a key role in the disease process (Webb and Holen 2008). Cavanaugh et al. (1996) concluded that these nerves are activated by capsular stretch and by neurogenic and non-neurogenic modulators of inflammation, including substance P, bradykinin, and phospholipase A2. Facet joint surfaces are covered with hyaline cartilage that undergoes degenerative changes to its mechanical properties similar to the processes that occur in other joints. The loss of articular cartilage leads to spur formation thought to stabilize the joint. The degenerative process also leads to loss of control of anterior shear forces, facet subluxation, and increased

anterior-posterior translation (Reily 2011). This begins early in the degenerative process with the loss of 1 mm of cartilage in the facet joint being shown to significantly increase the translational motion (Reily 2011). Degeneration and inflammation lead to pain with joint motion that causes restriction and thus deconditioning.

It is important to understand how each component of the functional spinal unit performs and how each component interacts and the impact when they begin to fail. The functional spinal unit has a neutral zone where the axial force transmitted by the spine is stiffer at the extreme range of motion and less stiff near the neutral position. In other words, it requires more force to move the functional spinal unit from the neutral zone to the endpoints of motion. When one looks at the facet joint, it is apparent that degenerative changes as well as surgical intervention such as in a fusion or disc arthroplasty changes the way the facet joints at the index level and adjacent levels behave. Facet joints can be overloaded if the surgical intervention substantially changes the way the disc behaves as in a disc replacement. With a fairly non-constrained lumbar disc arthroplasty, one might expect increased facet stresses. In a fusion, the adjacent segment will experience increased loads across the facet joint. It is important to consider the impact of any surgical procedure on the overall motion of each lumbar segment and the long-term potential impact.

Rationale and Biomechanics of Facet Arthroplasty Systems

The potential benefit of posterior motion preservation devices is load sharing with the anterior and other posterior structures. Additionally, by removing pathologic structures, the symptoms associated with the facet joints including local pain symptoms can be reduced while decompressing the neural structures. The goal of posterior motion preservation devices should be to preserve motion and, by load sharing with adjacent segments, slow the degeneration of these adjacent segments compared to fusion.

Artificial facet joints should provide stability similar to the native facet joint. Ideally the design will include measures to cause the artificial facet joint to behave similar to the native joint to include resistance to flexion and extension forces. Wear of the articular surfaces should also be minimal. Robust fixation to the spine is also critical. In the case of facet replacement, there have been different types of fixation. The Total Facet Arthroplasty System (Archus Orthopedics, Redmond, WA) was a cemented implant in an attempt to enhance the fixation to the vertebral body in a potentially osteoporotic patient. Subsequent implants ACADIA (Globus Medical, Audubon, PA), and TOPS (Premia Spine, Philadelphia, PA) are screw-based implants with coatings or texturing of the screws.

Kinematically all the facet joint replacement devices have done testing that indicates that if a functional spinal unit is destabilized with the removal of the facet joints the kinematics of that segment is restored with the utilization of a facet arthroplasty implant (Fig. 2). When the facet arthroplasty implants were tested in vivo and compared to fusion constructs with loads applied, the facet arthroplasty group experienced much lower implant stresses than the fusion implant (Webb and Holen 2008).

Kinematics

- The TFAS™ effectively
  - stabilizes motion in flexion and lateral bending
  - restores the motion in extension
  - limits the motion in axial rotation
- TFAS™ restored motion of an unstable FSU to that of an intact FSU allowing considerable range of motion in all directions when compared to the intact condition

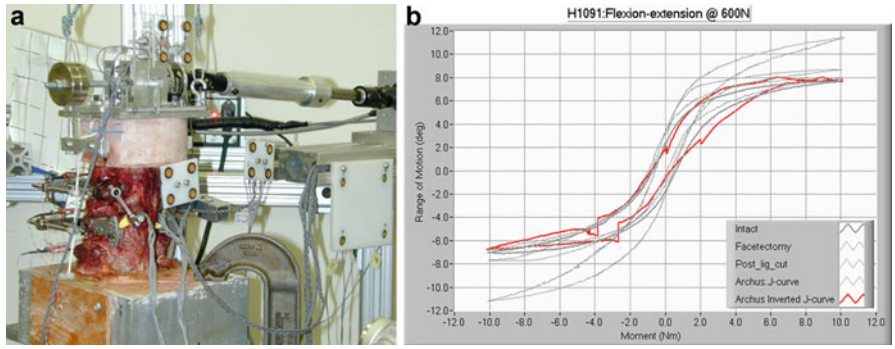

Fig. 2 Kinematic testing (**a**) demonstrated that TFAS effectively stabilized motion in flexion and restores motion in extension of an unstable functional spine unit to that of an intact unit (**b**)

History of Facet Arthroplasty Systems

The goal of posterior lumbar facet replacement systems is to use an alternative to fusion for facet degeneration and stenosis that allows for full decompression and stability while maintaining near physiologic motion (Zhu et al. 2007). The earliest facet replacements can be traced back to the 1980s, with the majority of these implants focused on articular surface replacement similar to the implants for peripheral joints (Serhan et al. 2011).

The TFAS was the initial facet replacement system to enter US investigational device exemption (IDE) in the mid-2000s. Other facet replacements soon followed including the Acadia by Facet Solutions and TOPS by Implant. They were all uniquely designed with different features to address the replacement of a facet joint in a wide decompression necessary to treat significant lumbar stenosis.

Total Facet Arthroplasty System (TFAS)

The first patient in the US IDE clinical trial of the Total Facet Arthroplasty System (TFAS) was performed on August 26, 2005 by Dr. Scott Webb (Figs. 3 and 4). This was the first time a total facet replacement had ever been performed in the United States. The TFAS implant was indicated in patients with lumbar spinal stenosis presenting predominantly with neurogenic claudicatory symptoms that required a wide decompression and stabilization.

The Total Facet Arthroplasty System (TFAS) is metal-on-metal joint prosthesis intended to provide stabilization of lumbar spinal segments in skeletal mature patients as an adjunct to a laminectomy/laminotomy/neural decompression and facetectomy in the treatment of single-level stenosis. Additional indications include degenerative facets at the index level with or without instability. Up to a Grade 1 degenerative spondylolisthesis could be present.

Due to the typical age group of patients with spinal stenosis and neurogenic claudication, the implant was designed to be implanted with cement fixation.

The implant's modularity allowed for a great deal of potential variability (Fig. 5).

Initial midterm clinical data of the US IDE trial demonstrated successful restoration of motion and clinically significant reduction of preoperative symptoms. ZCQ symptom and ZCQ function scores improved by 84% and 81% compared to preoperative scores in the 79 TFAS IDE patients. VAS back and leg pain scores improved in 73 of 79 and 75 of 79, respectively. Radiographic analysis showed all devices to be intact and functioning at time of follow-up (Sachs et al. 2008).Unfortunately,

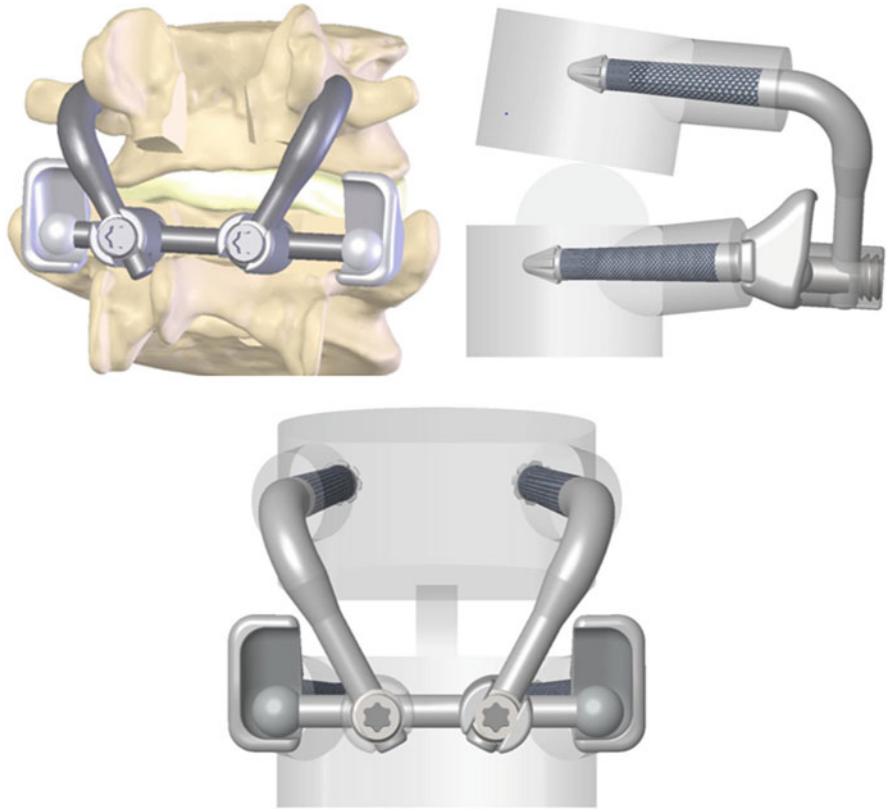

Fig. 3 Total Facet Arthroplasty System (Archus Orthopedics, Redmond, WA) (attempted to obtain permission from Archus Orthopedics but company no longer exists)

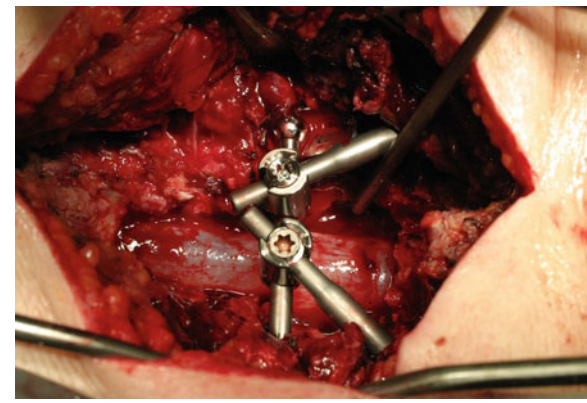

Fig. 4 Intraoperative imaging of TFAS (Scott Webb)

volume wear of metal debris in the TFAS implant was found to be comparable to metal-on-metal hip (M-o-M) implants in regard to particle size and distribution. The fear of similar outcomes despite significantly different biomechanics led to the removal of the product from the market. TFAS pioneered facet arthroplasty and demonstrated safety and efficacy in a small number of patients with limited follow-up.

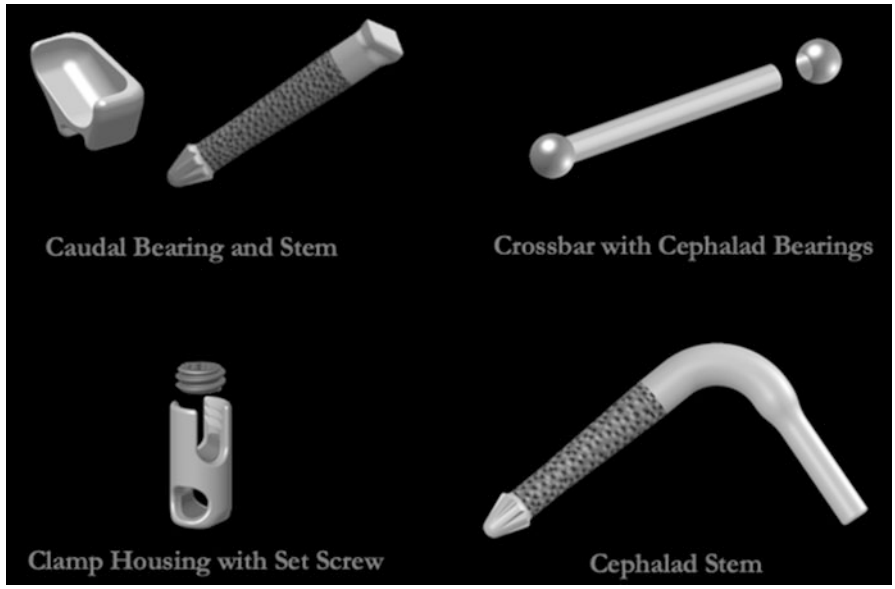

Fig. 5 TFAS components allowed for significant variability creating a custom fit for patient's anatomy

Fig. 6 ACADIA Facet Replacement System (AFRS) (Globus Medical, Audubon, PA)

ACADIA Facet Replacement System (AFRS)

The ACADIA Facet Replacement System (AFRS) (Globus Medical, Audubon, PA) formerly Anatomic Facet Replacement System (Facet Solutions, Logan, UT) evolved under the basic principles of other articulating synovial joint implant systems with a focus on restoring normal ROM with a uniform distribution of forces (Carl et al. 2008) (Fig. 6). International clinical evaluations began in São Paulo, Brazil, in 2005 with approval in the United States for FDA IDE study coming in 2006. AFRS was also intended to provide stabilization of spinal segments in skeletally mature patients as an adjunct to laminectomy, laminotomy, and facetectomy in the treatment of single level, L3–4 or L4–5, degenerative disease of the facets with or without instability including Grade I degenerative

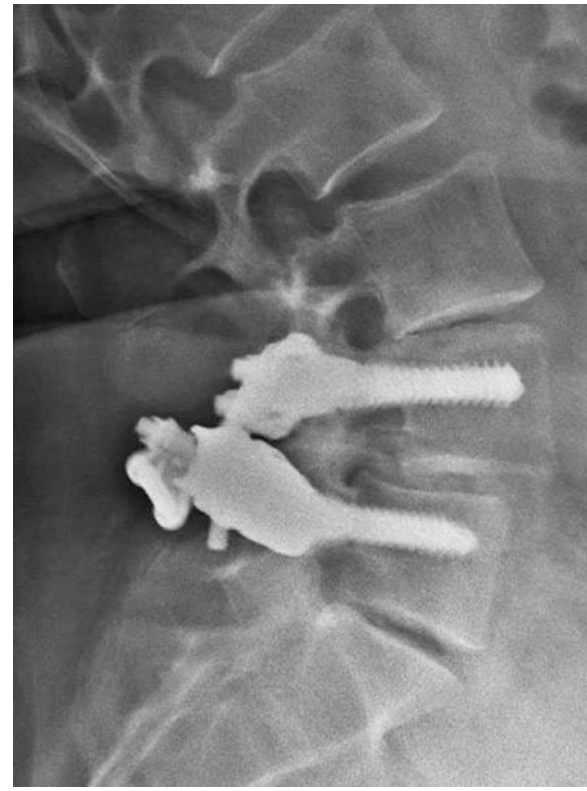

Fig. 7 Postoperative extension radiograph of ACADIA in a patient with a Grade 1 spondylolisthesis (Scott Webb)

spondylolisthesis with objective evidence of neurologic impairment, central or lateral spinal stenosis (Carl et al. 2008).

The device, like the TFAS system, is a pedicle-screw-based construct with superior and inferior facet implants with articulating surfaces made of cobalt-chromium-molybdenum. Unlike the spherical bearing TFAS system, AFRS creates metal-on-metal articulation that resembles the anatomic structure of the facet joint. A crossbar links the left and right inferior facet implants providing construct stability (Carl et al. 2008). Pedicle screws are made of titanium alloy with hydroxyapatite coatings that allow for improved bone-implant interface (Fig. 7). The polyaxial junction of the implant accommodates for $\pm 15^{\circ}$ of variability in pedicle screw placement (Goel et al. 2007).

Preliminary outcomes of the US IDE study involving 162 ACADIA patients demonstrate improvement in ZCQ, ODI, and VAS scores at 2 and 4 years post-op similar to posterior lateral fusion patients. Surgical intervention at subsequent levels occurred in 8% of ACADIA patients and 7.4% of PLF patients (Myer et al. 2014). Ultimately, the IDE trial was terminated in 2017, also due M-o-M wear debris concerns.

Total Posterior Arthroplasty System (TOPS)

The Total Posterior Arthroplasty System (TOPS) (Premia Spine, Philadelphia, PA) is a dynamic facet arthroplasty prosthesis designed to restore segmental stability following extensive posterior decompression, including facet joint resection, while maintaining near anatomic motion (Anekstein et al. 2009) (Fig. 8). The device replaces the degenerated facets and bony elements removed during decompression of the stenotic level without sacrificing motion. The TOPS device differs from previous facet replacement systems as it does not resemble an anatomic

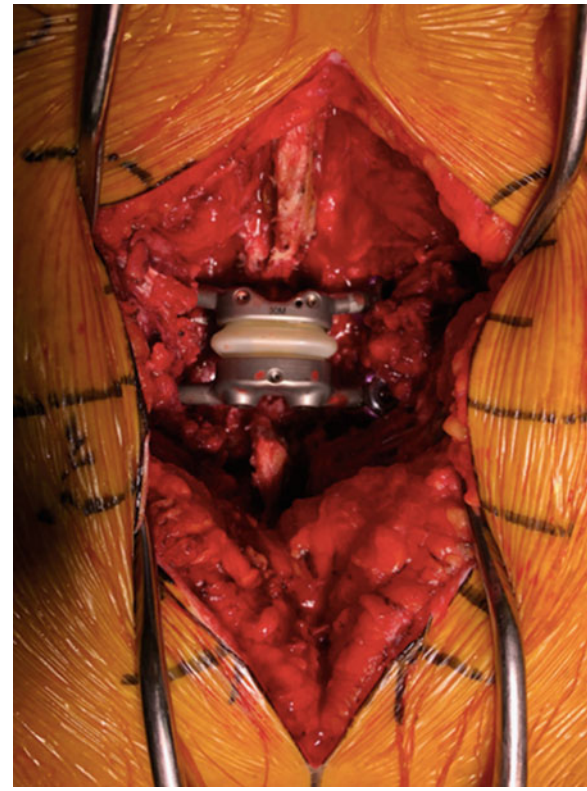

Fig. 8 Intraoperative imaging of Total Posterior Arthroplasty System (TOPS) (Premia Spine, Philadelphia, PA) (Scott Webb)

facet joint. The primary indication is symptomatic lumbar stenosis secondary to Grade 1 degenerative spondylolisthesis.

TOPS uses a cannulated pedicle-screw-based implant with superior and inferior titanium constructs fixed to a flexible, polycarbonate urethane (PCU) articulating core. The double horizontal crossbar connects pedicle screws of the same vertebrae creating better load sharing and eliminates screw head torque (Myers et al. 2008). The internal configuration of the bumper limits motion by dissipating energy during load sharing (McAfee et al. 2007). The central core is attached to all four pedicles stabilizing rotation and lateral bending as well as significantly decreasing the load transfer to adjacent segments (McAfee et al. 2007) The PCU bumper acts as a limiter of motion but also absorbs shock in the vertical axis; it incorporates a PEEK ribbon that acts as a restraint for excessive flexion. The boot creates a closed compartment that prevents wear debris from entering the spinal canal which was a major fear of product designers after the issues surrounding M-o-M hip prosthetics (Anekstein et al. 2009) (Fig. 9).

Initial investigational studies with the TOPS device began internationally in 2005, with the first US IDE study under FDA investigation beginning shortly afterward in 2006. Initial results of the study were very promising. McAfee et al. (2007) reported on 29 patients in the initial international study who had met criteria for single-level decompression and fusion of the lumbar spine underwent facet replacement. Outcomes were based on VAS, ODI, and ZCQ scores at 6 weeks, 3 months, 6 months, and 1 year. Preliminary data demonstrated improvement in all three scores and no device-related events or hardware failure. CT scans at 3 months and 1 year demonstrated no signs of subsequent disc height loss at treatment level or adjacent levels. The TOPS device has undergone some minor changes in the structure of the system and is currently undergoing a second IDE study which began in January 2017 (ClinicalTrials.gov 2017).

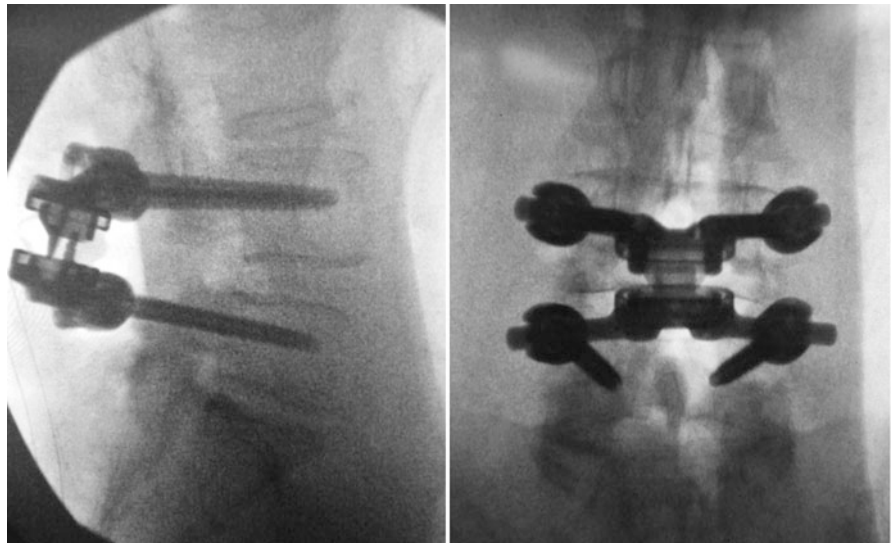

Fig. 9 Intraoperative fluoroscopic imaging (lateral and PA) of second generation of TOPS device (Scott Webb)

The TOPS device is the only posterior facet replacement device still in active US IDE study.

Interspinous Devices (ISD)

Interspinous devices have been primarily used to treat lumbar central stenosis with concomitant neurogenic claudication. These devices result in indirect decompression of the canal and neuroforamen. These devices are typically used in conjunction with decompressive surgery. Earliest documentation off interspinous devices was in the 1950's at which time metal "plugs" were placed between the spinous processes. Senegas et al. described one of the early interspinous spacers in 1988. This was a titanium device that was held to the spinous processes with Dacron tape. This was later redesigned as the Wallis Implant (Abbott Spine, Austin, TX) which used a PEEK material instead of the previous titanium. One of the more popular devices, the X-Stop (Medtronic, Minneapolis, MN) device received FDA premarket approval in 2005, initial studies were very promising, but as later data came out there appeared to be high rates of complications. Medtronic discontinued this device in 2015. The DIAM system (Device for Intervertebral Assisted Motion) (Medtronic Sofamor Danek, Memphis, TN) is another abandoned interspinous device. It is an "H-"shaped device secured by a cord to the spinous processes. The latest device to gain traction in the US market is the Coflex device (Paradigm Spine, New York, New York) (Fig. 10). The FDA has approved Coflex for 1–2 level stenosis in the lumbar spine, with some clinical data promising compared to traditional fusion. Superion (Vertiflex, Carlsbad, CA) is an interspinous device that is delivered percutaneously, similar to devices such as the X-Stop (Fig. 11). In 2015, a randomized controlled trial comparing the Superion to the X-Stop demonstrated a statistically significant benefit to the Superion over the X-Stop at 36 months.

Interspinous devices were primarily developed to treat lumbar spinal stenosis resulting in neurogenic claudication. Patients with these symptoms tend to improve with flexion; therefore these devices place the spinal segment into slight flexion or kyphosis (Richards et al. 2005). There is not compelling data to support ISD over traditional open laminectomy decompression, but it does offer an alternative to an open surgical procedure (Senegas et al. 1988). This may be an attractive alternative for elderly patients with medical comorbidities and higher surgical risk.

Conclusions

The role for motion preservation by means of facet arthroplasty and dynamic stabilization in lumbar spine surgery continues to evolve. Posterior facet remains in active FDA IDE study with promising early results for the treatment of spinal stenosis secondary to degenerative spondylolisthesis. Pedicle-screw-based posterior dynamic stabilization systems have largely fell out of favor. Interspinous spacers have developed a niche in the minimally invasive treatment of spinal stenosis. Overall, the use of posterior arthroplasty for the treatment of lumbar spine pathology remains in its relative infancy, and further study is warranted in defining its role in the future.

Abstract

Cervical disc arthroplasty (CDA) attempts to preserve normal motion at adjacent segments and in doing so may decrease the incidence of adjacent segment degeneration in comparison with cervical arthrodesis. Since 2006, the United States Food and Drug Administration (FDA) has approved seven CDA prosthetic devices for surgical management of symptomatic cervical spondylosis and disc herniation (seven for 1-level disease and two for two-level disease). Motion-preserving CDA has showed great promise with equivalent quality-of-life outcomes in many long-term comparative studies. Currently, follow-up duration of up to 10 years is available from some of the FDA trials comparing CDA to arthrodesis. In general, study findings have consistently demonstrated that both techniques result in significant clinical improvement by roughly 3 months post-op and that improvement may be maintained at final follow-up. Overall, there exists robust data to support CDA as a viable alternative to arthrodesis in select patients. However, complications such as heterotopic ossification have been reported. In this chapter, we review CDA, with an emphasis on highlighting the published long-term outcomes and complications for this motion-preserving operation in comparison with arthrodesis.

Introduction

Degenerative disc disease involving the cervical spine is part of the normal aging process (Traynelis 2004). When degenerative changes occur gradually, they may be asymptomatic; however, in a subset of patients, cervical spondylosis or disc herniation may result in compression of nerve roots or the spinal cord, resulting in radiculopathy, myelopathy, or both (Traynelis 2004). A common surgical treatment for patients with symptomatic cervical spondylosis or disc herniation is anterior cervical discectomy and fusion (ACDF) (Alvin et al. 2014). The ACDF procedure, first described over 50 years ago, has been shown to be safe and clinically efficacious (Alvin et al. 2014; Cloward 1959; Smith and Robinson 1958). However, there is debate about further degeneration at adjacent segments after fusion surgery (Gao et al. 2013; McAfee et al. 2012; Xing et al. 2013; Yin et al. 2013). Specifically, it is currently unclear if adjacent segment degeneration is part of the natural history of cervical spondylosis or whether it is related to the adjacent fused levels. Some studies have shown an average 3% reoperation rate, while other studies report revision rates exceeding 10% after 2 years to treat complications related to the index fusion operation (Hilibrand et al. 1999; Yin et al. 2013). By preserving physiologic cervical motion, one of the goals of CDA is to reduce the incidence of adjacent segment degeneration while maintaining the highly effective results of ACDF in maintenance or improvement of neck pain, arm pain, and myelopathy (Alvin et al. 2014).

The initial clinical experience with CDA began in the 1960s with Ulf Fernstrom, a Swedish surgeon, implanting stainless steel ball bearing prosthetic devices following laminectomy (Fernstrom 1966; Fisahn et al. 2017). A high failure rate and concern for hypermobility and device migration into adjacent vertebral cancellous bone ultimately led the industry back to favoring ACDF (Bertagnoli et al. 2005; Fernstrom 1966; Fisahn et al. 2017). Then later in the 1980s, CDA returned with a design by Cummins, who was developing an artificial disc to address the shortcomings of ACDF regarding motion preservation and adjacent segment degeneration. Cummins' artificial cervical disc was developed in collaboration with the Department of Medical Engineering at Frenchay Hospital in 1989, and resulted in improved clinical outcomes after implantation in appropriately selected patients (Cummins et al. 1998; Traynelis 2004; Wigfield et al. 2002b). After performing the index decompression or discectomy, the main advantage of CDA in comparison to ACDF is the possibility for postsurgical segmental motion preservation, which may prevent the occurrence of adjacent segment degeneration and disease (Alvin et al. 2014).

Since 2006, the United States Food and Drug Administration (FDA) has approved seven CDA prosthetic devices for surgical management of symptomatic cervical spondylosis and disc herniation at a single level (Coric et al. 2018; Gornet et al. 2016). In 2007, the Prestige ST (Medtronic Inc.), a metal-on-metal device made from stainless steel, was the first CDA device to receive FDA approval (Mummaneni et al. 2007). A later version with a low profile modification, the Prestige LP (Medtronic Inc.), was made from a titanium ceramic composite and received FDA approval in 2014 (Gornet et al. 2015). The other five FDA-approved devices are metal (cobalt-chrome or titanium alloy)-on-polymer (polyethylene or polyurethane) designs and include (by order of FDA approval for single-level CDA) ProDisc-C (2008; Synthes Spine), Bryan (2009; Medtronic Inc.), Porous Coated Motion (2012; Cervitech), Secure-C (2012; Globus Medical), and Mobi-C (2013; LDR Medical) (Heller et al. 2009; Hisey et al. 2014; Murrey et al. 2009; Phillips et al. 2013; Vaccaro et al. 2013). Two of these devices, the Prestige LP and Mobi-C, have since received FDA approval for CDA at two adjacent levels.

More recently, long-term studies have been published for these FDA-approved artificial discs and suggest CDA is safe and clinically efficacious in appropriately selected patients. Currently, follow-up duration of up to 10 years is available from some of the FDA trials comparing CDA to ACDF. In general, study findings have consistently demonstrated that both CDA and ACDF result in significant clinical improvement by roughly 3 months post-op and that improvement may be maintained at final follow-up (Davis et al. 2015; Heller et al. 2009; Hisey et al. 2016; Phillips et al. 2013; Radcliff et al. 2016a; Vaccaro et al. 2013; Zigler et al. 2013). CDA was found to produce noninferior results in all the studies for certain outcome variables and even demonstrated statistical superiority for some outcome measures. For single-level CDA, four of the seven discs (Prestige ST, Prestige LP, Bryan, and Secure-C) demonstrated superiority in overall success. Prestige ST showed superiority in three of four outcome variables (neurological success, revision surgery, and overall success), while the other discs showed superiority in ≤ 2 variables (Prestige LP, neurological and overall success; Bryan, Neck Disability Index [NDI] and overall success; Secure-C, revision surgery and overall success; and Pro-Disc C, revision surgery). The Porous Coated Motion (PCM) and Mobi-C discs demonstrated noninferiority for all outcome variables. For two-level (adjacent) CDA, Prestige LP and Mobi-C demonstrated superiority in three outcome variables (NDI, secondary surgery, and overall success), but not neurological success (Turel et al. 2017).

Although the aforementioned devices have met rigorous outcome requirements for FDA approval, there have been reports of complications such as heterotopic ossification (HO; abnormal bone formation around or within the intervertebral disc space) and/or implant migration (Gao et al. 2013; McAfee et al. 2012; Xing et al. 2013; Yin et al. 2013). Therefore, in this review, in addition to summarizing long-term

outcomes, we also report complications associated with CDA for the FDA-approved discs. Although not FDA-approved, we also report outcomes and complications for the Discover artificial cervical disc (DePuy Spine) due to its widespread use outside the United States (OUS). At the end of each section, we specifically report outcome variables (NDI, Visual Analogue Scale [VAS] neck score, VAS arm score, Short Form-36 Health Survey Physical and Mental component scores [SF-36 PCS; SF-36 MCS]) comparing CDA and ACDF, when available. Outcomes for two-level adjacent CDA are also summarized for the FDA-approved Prestige LP and Mobi-C discs.

Bryan Cervical Disc

Vincent Bryan designed the Bryan cervical disc (Medtronic Inc.) in the United States in 1992 (Basho and Hood 2012). The Bryan cervical disc (Fig. 1a) is a non-constrained device consisting of a low-friction, wear-resistant, polyurethane nucleus housed between titanium plates (Bryan 2002). These titanium plates have convex porous ingrowth surfaces that function to support bony fixation of adjacent vertebral end plates. Consistent with the goal of motion preservation, the Bryan disc was designed to allow normal or physiologic range of motion, as well as coupled motion in cervical flexion/extension, lateral bending, rotation, and translation (Bryan 2002). Several studies have reported significant improvement in postoperative standardized outcomes scores (NDI, VAS scores, and SF-36 scores) for Bryan CDA in comparison with ACDF, for both single- and two-level procedures in patients with discogenic cervical radiculopathy and/or myelopathy (although the Bryan disc is not FDA-approved for multilevel CDA) (Cheng et al. 2009, 2011; Coric et al. 2006, 2013; Garrido et al. 2010; Goffin et al. 2003, 2010; Hacker 2005; Heidecke et al. 2008; Heller et al. 2009; Lafuente et al. 2005; Leung et al. 2005; Quan et al. 2011; Robertson et al. 2005; Sasso et al. 2007a, b, 2011; Tu et al. 2011; Walraevens et al. 2010; Yang et al. 2008; Zhang et al. 2012). Table 1 summarizes Bryan CDA outcomes data (Alvin et al. 2014; Anderson et al. 2004; Bhadra et al. 2009; Bryan 2002; Cheng et al. 2009; Coric et al. 2006, 2010, 2013; Ding et al. 2012; Duggal et al. 2004; Garrido et al. 2010; Goffin et al. 2003, 2010;

Hacker 2005; Heidecke et al. 2008; Heller et al. 2009; Kim et al. 2008, 2009; Lafuente et al. 2005; Lee et al. 2010; Leung et al. 2005; Pickett et al. 2004, 2006; Quan et al. 2011; Ren et al. 2011; Robertson et al. 2005; Ryu et al. 2010; Sasso et al. 2007a, b, 2011, 2017; Sekhon 2003; Sekhon et al. 2005; Shim et al. 2006; Tu et al. 2011; Walraevens et al. 2010; Wang et al. 2008; Yang et al. 2008; Yoon et al. 2006; Zhang et al. 2012). The vast majority of these studies had follow-up duration of up to 2 years; however, some had over 6 years of clinical and radiographic follow-up (Pointillart et al. 2017; Quan et al. 2011).

Long-Term Outcomes for Single-Level Bryan CDA Versus ACDF

In 2012, Zhang and colleagues reported 24-month outcomes for Bryan CDA versus ACDF. Study results demonstrated no significant differences between treatment groups based on mean NDI or median VAS scores (Zhang et al. 2012). These results are consistent with a study by Coric and colleagues (with average follow-up 72 months) that also demonstrated no significant differences between groups based on mean NDI or median VAS scores (Coric et al. 2013). In contrast, Sasso and colleagues reported significantly greater improvement in the CDA cohort based on NDI, VAS neck and arm pain scores, and SF-36 PCS and MCS scores at 48 months post-op (Sasso et al. 2011). Sasso and colleagues also reported an advantage for CDA in comparison with ACDF as measured by 7- and 10-year NDI scores (Sasso et al. 2017). The same authors reported CDA having an advantage over ACDF based on 7-year VAS neck and arm pain scores; however, the comparison was no longer significant at final 10-year follow-up (Sasso et al. 2017).

The data from these studies suggests that Bryan CDA is at least a viable alternative to ACDF for symptomatic cervical spondylosis and/or disc prolapse. The data also suggests that there is a lower incidence of secondary surgery after CDA (Cheng et al. 2009, 2011; Coric et al. 2006, 2013; Garrido et al. 2010; Goffin et al. 2003, 2010; Hacker 2005; Heidecke et al. 2008; Heller et al. 2009; Lafuente et al. 2005; Leung et al. 2005; Quan et al. 2011; Robertson et al. 2005; Sasso et al. 2007a, b, 2011; Tu et al. 2011; Walraevens et al. 2010; Yang et al. 2008; Zhang et al. 2012). A study by Shang and colleagues that focused on "skip" cervical spondylosis provided more evidence for the benefits of Bryan CDA over ACDF (Shang et al. 2017). Also, in a study that utilized a workers' compensation patient cohort, a greater number of CDA patients returned to work at 6 weeks and 3 months after surgery compared to ACDF (Steinmetz et al. 2008).

However, despite the demonstrated benefits of Bryan CDA over ACDF, complications were still reported (Cheng et al. 2009, 2011; Coric et al. 2006, 2013; Garrido et al. 2010; Goffin et al. 2003, 2010; Hacker 2005; Heidecke et al. 2008; Heller et al. 2009; Lafuente et al. 2005; Leung et al. 2005; Quan et al. 2011; Robertson et al. 2005; Sasso et al. 2007a, b, 2011; Tu et al. 2011; Walraevens et al. 2010; Yang et al. 2008; Zhang et al. 2012). For example, new anterior osteophyte formation or enlargement, increased narrowing of the intervertebral interspace, new adjacent degenerative disc disease, and calcification of the anterior longitudinal ligament were reported radiological findings indicative of post-CDA adjacent-level disease (Robertson et al. 2005; Yi et al. 2009). The incidence of heterotopic ossification (HO) causing restricted range of movement of the artificial disc prosthesis appears to increase with time, especially in multilevel (bilevel) CDA. Longer follow-up duration after CDA, gender, and age were noted to be risk factors in the development of HO after CDA (Leung et al. 2005).

Preoperative cervical kyphosis is a contraindication to CDA; therefore, post-CDA alignment has been an important topic of interest (Leven et al. 2017; Nunley et al. 2018). Using Bryan CDA for patients with single- and/or two-level symptomatic disc disease, Kim and colleagues studied postsurgical sagittal alignment of the functional spinal unit (FSU), as well as overall sagittal balance of the cervical spine (Kim et al. 2008). Their results demonstrated that Bryan CDA resulted in preserved motion of the FSU, and although the preoperative lordosis (or kyphosis) of the FSU could not always be maintained at during follow-up, the overall sagittal balance of the cervical spine was usually preserved (Kim et al. 2008). Pickett and colleagues reported similar results. Specifically, they also demonstrated preserved motion of the FSU after CDA. Although both the end plate angle of the treated disc space and the angle of the FSU became kyphotic after CDA, overall cervical spine sagittal alignment was preserved (Pickett et al. 2004). Other authors have found that cervical spine sagittal alignment became kyphotic after surgery, but overall lordosis was restored at a later time on follow-up imaging (Yoon et al. 2006). Possible causes of kyphotic changes included "over-milling" at the dorsal end plate, suboptimal angle of disc insertion, structural absence of lordosis in the Bryan disc prosthesis, removal of the posterior longitudinal ligament, and preexisting cervical kyphosis (Yoon et al. 2006).

Cummins/Bristol and Prestige Cervical Discs

Authors of both single- and multicenter studies have reported statistically significant improved postoperative outcomes for Prestige CDA (Fig. 1b), as well as reduced rates of secondary surgery compared to ACDF (Burkus et al. 2010, 2014; Lanman et al. 2017; Mummaneni et al. 2007; Peng et al. 2011; Porchet and Metcalf 2004; Riina et al. 2008; Robertson and Metcalf 2004). In addition to improved neurological success and outcomes, some studies have also demonstrated that Prestige CDA may restore segmental lordosis and preserve segmental motion (Peng et al. 2011). The follow-up duration for many of these studies was 2 years, but up to 7 years of follow-up data was reported (Lanman

Table 2 Summary of single-level Prestige disc outcomes for symptomatic cervical spondylosis or disc herniation. Recreated and modified from Alvin et al. et al. 2017). Tables 2 and 3 summarize Prestige CDA outcomes data (Burkus et al. 2010, 2014; Gornet et al. 2015, 2016, 2017; Lanman et al. 2017; Mummaneni et al. 2007; Peng et al. 2011; Porchet and Metcalf 2004; Riew et al. 2008; Riina et al. 2008; Robertson and Metcalf 2004). Below, we highlight key design steps in the history of Prestige CDA and then summarize one- and two-level outcomes data for Prestige CDA versus ACDF.

In the late 1980s, Cummins introduced a simple ball-and-socket prosthetic cervical joint in an attempt to address some of the problems associated with ACDF (Cummins et al. 1998; Wigfield et al. 2002b). His efforts, in collaboration with the Department of Medical Engineering at Frenchay

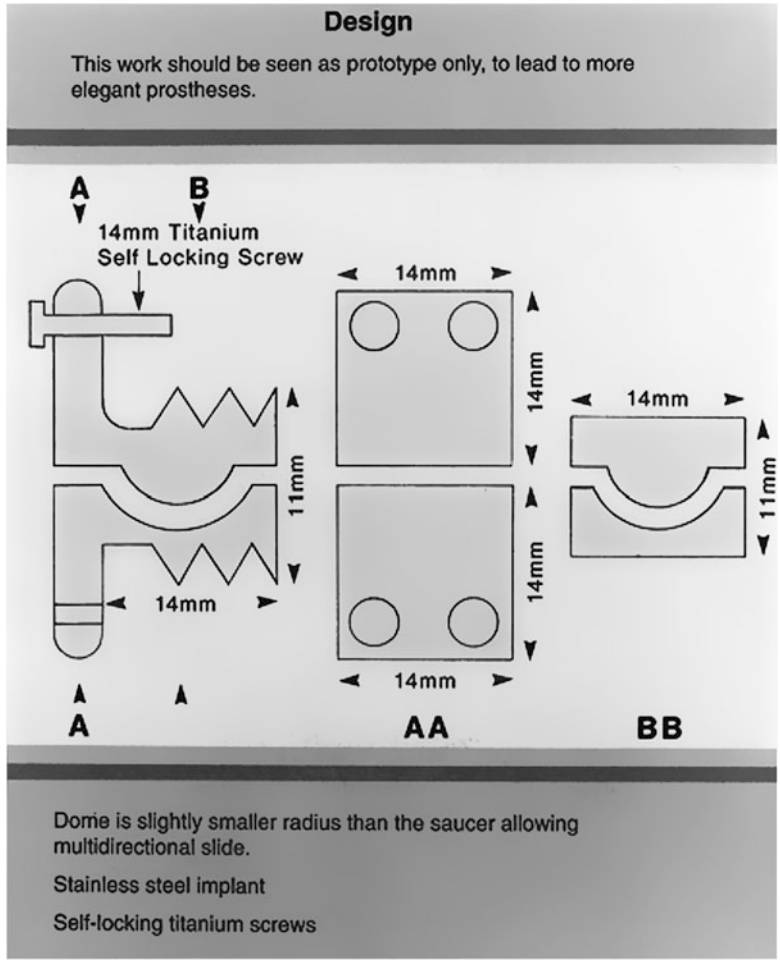

Fig. 2 Prototype design of the Prestige artificial cervical disc composed of stainless steel (made by Mr. Colin Walker at Frenchay Hospital). (Recreated from Cummins et al. Surgical experience with an implanted artificial cervical joint. Journal of Neurosurgery. (Cummins et al. 1998))

Hospital, led to the development of a prosthetic cervical disc constructed entirely of stainless steel with congruent surfaces and no point loading (Fig. 2) (Cummins et al. 1998; Traynelis 2004; Wigfield et al. 2002b). The Cummins disc occupied 11 mm of the intervertebral space and was secured to the vertebral bodies above and below the index level with screws (Traynelis 2004). Between 1991 and 1996, 22 Cummins discs were implanted in 20 "end-stage" patients who lacked motion over multiple cervical levels because of congenital block vertebrae or prior surgical fusion. On follow-up, two patients lacked motion at the index level. This was attributed to the relatively large implant size which may have caused over-distraction of the facet joints (Cummins et al. 1998). Although there were implant problems such as screw breakages, patients experienced clinical improvement (those with radiculopathy improved, and those with myelopathy improved or stabilized) (Cummins et al. 1998).

The work of Cummins set the foundation for the development of the next generation of artificial cervical discs. The next CDA device was developed in 1998 and was referred to as the Frenchay artificial cervical joint (Fig. 3) (Traynelis 2004; Wigfield et al. 2002b).

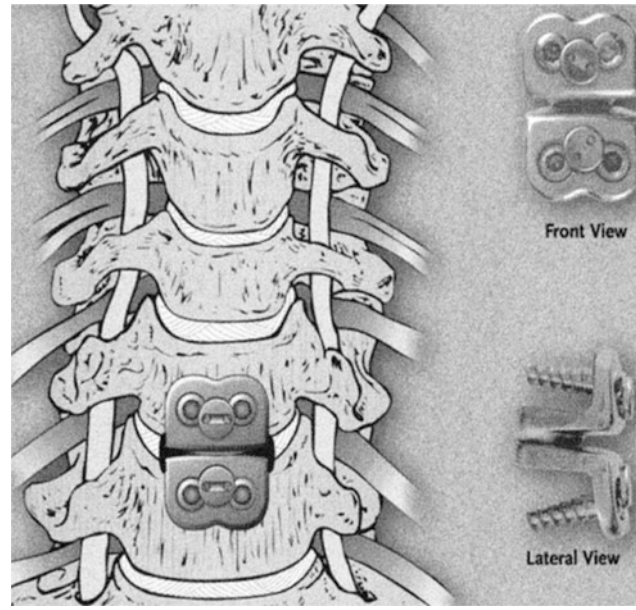

Fig. 3 The two articulating components of the Frenchay artificial cervical joint (or Prestige I) are shown with the bone and locking screws. (Recreated from Wigfield et al. The New Frenchay Artificial Cervical Joint: Results From a Two-Year Pilot Study. Spine (Phila Pa 1976). (Wigfield et al. 2002b))

Medtronic ultimately purchased the Frenchay disc, and it was renamed as Prestige (Medtronic Inc.) (Nunley et al. 2018). This device had some similarities to the prior Cummins joint but was redesigned with a trough rather than a ball-and-socket for articulation. Also, the lower component of the joint was redesigned for translation within three degrees of freedom for both translation and rotation (Wigfield et al. 2002b). Together, these design changes allowed more physiologic motion (anterior-posterior translation coupled with flexion/extension) (Traynelis 2004; Wigfield et al. 2002b). Wigfield and colleagues prospectively evaluated the Frenchay artificial joint in a cohort of 15 patients with cervical radiculopathy or myelopathy from cervical disc herniation or posterior vertebral body osteophytes (Wigfield et al. 2002b). Over the duration of their 2-year study, the Frenchay CDA maintained motion and intervertebral height at the index levels, there were no cases of dislocation screw backout, and clinical outcomes scores improved (Wigfield et al. 2002b).

The next iteration of Prestige CDA, Prestige II, was developed in 1999 (Traynelis 2004). This device had roughened end plate surfaces to promote bony ingrowth for long-term stability (Traynelis 2004). The Prestige II was the first artificial cervical disc to be compared to ACDF (non-instrumented arthrodesis with autograft) in a prospective randomized trial of patients with symptomatic single-level primary cervical disc disease (Porchet and Metcalf 2004; Traynelis 2004). Data after 2 years of follow-up demonstrated improvement in most outcome measurements that favored CDA over ACDF (Porchet and Metcalf 2004). Also, motion analysis demonstrated favorable results in the CDA cohort (motion was maintained in the CDA cohort compared to ACDF patients who displayed no significant motion) (Porchet and Metcalf 2004).

The next Prestige disc, Prestige ST, became available in 2002 (Traynelis 2004). The surfaces of the device contacting the end plates were grit-blasted to promote bone osteointegration (Traynelis 2004). In comparison with its predecessor, there was a 2 mm reduction in the height of the device's anterior flanges (Traynelis 2004). The Prestige ST ball-and-trough articulation design, combined with its angulation between the base and anterior portions of the device, allowed more physiologic motion comparable to normal cervical vertebrae (Traynelis 2004). Mummaneni and colleagues performed a

multicenter, prospective, randomized, non-inferiority clinical trial comparing the Prestige ST to ACDF (Mummaneni et al. 2007). The Prestige CDA patients maintained physiological segmental motion and had improved clinical outcomes (summarized below) and reduced rates of secondary surgery compared to ACDF (Mummaneni et al. 2007). Burkus and colleagues demonstrated that the Prestige ST disc maintained improved clinical outcomes (summarized below) and segmental motion after implantation after 5 years post-op (Burkus et al. 2010). Rates of reoperations for adjacent segment degeneration trended lower in the CDA cohort in comparison with the ACDF group, but the differences were not statistically significant (Burkus et al. 2010).

The Prestige LP is the latest generation in the Prestige family of cervical discs (Traynelis 2004). The FDA-approved Prestige LP disc (for both single- and two-level symptomatic cervical spondylosis or disc herniation) is a non-constrained ball-in-trough, metal-on-metal articulation made of a titanium ceramic composite. The unique titanium ceramic composite material is highly durable and results in less artifact during CT and MRI scans (Traynelis 2004). Also, the porous titanium plasma spray coating on the end plate surface facilitates bone ingrowth and long-term fixation (Traynelis 2004). Long-term outcomes for the Prestige family of discs are summarized below.

Long-Term Outcomes for Single-Level Prestige CDA Versus ACDF

Prestige LP: In 2015, Gornet and colleagues reported 24-month outcomes for Prestige LP CDA versus ACDF: NDI and VAS neck and arm scores were noninferior, and SF-36 MCS was noninferior as well as statistically superior (Gornet et al. 2015). Gornet and colleagues reported continued success for Prestige LP CDA versus ACDF at 84 months: NDI and VAS scores were still noninferior, SF-36 PCS was noninferior, and SF-36 MCS was noninferior as well as statistically superior (Gornet et al. 2016).

Prestige ST: Outcomes at 24 months for Prestige ST CDA versus ACDF demonstrated no differences in NDI, VAS neck score (which had been significantly better for the CDA group at 12 months), VAS arm score, and SF-36 PCS and MCS (Mummaneni et al. 2007; Riew et al. 2008). Burkus and colleagues reported outcomes at 60 months for Prestige ST CDA versus ACDF: NDI was significantly better, VAS neck score was significantly better, VAS arm score had no significant difference, SF-36 PCS had no significant difference, and SF-36 MCS comparison was not reported (Burkus et al. 2010, 2014). Later in 2014, Burkus and colleagues reported 84-month outcomes for Prestige ST CDA versus ACDF, and the results were similar to previously reported 60-month outcomes except the SF-36 PCS score for the CDA group was now significantly improved compared to the ACDF treatment group (Burkus et al. 2014).

Prestige II: In 2004, Porchet and colleagues reported outcomes at 24 months for Prestige II CDA versus ACDF: NDI was statistically equivalent, VAS neck score statistical equivalence could not be shown between treatment groups, VAS arm score was statistically equivalent, and no significant differences were demonstrated for SF-36 PCS and MCS (Porchet and Metcalf 2004).

Long-Term Outcomes for Two-Level Adjacent Prestige LP CDA Versus ACDF

Gornet and colleagues reported 24-month outcomes for Prestige LP CDA versus ACDF at two levels: NDI was statistically superior, VAS neck score was noninferior, VAS arm score was noninferior, SF-36 PCS was noninferior, and SF-36 MCS was not reported (Gornet et al. 2017). Lanman and colleagues reported similar results for 84-month CDA outcomes: VAS neck score was statistically superior, SF-36 PCS was statistically superior, and SF-36 MCS was noninferior (Lanman et al. 2017). Although there was no statistically significant difference in the overall rate of implant- or procedure-related

adverse events for up to 84 months post-op, the trend favored the CDA treatment cohort (Lanman et al. 2017).

Porous Coated Motion (PCM) Cervical Disc

The Porous Coated Motion (PCM) device (Cervitech) is a non-constrained artificial cervical disc that was originally invented by McAfee and then was improved upon by Helmut Link and Arnold Keller (Fig. 1c) (Pimenta et al. 2004). It has a unique biomechanical design feature that incorporates a large radius ultrahigh-molecular-weight polyethylene bearing surface attached to the inferior vertebrae. This allows the device more physiologic translational motion in an arc, which is consistent with the natural motion of the cervical spine (Pimenta et al. 2004). The porous ingrowth material is composed of two ultra-thin layers of titanium with electrochemically coated calcium phosphate (Pimenta et al. 2004). The pore size was designed to match the bony trabecular architecture of the cervical vertebra (Pimenta et al. 2004).

Pimenta and colleagues reported the results of a pilot study performed between December 2002 and October 2003 in which 82 PCM devices were implanted in 53 patients. Significant improvements in all scores were seen postoperatively (NDI, VAS pain scores, and Treatment Intensity Gradient Test). One device migration of 4 mm was seen at 3 months and was observed (no reoperation). Eighty percent of patients had a good or excellent result at 1 week, improving to 90% of patients having a good or excellent result by 1 month (Odom's criteria), and this result remained stable 3 months after surgery (Pimenta et al. 2004). Later in 2007, Pimenta and colleagues published the first prospective CDA study to show significantly improved clinical outcomes for multilevel compared to single-level CDA (PCM disc) (Pimenta et al. 2007). Table 4 is a summary of PCM CDA outcomes data (Alvin et al. 2014; Delamarter et al. 2010; Phillips et al. 2009, 2013, 2015; Pimenta et al. 2004, 2007).

Long-Term Outcomes for Single-Level PCM CDA Versus ACDF

The FDA randomized controlled trials comparing PCM CDA vs. ACDF were performed by Phillips and colleagues (Phillips et al. 2013, 2015). The study cohort consisted of patients 18–65 years of age with single-level symptomatic cervical spondylosis (radiculopathy and/or myelopathy) unresponsive to nonoperative treatment. This included patients with prior non-adjacent or adjacent single-level fusion operations. The 24-month outcomes demonstrated that NDI was significantly better, VAS neck and arm scores were not significantly different, and SF-36 PCS and MCS were not significantly different for PCM CDA compared to ACDF (Phillips et al. 2013). The patients with PCM CDA had lower rates of prolonged dysphagia, greater patient satisfaction, and superior overall success compared to ACDF (Phillips et al. 2013).

In 2015, Phillips and colleagues reported 60-month outcomes for PCM CDA vs. ACDF: NDI was significantly better, VAS neck score was significantly better, VAS arm score was not significantly different, and SF-36 PCS and MCS were significantly better (Phillips et al. 2015). PCM CDA patients also had a lower rate of radiographical adjacent-level degeneration and a trend toward fewer secondary surgeries (Phillips et al. 2015). The authors interpreted the results of these studies to support PCM CDA as a viable and sustainable alternative to ACDF in appropriately selected patients (Phillips et al. 2015).

ProDisc-C Cervical Disc

The ProDisc-C (Synthes Spine) is an artificial cervical disc designed with these principles in mind: implant stability, ease and safety of insertion, minimal end plate disruption, and optimization of functional range of motion (Fig. 1d). These principles and design characteristics were investigated in several studies, and clinical outcomes are summarized in

Table 5 (Alvin et al. 2014; Bertagnoli et al. 2005; Chin et al. 2017; Delamarter et al. 2010; Janssen et al. 2015; Kelly et al. 2011; Kesman et al. 2012; Mehren et al. 2006; Murrey et al. 2009; Nabhan et al. 2007; Peng et al. 2009; Suchomel et al. 2010; Zigler et al. 2013). The

specific advantages of the ProDisc-C device include the absence of anterior plate fixation hardware, preservation of osseous end plates, immediate keel fixation stability, and the possibility of multilevel application. Biomechanically, the ProDisc-C implant is considered to represent a ball-and-socket/semi-constrained design with a fixed axis of rotation (Bertagnoli et al. 2005). DiAngelo and colleagues performed an in vitro biomechanical study to compare the effects of ProDisc-C CDA and ACDF in a multilevel human cadaveric model. Their results demonstrated that ACDF decreased motion at the index level in comparison with CDA (DiAngelo et al. 2004). The reduced motion at the index level was compensated at adjacent segments by an increase in motion. ProDisc-C CDA did not alter the motion patterns at either the index or adjacent levels compared with control (except in extension) (DiAngelo et al. 2004). Long-term outcomes from the FDA trials comparing ProDisc-C CDA to ACDF are summarized below.

Long-Term Outcomes for Single-Level ProDisc-C CDA Versus ACDF

In 2007, Nabhan and colleagues reported no significant difference in 12-month VAS neck and arm scores for ProDisc-C CDA versus ACDF (Nabhan et al. 2007). Later in 2009, Murrey and colleagues reported no significant differences in all outcome variables (NDI, VAS neck and arm scores, SF-36 PCS and MCS) at 24 months post-op (Murrey et al. 2009). This trend continued in 2010 with Delamarter and colleagues reporting 48-month outcomes for ProDisc-C CDA versus ACDF: NDI and VAS neck and arm scores were still not significantly different (Delamarter et al. 2010). However, in 2013, Zigler and colleagues reported 60-month outcomes for ProDisc-C CDA vs. ACDF and found that NDI and VAS neck scores were significantly better (VAS arm score, SF-36 PCS, and SF-36 MCS were not significantly different) (Zigler et al. 2013). Then at 84 months post-op, two studies demonstrated no significant difference in all outcome variables for ProDisc-C CDA versus ACDF (Janssen et al. 2015). For these two studies, the VAS and SF-36 scores showed noninferiority of the Prodisc-C group, which trended toward statistical superiority (Kesman et al. 2012).

Mobi-C Cervical Disc

The Mobi-C cervical artificial disc (LDR Medical) is a semi-constrained, bone-sparing prosthetic device (Fig. 1e) (Davis et al. 2015; Kim et al. 2007). The implant is composed of two cobalt-chromium-molybdenum alloy shells with an ultrahigh-molecular-weight polyethylene mobile insert facilitating five independent degrees of freedom (Davis et al. 2015; Kim et al. 2007). The mobility of the polyethylene insert decreases the transmission of the constraints on the bone-implant interface and reduces the constraints of the posterior facet joints (Kim et al. 2007). The implant has lateral self-retaining, incline-shaped teeth that were designed to support reliable vertebral end plate anchorage and stability (Kim et al. 2007). Tables 6 and 7 summarize Mobi-C CDA outcomes data (Bae et al. 2015; Beaurain et al. 2009; Davis et al. 2013, 2015; Guerin et al. 2012; Hisey et al. 2014, 2015, 2016; Huppert et al. 2011; Kim et al. 2007; Lee et al. 2012; Park et al. 2008, 2013; Radcliff et al. 2016a). The Mobi-C disc has FDA approval for both single- and two-level symptomatic cervical spondylosis and/or disc disease. Long-term outcomes from the FDA trials are summarized below.

Long-Term Outcomes for Single-Level Mobi-C CDA Versus ACDF

Hisey and colleagues reported 24-, 48-, and 60-month outcomes in multicenter, prospective, randomized, controlled FDA investigational device exemption clinical trials comparing Mobi-C CDA to ACDF in the treatment of

Table 6 Summary of FDA single-level (and other multi-level) Mobi-C cervical disc outcome studies. Recreated from Alvin et al. Cervical arthroplasty: a critical review of the literature. symptomatic degenerative disc disease in the cervical spine (single level). The results demonstrated similar findings at each of these time points, namely, there were no significant differences in NDI or VAS neck and arm scores (Gornet et al. 2015; Hisey et al. 2014, 2015).

Table 8 Summary of single-level Kineflex-C cervical disc outcomes for symptomatic cervical spondylosis or disc herniation. Recreated from Alvin et al. Cervical arthroplasty: a critical review of the literature. The Spine Journal. (Alvin et al. 2014; Coric et al. 2011, 2013, 2018)

Long-Term Outcomes for Two-Level Adjacent Mobi-C CDA Versus ACDF

In 2013, Davis and colleagues reported 24-month outcomes for Mobi-C CDA versus ACDF at two adjacent levels: NDI was significantly better, and although VAS neck score was significantly improved at 3 and 6 months postoperatively, there were no statistically significant differences at any other time point. Also, there were no significant differences between treatment groups for VAS arm scores at any time point (Davis et al. 2013). Later in 2015, Davis and colleagues reported similar results at 48 months post-op: NDI was significantly better, but there were no significant differences in VAS neck and arm scores between treatment groups (Davis et al. 2015). For 60-month outcomes, Radcliff and colleagues reported that NDI was significantly better, and although there was more improvement in VAS neck and arm scores for the CDA group, the difference was not statistically significant (Radcliff et al. 2016a).

Kineflex-C Cervical Disc

The Kineflex-C artificial cervical disc (SpinalMotion Inc.) is a cobalt-chrome on cobalt-chrome alloy (metal-on-metal) semi-constrained device (Fig. 1f) (Coric et al. 2011). It is composed of three pieces (two end plates and a mobile center that translates within a retention ring). There is a midline keel on the device's end plate that provides immediate fixation, and the end plates are coated with a titanium plasma spray to promote bony ingrowth for long-term fixation (Coric et al. 2011). Table 8 summarizes Kineflex-C CDA outcomes data (Coric et al. 2011, 2013, 2018). Long-term outcomes for the FDA trials comparing Kineflex-C CDA and ACDF are summarized below.

Long-Term Outcomes for Single-Level Kineflex-C CDA Versus ACDF

Coric and colleagues reported 24- and 48-month outcomes for Kineflex-C CDA versus ACDF and found no significant differences between treatment groups based on NDI or VAS scores (Coric et al. 2011, 2013). However, clinical success (maintenance or improvement in neurological exam, minimum of 20% improvement in NDI, no device failure, no reoperation at the index level, no major device-related adverse event) was significantly higher in the Kineflex-C group compared to ACDF (Coric et al. 2011). Recently, Coric and colleagues reported clinical

Table 10 Summary of single- and multilevel Discover disc outcomes for symptomatic cervical spondylosis or disc herniation. Recreated from Alvin et al. Cervical arthroplasty: a critical review of the literature. The Spine Journal. (Alvin et al. 2014; Du et al. 2011; Fang et al. 2013; Li et al. 2013; Miao et al. 2014; Rozankovic et al. 2017; Shi et al. 2016; Skeppholm et al. 2015)

Imp improved, *LoE* level of evidence, *MCS* mental component score, *NDI* neck disability index, *PCS* physical component score, *R* retrospective, *RCT* randomized controlled trial, *SF-36* short form-36, *VAS* visual analogue scale

success was significantly improved for the Kineflex-C CDA group compared to ACDF at 60 months post-op (Coric et al. 2018). Also, the results demonstrated there were no significant differences between treatment groups in terms of reoperation/revision surgery or device-/surgery-related adverse events during the 5 years of follow-up (Coric et al. 2018).

Secure-C Cervical Disc

The selectively constrained Secure-C artificial cervical disc (Globus Medical) is an anterior articulating intervertebral device comprised of two cobalt-chrome alloy serrated end plates and a sliding polyethylene central core. The end plates have a titanium plasma spray coating on its bone-contacting surface to promote long-term bony ingrowth (Vaccaro et al. 2013). The Secure-C artificial cervical disc is designed for motion in flexion/extension up to 30 ± 15°, lateral bending up to 20 ± 10°, and sagittal translation of up to ±1.25 mm (Vaccaro et al. 2013). There is less available FDA trial outcomes data (compared to the aforementioned discs) comparing Secure-C CDA to ACDF (Table 9) (Vaccaro et al. 2013).

Long-Term Outcomes for Single-Level Secure-C CDA Versus ACDF

Overall success results (improvement of at least 25% in baseline NDI, no device failure requiring revision, and absence of major complications [major vessel injury, neurological damage, or nerve injury]) demonstrated statistical superiority of the randomized Secure-C group compared with the randomized ACDF group at 24 months post-op (Vaccaro et al. 2013). There was noninferiority of the randomized Secure-C group at all postoperative time points (up to 24 months) for both (1) 25% or more and (2) 15-point or more improvement in NDI (Vaccaro et al. 2013). Also, the study demonstrated statistical noninferiority of Secure-C compared to ACDF for VAS neck and arm pain scores (and also statistical superiority for VAS neck pain) (Vaccaro et al. 2013).

Discover Cervical Disc

The non-constrained Discover artificial cervical disc (DePuy Spine) is an MRI-compatible ball-and-socket design consisting of two end plates manufactured from titanium alloy and

a polyethylene core (Du et al. 2011; Shi et al. 2016). The inferior end plate is a two-piece design with an ultrahigh-molecular-weight polyethylene insert and features a spherical bearing surface that allows motion in all rotational directions (Du et al. 2011). The Discover disc has a 7° lordotic angle split evenly between the superior and inferior end plates for restoration of lordosis at the index level (Du et al. 2011). Table 10 summarizes Discover CDA outcomes data (Du et al. 2011; Fang et al. 2013; Li et al. 2013; Miao et al. 2014; Rozankovic et al. 2017; Shi et al. 2016; Skeppholm et al. 2015). In contrast to the aforementioned artificial cervical discs, the Discover disc is not approved by the FDA; however, its widespread use for CDA warrants a brief summary of its outcomes.

Long-Term Outcomes for Single- and Multilevel Discover CDA Versus ACDF

In 2017, Rozankovic and colleagues reported 24-month outcomes for Discover CDA vs. ACDF (single level): NDI and VAS neck and arm scores were significantly improved compared to ACDF (Rozankovic et al. 2017). In contrast, Skeppholm and colleagues did not find significantly better 24-month outcomes for CDA compared to ACDF based on NDI scores. In contrast to the Rozankovic study, the Skeppholm study included patients with multilevel cervical disc degeneration who received CDA at adjacent levels, which could explain the difference in results (Skeppholm et al. 2015).

Summary of Complications Associated with Cervical Disc Arthroplasty

Biomechanical and clinical studies suggest that the rate of adjacent segment degeneration (ASDG; *radiographic* evidence of degeneration at the adjacent level) is significantly higher for ACDF compared to CDA (Baba et al. 1993; Chang et al. 2007; Coric et al. 2010; DiAngelo et al. 2003; Dmitriev et al. 2005; Eck et al. 2002; Matsunaga et al. 1999; Nunley et al. 2018; Park et al. 2011; Puttlitz et al. 2004; Reitman et al. 2004; Wigfield et al. 2002a). However, rates of adjacent segment disease (ASDI; development of new *clinical* symptoms correlating with adjacent segment degeneration) between CDA and ACDF continue to be debated. Jawahar and colleagues found no difference in the incidence of ASDI between CDA and ACDF. On the contrary, there has been growing evidence from other long-term follow-up studies and meta-analyses that suggest CDA may reduce ASDI and reoperation rates in comparison with ACDF (Gao et al. 2013; Ishihara et al. 2004; Jawahar et al. 2010; McAfee et al. 2012; Robertson et al. 2005; Upadhyaya et al. 2012).

Other adverse outcomes associated with CDA include heterotopic ossification (HO), delayed fusion around cervical disc prosthesis, asymmetric end plate preparation resulting in postoperative kyphosis, and reduction in caudal vertebral body height (Yi et al. 2010). Rates of HO with the FDA investigational device exemption publications have been reported, and grade 4 HO rates are as high as 13% (Gornet et al. 2016; Hisey et al. 2016; Janssen et al. 2015; Nunley et al. 2018; Radcliff et al. 2016a). Table 11 is a summary of the commonly reported complications associated with CDA in the literature (Alvin et al. 2014; Anderson et al. 2004; Beaurain et al. 2009; Bertagnoli et al. 2005; Bhadra et al. 2009; Bryan 2002; Cheng et al. 2011; Coric et al. 2006, 2011; Ding et al. 2012; Du et al. 2011; Duggal et al. 2004; Garrido et al. 2010; Goffin et al. 2003, 2010; Hacker 2005; Heidecke et al. 2008; Heller et al. 2009; Huppert et al. 2011; Kelly et al. 2011; Kesman et al. 2012; Kim et al. 2007, 2008, 2009; Lee et al. 2010; Leung et al. 2005; Li et al. 2013; Mehren et al. 2006; Mummaneni et al. 2007; Murrey et al. 2009; Nabhan et al. 2007; Park et al. 2008, 2013; Peng et al. 2009, 2011; Phillips et al. 2013; Pickett et al. 2004; Pimenta et al. 2004, 2007; Porchet and Metcalf 2004; Quan et al. 2011; Ren et al. 2011; Riew et al. 2008; Riina et al. 2008; Robertson and Metcalf 2004; Robertson et al. 2005; Ryu et al. 2010; Sasso et al. 2011; Sekhon 2003; Sekhon et al. 2005; Shim et al. 2006; Suchomel et al. 2010; Tu et al. 2011; Walraevens

[a]Complication rate reported for the arthroplasty investigational cohort
ASDI adjacent segment disease, *ASDG* adjacent segment degeneration, *HO* heterotopic ossification, *PCM* porous coated motion

et al. 2010; Wang et al. 2008; Yang et al. 2008; Yoon et al. 2006; Zigler et al. 2013).

Metal Ion Toxicity

Articulating prosthetic implants are subject to wear and corrosion following implantation. An advantage of metal-on-metal bearings is the substantially lower volumetric wear debris when compared with conventional metal-on-polyethylene bearing couples. A concern regarding any metal-on-metal CDA (e.g., Prestige LP CDA) is that patients may have increased serum metal ion concentrations after surgery since implant wear can lead to local and systemic transport of metal debris (Coric et al. 2018; Gornet et al. 2016). Toxicology-related sequelae from chronically elevated metal ion levels have not been determined. In support of CDA, a 5-year randomized control trial (comparing single-level Kineflex-C CDA with ACDF) demonstrated that serum ion levels (cobalt and chromium) were significantly lower than the levels that merit monitoring (Coric et al. 2018). However, several case studies have reported some early local effects of wear debris (Cavanaugh et al. 2009; Gornet et al. 2016; Hacker et al. 2013).

Patient Selection

CDA is associated with high success rates when performed for appropriately selected patients. However, complications may occur with

improper patient selection, technical errors, or progression of underlying cervical disease (Leven et al. 2017; Nunley et al. 2018; Nunley et al. 2012). Current indications for CDA in the United States (largely dictated by FDA approval of the various prosthetic devices) include skeletally mature patients with cervical radiculopathy and/or myelopathy at a single or two adjacent levels without severe facet joint degeneration, instability, malalignment or kyphosis, or severe neck pain only (Leven et al. 2017; Nunley et al. 2018). Other contraindications include retrovertebral compression (i.e., congenital stenosis or ossification of the posterior longitudinal ligament) and spondyloarthropathies (ankylosing spondylitis) (Leven et al. 2017; Nunley et al. 2018). Patients with a severe axial neck pain due to facet degeneration should be counseled appropriately since these symptoms may not improve after CDA (Leven et al. 2017). Also, some authors have recommended a disc height of 3 mm or greater for adequate disc space access and removal (Ding and Shaffrey 2012). Placing an oversized implant into a collapsed disc space can potentially place excessive forces through the facet joints and lead to worsening of axial neck pain (Ding and Shaffrey 2012).

Cost Efficacy

Although many studies have demonstrated successful treatment with CDA, economic analysis and health costs are also important determinants for obtaining insurance coverage in the United States (Nunley et al. 2018). Therefore, recent studies have focused on analyzing the incremental cost-effectiveness of CDA in comparison with the ACDF. Ament and colleagues reported the incremental cost-effectiveness ratio of CDA compared to ACDF at 2 years post-op for two-level disease was $24954/quality-adjusted life year (QALY). This value is considered to be well within the commonly accepted threshold of $50000/QALY (Ament et al. 2014). Ament and colleagues updated their cost utility analysis at 5 years post-op and reported that the incremental cost-effectiveness ratio for CDA continued to remain below this $50000/QALY threshold (Ament et al. 2016).

In 2014, McAnany and colleagues analyzed 5-year outcomes data and reported cost benefits of CDA compared to ACDF (McAnany et al. 2014). The CDA cost-effectiveness ratio was $35976/QALY compared to $42618/QALY for ACDF (McAnany et al. 2014). In two studies by Radcliff and colleagues, the results suggested that CDA was also the more cost-effective treatment over ACDF (Radcliff et al. 2015, 2016b). Using 3-year data, they found that the total costs paid by insurers for CDA were $34979 compared to $39829 for ACDF. This difference may have been from readmissions and reoperations, which were higher for the ACDF cohort (Radcliff et al. 2015). In another study which analyzed 7-year data, Radcliff and colleagues reported continued cost benefits of CDA over a range of scenarios (Radcliff et al. 2016b).

In 2016, Ghori and colleagues performed a Markov analysis to evaluate the societal costs of ACDF versus CDA in a theoretical cohort of 45–65-year-old patients (Ghori et al. 2016). Their results demonstrated that the long-term costs for CDA were less expensive throughout the model's age range (Ghori et al. 2016). Factors driving lower costs included lower perioperative costs, earlier return to work, and lower reoperation rates (Ghori et al. 2016).

Conclusions

Total cervical disc replacement attempts to preserve normal motion at adjacent segments and in doing so may decrease the incidence of adjacent segment degeneration and disease. Motion-preserving CDA has showed great promise with equivalent quality-of-life outcomes to ACDF in many long-term comparative studies. However, complications such as heterotopic ossification have been reported to occur with some frequency, but the ultimate clinical consequences or implications (in comparison with ACDF) are yet to be determined. Overall, there exists robust data to support CDA as a

viable alternative to ACDF in select patients, but further investigation and continued long-term comparison between CDA and ACDF is warranted.

Adjacent disease · Arthroplasty · Cervical fusion · Disc replacement · Motion preservation

Introduction

The topics of adjacent segment (AS) degeneration and disease have been increasingly discussed with the development and adoption of motion preserving devices. AS degeneration is defined as new degenerative radiographic changes at a spinal level immediately above or below surgically treated levels. When this degeneration is associated with clinical symptoms, including radiculopathy, myelopathy, or mechanical instability, then the appropriate terminology is AS disease. Controversy exists as to whether AS disease is primarily due to the natural progression of an underlying degenerative process or an accelerated process due to increased forces placed on adjacent segments following fusion surgery. In theory, motion preserving devices would eliminate or significantly decrease any accelerated degeneration related to fusion and increased biomechanical stress. Both clinical and laboratory studies have addressed

AS degeneration and disease as well as the factors leading to their development. In this chapter, we will review these studies as well as examine the evidence basis regarding the effect of motion preservation technology on the incidence of AS disease.

Historical Perspective

The etiology of AS disease has been controversial with some studies suggesting that fusion places significantly increased stress on adjacent segments while others arguing that AS disease is primarily due to the natural progression of underlying disease. Furthermore, there is debate over whether motion preservation devices with their ability to eliminate increased forces on the adjacent discs can decrease AS disease.

Historically, the annual incidence of AS disease following fusion is generally reported to range from 1.5% to 4.5% (Bohlman et al. 1993; Cauthen et al. 1998; Gore and Sepic 1998; Hilibrand et al. 1999). Hilibrand et al. (1999) reported on 409 total procedures in 374 patients followed for 10 years. In this series, symptomatic AS disease was defined as a combination of new radicular or myelopathy symptoms referable to an adjacent degenerated level on two consecutive office visits based on chart review and surgical records (a nonvalidated outcome measure). The annual incidence was 2.9% per year over the 10-year study period (range, 0.0–4.8% per year). In this frequently cited study, only 27 patients (6.6%) had adjacent level surgery with an annual adjacent level reoperation rate of 0.7%. A similar study by Goffin et al. (2004) evaluated long term outcomes in 180 patients with a mean follow-up of 30.9 months. 92% of patients had radiographic evidence of increased degeneration at long-term follow-up. Interestingly, age and number of levels fused showed no correlation with degeneration (Spearmen $r_s = -0.033$, $P = 0.660$ and Spearman $r_s = -0.011$, $P = 0.879$, respectively), but the length of time after operation was correlated with degeneration (Spearman $r_s = 0.156$, $P = 0.036$). This suggests a multifactorial etiology to AS degeneration given such a high incidence after fusion surgery, but the correlation with length of time after operation suggestive of natural progression.

Though these studies addressed the incidence of AS disease, they did not provide a definitive etiology. Biomechanical studies by Eck et al. (2002) were performed to evaluate the intradiscal pressure after cervical fusion. In cadaveric specimens, the authors found that increased intradiscal pressure resulted with normal range of motion after fusion. Increased segmental motion adjacent to fusion segment resulted in increased pressures. They were unable to make conclusions regarding increased intradiscal pressure and effect on normal degenerative changes. Additional biomechanical studies using a finite element model of the cervical spine by Lopez-Espina et al. (2006) showed significant increases in stress of up to 96% on the annulus, nucleus, and endplates of adjacent levels in fused (single and double level) versus normal cervical spines. The authors argued that increased rotation and stress may explain the disc degeneration and osteophyte formation after fusion.

The counter argument for natural progression of spinal degeneration over time is also well supported with radiographic and clinical data. Matsumoto et al. (1998) performed 497 MRI on asymptomatic subjects and found a significant occurrence of degenerative changes and age. In their initial study, 17% of men and 12% of women in their 20s had evidence of degenerative changes compared to 86% of men and 89% of women over 60 years of age. A follow-up of 223 of those patients showed progression of degenerative changes in 81.1% of patients with only 34.1% developing clinical symptoms. These studies suggest a rate of natural progression with age for AS degeneration. Similarly, Gore et al. (2002) followed 159 patients for 10 years with asymptomatic cervical disease. Radiographic degeneration was seen in 72 patients at initial imaging and degeneration progressed in 70 (97.2%) of these patients with15% of patients developing pain over the 10-year study period. These studies identify a clear progression of degeneration over time. In regard to the effect of cervical surgery on the

rate of AS degeneration, Lunsford et al. (1980) reported on 253 patients who underwent anterior cervical discectomy with and without fusion (ACD and ACDF). There was no difference in symptomatic relief and recurrence of symptoms. Further, there was no difference in subsequent development of AS degeneration requiring re-operation.

Motion Preservation Devices

Given the rate of AS degeneration and need for further surgery following fusion, motion preserving devices were developed to theoretically reduce effects of AS disease. Initially developed for the lumbar spine, artificial disc replacement has been performed to prevent loss of vertebral interspace height and reduce pain while maintaining motion. Cadaver studies by Wigfield et al. (2003) showed that artificial disc resulted in reduced stresses in the annulus of neighboring cervical segments compared to simulated fusion. These studies supported the theory that motion preservation resulted in less adjacent segment mechanical stress compared to fusion. The earliest clinical reports of disc replacement in the cervical spine were reported by Fernstrom in 1966. His device was used in a series of 32 patients with 74 cervical disc prosthesis reported by Reitz and Joubert (1964) with good results in all patients and preservation of mobility. The earliest reports of AS degeneration after artificial disc replacement were reported by Cummins et al. (1988). In 18 patients with 5-year follow-up, there was no reported adjacent joint degeneration and motion was preserved on flexion and extension x-ray films.

Motion Preservation Effect

Early US Investigational Device Exemption (IDE) trials of artificial disc replacement showed that results were equivalent in regard to neurologic outcome and surgical success, but data regarding AS degeneration was more difficult to assess given the short follow-up. Heller et al. (2009) reported on 24-month outcome for BRYAN cervical disc (Medtronic Sofamor Danek, Memphis, TN). 242 patients were randomized to the BRYAN cervical disc and 221 were in the control ACDF group. The rate of secondary surgical procedures at the treated level was 2.5% in the total disc replacement (TDR) patients and 3.6% in the fusion group though this was not statistically significant. Interestingly, composite overall success was achieved in 82.6% artificial disc patients and only 72.7% of fusion patients ($p = 0.010$). Another randomized, controlled IDE study by Mummaneni et al. (2007) enrolled 276 patients to arthroplasty with PRESTIGE ST cervical Disc System (Medtronic Sofamor Danek, Memphis, TN) and 265 patients to ACDF with 24-month follow-up. The groups showed similar improvement in validated outcome measures (NDI and VAS arm/neck pain scores), but the composite overall success rate was significantly higher at 24 months in the arthroplasty group than ACDF control group (79.3% vs. 67.8%, $p = 0.0053$). The reoperation rate in the arthroplasty group was lower (1.1% vs. 3.4%, respectively, $p = 0.0492$, log-rank test) for AS disease than the control group. Though these 2-year outcomes showed equivalence in this noninferiority statistical design and the effect on AS degeneration was promising, long-term studies of the effect on AS disease with motion preservation were still needed.

One of the earliest attempts to analyze AS disease following cervical artificial disc replacement was performed by Jawahar et al. (2010). In this study, a total of 93 patients were enrolled in 3 prospective randomized trials of artificial cervical discs. Patients showed equivalence in symptomatic relief (71% in TDA vs. 73.5% in ACDF). At last follow-up (median 36.4 months), 15% of patients with ACDF and 18% of TDA had clinical and radiographic AS disease which was not statistically different. A follow-up study by Nunley et al. (2012) included 170 patients with 3- and 4-year follow-up after treatment for 1 and 2-level cervical disc degeneration with cervical artificial disc or ACDF. AS degeneration and disease was reported in 16.5% of patients during follow-up ranging from 32 to 54 months (median 38 months)

though only 4.1% of patients required a second surgery at adjacent level. At 4 years, adjacent level degeneration-free rate was 76.7% in artificial disc group and 78.3% in the ACDF group, suggesting no difference in development of AS disease after arthroplasty.

Another study by Maldonado et al. (2011) prospectively studied 190 patients with a minimum of 3-year follow-up after ACDF or artificial disc to evaluate the incidence of AS degeneration. Radiographic evidence of AS degeneration was defined as new or enlarging anterior osteophytes or new or increased calcification of the anterior longitudinal ligament. AS degeneration was found in 10.5% of patients in the ACDF group and in 8.8% of patients in the arthroplasty group though this did not reach clinical significance ($p = 0.69$). This study did not address AS disease requiring operative intervention.

Another prospective, randomized IDE trial by Davis et al. (2015) followed 291 patients for 48 months after arthroplasty with MOBI-C cervical artificial disc (LDR Medical; Troyes, France) and ACDF. At 4-year follow-up, TDR group had significantly less AS degeneration than the ACDF group (41.5% vs. 89.5%, respectively, $p < 0.0001$). Re-operation at the index level was significantly lower for TDR group (4.0%) versus ACDF group (15.2%, $p < 0.0001$). Indication for TDR group re-operation was stenosis, device migration, poor endplate fixation, and persist neck and/or shoulder pain. The most common indication for re-operation in ACDF group was symptomatic pseudarthrosis. This study also did not address AS disease.

Studies addressing AS re-operation rate provide a more objective assessment of the effect of motion preservation on adjacent levels. In a single institution study by Coric et al. (2010) with 3 separate prospective randomized trials for artificial cervical discs, lower re-operation rates were observed for arthroplasty than fusion. 90 patients were randomized to ACDF (37 patients) or cervical disc arthroplasty (53 patients) with 2-year minimum follow-up (mean 38 months). Clinical success, defined as a composite measure of five separate components, was significantly higher in the arthroplasty group (85%) compared to the ACDF group (70%, $p = 0.035$). Adjacent level disease requiring re-operation occurred at a rate of 1.7% (0.5%/year) in the arthroplasty group which was lower (but not statistically significant) than the rate of 8.1% (2.6%/year) in the ACDF group. A multicenter randomized US FDA IDE trial also by Coric et al. (2011) addressed radiographic adjacent-level changes and re-operation rate. A total of 269 patients were enrolled with 135 patients randomized to TDR with the Kineflex-C disc and 133 to ACDF. There were no preoperative differences in the radiographic changes at adjacent levels. Radiographic deterioration was graded as none, mild, moderate, or severe. At 2-year follow-up, severe adjacent-level deterioration was evident in 24.8% of ACDF patients and only 9% in TDR group ($p < 0.0001$). Index-level re-operation rate was similar (5.0% TDR vs. 6.1% ACDF) and there was no significant difference in AS re-operation rate (7.6% for TDR and 6.1% for ACDF).

Given the low incidence of AS disease requiring re-operation, long term studies and large number of subjects are required to adequately assess the potential positive effect of motion preservation. A single institution study by Coric et al. included two devices (Bryan Disc or Kineflex/C) and enrolled 41 patients in CDR and 33 patients in ACDF control. A total of 63 patients had a minimum of 4-year follow-up. Both arthroplasty and ACDF patients showed a low rate of index level re-operation rate (2.4% vs. 0%, respectively) and adjacent level re-operation (4.9% vs. 3.0%, respectively) without statistically significant differences. Two studies have presented 7-year follow-up on arthroplasty outcomes. Vaccaro et al. (2013) reported a US FDA IDE trial of the SECURE-C device. At 24 months, patients in the arthroplasty group had statistically lower index level re-operations than ACDF (2.5% vs. 9.7%, respectively) and similar AS re-operation rate at 2-years (1.7% vs. 1.4% respectively). Recently, follow-up 7-year data was released that showed very significant differences in index and adjacent level re-operation rates. Index level re-operation rate was significantly lower in TDR group (4.2% vs. 15.3%). For AS re-operation rates, the incidence for cervical TDR was 4.2% compared to 16.0% in the ACDF group. Another long-term

7-year study by Burkus et al. (2014) reported on the efficacy of cervical disc replacement with Prestige Disc (Medtronic, Memphis, TN). 541 patients were randomized at 31 investigational sites to TDR or ACDF. At 84 months, surgery at the index level were lower for TDR than ACDF (4.8% vs. 13.7%, $p < 0.001$) as well as at adjacent levels (4.6% vs. 11.9%, $p = 0.008$).

Long term results have also been observed to be significant for 2 level cervical disc arthroplasty compared to ACDF. Radcliff et al. (2015) reported on 5-year results of TDR and ACDF for 2-level degenerative cervical disease. A total of 225 patients underwent 2-level TDR and 105 patients underwent 2 level ACDF. At 60-month follow-up, there were significantly fewer second surgeries in TDR group than in the ACDF group (71% vs. 21.0%, $p = 0.0006$). In regard to AS degeneration, there also were significantly less AS degeneration in TDR group than in the ACDF group (50.7% vs. 90.5%, $p < 0.0001$). Furthermore, there were significantly fewer AS reoperations in TDR group than in the ACDF group (3.1% vs. 11.4%, $p = 0.0004$). For TDR, the annual rate of AS re-operation was 0.6%/year which is similar to the actual re-operation rate (0.66%/year) reported by Hillebrand.

Radcliff et al. (2015) also reported on a "real-world" application of arthroplasty versus ACDF. A retrospective, matched cohort analysis of patients enrolled in a Blue Cross Plan assessed a "real-world" population with symptomatic cervical disease treated with TDR or ACDF. A total of 6635 patients in the ACDF group and 327 patients in the cervical TDR group. At 36 months, the incidence of reoperation at index level in TDR group was 5.7% compared to 10.5% in ACDF group ($p = 0.0214$). Further, AS re-operation rate was significantly lower for cervical TDR group compared to ACDF (3.1% vs. 11.4%, respectively). This study was performed outside of randomized trials and therefore represents "real world" outcomes supporting a lower incidence of index and adjacent level re-operation after cervical TDR than ACDF. Interestingly, this study also showed a significant reduction in all costs at 2 years of 12% in the TDR group ($34, 979 vs. ACDF $39,820).

Two meta-analysis have also addressed AS disease after cervical arthroplasty and ACDF. Upadhyaya et al. (2012) included 3 randomized, multicenter, US FDA IDE studies. A total of 621 patients received an artificial disc and 592 patients were treated with ACDF. At 24 months, 1098 patients were available for follow up. The rate of secondary surgery at the index level was significantly lower for arthroplasty with an RR of 0.44 (95% CI 0.26–0.77, $p = 0.004$, $I^2 = 0\%$). There was also a significant reduction in the adjacent-level reoperation risk favoring arthroplasty with an RR of 0.460 (95% CI 0.229–0.926, $p = 0.030$, $I^2 = 2.9\%$). McAfee et al. (2012) meta-analysis of the 3 FDA-approved TDR IDE studies above and PCM cervical disc (NuVasive Inc., San Diego, CA). A total of 1226 patients had a with minimum 2-year follow-up. Overall survivorship was defined as the absence of revision, reoperation, supplemental fixation, or device removal within 24-month follow-up period. Survivorship was achieved in 96.6% of arthroplasty patients (804 of 832) and 93.4% of ACDF patients (725 of 776). The difference in proportions was 3.2% (95% CI:1.1–5.3%, $P = 0.004$), suggesting that arthroplasty is superior to ACDF in regard to secondary surgical procedure. Unfortunately, this meta-analysis did not specifically address AS re-operation rate.

Conclusions

AS degeneration leading to re-operation is a multifactorial process. Factors contributing to the etiology of this process include: (a) the natural history of the underlying degenerative disease, (b) surgical technique, e.g., minimally invasive, muscle, and ligament sparing versus open procedures, (c) surgical decision-making, e.g., single versus multilevel surgery, (d) surgical procedure, i.e., fusion versus decompression alone versus arthroplasty, (e) patient specific factors such as overall sagittal balance. Due to inherently low incidence of AS re-operation following cervical spine surgery (<1%), long-term follow-up and/or large patient numbers are needed to demonstrate

statistically significant differences between procedures such as arthroplasty and fusion. Studies aim at detecting differences with only 2-year follow-up with less than several thousand patients are simply not powered to show statistically significant differences. Biomechanical studies have indicated cervical arthroplasty puts less stress on adjacent segments compared to fusion. Some prospective, randomized clinical studies indicate that arthroplasty decreases the rate of AS degeneration. Limited studies with long-term follow-up also support that arthroplasty may lead to less subsequent surgical intervention at index and adjacent segments. But continued long term data is required to confirm that this trend remains significant.

Posterior Dynamic Stabilization

Contents

Abstract

Posterior dynamic stabilization (PDS) systems arose with the promise of stability without fixation. In particular, these systems address the two prevailing models of spinal biomechanics – the Panjabi model of the Neutral Zone and Mulholland-Segupta theory of abnormal load transmission. By both limiting the range of motion of the diseased level and off-loading the disc space of some axial stress, PDS systems hope to treat back pain while preserving motion. However, these design constraints post a significant design challenge, as demonstrated by the multiple models that have been visited over the years. Though a successful PDS system has yet to emerge, surgeons have found other ways to use the technology, including as an adjunct to improve fusion rates when paired with interbody devices.

standard is spinal fusion, which internally fixes spinal elements until a patient can undergo a boney fusion across the levels in questions. However, a spinal fusion will abnormally fix two spinal vertebral bodies, which not only reduce a patient's mobility, but increases the risk of developing adjacent level pathology.

To begin addressing these concerns, posterior dynamic stabilization (PDS) was introduced with the development of the Graf ligament in 1989 and the Dynesys in 1994 (Gomleksiz et al. 2012). The promise of these devices and the multiple iterations since was stability without fixation and therefore pain relief without the long-term repercussions of a rigid construct. However, enthusiasm for these devices has waned considerably in recent years given the mechanical failure of the devices and the failure of clinical success has become increasingly documented (Sengupta and Herkowitz 2012).

The following chapter will review some of the conceptual underpinnings of dynamic stabilization and its proposed benefits, briefly describe some of the key devices designed in this space along with lessons learned from them, and finally, discuss the current literature regarding the use of dynamic stabilization devices in hybrid constructs as a potential path forward with the technology.

Biomechanics of Dynamic Stabilization

Two prevailing theories of spinal biomechanics are used to explain low back pain, and PDS theoretically would address both as pain generators. Panjabi's model describes pain in terms of Neutral zone (NZ) and the range of motion (ROM) of vertebral segments (Panjabi 1992). In his 2003 paper, he described the NZ as the range of motion to which there is minimal resistance to vertebral motion. In the nonpathologic spine, the neutral zone encompasses a smaller ROM than the joint's painful zone – that is, the ligaments and other support structures of the spine limit vertebral motion before it causes pain. However, with ligament laxity or other pathology, the neutral zone of the spine can expand and permit positions of flexion and extension which are painful (Panjabi 2003). PDS seeks to reduce a patient's pain by restoring a more physiologic NZ. Where spinal fusion reduces the neutral zone to very limited motion, dynamic stabilization would theoretically restore a more natural NZ.

According to a second hypothesis, spinal instability should not be thought of as unnatural movement of the segment, rather as abnormal load transmission at the level. According to Mulholland and Segupta, disc degeneration makes it nonhomogeneous with areas with increasingly larger loads transmitted through the annulus. Load transmission therefore becomes uneven, which in turn leads to focal in-folding of endplate cartilage and subchondral bony trabeculae, analogous to a stone a shoe (Mulholland and Sengupta 2002; Simpson et al. 2001; Keller et al. 1989). PDS can help unload the disc space by providing a posterior tension band, ultimately reducing the back pain caused by the uneven load distribution. Some researchers argue that by unloading the disc, the patient will actually begin to repair the damage (Beckmann et al. 2019; Cho et al. 2010).

In addition to addressing the biomechanical foundations of back pain, PDS also aims to limit the risk of adjacent level disease. One of the largest limitations of a rigid fusion construct is the stress it places on levels above and below the initial pathology, likely due to an increased lever arm and the development of a nonphysiologic center of motion. This in turn leads to fractional increases in joint ROM, which in time develops to gross spinal instability and low back pain (Park et al. 2004). Put another way, hard fusion constructs force adjacent levels to expand their neutral zones to adjust to limited mobility, until the neutral zone of the adjacent level extends beyond the pain-free ROM of the joint. PDS would theoretically limit this risk by maintain a physiologic ROM at the diseased level and decrease the stress placed on adjacent levels (Bono et al. 2009; Aygun et al. 2017).

Though PDS devices have many theoretical advantages, it should be noted that these pose a significant design challenge. First, in order for a device to be considered a dynamic stabilization device, it must limit joint motion to a physiologic

range and unload the pathologic disk space. Additionally, the dynamic stabilization devices are fundamentally different from a fusion construct – whereas a traditional fusion construct needs to last just long enough for the patient's own bone remodeling to fuse across the segment, the PDS systems need to last indefinitely. Dilip Sengupta argues that these devices need to have uniform motion restriction and load-sharing throughout the ROM (Sengupta and Herkowitz 2012). Any asymmetry in load or motion would lead to an increase of stress on the device and lead to its premature failure.

PDS Devices

There are three main categories of PDS systems depending on the location of where the device is implanted. These focus on the pedicles, the facets, or the spinous processes.

Pedicle Based Systems

The Graf Ligament was one of the earliest pedicle based systems first reported in 1992 (Graf 1992). It was developed in Europe and used braided polyester cables looped around pedicle screws (Fig. 1). There have been several studies that have shown inconsistent outcomes of the device. One study reported patients undergoing the Graf ligamentoplasty doing clinically better in comparison to anterior lumbar interbody fusions (ALIFs) (Madan and Boeree 2003), while another showed worse outcome at 1 year and increased revision rate at 2 years with the Graf ligamentoplasty when compared to posterolateral fusions in the management of low back pain (Hadlow et al. 1998). As regards to patient satisfaction, studies have reported anywhere from 96% of patient feeling that the operation was worthwhile to 41% of patients stating they would not have chosen to have the operation again (Grevitt et al. 1995; Rigby et al. 2001).

The Dynesys system manufactured by Zimmer Spine uses nylon cords combined with plastic spacers (Fig. 2). In comparison to traditional posterior lumbar interbody fusions (PLIFs), the Dynesys was shown to offer similar improvement in clinical outcomes for lumbar degenerative disease. In addition, the Dynesys system was reported to have significantly less adjacent segment disease radiographically when compared to PLIFs and also offered more range of motion (ROM) (Zhang et al. 2016).

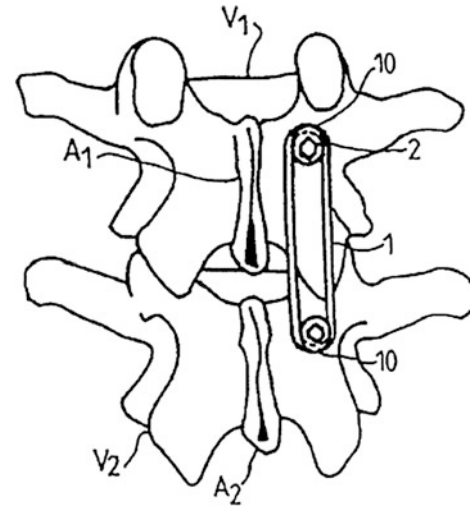

Fig. 1 Graf ligament. (Taken from original 1990 patent filing)

Fig. 2 Dynesys pedicle screws and spacer

The Dynamic Soft Stabilization (DSS) system uses pedicle screws with metal coils connecting the screws to control motion (Figs. 3 and 4). And the Isobar is essentially the tradition rod system but with a mobile joint within the rod.

Fig. 3 Dynamic soft stabilization (DSS) (Courtesy of Paradigm Spine, Device not available in the U.S.)

Facet Replacements

The majority of the facet replacement systems have some involvement of the pedicles, although the focus is on motion preservation at the facet joints. The Total Posterior Element Replacement (TOPS) system requires complete removal of the posterior elements for the device to be implanted and is anchored through the pedicles and is the only such device currently in active clinical study.

Interspinous Process Spacers

The Coflex system is the most common interspinous implant currently used in clinical practice. The device is a "U" shape allowing for distraction of the neuroforamina as well as controlled forward and backward bending. Previous studies have shown favorable outcomes with reports of 33% and 66% reductions in back pain and leg pain severities, respectively, with 95% satisfaction form patients (Errico et al. 2009).

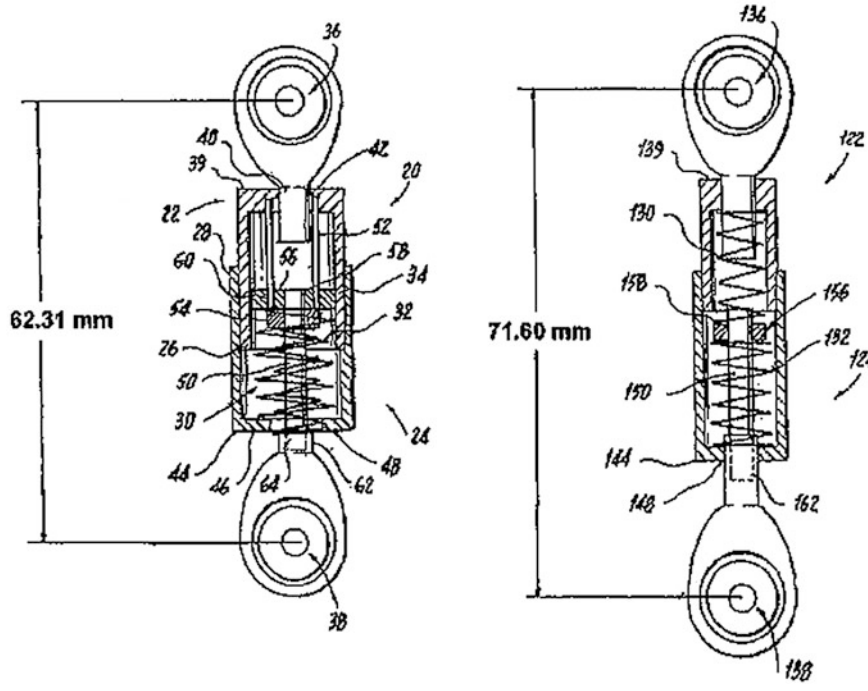

Fig. 4 DSS detail (Hildebrand and Trimm 2005)

This device does require a fair amount of laminotomy to be performed as well as drilling of the spinous processes for implantation with avoidance of posterior canal compression.

PDS as an Adjunct to Fusion

Given the long list of design requirements for a successful device, it is not surprising that in the United States, PDS devices have not been approved as a stand-alone construct. Instead, PDS devices are used as adjuncts to interbody devices to theoretically improve fusion rates.

The foundation of any fusion can be described by Wolff's Law (Wolff 1986), also known as the law of bone remodeling. In brief, Wolff's law describes cellular mechano-transduction – the conversion of mechanical stressors into biochemical signals. In the context of spinal fusion, the law implies that bone remodeling and growth may be enhanced through greater loading on the graft. Though rigid spinal fusion constructs are adequate in this regard, they are still plagued by high rates of pseudoarthrosis, and one reason may be the stress shielding phenomenon. If the pedicle screw-rod complex is too rigid, it can theoretically offload the anterior column. According to Wolff's law, that can only undermine the efficacy of fusion and could potentially play into rates of pseudoarthrosis. In contrast, PDS can maintain a controlled amount of motion when paired with an interbody. As the bone settles and remodels, the microadjustments allowed by a dynamic system can ensure a constant loading force on the anterior column and theoretically a better rate of fusion (Yu et al. 2016). Though this use of the PDS is contrary to the device's initial intent, it is a welcome windfall as the research community continues to search for the ideal motion preservation stabilization device.

with successes, failures, and the popularity of these procedures waxing and waning over time. Much in vitro and in vivo research has been done on both past and current devices to facilitate understanding of this technology and optimize utilization for clinical success and progress. This chapter describes some of the historical background, current uses and approved devices, surgical techniques, complications, revision options, and outcomes of both lumbar and cervical disc replacement.

Introduction

Historically, the initial management of painful degenerative spinal disc disease has been conservative and supportive measures. When these efforts fail to provide meaningful relief, decompression and arthrodesis is generally considered the accepted surgical intervention for its effectiveness in maintaining intervertebral height, establishing segmental stability, and improving pain. Overall, arthrodesis has proven quite successful over time. However, the reported reoperation rates cannot be ignored. These reoperations are frequently reported due to persistent or recurrent pain from symptomatic adjacent level degeneration or pseudarthrosis. Although heavily debated, current thought suggests that the complications associated with arthrodesis, namely, adjacent level disease, exist secondary to the alteration of normal spine biomechanics associated with the fusion of a previously mobile segment. There has been a considerable amount of literature dedicated to not only uncovering the presumed association between arthrodesis and adjacent level deterioration but also to investigating the biomechanical and biochemical basis behind this theoretical relationship.

In vitro cadaveric studies have demonstrated increased stresses at mobile segments adjacent to the site of fusion in the cervical spine. Eck et al. found that intradiscal pressure (IDP) increased significantly both cranial and caudal to a cervical fusion during flexion compared to an intact spine by 73% and 45%, respectively (Eck et al. 2002). Similarly, Chang and colleagues reported significantly elevated IDP in the cranial mobile segment during both flexion and extension following cervical fusion. These investigators also demonstrated effects on posterior element stress levels following cervical fusion and found that facet joint forces were significantly greater at both adjacent mobile segments during extension (Chang et al. 2007). A similar group of cadaveric biomechanical studies have been performed in the lumbar spine following instrumented arthrodesis with comparable findings of increased stress within the intervertebral discs and/or facet joints (Cunningham et al. 1997; Lee and Langrana 1984). Examination of intervertebral disc physiology shows that the health of this avascular structure is related to the relative concentrations of specific collagen and proteoglycan subtypes. The maintenance of this extracellular matrix is, in turn, reliant upon adequate diffusion of nutrients through the vertebral body cartilaginous endplate. It can be reasonably inferred that the discs within adjacent mobile segments exposed to chronically elevated intradiscal hydrostatic pressures following spinal arthrodesis may degenerate at an accelerated rate due to the disruption of this intricate metabolic balance (Buckwalter 1995; Hutton et al. 1998).

Long-term radiologic follow-up studies after spinal fusion have reported high incidences of adjacent level degenerative changes. In 2004, Goffin et al. published their radiologic findings for a series of 180 patients an average of 8 years following cervical interbody fusion. They found that 92% of the patients demonstrated an increase in degeneration score at adjacent levels at long-term follow-up. A suggestive trend of correlation, albeit not statistically significant, was appreciated between adjacent level radiologic degeneration and clinical outcomes (Goffin et al. 2004). Other authors have tried correlating these observed

radiologic changes with clinical outcomes. In a landmark study, Hilibrand and colleagues studied the development of new radiculopathy or myelopathy referable to mobile segments adjacent to previous anterior cervical arthrodesis in 374 patients available for 10-year follow-up. They reported a nearly 3% annual incidence of symptomatic adjacent segment degeneration and a Kaplan-Meier survival analysis predicted an overall prevalence of 25.6% within the first 10 years after the procedure. Twenty-seven patients underwent a second operation for fusion at the adjacent symptomatic level (Hilibrand et al. 1999). Ghiselli et al. studied adjacent segment disease in the lumbar spine and reported similar clinical outcomes. Fifty-nine of 215 patients, followed for an average of 6.7 years after posterior lumbar arthrodesis, developed symptomatic adjacent segment degeneration that warranted additional surgery. The authors reported a nearly 4% annual incidence of surgical intervention for adjacent segment disease and their survivorship analysis predicted that 36.1% of patients would have new disease requiring reoperation within the first 10 years following the index procedure (Ghiselli et al. 2004). There is a sizeable amount of literature further investigating clinical outcomes following spinal arthrodesis with a focus on defining its contribution to the development of symptomatic adjacent segment degeneration (Park et al. 2004; Gore and Sepic 1998).

Despite the substantial supporting data, no causation has been definitively proven. Randomized controlled trials investigating the relative rates of symptomatic adjacent segment disease with and without arthrodesis do not exist as it would be unethical to deny patients a fusion operation for a situation in which they would otherwise be indicated. Some experts would argue that adjacent segment degeneration is a consequence of natural history and can be expected as an inherent fate in a spine that has already shown signs of degenerative disease. To this end, studies have attempted to decipher the relative contributions of fusion and the natural aging process. Matsumoto et al. evaluated the pre-surgery and 10-year follow-up MRI images of 64 patients who underwent anterior cervical decompression and fusion (ACDF). They compared the observed radiologic changes to a group of asymptomatic volunteers who, likewise, underwent a baseline and 10-year follow-up MRI. The incidence of progression of degenerative disc disease was significantly higher in the ACDF group (Matsumoto et al. 2010). Nonetheless, this study was limited by differences in group characteristics including both a higher mean age and observed frequency of baseline MRI degenerative findings in the ACDF group. Interestingly, two of the landmark publications referenced earlier found that multilevel fusion is actually protective rather than promotive when it comes to adjacent segment degeneration. Hilibrand et al. discovered that only 12% of patients who underwent multilevel arthrodesis developed symptomatic adjacent segment degeneration, an odds ratio of 0.64 when compared to single level (Hilibrand et al. 1999). In the lumbar spine, mobile segments adjacent to single-level arthrodesis were three times more likely to develop symptomatic adjacent segment degeneration than segments adjacent to a multilevel arthrodesis (Ghiselli et al. 2004).

Another frequently studied complication of spine arthrodesis is the development of a symptomatic pseudarthrosis. There are established but quite variable rates of pseudarthrosis within the cervical and lumbar spine literature. Rates are technique-dependent and vary based on multiple factors including the use of an interbody device, fixation rigidity, whether or not instrumentation was performed, choice of graft, etc. Martin and colleagues used a registry of statewide (Washington) hospital discharges to investigate rates of reoperation following lumbar spinal surgery and found that the cumulative 11-year incidence of reoperation following an index fusion procedure was 20%. Of the 471 reoperations following an index fusion, 23.6% were associated with a coding of pseudarthrosis (Martin et al. 2007). A 47-article meta-analysis conducted to determine success and complication rates for lumbar spinal fusion found pseudarthrosis as the most frequently reported complication (14%). Authors also noted a positive relationship between satisfactory patient outcomes and achievement of solid

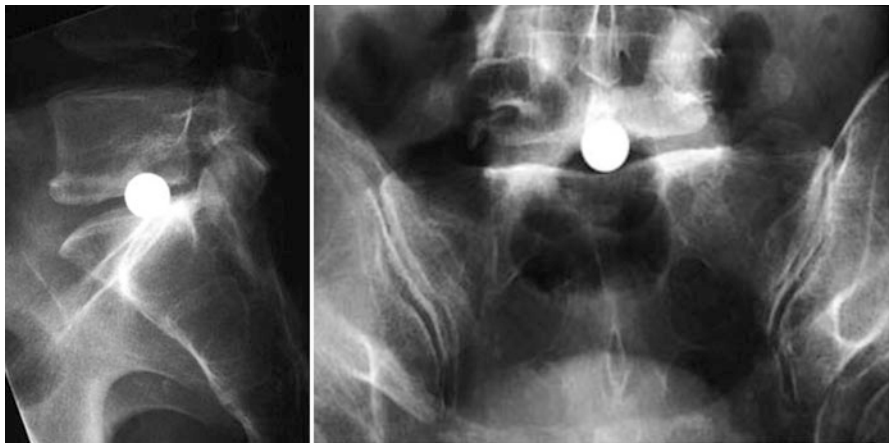

Fig. 1 Fernstrom Ball prosthesis. (Reprinted with permission from Szpalski et al. *Eur Spine J* 2002)

arthrodesis (Turner et al. 1992). A similar meta-analysis investigating the overall incidence of pseudarthrosis following fusion in the cervical spine found a much lower overall rate of 2.6% (Shriver et al. 2015). The true incidence of spine pseudarthrosis is probably underestimated as a percentage are asymptomatic and prompt no further diagnostic workup or additional management.

To combat the pitfalls discussed above that are associated with spinal fusion, the field of spinal arthroplasty and the concept of motion sparing spinal implants evolved. The growth of this field was heavily influenced by the technologic successes of motion-preserving joint prostheses for the treatment of degenerative joint disease in the hip and knee. Motion sparing technology could potentially circumvent the limitations of arthrodesis. In theory, by implanting a motion sparing prosthetic within the intervertebral space, accelerated adjacent segment degeneration could be mitigated. The potential for pseudarthrosis development could be eliminated with no attempt at surgical fusion. In addition, maintaining the mobility of the spinal segment could lead to preservation of normal spine biomechanics and could maximize patient motion, function, and improve clinical outcomes. Along these lines, investigators began to define the characteristics of an ideal spinal arthroplasty system which would include the reproduction of native disc viscoelastic properties, the reproduction of native disc motion characteristics, and the ability to withstand the mechanical and chemical environment of the intervertebral space.

A Swedish surgeon, Ulf Fernström, is historically credited with implantation of the first artificial disc in a human patient, and his experiences were published in the late 1960s and the early 1970s. His prosthesis was quite simple and consisted of a single, corrosion-resistant stainless steel ball bearing implanted into the center of the intervertebral disc space (Fig. 1). It is estimated that he implanted approximately 250 of these devices in total, both in the lumbar and cervical spine (Le et al. 2004; Basho and Hood 2012; Baaj et al. 2009). A duo of South African surgeons, impressed with Fernström's early results, also implanted 75 of these devices in the cervical spine during the same time period, for the treatment of intractable headache and cervico-brachialgia (Reitz and Joubert 1964). Ultimately, with longer-term follow-up, these mobile bearings failed miserably. The unconstrained nature created segmental spinal hypermobility, and the lack of endplate support resulted in a tendency for subsidence and migration into the superior endplate (Le et al. 2004). These early disappointments lead to a temporary abandonment of spinal arthroplasty surgical practice in favor of arthrodesis until the 1980s. Nonetheless, Fernström was ahead of his time in recognizing the potential benefits of motion sparing devices, and other researchers continued to investigate alternative designs.

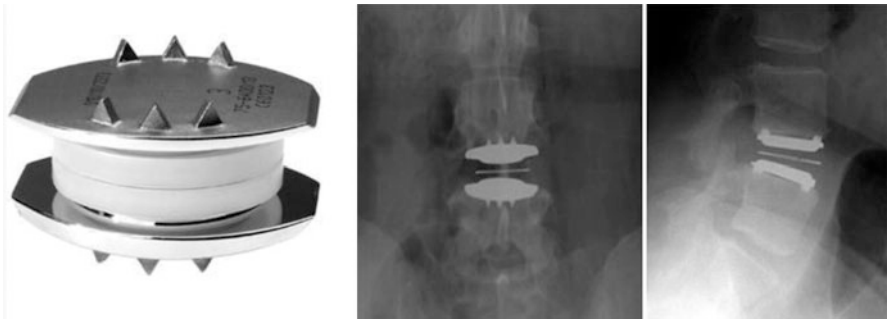

Fig. 2 Charite III prosthesis. (Reprinted with permission from Atkins, et al. *Lumbar Disc Arthroplasty.* In: Essentials of Spinal Stabilization. Holly L., Anderson P. (eds). Springer, Cham. 2017)

Multiple spine arthroplasty models were subsequently developed during the second half of the twentieth century, a majority of which were patented or published but never reached the stage of human implantation (Szpalski et al. 2002).

Spine arthroplasty then garnered renewed interest in 1984 after the maiden implantation of the German-engineered SB Charité I prosthesis, which was the first approved and commercially available lumbar total disc replacement system available in Europe (Link 2002). The SB Charité I was an unconstrained device featuring small, circular, polished steel alloy endplates with anchoring teeth for cementless fixation and a sliding ultrahigh molecular weight polyethylene (UHMWPE) core marked with a radio-opaque circumferential wire (Büttner-Janz et al. 1989). The sliding core allowed for a dynamic instantaneous axis of rotation that could translate during flexion and extension, more closely mimicking normal lumbar spinal motion (Bono and Garfin 2004). Similar to Fernström's ball bearing implants, the earliest SB Charité model lacked sufficient endplate contact surface area secondary to its undersized metal endplates and was noted to subside or migrate axially (Link 2002). This design flaw prompted development of a second version, the SB Charité II, with enlarged metal endplates. Problems with fatigue fractures ultimately lead to the third- and final generation Link SB Charité III (DePuy) device which started production in 1987 in Europe and eventually received FDA approval in the United States in 2004 after 2-year follow-up results from its investigational device exemption (IDE) randomized controlled trial showed noninferiority to lumbar arthrodesis (Fig. 2) (Blumenthal et al. 2005). Subsequent 5-year follow-up data showed a FDA-defined clinical success rate of 58% in the Charité group and 51% in the arthrodesis group (Guyer et al. 2009). Even longer-term follow-up and device retrieval studies have become increasingly available and shed light onto some of the device late failure mechanisms. Punt et al. published a case series analyzing late complications following SB Charité III disc implantation in a group of 75 unsatisfied patients that presented to their institution with persistent leg and back pain. Forty-six of the 75 patients ultimately ended up undergoing a salvage operation, and the authors were directly involved in 37 of these cases. They reported implant subsidence, adjacent disc degeneration, and index-level facet arthrosis as the three most common late complications. Of the 39 cases of observed implant subsidence, they estimated that 24 were secondary to an undersized prosthesis. The authors also reported on 8 cases of anterior-posterior migration and 10 cases of polyethylene core wire breakage (Punt et al. 2007). Van Ooij and colleagues reported very similar findings in their 27 patient case series (van Ooij et al. 2003). In a 2007 international multicenter retrieval study of 21 explanted SB Charité III implants from patients undergoing revision surgery due to persistent pain, Kurtz et al. analyzed polyethylene wear patterns and found the peripheral rim to be susceptible to pinching as evidenced by the observation of plastic

deformation, fracture, cracking, and other fatigue damage in most of the specimens (Kurtz et al. 2007). Current long-term clinical outcome data and the results of the most recent FDA IDE randomized controlled trials for the SB Charité III, its contemporaries, and its successors will be covered elsewhere in this chapter. Overall, however, the SB Charité III was quite successful and underwent widespread implantation for many years. It was removed from the US market in 2013 as part of a business decision when DePuy purchased Synthes and elected to sell its lumbar arthroplasty system, the ProDisc-L.

Currently, there are two FDA-approved lumbar arthroplasty systems. The Synthes ProDisc-L was developed concurrently with the SB Charité III in the late 1980s. Like the Charité, it underwent stepwise modifications from its initial design to the release of the current model, which received FDA approval in 2006. Unlike the Charité, the ProDisc-L is a semiconstrained device. There is a single articulating interface between a polyethylene bearing and the superior endplate. The polyethylene bearing is fixed to the inferior endplate and does not slide or translate as in the Charité. The ProDisc-L is secured to the neighboring vertebral bodies via a keel or midline sagittal fin (Bono and Garfin 2004). There is currently a considerable amount of longer-term follow-up studies (>5 years) supporting the use of this device in patients with lumbar degenerative disc disease. The ActivL (Aesculap Implant Systems) prosthesis received FDA approval in 2015 after its 2-year follow-up data showed noninferiority to the other two previously mentioned lumbar arthroplasty prostheses. This implant has been marketed as next generation in that it is designed to be inserted as a single unit, obviating the need for multiple spinal distractions. In addition, its polyethylene inlay is affixed to the inferior endplate in a way that permits a limited amount of translational motion (Garcia et al. 2015).

The technological triumphs in lumbar arthroplasty motivated the pursuit for a counterpart in the cervical spine. The first modern era artificial cervical disc was developed in the United Kingdom and was implanted in 1991. This device came to be known as the Cummins-Bristol and had two distinctive design features when contrasted to the previously discussed lumbar prosthetics: (1) a metal-on-metal articulation with no separate intercalary polyethylene bearing and (2) anterior flanges for the purpose of obtaining immediate anchoring screw fixation into the cranial and caudal vertebral bodies. Early results were quite poor and related to failure of the anterior screw fixation via screw pullout and screw fracture. Following modifications to screw hole positions and the addition of locking screw capabilities, a subsequent group of 20 patients, implanted with the device between 1991 and 1996, fared much better according to Cummins and colleagues. The authors reported that 75% of the patients experienced an improvement in preoperative symptoms and that 88% of the patients available for follow-up in 1996 had radiographic evidence of maintenance of index level motion (Le et al. 2004; Cummins et al. 1998). There were also four patients with persistent dysphagia attributed to the high profile of the anterior flanges. Two years later, a redesigned second-generation version of the Cummins-Bristol artificial disc, known as the Frenchay, was implanted into 15 patients as part of a pilot study (Fig. 3). The Frenchay's superior component "ball" remained hemispherical, while the inferior component "socket" was shallow and ellipsoid making for an incongruent articulation. Theoretically, this permitted the cranial vertebral body to passively align with the dynamic center axis of rotation as dictated by the facet joints. At 2 years, the prosthetic joints remained mobile with an average arc of 6.5° in flexion and extension, there were no cases of joint subluxation or subsidence, and there were 3 reoperations, only one of which involved explanation of the prosthesis for looseness (Wigfield et al. 2002). The Frenchay would eventually become the Prestige (Medtronic), which is one of the commercially available cervical total disc replacement systems on the market today. This device received US FDA approval in 2007, and the latest long-term (7-year) clinical outcome data has been very favorable showing a statistically significant greater overall success rate of 75% in the

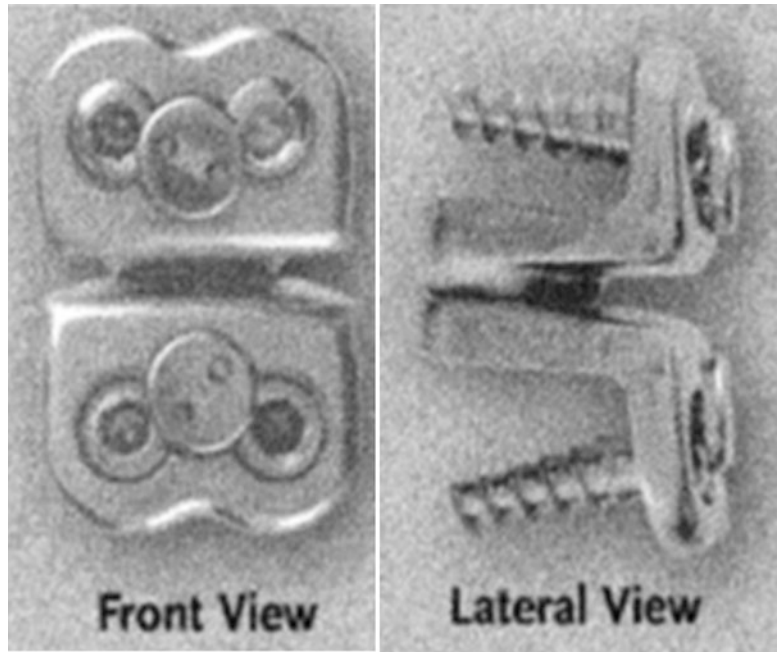

Fig. 3 Frenchay prosthesis. (Reprinted with permission from Buell, et al. Cervical Arthroplasty: Long-Term Outcomes. In: Handbook of Spine Technology. Cheng B. (eds). Springer, Cham. 2019)

arthroplasty group compared to 64% in the control arthrodesis group. These authors also reported maintenance of physiologic segmental angular motion at the index level and an index level secondary surgery 11-year cumulative rate of 4.8% compared to 13.7% in the arthrodesis group (Burkus et al. 2014).

Another unique, albeit unsuccessful, cervical arthroplasty concept is worthy of brief mention. The Pointillart cervical prosthetic entered the scene momentarily between 1998 and 1999, and its concept was influenced by unipolar hip replacement designs (Fig. 4). It featured a single titanium base piece which was anchored via screws into the caudal vertebral body and a carbon sliding cranial surface meant to articulate with the inferior endplate of the cranial vertebral body. The inventing surgeon implanted this device into ten patients and reported "total failure" after 1-year follow-up radiographs showed spontaneous fusion and resultant absence of motion across the index level in eight of the patients (Pointillart 2001).

There are currently six FDA-approved cervical total disc replacement systems: Prestige (Medtronic), Bryan (Medtronic), Mobi-C (Zimmer-Biomet), ProDisc-C (DePuy Synthes), PCM (NuVasive), and Secure-C (Globus Medical). All of these devices have 2–7-year US FDA IDE prospective randomized controlled trial clinical outcome data showing non-inferiority to anterior cervical decompression and fusion (Sasso et al. 2011; Hisey et al. 2016; Janssen et al. 2015; Phillips et al. 2015; Vaccaro et al. 2013). As with any surgical procedure, particularly in the spine, strict adherence to appropriate criteria of both patient selection and surgical indications is paramount for successful outcomes.

Surgical Techniques: Cervical Disc Replacement

Indications

- Subaxial spinal motion segments between C3 and C7
- One or two-level pathology
- Radiculopathy and/or myelopathy secondary to neural element compression by:
  - Soft disc herniation
  - Osteophyte formation

Fig. 4 Pointillart prosthesis. (Reproduced with permission from Pointillart, *Spine* 2001)

Contraindications

- Spondylolisthesis, instability with translation of greater than 3.5 mm
- Deformity
  - Including kyphosis of greater than 11° at the target level
- Trauma (concern for disruption or irregularity of vertebral endplates)
- Prior cervical laminectomy (concern for disruption of posterior stabilizing elements at the level of interest)
- Prior surgery at the level of interest
- Osteoporosis (T-score less than −2.5)
- Other metabolic bone diseases which may result in abnormal bony architecture and/or stability
  - Rheumatoid arthritis, other inflammatory arthropathies
  - Renal disease
  - Cancer
  - Long-term steroid use
- Infection
- Severe facet arthropathy
- Ankylosing disorders
  - Ankylosing spondylitis
  - Diffuse idiopathic skeletal hyperostosis (DISH)
  - Ossification of the posterior longitudinal ligament (OPLL)
- Metal allergy
- Isolated axial neck pain without radiculopathy or myelopathy

Relevant Anatomy

A standard Smith-Robinson approach to the anterior cervical spine is utilized for cervical disc replacement. While this is generally regarded as a common and safe approach, detailed knowledge and understanding of the local anatomy is necessary to minimize inadvertent injury to several important structures:

Nerves

- **Superior laryngeal nerve** is typically encountered for procedures in the upper cervical spine, at or above C3 and C4. It can be identified traversing from the carotid sheath to the larynx at the thyrohyoid membrane along with the superior laryngeal artery. As this nerve contributes to control of a vocal cords, injury to it may result in difficulty with voice control (dysphonia) and swallowing or aspiration (dysphagia).
- **Recurrent laryngeal nerve** is occasionally visualized on its recurrent path in the tracheoesophageal groove. On the left, once the nerve exits the carotid sheath, it

courses inferiorly under the aortic arch prior to returning cephalad in the tracheoesophageal groove. The recurrent laryngeal nerve on the right is beneath the right subclavian artery and is less constant. For this reason, it is sometimes dogmatically believed to be safer to perform the approach on the left side as this course was previously felt to be more predictable; however this has not been demonstrated clinically, and there are many surgeons that perform this approach on the right side without any increased complication rate related to phonation or swallowing. This nerve also contributes to control of vocal cords well as all of the laryngeal muscles and the esophagus. Similar to injury of the superior laryngeal nerve, injury to this nerve can also result in difficulties with dysphonia and or dysphagia.

- **Sympathetic chain** lies on the ventral surface of the longus coli muscles. Because of this, manipulation in this area is generally avoided, with dissection generally limited to the medial aspect of the longus coli. Injury to the sympathetic chain can result in an ipsilateral Horner's syndrome.

Vessels

- **External jugular vein** lies between the platysma and the caudal mastoid. It often is lateral to the operative field; however occasionally the main external jugular or large branches of it can cross the surgical field. Injury to it may not result in significant functional impairment; however it can bleed quite vigorously, adding difficulty and time to the surgery.
- **Carotid artery** travels within the carotid sheath. It can be easily palpated as a pencil-like structure deep to the sternocleidomastoid muscle belly and used as a landmark for the approach as the entirety of the approach should be medial to this structure along with the other contents of the carotid sheath.
- **Vertebral artery** travels within the foramen transversarium of the cervical vertebrae. It typically enters at C6, although can also enter at C7, and travels proximally to supply the brainstem and posterior cranial contents. The longus colli muscle lies ventral to the transverse foramen containing these vessels, and so dissection deep to the longus muscle belly is very limited and cautious to avoid injury to the vertebral arteries. However, should a vertebral artery injury occur elsewhere during the procedure, dissection deep to the longus colli can be utilized to gain access to the vessel and control bleeding. Injury to this blood vessel can result in rapid exsanguination. The overall implications of vertebral artery injury varies widely, from asymptomatic to stroke or even death.

Trachea and Esophagus are midline structures medial to the plane of approach. Further mobilization is often necessary for adequate exposure to the targeted disc site(s). Because of its cartilaginous rings, the trachea is more easily identified. The esophagus lies deep to the trachea. As it is composed of smooth muscle of varying degrees of thickness, it is more prone to inadvertent injury during anterior cervical approaches. Injuries to these structures are often occult and not always identified intraoperatively but can lead to profound morbidity and even mortality if not identified and treated appropriately. For these reasons, a high index of suspicion is mandatory during both the index procedure and follow-up if anything is amiss.

Positioning and Approach

The patient is positioned supine on a radiolucent operating table. The authors prefer to have the patient as caudal on the table as patient's height will allow to provide space for the C-arm rostral to the patient when not in use. The neck is positioned in neutral alignment. The arthroplasty devices are not intended to correct or change alignment, and so native alignment is maintained during positioning so as to avoid improper implant placement. If the shoulders preclude adequate visualization of the targeted surgical level, gentle traction can be gained by either taping the shoulders down caudally to the table or placing wraps about the wrists

that can then be utilized for intermittent traction. If continuous traction is utilized, the surgeon must ensure that excessive traction is not sustained on the brachial plexus for the entirety of the procedure to decrease the chance of root palsies.

A standard Smith-Robinson approach is performed. This is often a left-sided approach, although can be performed on either side depending on surgeon preference. The location of the incision is planned over the targeted disc space based on manual palpation of landmarks and/or fluoroscopy. If possible, the incision is placed within a natural skin crease for cosmesis. Prior to incision, it can be helpful to mark the sternal notch to facilitate orientation to the midline throughout the procedure, as precise alignment is of utmost importance for accurate placement of arthroplasty implants. A 2–3 cm transverse incision is made, extending approximately from midline to the medial border of the sternocleidomastoid muscle. Subcutaneous fat and platysma are then divided. The superficial layer of the deep cervical fascia is divided in the plane visualized between the sternocleidomastoid laterally and the strap muscles medially. The omohyoid can be sacrificed if needed to gain access to the lower cervical levels. Continued blunt dissection in this plane will then lead to the spine, with the carotid sheath the laterally and the larynx and esophagus medially. When the spine is encountered following this plane, a snap is placed on the annulus of the intended surgical level, and localization is confirmed using lateral cross-table fluoroscopy. Adjacent to the target disc level, the longus colli are gently elevated bilaterally to allow adequate access to the disc space out to the uncovertebral joints, however taking care not to dissect too far laterally as the anterior aspect of the vertebral body slopes down and away from the ventral surface to avoid injury to the vertebral arteries. At this point, self-retaining radiolucent retractors can be placed deep to the elevated longus flaps. The annulotomy is performed followed by the discectomy portion of the procedure.

Implant-Specific Instrumentation

Prestige LP (Medtronic Sofamor Danek) (Prestige LP 2009) (Fig. 5)

- *Device type:*
  - Metal-on-metal (titanium alloy)
  - Ball and socket
- *Procedure*

  Caspar pins are placed in the rostral and caudal vertebral bodies, taking care to ensure that placement is midline, parallel to the endplates and with sufficient distance to prevent violation of the endplates during placement or disc space preparation, and parallel to one another so as not to introduce any kyphosis or lordosis during disc space preparation. Fluoroscopic guidance is highly

Fig. 5 Medtronic Prestige LP prosthesis. (Reproduced with permission from Nasto et al. *Cervical Disc Arthroplasty.* In: Cervical Spine. Menchetti P. (eds) Springer, Cham. 2016)

advised when placing these pins. The remainder of the decompression is completed using Kerrison, curettes, and a bur to facilitate complete osteophyte removal for a wide bilateral foraminal decompression. The posterior longitudinal ligament (PLL) is resected. The endplates are gently burred to provide a flat and parallel disc space; however care is taken to limit amount of cortical bone removed to minimize risk of subsidence. The rasp can facilitate fine-tuning of this step after burring. The anterior vertebral bodies are also flattened with the bur so that to the flanges of the prosthesis will lie flush to the anterior aspect of the vertebral body. Periosteum present on the adjacent vertebral bodies is removed with the monopolar cautery, and all bone dust is copiously irrigated and removed to decrease chance of heterotopic ossification formation. The trial is inserted, and sizing is confirmed using lateral fluoroscopy as well as manual assessment of the resistance encountered for insertion and removal. Ensure the tabs on the trial fit flush with the anterior vertebral body. Compare the trial size and space to adjacent healthy disc spaces and facet joints on fluoroscopy. At this point, the Trial Cutter Guide is placed into the prepared disc space. Confirm that the cutter guide is perfectly midline using fluoroscopy because all steps moving forward will now dictate the final positioning of the implant. The Rail Cutter Bit is then used to prepare the rail tracts; the guide is held in place between rail preps with the Temporary Fixation Pins. When all four rails have been cut, all instruments are removed from the disc space. The Rail Punch is tapped into the disc space to complete the rail preparation. The prosthesis is then implanted into the prepared disc space, with the ball endplate rostral. Bone wax can then be applied over the exposed anterior aspect of the implant and over the exposed vertebral bodies to minimize heterotopic ossification. Ensure that the prosthesis remains parallel and the inserter perpendicular to the prepared disc space. Lateral fluoroscopy is used to guide depth of placement, and AP views confirm accurate coronal positioning.

Mobi-C (Zimmer Biomet) (Mobi-C 2016) (Fig. 6)

- *Device type:*
  - Metal on plastic (ultrahigh molecular weight polyethylene)
  - Semiconstrained
- *Procedure*

  Caspar pins are placed in the rostral and caudal vertebral bodies, taking care to ensure that placement is midline, parallel to the endplates and with sufficient distance (5 mm) to prevent violation of the endplates during placement or disc space preparation, and parallel to one another so as not to introduce any kyphosis or lordosis during disc space preparation. The Intervertebral Distractor Device is used to distract the vertebral bodies, and then the distraction is maintained through the Caspar distractor pins. The recommended method of the remainder of the decompression for this device by the manufacture is without

Fig. 6 Mobi-C prosthesis. (Reprinted with permission from Buell, et al. Cervical Arthroplasty: Long-Term Outcomes. In: Handbook of Spine Technology. Cheng B. (eds). Springer, Cham. 2019)

the use of a burr to optimally preserved bony endplate integrity. Bilateral foraminotomies are performed with Kerrison. The PLL is resected to facilitate perpendicular disc space preparation and distraction. The inferior endplate is squared off as wide as possible within the corners of the uncus without complete removal of the uncinates to maximize the width of the footprint of the implant. Next, the Width Gauge is placed into the prepared disc space to determine the width and adequacy of endplate preparation. If this gauge does not lie flat on the endplate, then the uncinates are squared off further using curettes. The Paddle Distractor, Caspar pin, or depth gauge can be used to estimate the depth of the footprint. Do not include anterior osteophytes in this measurement to ensure accuracy of the anterior-posterior footprint measurement. Anterior osteophytes can be removed as needed to create a flat anterior surface; however do not remove the overhang of the superior endplate as this concavity is required to match the shape of the superior endplate of the implant. Place bone wax as needed on exposed or decorticated surfaces of the anterior vertebral body to decrease risk of heterotopic ossification formation. Placed the selected trial with slight distraction on the Caspar pins, and then release the distraction to confirm fit both manually assessing resistances as well as on AP and lateral fluoroscopy. Re-distract the Caspar pins, remove the trial, and place the pre-assembled implant into the prepared disc space, avoiding any rotation during implantation. This can be confirmed using lateral fluoroscopy, ensuring that the Alignment Tabs on the inferior plate remain in line with one another such that only one line is visible without obliquity. The inserter and PEEK cartridge are removed. The implant position can be fine-tuned with the plate impactor and tamp. Prior to removal of the, gently compress through them to seat the prosthesis teeth into the endplates. The Caspar pins are removed and bone wax placed within the defects to control bleeding. Final positioning is confirmed using AP and lateral fluoroscopy.

Bryan Disc (Medtronic Sofamor Danek) (Bryan 2005) (Fig. 7)

- *Device type:*
  - Metal on plastic (soft polyurethane core)
  - Semiconstrained
- *Procedure*

  The remainder of the discectomy is performed with hand instruments, taking care not to remove the uncinates to preserve reference anatomy. The overhanging lip of the anterior superior vertebral body is removed, and the anterior vertebral bodies are smoothed to create a flat surface. The Transverse Centering

Fig. 7 Bryan Disc prosthesis. (Reprinted with permission from Buell, et al. Cervical Arthroplasty: Long-Term Outcomes. In: Handbook of Spine Technology. Cheng B. (eds). Springer, Cham. 2019)

Tool and Centering Level are used to identify and mark the center of the superior vertebral body. This can be confirmed with fluoroscopy if needed. Use the Intradiscal Distractor to distract the disc space to 8.5 mm and maintain this for 60 s to stretch the ligaments. Select the appropriate Alignment Guide, attached it to the Milling Guide, and place it into the prepared disc space over a Steinmann pin which has been placed at the reference point previously marked by the Centering Tool. Place the Stabilizer with the Centering Level on the Alignment Guide. Confirm that the alignment Visualization Slots are parallel to and centered between the endplates using fluoroscopy. The drill pilot holes, place Anchor Posts, distract the disc space, and complete a thorough decompression. Prepare the endplates using provided rasps up to 8.5 mm. Mill the superior and inferior endplates with the included Milling Assembly. Fill the implant with sterile saline. Place the implant into the prepared disc space. Irrigate copiously and place bone wax into screw holes and on exposed cortical surfaces to decrease chance of heterotopic ossification formation. Confirm final placement on lateral and AP fluoroscopy.

Postoperative Protocol

Amount of activity as well as the use of a hard or soft collar is at the discretion of the surgeon. A course of nonsteroidal anti-inflammatories is often utilized to decrease heterotopic ossification. The type, amount, and duration are variable, although a 2-week course is common.

Complications

Adverse events related to the approach such as dysphagia, dysphonia, vascular, or tracheoesophageal injury are possible, but reported rates are not significantly different compared to standard anterior cervical discectomy and fusion procedures (Mummaneni et al. 2007). There are, however, complications unique to total disc arthroplasty. While the goal of cervical disc replacement is maintenance of motion to theoretically protect adjacent levels, heterotopic ossification at these levels of preserve motion has been reported. The rates of heterotopic ossification development very widely; however it is felt to infrequently negatively impact range of motion or postoperative outcome (Lee et al. 2010; Chen et al. 2011). Leung reported 17% incidence of heterotopic ossification with the Bryan total disc arthroplasty device as assessed with radiographs. About 11% of these patients had significant loss of motion; however this was not correlated to clinical outcome such as pain or function (Leung et al. 2005). Similarly, Tu assessed the presence of heterotopic ossification using CT. With this more sensitive method, it was detected in 50% of one- and two-level Bryan total disc arthroplasty recipients, but again without adverse effects on clinical outcomes (Tu et al. 2011). Copious irrigation throughout the procedure including endplate preparation as well as postoperative utilization of nonsteroidal anti-inflammatory medications is often recommended to minimize risk for heterotopic ossification formation.

Subsidence is another complication which is often suggested as a possibility; however it is not often demonstrated or reported in the literature (Hacker et al. 2013). Recommendations for avoidance of this complication are relative contraindication in osteoporotic patients, maximizing the footprint of the implant, avoidance of oversizing the disc space, and preserving the endplate integrity during disc space preparation.

Postoperative kyphosis has been observed following total disc arthroplasty. This is also felt to be multifactorial, with contributions such as excessive anterior superior endplate removal during endplate preparation, incorrect angle of insertion, and amount and direction of distraction during endplate preparation (Sears et al. 2007). Again, outcomes have been evaluated in the setting of postoperative kyphosis. Pickett demonstrated preserved range of motion and no significant difference in outcomes despite focal kyphosis, and overall cervical alignment was maintained (Pickett et al. 2004).

Vertebral body fractures are postulated to be a possible complication, particularly with the keeled implant either during insertion or postoperatively. This is potentially more relevant if multilevel keeled implants are placed, but reports are infrequent to date (Shim et al. 2007; Datta et al. 2007).

In an era of heightened awareness to bearing surface wear with resultant particulate debris and metallosis, this is certainly a concern for the majority of cervical disc replacement implant designs. There is, however, a paucity in the literature regarding clinical examples of this problem. In the cervical spine, Cavanaugh presented a case report of metal ion reactivity resulting in hypertrophic tissue formation posterior to the device and subsequent neural compression. This was addressed with removal of the implant, revision decompression, and anterior fusion with resolution of symptoms (Cavanaugh et al. 2009). More instances of bearing wear-related complications have been presented in the lumbar literature, although true incidence remains unknown (Kurtz et al. 2007; van Ooij et al. 2007; Hallab 2009).

Finally, persistent pain is always a concern following any surgical procedure intended to address pain. As related to cervical disc arthroplasty, ongoing radiculopathy is most often due to incomplete decompression, particularly in a motion sparing technique where osteophytes can progress if not completely removed at the time of the index procedure (Goffin et al. 2002).

Revision Options

While interest in cervical disc arthroplasty continues to grow, the extent of need for revision remains to be seen. There is a paucity in the literature regarding this topic at this time. In general, the revision procedure will largely depend on the underlying problem. Replacement of the device may be considered if the issue is positioning or inadequate decompression after the index procedure. If there is particulate reaction, revision may necessitate conversion to fusion. Corpectomy and anterior column reconstruction may be needed if there is excessive bone loss. Most surgical technique guides recommend simply separating the bone-implant interface with an osteotome or similar device and removing it in a manner similar to which it was placed for implant removal; however in practice this may not always be the case. In the author's experience, some painful cervical arthroplasty devices have been grossly loose and are easily removed during the revision procedure. If radiculopathy is felt to be from recurrent foraminal stenosis secondary to osteophyte formation, some others advocate for posterior foraminotomy to avoid a revision anterior procedure. Likewise, if the pathology dictates, posterior cervical fusion alone is also sometimes a consideration, again to avoid anterior reoperation.

Outcomes

Overall, anterior cervical disc arthroplasty seems to be favorable compared anterior cervical discectomy and fusion in both short- and medium-term studies for both one- and two-level disease (Sasso et al. 2011; Mummaneni et al. 2007; Heller et al. 2009; Murrey et al. 2009; Zou et al. 2017). There is some evidence that two-level cervical arthroplasty procedures may fare better than single-level procedures, perhaps by protection of levels that are already degenerating (Radcliff et al. 2017; Mehren et al. 2018; Sasso et al. 2017). With the technology being available for the better part of two decades at this point, longer-term data are continuing to show favorable outcomes. Some of these longer-term reports are smaller cohorts and without similar rigor as was reported in the original IDE studies that had robust comparisons to traditional anterior cervical fusion, but there is some data suggesting that this option is durable and at least no worse than anterior fusion at these longer intervals. Rates of reoperation for adjacent segment degeneration remain lower than for fusion, although the differences not reach statistical significant (Ghobrial et al. 2018). Sasso and Dejaegher have shown durable outcomes

at 10 years, with favorable results and reoperation profiles compared to anterior cervical fusion. Likewise, Pointillart recently reported excellent outcomes in 80% of their patients 15 years out from cervical disc arthroplasty (Sasso et al. 2017; Dejaegher et al. 2017; Pointillart et al. 2018).

Surgical Techniques: Lumbar Disc Arthroplasty

Indications

- Degenerative disc disease
  - Most often single level, although multilevel use has been reported.
  - Demonstrated on MRI, CT, and/or plain radiographs.
  - Utilization of discography for confirmation of degenerative disc disease being causative for low back pain is suggested in some prior studies and technique guides as some have found it helpful for predicting improved outcome after surgery; however subsequent studies have shown increased rates of degenerative disc disease progression with the use of discography (Colhoun et al. 1988; Carragee et al. 2009). At this time, use of discography remains controversial, although anecdotally seems to have largely fallen out of favor.
- L3-S1 levels
- Failure of conservative measures for at least 6 months

Contraindications

- Instability
  - Spondylolisthesis
  - Spondylolysis
- Deformity
- Severe facet degeneration
  - With or without hypertrophy resulting in lateral recess stenosis
- Herniated nucleus pulposus resulting in radiculopathy
- Osteoporosis or osteopenia (T-score less than −1.5)
  - Metabolic disease resulting in compromised integrity of a bone architecture and/or remodeling
- Infection
- Pregnancy
- Prior trauma or fracture at affected level
  - Large Schmorl's nodes involving endplate at the affected levels
- Vascular calcification
- Metal or materials allergy

Relevant Anatomy

For the lumbar total disc replacements discussed in this section, an anterior approach to the spine is utilized. This can be trans- or retroperitoneal, depending on surgeon preference. Some spine surgeons may utilize an access surgeon to perform the approach.

Vessels

- **Aorta** is the largest artery in the body and courses anterior to the spine, left of and ventral to the inferior vena cava. The bifurcation into the common iliac arteries often occurs near the L5 vertebral body. While injury to the aorta itself is rare, if the great vessels need to be mobilized proximal to the bifurcation, segmental lumbar arteries that come directly off the aorta must be identified, isolated, and ligated to prevent significant blood loss, which can be more difficult to control if the vessels retract when avulsed.
- **Inferior vena cava** (IVC) is rarely encountered as it is predominantly a right-sided structure, and most approaches are left sided to (1) avoid injury to the IVC and (2) because there often is a more favorable plane on the left compared to the right of the great vessels leading to the anterior spine. If the IVC or a direct branch going to it is injured, hemorrhage can be massive and swift.

- **Iliac arteries and veins** – Injury to the left common iliac vein is one of the most commonly reported vascular injuries sustained during this approach and can result in massive hemorrhage in a relatively short amount of time. Often, the vessel can be repaired and the remainder of the procedure completed. Anterior lumbar procedures targeted at the L5-S1 level are typically performed caudal to the bifurcation of the aorta and vena cava and between the common iliac arteries and veins. At more proximal levels rostral to the bifurcations, these vessels need to be mobilized to allow adequate access to the targeted disc spaces.
- **Segmental vessels including the iliolumbar vein** can also cause significant bleeding which can be difficult to control unless these vessels are anticipated, identified, and ligated. Particularly the iliolumbar vein, which can be a large but very thin-walled structure traversing from the posterior aspect of the psoas muscle coursing to the left common iliac or IVC at the L4–5 level. This structure can often be identified on preoperative imaging to facilitate planning; however the surgeon must be aware of this vessel to control a prior to avulsion and retraction into the psoas, which can make it particularly difficult to control.

Ureter is a retroperitoneal structure which is identified by its peristalsis and mobilized medially along with the peritoneal contents during a retroperitoneal approach. One must avoid injuring it.

Sympathetic plexus is a latticework of nerve fibers, the superior hypogastric plexus, that runs anterior to the spine and the great vessels and medial to the iliac vessels. Injury to this structure can result in sexual dysfunction, specifically retrograde ejaculation. Patients must be counseled preoperatively on this potential risk, and younger patients may wish to consider further family planning options prior to undergoing an anterior lumbar procedure. A retroperitoneal approach carries a lower risk of injury to the structure compared to a transperitoneal approach. Additionally, blunt or bipolar dissection is recommended at the level and depth of the vessels to minimize risk of injury to these nerve fibers. Although rare, sympathetic dysfunction may occur resulting in ipsilateral lower extremity vasodilation which can mimic deep vein thrombosis. Subjectively the contralateral leg may feel cool relative to the warm ipsilateral lower extremity. This dysfunction typically resolves with observation.

Positioning and Approach

The patient is positioned supine on a radiolucent operating table with the arms out to the sides or crossed over a pillow on the chest. Some surgeons advocate for placement of a bump beneath the sacrum to bring the lumbar spine into a more accessible position. It should be noted, however, that the bump should not be placed beneath the lordotic portion of the lumbar spine so as not to exaggerated lumbar lordosis which may result in improper implant positioning. If possible, the patient position on the operating table should facilitate storage of the fluoroscopy machine when not in use.

There are several options to gain anterior exposure to the lumbar spine such as trans- or retroperitoneal, midline or paramedian, open, mini open, or laparoscopic assisted. For an open, retroperitoneal approach, the incision is localized over the target disc space using lateral fluoroscopy. Subcutaneous dissection is performed down to fascia, which is also incised. The rectus is mobilized either medially or laterally, depending on the approach and the necessary trajectory. The preperitoneal space is identified and entered, and the peritoneum and its contents are mobilized medially to allow access to the retroperitoneum. The ureter should be identified in this plane and mobilized with the peritoneum. The great vessels are identified and gently mobilized as needed for access to the desired disc space. At L4–5, the iliolumbar vein is identified, ligated, and divided to

avoid inadvertent avulsion and hemorrhage. At L5-S1, the middle sacral artery is isolated and ligated to allow unimpeded access to this disc space. At the level of the vessels and spine, blunt and bipolar dissection is used to minimize risk of injury to the sympathetic plexus. Fixed retractors can then be placed. The targeted disc is confirmed with lateral fluoroscopy, and the midline is marked using AP fluoroscopy. A standard annulotomy and diskectomy are performed, avoiding violation of the endplates.

Implant-Specific Instrumentation

ProDisc-L II (DePuy Synthes) (Prodisc-L 2017) (Fig. 8)

- *Device Type*
  - Metal on plastic (polyethylene)
  - Ball and socket
- *Procedure*

  After a standard discectomy has been performed, the intervertebral space is distracted with the spreader. A trial is placed to assess the implant height, size, and degree of lordosis. The keel tract is prepared with the chisel. During this step, position and trajectory of the keel must be confirmed as this will establish the implant position. The prosthesis is modular such that there are several options for lordosis of each endplate and insert heights to most accurately reconstruct the native disc space. The selected prosthetic endplates are inserted. Disc space is distracted, and the polyethylene inlay is inserted into the caudal endplate. Final position is confirmed using lateral and AP fluoroscopy.

Postoperative Protocol

Much of the postoperative protocol is at the discretion of the surgeon. In general, avoidance of aggressive bending, twisting, or lifting is recommended for 6 weeks followed by gradual return to full activity thereafter. Postoperative bracing is utilized based on surgeon preference, but not required.

Complications

As can be seen with anterior lumbar interbody fusion, approach-related complications do occur. These include injuries to adjacent vasculature, sympathetic plexus, ureter, and rarely lymphatic ducts. The rates of these complications are similar as to what is seen in anterior lumbar interbody fusion (Blumenthal et al. 2005). Heterotopic ossification has been reported in up to 50% of patients; however this often does not result

Fig. 8 Prodisc-L prosthesis. (Reprinted with permission from Atkins, et al. *Lumbar Disc Arthroplasty.* In: Essentials of Spinal Stabilization. Holly L., Anderson P. (eds). Springer, Cham. 2017)

in inferior clinical outcomes (Park et al. 2018). Jackson et al. did report a case in which heterotopic ossification along with implant malposition resulted in a new radiculopathy (Jackson et al. 2015). Symptoms resolved with revision for implant removal, anterior interbody fusion, posterior decompression, and pedicle screw fixation. Implant-related complications such as subsidence, dislocation, or luxation have been reported (Kurtz et al. 2007; Kostuik 2004). Additionally, bearing surfaces do raise the concern abnormal wear, particulate degeneration, and adjacent inflammatory changes. There are case reports and small series of the instances resulting in inflammation and osteolysis. Authors have postulated that suboptimal local biomechanics such as adjacent level fusion, incorrect implant sizes, and impingement may all be contributing factors. Study of removed implants has demonstrated both abrasive and adhesive wear of the polyethylene (Kurtz et al. 2007; van Ooij et al. 2007). Finally, persistent pain postoperatively has been reported. This is also likely multifactorial. It is well-known that there are multiple possible pain generators in the lumbar spine, and disc replacement does not address all of these. Facet degeneration pre- or postoperatively may be may be a major contributor to ongoing pain. Of 91 patients at a single IDE site, 50% of failures were secondary to facet pathology (Pettine et al. 2017).

Revision Options

As is the case with cervical disc arthroplasty revision, the lumbar revision procedure performed ultimately depends on the underlying pathology to be addressed at the time of surgery. Options include revision for replacement of an arthroplasty device, anterior revision for lumbar interbody fusion with or without posterior instrumentation, or posterior lateral instrumented fusion alone without anterior revision. Repeating an anterior exposure may be needed for situations such as arthroplasty device migration but should otherwise be considered with caution as adhesions can be problematic, and there is higher risk of vascular and visceral injury.

Outcomes

The SB Charité lumbar prosthetic was implanted for a period of nearly 20 years. Despite its eventual withdrawal from the market in 2013, this lumbar device has the longest available follow-up data and permits inquiry into the longevity of lumbar total disc replacement systems. Lemaire and colleagues presented 10-year minimum follow-up results in their retrospective case series of 100 patients implanted with the SB Charité III between 1989 and 1993 for the indication of intractable discogenic back pain. The authors used a modified Stauffer-Coventry scoring system which expresses results as relative gain. A relative gain of $\geq$70% indicates an excellent outcome and is defined as no pain, no medication use, and resumption of activity in the same job after 3 months. Ninety percent of patients in their series had an excellent or good outcome at 10 years, and 92% of eligible patients returned to the work force in some capacity. Radiographic analysis at 10 years showed that the Charité maintained normal range of motion in 95% of patients with a mean flexion/extension arc of 10.3°. Five patients underwent secondary arthrodesis at the index level for poor outcomes and the symptomatic adjacent level disease reoperation rate was 2% (Lemaire et al. 2005). David et al. found very similar positive results (82% with excellent or good outcomes) in their 10-year minimum retrospective case series of 106 patients. These authors reported a 10% index level and a 3% adjacent level reoperation rate (David 2007). The longest prospective data reported is the 5-year results from the US FDA IDE randomized controlled trial comparing the Charité to lumbar fusion. Ninety patients randomized to the Charité group between 2000 and 2002 were available for follow-up 5 years later. Guyer et al. found that Oswestry Disability Index (ODI), SF-36, and Visual Analog Scale (VAS) scores maintained clinically significant improvements over baseline. Overall clinical success, defined by the FDA, was achieved in 58% of the Charité patients and 51% of the arthrodesis patients still after 5 years. Seven of 90 cases were reported as "failures" necessitating index level reoperation, and adjacent level disease

Fig. 9 ActivL prosthesis. (Reprinted with permission from Atkins, et al. *Lumbar Disc Arthroplasty.* In: Essentials of Spinal Stabilization. Holly L., Anderson P. (eds). Springer, Cham. 2017)

reoperation rates were 1.1% and 4.7% for the Charité and arthrodesis, respectively (Guyer et al. 2009).

Outcomes of the ProDisc-L (DePuy Synthes) lumbar artificial disc are perhaps the most relevant at this juncture given that it remains commercially available and has the longest track record. Park et al. followed 35 patients for a mean of 6 years. Subjective outcome surveys were quite encouraging as 31 of 35 patients reported being completely or somewhat satisfied with their results. Similarly, 21 of 35 reported that they would definitely or probably undergo lumbar total disc replacement again if represented the option (Park, Spine 2012). Per the FDA-defined clinical success criteria, 71% of the cases qualified (Park, Spine 2012) (Park et al. 2012). In another retrospective case series of 55 patients with an average follow-up of 8.7 years, 75% had excellent or good results (Tropiano et al. 2005). Prospective data also supports lumbar arthroplasty as a reliable alternative to arthrodesis. Siepe and colleagues prospectively reviewed 181 patients after a mean of 7.4 years and found that both VAS and ODI scores were improved with statistical significance compared to baseline preoperative values (Siepe et al. 2014). Eighty-six percent of their patients were highly satisfied or satisfied. They also reported a low adjacent level disease reoperation rate of 2.2% which was comparable to that of the Charité. The most influential data comes from this device's US FDA IDE randomized controlled trial which showed very comparable results at 5 years between the ProDisc-L and circumferential lumbar arthrodesis. FDA-defined clinical success was met by 54% of the lumbar arthroplasty cases and 50% of the fusion cases. Both groups maintained significant improvements in ODI and SF-36 scores compared with baseline values. Restoration of normal lumbar motion, dictated by level, was achieved in 92% of the ProDisc-L cases with a mean flexion-extension arc of 7.2°. The index level reoperation rate was lower in the arthroplasty group (8%) compared to arthrodesis (12%) (Zigler and Delamarter 2012).

There is no long-term follow-up data for the second FDA-approved lumbar total disc replacement system, the ActivL (Aesculap Implant Systems, Fig. 9). It has only been commercially available since 2015. Nonetheless, its 2-year follow-up data appears to show statistically superiority to its predecessors (Garcia et al. 2015).

Conclusion

The theoretical advantage of motion sparing technology for degenerative spinal pathology is appealing. There has been much research and progress on this topic of intervertebral disc replacement over the last several decades, and the future is promising. Despite the advances, an understanding of the failures remains necessary so as not to repeat them. Currently, cervical disc arthroplasty has outpaced lumbar disc arthroplasty. There are more FDA-approved cervical devices than there are lumbar devices, and anecdotally, cervical disc replacement is more

widely favored than lumbar. The greater success of cervical disc replacement may stem from the underlying indications when compared to that of lumbar disc replacement; cervical procedures are indicated for degenerative disc disease resulting in radiculopathy or myelopathy, which are more predictably treatable entities, whereas lumbar disc procedures are often contraindicated in the setting of radiculopathy and predominantly indicated in degenerative disc disease only with axial pain, which is a notoriously difficult entity and patient population to treat successfully and predictably. For both cervical and lumbar disc replacement, early and midrange follow-up are now becoming available up and seemingly favorable, but we will need to continue to follow these technologies for long-term data to show whether it is more definitively a durable alternative to arthrodesis.

Abstract

Advancements in technology have been a driving force in the development of medical imaging equipment. There are now multiple, varied, and intertwined imaging modalities which visualize the spine in many different formats and positions. This has facilitated an increase in accuracy of diagnosis, and then at the same time allowed medical imaging to be an essential tool, in treatment of spinal conditions. Multiple image-guided therapies are now available to assist physicians/surgeons with treatment regimens and pre- and postoperative surgical planning. This chapter will detail the above.

Keywords

Radiology · Spinal · Neuroradiology · CT · Computed tomography · MRI · Magnetic resonance imaging · Nuclear medicine · EOS · Myelography · Medial branch block · Discography · Intervention · Corticosteroid injection · Aspiration · X-ray · Fluoroscopy

Introduction

Radiology, or medical imaging, has advanced dramatically since the discovery of the X-ray by William Roentgen in 1895. Over the last 120 years, this scientific discovery has evolved from being a novelty nonmedical commercial and social photographic studio tool to a necessity, essential to physicians and surgeons throughout the world (American Society of Radiologic Technologists 2018).

The computer age and advancing technologies allowed the use of X-rays and then other forms of radiation to be progressed into more sophisticated imaging equipment. Thus, medical diagnosis has progressed well beyond the first point of physician-patient contact – history and examination – as the diagnosis or differential diagnoses can be radiologically narrowed or confirmed and the pathology directly viewed within the patient.

The radiology/medical imaging field has taken a dual role of diagnosing and treating. Radiology canbe a primary source of treatment or an adjunctive intervention to both surgical pre- and postoperative care.

Within the field of spine care, radiology has assumed such an important role in the detection, diagnosis, and treatment of spine and spine-related disorders. Thanks to the radiologists, the spine surgeon can deliver a precision diagnosis and with that therapeutic options. When combined with the quantification and prognostication afforded by imaging (e.g., the grade of spondylolisthesis or the amount of sagittal imbalance), this forms an invaluable trinity of diagnosis, quantification, and therapy (see Fig. 1).

The diagnostic and treating armamentarium available to the patient and physician from the radiology specialty is as follows:

- Diagnostic:
  - Noninvasive:
    - *X-ray*
    - *Fluoroscopy*
    - *CT*
    - *MRI*
    - *Nuclear medicine*
  - Invasive:
    - *Myelography*
    - *Medial branch block*
    - *Discography*
- Therapeutic:
  - *Facet joint/medial branch corticosteroid injections*
  - *Epidural/perineural corticosteroid injections*
  - *Synovial cyst puncture and aspiration*
  - *Sacroiliac joint corticosteroid injections*
  - *Coccyx injections*
  - *Facet joint denervations*
  - *Vertebroplasty and kyphoplasty*
  - *Insertion of stimulators*

Comments About Radiation

Plain radiographs, CT, and fluoroscopy all produce ionizing radiation and hence the ability to cause cancer or birth defects, via damage either

Fig. 1 The unity of diagnosis and treatment clearly shown in verification of deformity correction

to the reproductive organs or to the developing embryo directly. However, the use of radiation from medical imaging procedures when ordered prudently and for the specific benefit of diagnosis or treatment leads to minimal hypothetical risks especially in relation to cancer deaths and estimated cancers produced and even more so when the principles of ALARA (radiation dose as low as possible), ASARA (medical procedures as safe as reasonably achievable), and AHARA (medical benefits as high as reasonably achievable) are followed (Hendee and O'Connor 2012). With technologies improving all the time, the radiation dose from all forms of imaging is becoming less, and the major equipment suppliers make this a standard in design and development and market accordingly. Despite lessening radiation doses from improving technology, the link of abdominal radiation dose with solid organ malignancy mandates careful assessment of risks and benefits from the ordering of tests involving ionizing radiation.

Noninvasive Techniques

X-ray

The humble radiograph. With all the new modalities for imaging now available, the spine radiograph is of less diagnostic importance as CT and MRI provide far more detail. The fact the plain radiograph cannot show soft tissue details of the spine, only bone, and can only image in limited planes is its major drawback, and the radiograph provides a 2D representation of a 3D structure.

However it still does play an essential role in the investigative role of diagnosing spine and spine disorders and as such should not be dismissed as an irrelevant investigation but a useful investigation in the first line of the diagnostic pathway. Despite government detractors that criticize the plain radiograph from the point of view of ionizing radiation and the lack of benefit, the radiograph provides a positive yield in many

situations, clinical and diagnostic, when applied specifically to the clinical situation.

Traditional images are AP and lateral views with oblique or functional views being added depending upon the request of the referrer or individual protocols of the radiology practice. The lateral view plain film will show alignment of the spine – confirming the normal or abnormal lordosis or kyphosis of the cervical, lumbar, and thoracic spines, respectively, and the AP film curvature or more scoliosis. Also disc space narrowing, i.e., degeneration and possibly foraminal stenosis, may also be revealed and of course a bony lesion. Oblique lumbar radiographs may be ordered in the case of spondylolysis to detect pars defects.

For a lumbar spine radiograph, the question of radiation to the reproductive organs is always of some concern. However, like with any radiograph, it must be balanced against its benefit, particularly in the younger person.

An exciting new technology, which has only become available in the last few years, is EOS™. It takes plain film spinal radiography to a new level. Firstly, the radiation dose is about 50% less than for digital radiography; hence the dose is almost negligible. Secondly, the entire skeleton – the chest, upper limbs, entire spine, pelvis, hips, and lower limbs – can be viewed in the weight-bearing position. Both frontal and lateral images are obtained, and from the images, 3D modelling is performed. This allows detailed analysis of the kyphotic and lordotic state of the spine and, of course, scoliosis (see Fig. 2). Hence, the normal distribution of weight, stresses, and angles throughout the axial skeleton can be assessed. Many parameters are measured including the C7 plumb line, kyphosis and lordosis, thoracic and lumbar vertebral and intervertebral rotations, spino-sacral angle, pelvic incidence/version and sacral slope, pelvic obliquity and rotation/tilt, Cobb angle, and scoliosis. Further measurements in relation to lower limb leg lengths and hip and knee angle and alignment parameters can be carried out. With all this additional

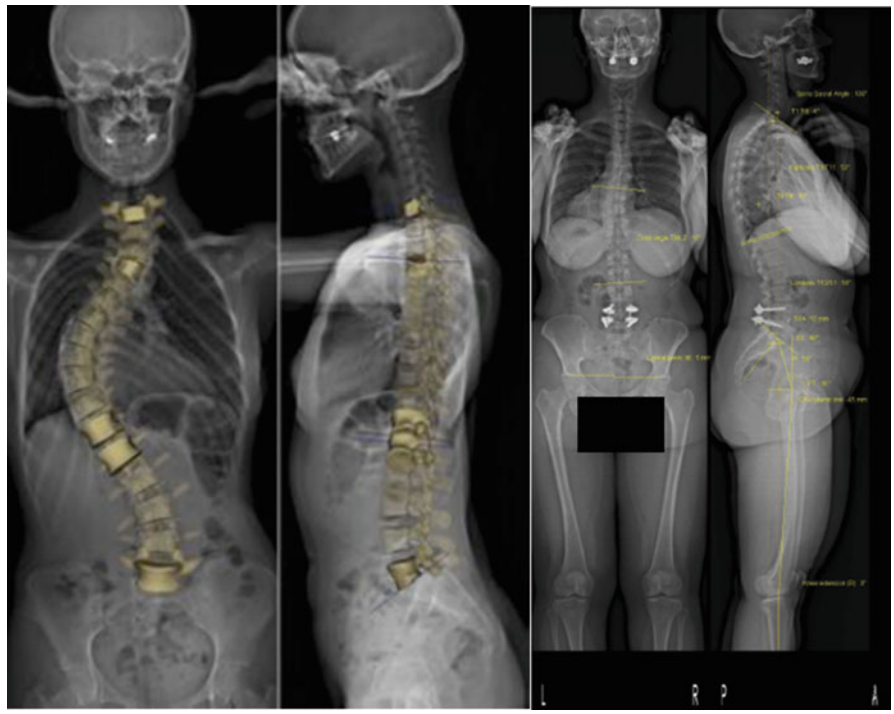

Fig. 2 EOS™ showing images of the whole spine – AP, lateral, and 3D reconstructions – with measurements for assessment of surgical balance as a forerunner to surgical treatment and planning

information, surgical procedures can now be planned (including types and requirements of reconstructions) to take into account the entire axial skeleton rather than solely the symptomatic area in question (Amzallag-Bellenger et al. 2014).

Fluoroscopy

This is using X-rays to allow real-time (i.e., dynamic) imaging. The machinery and technology have developed over time like that of the X-ray machine. It works on a similar principle to the traditional X-ray machine; however it is of low intensity (and hence low radiation) and therefore is coupled with an image intensifier which allows the image to be seen (without the need for a darkened room) (Amzallag-Bellenger et al. 2014).

The fluoroscopy unit has its main use as an adjunct to spinal procedures particularly aiding in needle placement for injections, both for diagnostic, e.g., discography and myelography, and treatment regimens, e.g., corticosteroid – *see below*. It is also used in theater for spinal level checks and aids in planning and confirming spinal surgical hardware placement and position. Such advancements have allowed reduction in malpositioned screws and cages that, if unrecognized, could present problems in the perioperative period for the patient (Amzallag-Bellenger et al. 2014; Goodbody et al. 2017; Deschenes et al. 2010; Laredo et al. 2010).

Computed Tomography

CT was part of the spinal imaging evolution, both diagnostically and therapeutically. The spine could now be imaged in much greater detail than was possible with the plain radiograph and fluoroscopy. The soft tissues, i.e., disc, ligaments, muscle, nerve roots, and CSF, could now be seen as could the size and state of the spinal canal (see Fig. 3). Tumors and fractures were depicted far more clearly. Further benefits were found as CT could image in multiple planes – coronal, sagittal, and axial – as well as oblique planes with rotation and 3D images. Hence, the name changed from computed axial tomography when it originated as a single-slice machine to now just computed tomography with the current cohort being multislice/multidetector up to 640. It remained the most accurate method of neural and soft tissue assessment until advancements in the mid-late 1980s made MRI feasible for routine use. CT remains superior to MRI, however, for assessment of bony structures and is still the gold standard for assessing fusion.

Continued refinements in CT have allowed faster, higher resolution and more accurate scans as well as significant reductions in radiation. CT now has the added benefit of CT fluoroscopy

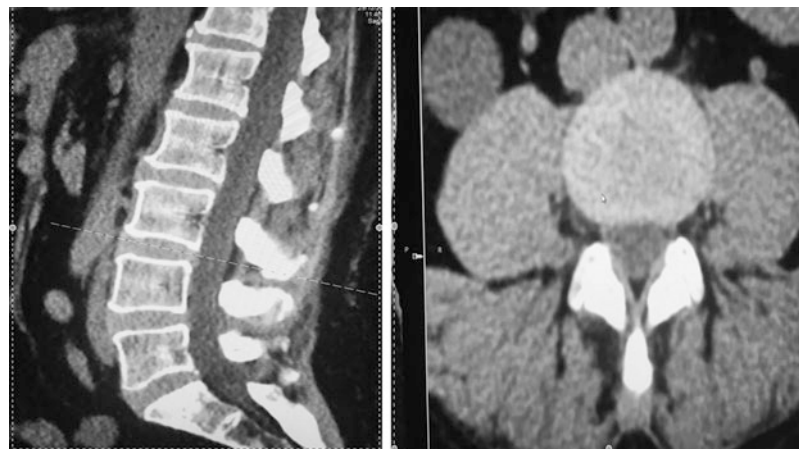

Fig. 3 Sagittal and axial CT of lumbar spine, showing bones, disc, canal, foramina, and nerve roots

– real-time imaging via the CT scanner in procedures.

Diagnostically, CT allows the disc (+/− disc osteophyte complex) to be analyzed, whether or not there is herniation or stenosis and to what degree – both foraminal and central canal. The origin and descending nerve roots can also be seen; hence nerve root compression and displacement becomes available allowing the clinician to diagnose and treat the symptoms with far greater accuracy. This is particularly important in cervical spine surgery where disc osteophytes and uncovertebral complexes need to be cleared to enable unimpeded passage of the nerves. Further diagnostic value is found with discography and myelography, both of which require specific needle tip placement, and this may be done with the use of CT alone or in conjunction with fluoroscopy. All spinal levels – cervical, thoracic, or lumbar – can be analyzed.

Therapeutically, CT (or fluoroscopy alone or CT fluoroscopy) allows the interventionist to perform numerous procedures to treat the patient with spinal pain. Biopsy of perispinal lesions in the case of suspected infection or tumor is an example of a procedure with diagnostic value but also important in planning therapy, e.g., identification of organism or tumor subtype. CT angiogram is particularly useful if an anterior lumbar or high cervical approach is planned and there is concern about vascular anatomy or if there is a thoracic lesion where the spinal cord blood supply is of particular importance when considering embolization of a high vascularity lesion.

MRI

Magnetic resonance imaging is the gold standard for spinal imaging. Like all diagnostic modalities in spinal imaging, it has advanced over time with technology. In particular the availability of high magnetic fields strength systems, increase gradient performance, the use of RF coiler rays and parallel imaging, and increase pulse sequence efficiency allowed for better acquisition speed and improved low signal-to-noise ratio. It provides detailed and conspicuous imaging of the spinal structures, showing greater detail than other modalities (see Figs. 4, 5, 6 and 7). There are categories of MRI available. First is the traditional tunnel lie down 3T MRI (Tesla, the magnetic field strength) which is the most widely used global static imaging tool. The alternative or adjunct to this is the open/upright MRI. The latter provides positional imaging – sitting, standing, flexing, and extending. Different positions can reveal dynamic pathologies that the supine tunnel MRI cannot demonstrate, e.g., instability, herniated discs, and annular tears that may not be detectable when in the unloaded, non-functional position (see Fig. 5a–b).

MRI imaging has the advantage of no ionizing radiation and clearly displays the type and extent of spinal pathology. Additional information can be realized with MR imaging. In particular:

(i) Degenerative state of the disc: It can be clearly characterized by MRI, unlike X-ray or CT where, unless there is a decrease in the disc height or a distinctive disc bulge,

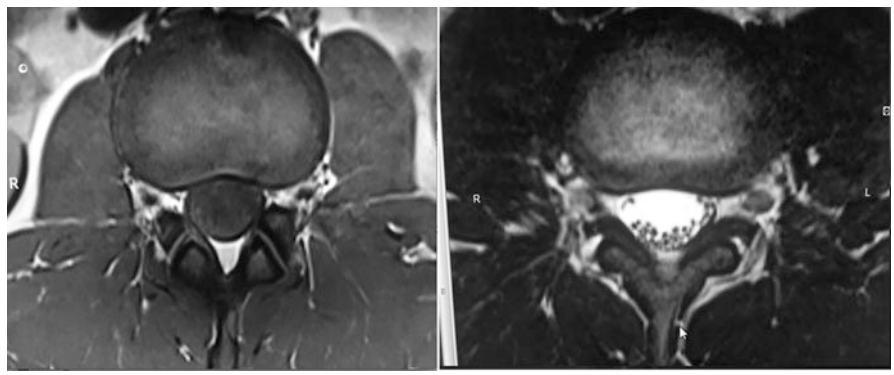

Fig. 4 MRI: note the far clearer delineation of all structures compared to Fig. 3; disc, canal, and nerve roots

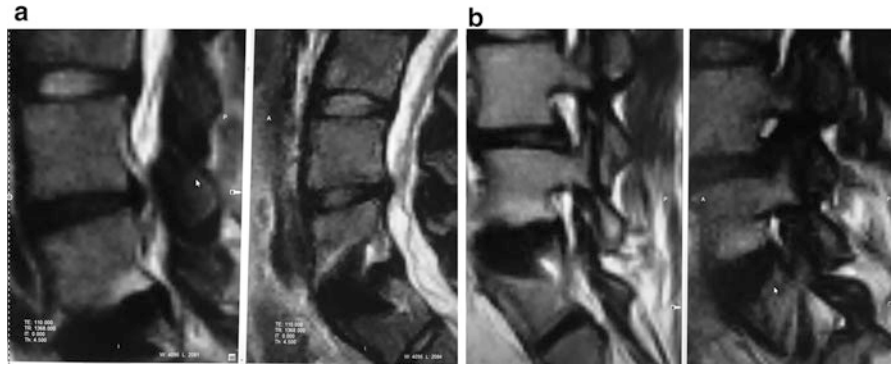

Fig. 5 Note in (**a**) the difference in the degree of herniation and in (**b**) the foraminal stenosis in the weight-bearing position comparing the static lie down images

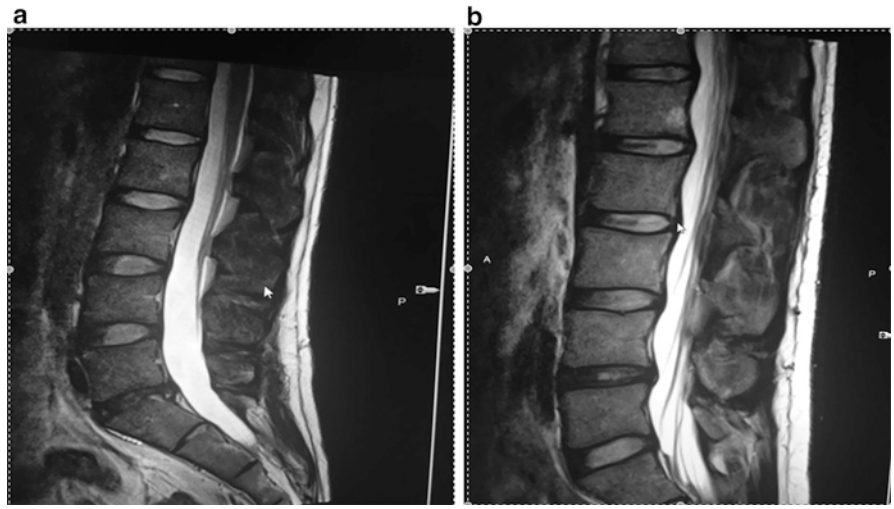

Fig. 6 (**a**) and (**b**) Note also the state of the discs: L1-4/5, all normal; L5/S1, degenerate grade 4, i.e., nucleus no longer white, loss of height, and with the high signal intensity zone/annular tear. a Note in b the degenerate L4/5 disc, grades 3–4

the morphology of the disc is not ascertained. An MRI classification of the disc degeneration has ensued – Pfirrmann grades I–V. The grading is based upon T2-weighted imaging with the low-signal changes to the nucleus pulposus becoming more pronounced and diffuse within the disc as well as loss of disc height as the degenerative process progresses.

(ii) Further markers of intervertebral disc degeneration shown on MRI are:
   (a) High-signal-intensity zone (HIZ) located in the posterior annulus fibrosis, separated from the nucleus pulposus – a relationship between the HIZ and pain has been observed.
   (b) Modic changes (Modic et al. 1988) – signal changes to the vertebral end plate and bone deep to the cartilage; these are graded I–III combining both T1W and T2W images. Type I, also known as the inflammatory phase, is denoted by inflammation of fibrous tissue, low signal intensity on T1W, and high signal intensity on T2W imaging. Type II, known as

Fig. 7 MRI lumbar spine sagittal slices. Note the detail of the study which enables differentiation of extruded and sequestered disc material in the canal contacting the thecal sac from the broad-based herniation present at L5/S1 and degenerate disc at L4/L5

the fat phase, is marked by a large deposition of fat cells in the end plate and the area underneath it, as well as a high signal intensity on T1W and an equivalent or mildly high signal on T2W imaging. Type III, also known as the bone sclerosis period because the bone becomes hardened in the end plate and the area underneath it, is also characterized by low signal intensity in T1W and T2W imaging (Rahme and Moussa 2008). It has also provided prognostic value for interventions for diagnosed discogenic back pain (Furunes 2018) and has been associated with increased vascular adhesions during anterior lumbar surgery (Malham 2018).

Other value in ordering an MRI includes:

(iii) The exact relation of the herniated disc to the nerve roots and whether or not direct compression is present.

(iv) The status and size of the paraspinal muscles. For example, severe multifidus wasting may suggest radiculopathy and be associated with poorer outcomes for decompression (Zotti et al. 2017) and disc replacement surgery (Le Huec et al. 2005; Storheim et al. 2017).

(v) Vascular pattern: particularly if anterior or oblique or lateral surgery is being considered, then vascular pattern including any anomalies should be studied to anticipate problems.

(vi) Assessment post-surgery for recurrent herniation, stenosis, and/or presence of fusion. This modality can be useful if a patient's leg symptoms recur to the point where intervention would be considered; then MRI with contrast can be of use in assessment to differentiate scar tissue from recurrent disc herniation. Recent studies suggest that MRI is comparable to CT for assessing lumbar spine fusion (Kitchen et al. 2018) (Fig. 7).

MR spectroscopy is an emerging technology whereby differential water and protein contents within the region of interest can be measured

and correlated to the patient's symptoms allowing differentiation of painful from non-painful discs (Zuo 2012). This may in time and with maturity enable diagnosis of discogenic pain without invasive provocative discography. Intraoperative MRI can be performed (more in the setting of craniocervical or spinal cord tumor surgery) but is not routine or widespread.

Nuclear Medicine

Radionuclide bone scanning is a well-accepted and sensitive method for uncovering a variety of bony lesions including abnormalities of vertebral bodies or facet joints that may be contributing to spinal pain. It has a more functional basis than the other imaging modalities as it has the ability to detect the most avid area of "inflammation," seen as increased regional blood flow, as determined by the degree of tracer uptake. Single photon emission computed tomography (SPECT) is especially useful in such an evaluation because it allows for precise localization of a lesion to the vertebral body, disc space, or facet joint. Greater diagnostic accuracy is achieved with this dual technique – using both radionuclide tracer, e.g., technetium 99, and integrated CT – allowing the level and anatomical location of pain generation to be imaged. This anatomic distinction is necessary in order to accurately diagnose the underlying condition detected by the bone scan. Most bony abnormalities result in focal areas of abnormal tracer activity but do not affect all components of a vertebra with equal frequency nor have a random pattern of involvement. Vertebral diseases tend to conform to predictable patterns that can be more readily identified by SPECT scan compared to planar imaging (Gates 1988, 1998). In some applications, such as in symptomatic pars defects, SPECT has sensitivity at least equivalent if not superior to MRI (Fig. 8).

Fig. 8 SPECT scan of the thoracolumbar spine visualized in the coronal plane. Note tracer uptake most pronounced at the T12/L1 end plates asymmetrically which correlated with the patient's pain

Comments About Pain Generators

As with anywhere in the body, the causes and origins of pain are vast and extensive and include referral from extra-spinal regions. In the spine itself, the main pain generators are:

(A) The joints – facet and sacroiliac
(B) The intervertebral disc
(C) The nerve roots
(D) The bones
(E) The muscles

Biomechanical and Chemical Models for Disc and Facet Pain

Intervertebral disc degeneration has been reported to be a source of low back pain in adults. The intervertebral disc consists of the nucleus pulposus, surrounding annulus fibrosus, and the superior and inferior cartilage end plates. Collagen and elastin fibers are present in different orientations lying within a proteoglycan (most prominently aggrecan) and non-cartilaginous protein mixture, forming a complex matrix. Disc degeneration occurs with the breakdown of this matrix with replacement of fibroblasts with chondrocyte-like cells and alteration in the lamellar structure of the annulus and when the nucleus gel becomes fibrous. Annular tears have been strongly associated with the development of degenerative disc disease. In other words as the nucleus can no longer support the load, the annulus can buckle and tear promoting radial and circumferential tears. Neurovascular structures can migrate into these tears. Numerous biomechanical-biochemical studies have shown that following annular tears, the axial load that is normally carried through the center of the disc can shift posteriorly over the nerve concentrated posterior and posterolateral annular fibrosis. Therefore in addition to the painful inflammatory reaction, one can get mechanical irritation of these already inflamed and irritated *nociceptive* fibers in the peripheral annulus. The fundamental basis of this breakdown at the molecular level is the production of an abnormal matrix or an increase in the constituents which cause matrix degradation, e.g., IL-1 and TNF and matrix metalloproteinases (MMPs), and a reduction in the amount of tissue inhibitors of metalloproteinases. The normal disc posteriorly is innervated by branches of the sinuvertebral nerve (from meningeal branches) and sympathetic fibers. Only the outer aspect of the annulus is innervated, and the sensory fibers are primarily nociceptive and proprioceptive (although less so). In a degenerate disc, the number of nerve fibers increases, and nerve nociceptive fibers grow into the normally aneural part of the annulus and nucleus. Many factors may contribute to the degenerative process – genetics, mechanical load, trauma, and nutrition; however, the exact etiology and relationships still require further research.

Studies have linked pathological changes in facet joints with preceding disc degeneration. The intervertebral discs support most of the weight during flexed postures, but the facet joints bear an increasingly greater burden as the lumbar spine is ranged into extension. In addition to stabilizing the spine and guiding segmental motion, facet joints function as weight-bearing structures that support axial loading along with the intervertebral discs. Studies have shown that the facet joints can carry up to 33% of the dynamic axial load. Disc degeneration with associated narrowing of the disc space alters the mechanical load distribution and may result in a degenerative cascade with increased mechanical stress on the facet joint and joint capsule. Within the active range of the lumbar spine, the paraspinal muscles act as the principal contributors to vertebral stability. However, both cyclic and sustained flexion movements decrease the reflexive muscle activity of the paraspinal muscles such as the multifidus muscle. In theory, this may result in increased laxity across the facet joint leading to both decreased stability and increased stress on the facet joint capsule.

The role of the facet joint capsule in stabilizing the motion characteristics of these joints cannot be understated. Studies have suggested that disc degeneration results in increased range of

axial rotation. It has been postulated that the increase in axial rotation and subsequent instability place additional stressors upon the facet joint capsules leading to a molecular response, which results in fibrocartilaginous metaplasia in the capsules of facet joints. Boszczyk et al. (2003) reported hypertrophic and fibrocartilaginous changes in the facet joint capsules of patients who had undergone lumbar fusion for degenerative instability.

The facet joint (or zygapophyseal joint) is innervated by the medial branch of the dorsal ramus of the nerve exiting at the same level and also the medial branch of the nerve one level above. The joint has a strong capsule, and hyaline articular cartilage is present.

Changes in load distributions (from a degenerative disc or from spinal malalignment or pelvic tilting or rotation) can lead to osteoarthrosis, osteophyte formation, and inflammation. The cartilage and synovium of facet joints are sources of inflammatory cytokines. It has been proposed that painful symptoms may arise not only from mechanical stress discussed previously but also from the associated inflammatory response involving cytokines such as tumor necrosis factor alpha, interleukin-6, and interleukin-1 beta, oxygen-free radicals such as nitric oxide and inflammatory mediators such as prostaglandins. Interestingly, some have suggested that inflammatory cytokines originating from inflamed synovium may spread to adjacent nerve roots and produce radicular lower extremity symptoms.

The sacroiliac joint (SIJ) is a true diarthrodial joint with unique characteristics not typically found in other diarthrodial joints. The joint differs with others in that it has fibrocartilage in addition to hyaline cartilage, there is discontinuity of the posterior capsule, and articular surfaces have many ridges and depressions. The sacroiliac joint is well innervated. Histological analysis of the sacroiliac joint has verified the presence of nerve fibers within the joint capsule and adjoining ligaments. It has been variously described that the sacroiliac joint receives its innervation from the ventral rami of L4 and L5, the superior gluteal nerve, and the dorsal rami of L5, S1, and S2. Abnormalities with joint function and mobility – hypo- or hypermobility – are the primary cause of the irritation. Inflammatory systemic disease, e.g., ankylosing spondylitis, is of course another reason for pain generation.

As with other diarthrodial joints, the cartilage of facet joints may also be sex-hormone sensitive. Estrogen has been associated with chondrodestruction, although controversy exists as to its actual role in the development of osteoarthritis. However, Ha and Petscavage-Thomas (2014) have found a statistically significant association between the increased expression of estrogen receptors on the articular cartilage of facet joints and the severity of facet arthritis (Binder and Nampiaparampil 2009).

Invasive Interventions

Myelography – an invasive procedure with contrast media (iodinated) being injected into the subarachnoid space, penetrating the thecal sac, to analyze the spinal canal, including the cord, nerve roots, and foramina. With the introduction of MRI, myelography has diminished in importance as a diagnostic tool. Yet it still can play an important role in diagnosis for those for whom MRI is contraindicated, e.g., those with a pacemaker in situ.

Discography – an invasive provocative procedure to determine whether or not the disc is the cause of the pain. One or a number of needles are placed in the nucleus pulposus (i) of the disc(s) at varying levels and then contrast media injected to attempt to reproduce the patients symptoms. Positive discography is defined as follows: (1) abnormal morphology of the examined disc; (2) consistency of pain by provocation; (3) no pain experienced by provocation of the nearest disc; and (4) less than 3 mL of injected contrast agent.

Discography has been the subject of vigorous debate and controversy with strong advocates for and against this functional test. Many studies have shown it to be valid with high correlation to the person's pain (Walsh et al. 1990; Peng et al.

2006). Other studies have questioned the usefulness of the technique. One of the main points of concern was that pain provocation is a subjective measure dependent on the patient, which despite quantification by the VAS, inevitably yields a high rate of false positives in patients with a psychological fear of pain or hyperesthesia from chronic pain or personality trait scores. Also it can be operator dependent with pressure and flow rates of injection leading to reduced stimulation of pain receptors (Derby et al. 2005; Ohnmeiss et al. 1995).

If used it must be critically examined in association with the patients profile, pain diagnosis, and other image-guided treatments performed, e.g., facet joint injections or nerve root blocks.

The Dallas discogram description grade is the mainstay of reporting (Saboeiro 2009) and is a combination of the interventional procedure followed by a diagnostic CT scan.

The Dallas discogram protocol for performance and reporting (or now more appropriately the modified Dallas classification system) is a widely used and accepted method for describing the CT findings of the test in association with the patient's intra-procedural symptoms (Sachs et al. 1987; Resnick et al. 2005; Carragee and Alamin 2001; Cohen and Hurley 2007; Cohen et al. 2005; Madan et al. 2002). When properly performed, low false-positive rates in the order of 6–10% can be anticipated (Bogduk et al. 2013).

There are six possible categories that describe the severity of the radial annular tear.

The grade 0 is a normal disc, where no contract material leaks from the nucleus.

The grade 1 tear will leak contrast material only into the inner 1/3 of the annulus.

The grade 2 tear will leak contrast through the inner 1/3 and into the middle 1/3 of the disc.

The grade 3 tear will leak contrast through the inner and middle annulus. The contrast spills into the outer 1/3 of the annulus.

The grade 4 tear further describes a grade 3 tear. Not only does the contrast extend into the outer 1/3 of the annulus, but it is seen spreading concentrically around the disc. To qualify as a grade 4 tear, the concentric spread must be greater than 30°. Pathologically, this represents the merging of a full-thickness radial tear with a concentric annular tear.

The grade 5 tear describes either a grade 3 or grade 4 radial tear that has completely ruptured that outer layers of the disc and is leaking contract material out of the disc. This type of tear, which one is most likely to suffer from, can cause a chemical radiculopathy in one or both of the extremities and result in persistent leg pain (Fig. 9).

Irrespective of the controversy, it is currently the only test which can directly link symptoms felt to be significant to the patient to the presumed pathology, and studies have shown that patients selected for intervention in this way have improved outcomes compared to those without precision diagnosis (Colhoun et al. 1988; Margetic et al. 2013; Xi et al. 2016).

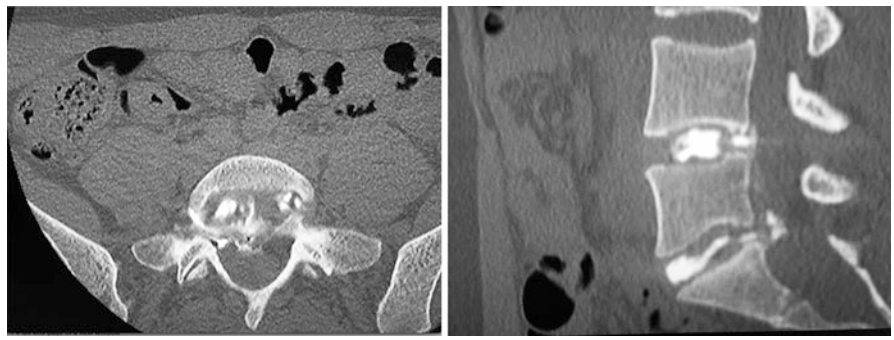

Fig. 9 Note the contrast passing from the nucleus through the outer annulus into the epidural space

Corticosteroid Injections

Which corticosteroid?

- There is great variability in the use of the injected corticosteroid.

Commonly used steroids are:

- Dexamethasone sodium phosphate
- Betamethasone acetate
- Methylprednisolone acetate
- Triamcinolone acetonide

The amount used may also vary considerably and below are examples:

- Dexamethasone sodium phosphate 4–8 mg
- Betamethasone acetate 0.25–1.0 ml
- Methylprednisolone acetate 4–10 mg
- Triamcinolone acetonide 2.5–5 mg

Commonly used local anasthetics and doses:

- Lidocaine hydrochloride (0.25–2 mls)
- Bupivacaine hydrochloride (0.25–2 mls)
- Procaine hydrochloride

Safety

A comprehensive review of the use of injected corticosteroids was undertaken by MacMahon et al. (2009), and this had particular relevance to spinal pain therapy. A number of factors were revealed which previously were not taken into account in terms of safety and protocol. In particular, this related to the particulate composition of steroids. Most corticosteroid preparations contain corticosteroid esters (apart from dexamethasone), which are highly insoluble in water and thus form microcrystalline suspensions. This property cannot only cause adhesions (problematic at subsequent open decompression procedures) but also cause particulate steroid emboli; thus they are likely the primary cause of the reported CNS complications, e.g., paraplegia or stroke. Non-particulate steroid is not known to cause this complication (MacMahon et al. 2009).

Other general complications range from common but minor risks of skin changes or transient hyperglycemia to rare but more significant complications including durotomy causing CSF meningocele and/or arachnoiditis and infection causing osteomyelitis or epidural abscess. Such material risks may be mentioned in discourse if relevant as part of informed consent prior to the injection being performed (Zotti et al. 2012). Cervical injections, particularly, carry the unique risk of vascular injury – particularly radicular artery injury – which can impair spinal cord and brain stem perfusion.

Specific contraindications should be sought and include bleeding diatheses or active use of anticoagulant (for epidural or perineural injections), infection at targeted site (unless for purpose of obtaining a biopsy), immunosuppression, poorly controlled diabetes, and noted contrast or injectable allergy.

Given the above, the alternatives and expected benefits need to be considered for any intervention. In common neurointerventional and spinal surgical practice, corticosteroids when combined with appropriate education and rehabilitation strategies can cure and assist patients with conditions of favorable natural history and who are either unsuitable for or do not wish to undergo formal surgical intervention or, alternatively, palliate patients' conditions.

Mechanism of Action

Corticosteroids predominantly affect the action of cytokines and inflammatory mediators (e.g., substance P, PLA2, arachidonic acid, IL-1, and prostaglandin E2) involved in inflammation. They lead to increased blood flow and down-regulation of immune function, inhibiting cell-mediated immunity, reducing cellular accumulation at inflammatory sites, and decreasing vascular responses. Corticosteroids cause these effects through a mechanism that ultimately involves its active moiety entering cells and combining with receptors to alter messenger RNA production, mainly altering the protein annexin-1 (previously called lipocortin-1) (Barnes 1998; Eymontt et al. 1982; Buckingham et al. 2006; D'Acquisto et al. 2008).

Types of Corticosteroid Injection

Facet joint injection (intra-articular) – the spinal needle is placed into the facet joint cavity and steroid injected along with local anesthetic. Indications include presumed facetogenic lumbar and thoracic or cervical pain. This may include facet-related pain resulting from posterior load-bearing transfer from patients with degenerative disc disease and anterior column pathology where treatment of anterior spinal structures (e.g., intervertebral disc) is thought to be high risk or undesirable. It is important that these patients are counselled that only a portion of their pain will be treated (appropriated to pain relief that may have been experienced from the medial branch block).

There is dispute over the efficacy of these injections, and some of it likely stems from only a limited proportion, perhaps 10–20% of patients having "pure" facetogenic pain. For some, common practice/convention may prevail over scientific evidence as to their efficacy and validity. For greatest accuracy the injection needs to be image controlled. An alternative, which also covers nociceptors from the facet joint but does not violate it, is the medial branch block of the dorsal ramus (Boswell et al. 2007; Sehgal et al. 2007a; Manchikanti et al. 2010; Cohen and Raja 2007; Jackson et al. 1988; Schwarzer et al. 1994, 1997; Sehgal et al. 2007b) (Fig. 10).

Medial branch block – a minimally invasive procedure whereby local anesthetic is injected along the pathway of the medial branch of the dorsal ramus of the spinal nerve, which supplies the facet joints, to determine if the origin of the pain is from the facet joints. It is important to note the innervation of the joint, recognizing that it is not single. The facet joint receives branches from the level above and below. The innervating branch lies with the depression/junction of the transverse process with the body of the vertebra.

Blockade of the medial branch of the posterior ramus nerve is generally preferred over intra-articular facet blocks as it is easy, less traumatic, and less risky than intra-articular injections (including no risk of joint infection) (Dreyfuss et al. 1997). Generally, when facet joint denervation is being considered, it is preferable to assess the patient's response to medial branch blocks given that it allows assessment of analgesic response due to blockade of the anatomic structure to be ablated. A response of 50% or more reduction of pain is an indication for RFD. However, in the presence of inflammation, intra-articular injections may be superior to medial nerve blocks.

Lumbar facet injections and medial branch blocks are both valuable in terms of diagnosis of the patient's pain generator and suitability for other interventions, e.g., radio-frequency neurotomy. However, in themselves there is limited relief of "facetogenic" low back pain. Marks, Houston, and Thulbourne reported limited relief after 3 months with relief of pain diminishing between 1 and 3 months (Marks et al. 1992). Manchikanti and colleagues reported the

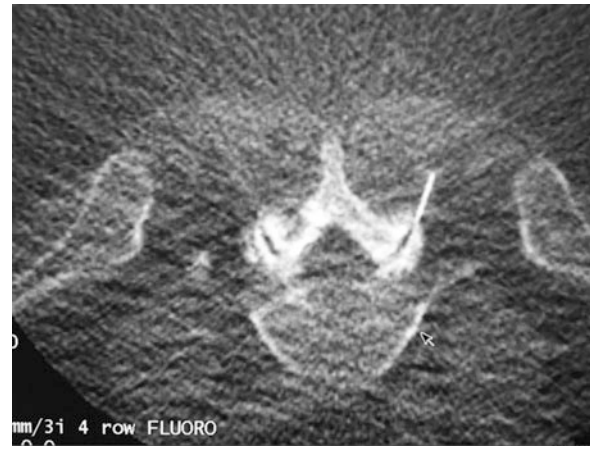

Fig. 10 The needle within the facet joint during an intra-articular injection of L5/S1

majority of patients having improvement in their facet pain at 1 year, however, irrespective of whether treated with local anesthetic alone or with steroid (Manchikanti 2001, 2010).

Most studies report that cervical medial branch facet blocks tend to have longer duration compared to lumbar facets with effect lasting between 3 and 5 months for each injection (Manchikanti 2008). The mean duration of effect for cervical facet block can be up to 8–12 months (Kim 2005), and repeated injections can provide sustained relief at a year and beyond (Manchikanti et al. 2015a). Thoracic facet interventions have not been well studied, and, as such, fair evidence is only available for medial branch blocks in the thoracic spine.

In the lumbar spine, for long-term effectiveness, there is Level II evidence for radio-frequency neurotomy and lumbar facet joint nerve blocks, whereas the evidence is Level III for lumbosacral intra-articular injections. In the cervical spine, for long-term improvement, there is Level II evidence for cervical radio-frequency neurotomy and cervical facet joint nerve blocks and Level IV evidence for cervical intra-articular injections. In the thoracic spine, there is Level II evidence for thoracic facet joint nerve blocks and Level IV evidence for radio-frequency neurotomy for long-term improvement (Manchikanti et al. 2015a). Evidence for diagnosis of cervical facet joint pain with controlled comparative local anesthetic blocks is Level I or II-1. The indicated evidence for therapeutic facet joint interventions is Level II-1 for medial branch blocks and Level II-1 or Level II-2 for radio-frequency neurotomy (Manchikanti et al. 2015a).

Facet joint denervation – this is the "follow on" from a positive medial branch block, which has confirmed that the pain generator is the facet joint. The next step is to denervate the facet joint via radio-frequency ablation or with 90% alcohol. Radio-frequency denervation, involving heating of the targeted nerve typically at 90 °C for 90 s, can provide longer-term relief than the standard facet joint corticosteroid injection. Alcohol denervation also provides significant relief, and some studies show a longer benefit than radio-frequency ablation (Joo et al. 2013).

As a day procedure usually under light sedation and performed with specialized radio-frequency equipment (an addition to standard radiology machine), the medial branches of the dorsal rami are ablated. The technique is very important, and good understanding of anatomy and physical properties of the equipment is paramount. Risks are minimal, but there have been case reports of transient radiculopathy, neural injury, and thermal burns which relate to inappropriate technique and preparation (Barr et al. 2000).

In the cervical spine, the main indication for injections or radio-frequency neurotomy remains facetogenic pain, but facet-pain targeted injections have also been used with varying success for facet pain resulting from herniated nucleus pulposus (load transfer to posterior elements from disc compromise), whiplash, and myofascial pain (Kim et al. 2005).

Like with all forms of thoracolumbar spinal treatment, radio-frequency denervation has been shown in some studies to provide significant pain reduction in patients with chronic low back pain selected with a positive medial branch block for between 6 and 18 months. In addition, this low-morbidity procedure is found to be efficacious on case series when repeated in patients who had a successful prior procedure (Zotti and Osti 2010; Schofferman and Kine 2004; Son et al. 2010) effective in around ~70% of patients for 8–9 months (Zotti and Osti 2010).

Patient selection (i.e., use and quantitative response to intra-articular compared to medial branch blocks) and mode and location of lesioning have been cited for potential inconsistencies in the results of these studies. The majority of patients, in the order of 60–80%, obtain at least 90% relief of pain when selected correctly with a mean effect typically lasting 9–12 months for both cervical and lumbar facet denervation. The evidence for radio-frequency neurotomy for sacroiliac pain is mixed in terms of quality, but sham surgery placebo-controlled trials overall were supportive of this technique (Rupert et al. 2009). However, other studies have shown little benefit to this procedure (Evans et al. 2003; Blasco et al. 2012; Zotti and Osti 2010; Bogduk et al. 2011).

A recent study by Van Tilburg and associates (2016) which was a randomized sham-controlled double-blinded study design was unable to reject the null hypothesis of efficacy for this intervention. However, several studies support the efficacy for this procedure compared to comparative controls (Gallagher et al. 1994; Van Kleef et al. 1999, 2005; Tekin et al. 2007; Kroll 2008).

Synovial cyst puncture and aspiration – a symptomatic synovial cyst from a degenerate facet joint can cause compression upon a descending nerve root and inflammation. The aim of the radiologist to achieve therapeutic relief is to puncture and if possible aspirate the cyst or rupture it, followed by an injection of steroid and local anesthetic. There are two mechanisms for the above:

(i) A direct puncture (which is not always possible due to its position in the canal as access may not be not possible due to the lamina or facet joint covering the anticipated needle pathway).
(ii) An indirect rupture via the facet joint – filling the latter with injectate – steroid and local anesthetic and saline until the cyst ruptures. This technique can be very painful.

Percutaneous treatment for facet cysts has been reported to only fair long-term success, approximately 50–80% of patients in literature reviews, and relief for up to 1 year has been reported (Vad et al. 2002; Carmel et al. 2007). Many of the cysts targeted are gelatinous and not amenable to aspiration, leaving the large residual cyst capsules to continue compressing the neural/dural structures, and cause ongoing neurological dysfunction. Along with the 37.5–50% risk of recurrence is a 45–50% chance of success with repeated cyst rupture attempts (Imai et al. 1998; Rauchwerger et al. 2011; Sabers et al. 2005; Schulz et al. 2011; Shah and Lutz 2003). A further trial can be attempted in refractory cases or recurrence, but a high proportion of these patients (50–60%) will require open spinal surgery. The uncertain efficacy of this intervention has led some authors to advocate for surgical intervention rather than repeated attempts (Epstein and Baisden 2012).

Selective nerve root injections/perineural injections and epidural injections – the spinal needle is placed next to the suspected pain-generating nerve, and a mixture of local anesthetic and steroid (e.g., dexamethasone and bupivacaine being injected) is injected. Again the steroid used varies as does the utilization of the radiology modality and the amount. The technique is most commonly done with fluoroscopy or under CT guidance. There are a number of different techniques/approaches which include transforaminal, interlaminar, and caudal. The most widely used and accepted is the transforaminal approach. The consensus from the literature (and certainly anecdotally) is that epidural steroid injections are effective and of value particularly for limb and girdle pain. However, the degree of efficacy is much and varied. In saying this, the degree of efficacy of the injection is based upon many factors which include the spinal pathology, the severity of the pathology, the expertise and skill of the operator, the exact position of the needle, the patient's mental state, and other systemic or local pathologies. As aforementioned, the mechanism by which the steroid works is manyfold including reducing inflammation/swelling via neutralizing inflammatory mediators, e.g., substance P, PLA2, arachidonic acid, IL-1, and prostaglandin E2. The steroid also increases blood flow and reduces the activity of the immune system (Akuthota et al. 2013; De Smet et al. 2005; Salahadin et al. 2007; Vad et al. 2002; Carmel et al. 2007; Lutz et al. 1998) (Fig. 11).

Many studies report the effectiveness of this intervention, including randomized trials, but large level 1 double-blinded studies with a placebo comparator are lacking. This is particularly so for contained herniated pulposus lesions (MacVicar et al. 2013) with mild neural compression, whereas injections into segments affected by extruded or sequestered disc fragments are thought to be less effective. While the addition of CSI is generally favorable, some studies have suggested that they alter the natural history of the patient and reduce the number of patients who undergo surgery of continued symptoms.

Interestingly, some trials have reported benefit of injection but no additional benefit to

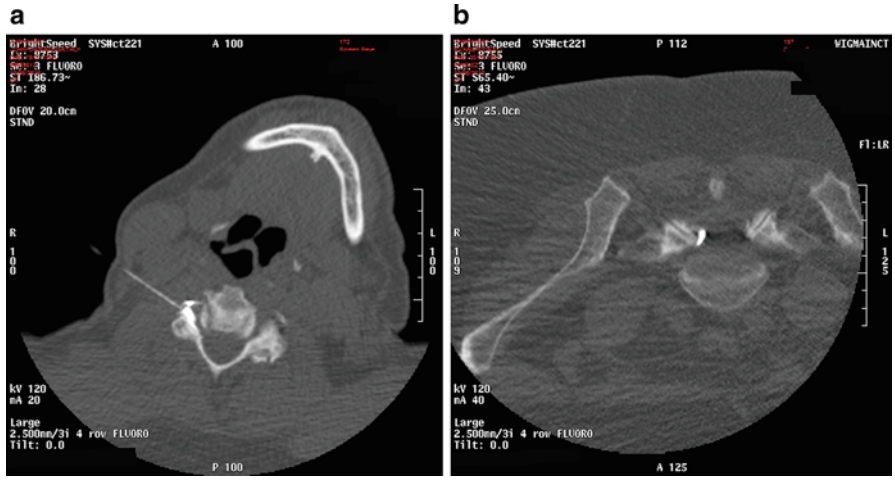

Fig. 11 (**a**) and (**b**) Note the transforaminal approach with contrast (prior to steroid injection) to confirm position around the exiting nerve root and also passing into the epidural space. Note in the next picture the paramedian interlaminar approach noting contrast between the ligamentum flavum and thecal sac in the epidural space

corticosteroids added to local anesthetic (Ng 2005). The majority of patients, in the order of 70–75%, will have significant reduction of their symptoms when they have been presented for less than 3 months. However, patients with symptoms longer than 3 months tend to have more variable success. Furthermore, patients with shorter duration of symptoms can be expected to experience more sustained relief than those with chronic symptoms. When effective, a reduction of at least 50% for 1–2 months can be expected in around 70% of patients and complete resolution in around 30% of patients (Ackerman and Ahmad 2007).

Cervical transforaminal epidural injections are effective for around 70–80% of patients with radiculopathy and have been shown to prevent the need for surgery in around 70% of patients (Costandi 2015; Vallee 2001). While at 3 and 6 months, around 30% of patients have complete resolution of symptoms, this reduces to around 20% at 1 year (Vallee 2001). To achieve sustained and effective relief, repeated injections may be required. For example, Slipman et al. (2000) reported pain reduction, return to full-time work status, reduction or elimination in analgesic use, and satisfaction with treatment in 60% of patients at 12–45 months' follow-up, but treatment on average consisted of 2.2 injections.

Interlaminar injections have good evidence for usage in the setting of herniated discs and radiculitis and fair evidence for axial/discogenic pain without facet joint pain and are technically simpler in the hands of experienced operators. They have been shown to have superior effect for chronic lumbar disc herniation at 2 years compared to caudal and transforaminal injections (Manchikanti 2015b). They have also been shown to be superior to caudal injections for lumbar central spinal stenosis (Manchikanti et al. 2014). In addition, there is Level II and Level II/III evidence for long-term management of cervical disc herniations or stenosis and thoracic disc herniations, respectively. Caudal injections, on the other hand, have good evidence for herniated disc and radiculitis with only fair evidence for axial/discogenic back pain, spinal stenosis, and post-surgery syndrome.

Both interlaminar and caudal injections for axial or discogenic pain are shown to be effective, but interlaminar injections have marginal superiority over caudal injections for this indication (Manchikanti 2015b). Interlaminar and caudal techniques have been reported to be effective for lumbar disc herniation or radiculitis (Kaye et al. 2015); however, some studies have reported them to be less effective than transforaminal injections for radiculopathy due to herniated nucleus

pulposus (Kamble et al. 2016; Ackerman and Ahmad 2007; Lee et al. 2009; Thomas et al. 2003).

Sacroiliac Injections

Sacroiliac joint pain – the great mimicker. One of the greatest challenges in diagnosing the pain from this joint is that the symptoms can imitate other pain-generating conditions, e.g., facet joint arthropathy and discogenic or radicular pain from herniated discs with the malady being both around the sacroiliac joint but also radiating down the lower limb or into the groin. As always, imaging can provide both diagnosis and treatment. The issue the clinician faces is that in many cases, the imaging does not directly confirm the provisional diagnosis. Arthropathy may be present; however the joint may show no signs of pathology on plain X-ray, CT, and MRI. The physical examination is therefore paramount to test the suspicion of SI pain with the location of the patient's symptoms and any worsening with provocative tests. Like with other joint-related conditions, steroid and local anesthetic blocks can aid in both diagnosis and treatment.

Patients are prone and the needle advanced before a sensation of entering the joint which is confirmed on multiple planes to be in the joint. It is performed by imaging guidance due to the highly variable morphometry of pelvises between patients for diagnostic and therapeutic purposes. Smaller doses of LA/steroid focusing on the posterior-inferior hyaline portion of the joint tend to be diagnostic, while larger doses that aim to bathe the entire joint are therapeutic. Some clinicians favor the addition of separating more superior injection into the fibrous component of the joint. The controlled diagnostic blocks utilizing the International Association for the Study of Pain (IASP) criteria demonstrated the prevalence of pain of sacroiliac joint origin in 19–30% of the patients suspected to have sacroiliac joint pain (Forst et al. 2006).

Evidence from meta-analyses (Hansen et al. 2007; McKenzie-Brown et al. 2005), albeit based on low quality data, supports the role of SI injections in treating painful sacroiliac dysfunction and spondyloarthropathy. Maugars et al. (1996) performed a double-blinded placebo assessment of CSI versus placebo and found a statistically and clinically important difference. Eighty-six percent had positive effect at 1 month, while the majority continued to have efficacy of the injection with 58% reporting relief at 6 months (Fig. 12).

Coccyx Injections

Diagnostic and therapeutic injections into the coccygeal region are performed for coccydynia. Ideally, the local infiltration blocks the ganglion

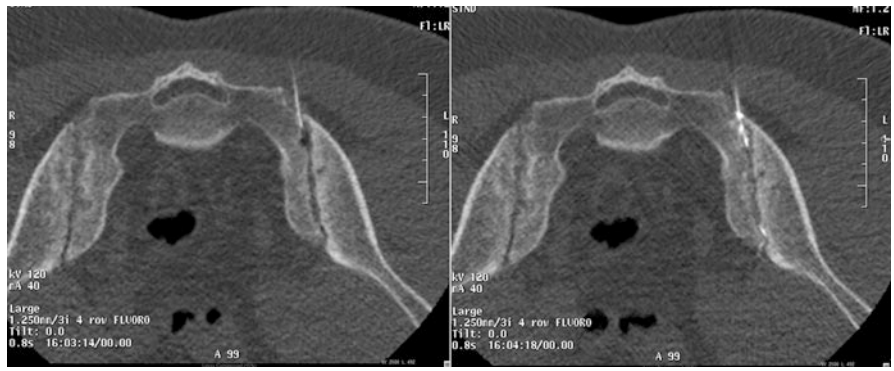

Fig. 12 CT-guided left sacroiliac joint injection. Note the needle confirmed to be within the sacroiliac joint

impar, which is a relay station for nociceptive pain emanating from the sacrococcygeal joint. Indications include coccydynia due to post-traumatic pain/hypermobility or pain from the sacrococcygeal disc. Unique complications to this procedure include rectal laceration and bowel content contamination of the injected field.

The patient is generally prone with sterile preparation and draping and sometimes sedation. Direct percutaneous placement of needle through and proceeding just anterior to the margin of the sacrococcygeal disc with confirmation on lateral and anteroposterior views with dye (if the procedure is done under Xray control rather than CT) followed by injection of LA and CSI to ganglion impar. Occasionally combined with per rectal manipulation in the setting of hyperflexed posture due to trauma or laxity.

Literature for effectiveness is generally limited to smaller cohort studies and case series making it hard to recommend treatments (Howard et al. 2013). Injection alone is effective in around 60–85% of patients with long-term success in around 45–50% with median relief at 6 months (Maigne 2011; Gunduz et al. 2015). Repeated injections were effective in the majority of those presenting with recurrent symptoms (Hodges 2004). Injection combined with manipulation results in around 85% successful outcomes with long-term success in around 60% with the theory for additional manipulation being that abnormally flexed posture of the coccyx leads to increased dural tension.

Other Invasive Forms of Image-Guided Treatment

Vertebroplasty and Kyphoplasty

These are procedures done under image guidance for the treatment of pain due to vertebral compression fractures, usually from osteoporosis. The combination of orthopedic bone cement and direct image guidance of a needle into the vertebra has allowed the past treatments for compression fractures – typically weeks to months of bed rest, analgesia, and sometimes bracing to be replaced or at least supplemented. Kyphoplasty involves partial reduction of fractures by use of an image-guided transpedicular balloon implant prior to cement insertion into the void. These techniques can also be applied to fractures from primary or secondary neoplasia affecting the vertebral body. Success rates vary, but overall significant pain reduction and improvement in the ability to perform ADL have been shown to be statistically significant (Barr et al. 2000; Evans et al. 2003; Blasco et al. 2012). Although felt to be a successful intervention, vertebroplasty for osteoporotic fractures (as distinct from metastases) has been removed from payer coverage in several countries because of equivocal results in sham-controlled procedures.

Spinal Stimulators

Spinal dorsal column stimulators can be inserted either under image guidance or by open techniques in theater with a formal approach and laminectomy. The principle is neuromodulation via electrodes placed onto the spinal cord through interference of emitted frequencies upon pain transmission in the spinal cord. It is believed to take effect through either blockage of pain transmission pathways or upregulation of inhibitory pathways. The patient generally has to meet strict criteria and has a trial period before definitive implantation occurs. The apparatus includes a battery, wires, and an electrode paddle that is applied to the targeted area (depending on pathology).

While the indications are evolving, they are generally indicated for refractory neuropathic pain despite other treatments in patients not amenable to or suitable for any further surgical intervention (low prospect of surgery being able to correct any neuroanatomic abnormality). A classic indication would be arachnoiditis after multiple posterior surgeries but may also include true "failed back surgery syndrome" and complex regional pain syndrome.

Measuring Success of Injections/ Radiology Treatments

There are numerous indicators for pain analysis and benchmarking the premorbid severity and therapeutic impact of interventions and thus providing a means of objectively measuring outcomes and success of treatments. Both statistical and clinical significance of outcomes are both important and measured. More so than other forms of medicine, interventional treatments involving needle injections into joints have undergone extensive analysis against placebo (sham) controls in multiple studies.

Below are listed some of the many available unidimensional assessments relating to pain in such trials but also commonly used in clinical practice (e.g., post-discography or diagnostic injection):

(a) VAS (visual analogue scale)
(b) NRS (numerical rating scale)

Multidimensional scales (looking at both dimensions of pain and effects on life quality):

(c) Brief Pain Inventory Short form
(d) McGill Pain Questionnaire
(e) West Haven Multidimensional Pain Inventory
(f) SF-36 and Oswestry Disability Questionnaire

All of the above have been combined into the Treatment Outcomes of Pain Survey which is a comprehensive and detailed instrument for measuring pain and outcomes (Younger et al. 2009). Future analytic tools should elaborate upon existing ones by assessing indirect and direct effects upon the patient and the economy including changes in need for aids, opioid usage, employment capability, use of healthcare resources (visits/hospitalizations), and need for care in daily living.

Conclusions

Radiology provides a harmonious and encompassing trinity of diagnosis, quantification, and therapy in relation to spinal pathology. Technology has allowed radiology to become an integral part of diagnosis and treatment, both pre- and postoperatively in those with spinal pain. Radiology provides the clinician with numerous adjuncts to the clinical history and examination by allowing direct analysis of the suspected spinal pain generator and the additional means of providing accurate treatment via targeted imaging. Although the success of image-guided therapeutic techniques is open to some contention, two points should always be kept in mind. First, the skill and subspecialization of the operator are paramount, with them having an interest and formal training and education in the field of spinal pathology. This allows safety for the patient and provides the best chance of obtaining a positive result. Secondly, the majority of patients with back and neck pain will be amenable to several minimally invasive therapeutic technique to obtain relief and return to more "normal" lives, hence, the importance of the first point. With all of the above considered, the usefulness of radiology is self-evident in its ability to provide benefits and alter the natural history of painful conditions with a limited risk profile in selected patients.

Abstract

Surgical site infections (SSIs) after spinal surgery are an important cause of postoperative morbidity and a multidisciplinary approach should focus on prevention. Screening for preoperative and recognition of intraoperative risk factors that increase the incidence of SSIs should be routine practice. Factors shown to influence SSIs include diabetes, obesity, previous SSI, complex multilevel procedures, and excessive surgical time and blood loss.

Multidisciplinary awareness and monitoring for SSIs is required with a high index of suspicion based on a combination of clinical findings including pain in the surgical area, swelling, fever, and wound discharge and diagnostic tests including WCC, CRP, ESR, wound microbiology, and blood cultures. Imaging the area with ultrasound, CT, or MRI and guided needle sampling of any detected collections may be required. Prompt treatment with antibiotics reflecting regional bacterial isolates and their sensitivity patterns should be implemented. Surgical wound wash outs, often performed repeatedly, may be necessary in selected cases.

Surgical site infection · Prevention · Risk factors · Diagnosis · Management · Staphylococcus aureus · Implant multidisciplinary · Inflammatory markers · Spinal surgery

Introduction

Surgical site infections (SSIs) represent a significant morbidity after spinal surgery and a multidisciplinary approach is required to minimize their risk and manage them when they occur. They are defined as infections as demonstrated by clinical features with support of ancillary tests and microbial testing in the perioperative area of a spinal intervention. These are subclassified into superficial SSIs, which are localized to the skin and subcutaneous tissue, and deep SSIs, which are deep to the fascia and include either deep incision SSI or organ/space SSI (see Fig. 1). Although rates of SSI in spine surgery are low, recognition of high-risk situations for SSI and knowledge of general and specific measures for prevention is critical for the practicing spinal surgical team. Prompt and appropriate diagnosis and intervention, which may be aggressive, is required to prevent a further complication cascade for the patient. This is particularly so as SSIs are not only associated with potential failure of the intended treatment but are also associated with significant increases in hospital inpatient length of stay, readmission, prolonged antibiotics administration, and, hence, increased health costs (Pull Ter Gunne and Cohen 2009; Van Middendorp et al. 2012) (Table 1).

Epidemiology

In most reports analyzing modern spinal surgery in large cohorts with robustly collected data, the incidence of SSI is typically 1–7% (Van Middendorp et al. 2012). However, this figure has been reported to be as low as 0.5% and as high as 25% (Mistovich et al. 2017). It is difficult to generalize and compare the incidence of SSI between study populations given the large variation in patient factors (including pathology to be treated, comorbidities, risk factors, and regional differences in microbial carriage), surgical factors (including approach and complexity), classification (e.g., Superficial SSI which often presents earlier compared to deep), and methods

Table 1. Criteria for Defining a Surgical Site Infection (SSI)*

Superficial Incisional SSI

Infection occurs within 30 days after the operation *and* infection involves only skin or subcutaneous tissue of the incision *and* at least *one* of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision.
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture-negative.
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician.

Do *not* report the following conditions as SSI:

1. Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration).
2. Infection of an episiotomy or newborn circumcision site.
3. Infected burn wound.
4. Incisional SSI that extends into the fascial and muscle layers (see deep incisional SSI).

Note: Specific criteria are used for identifying infected episiotomy and circumcision sites and burn wounds.[433]

Deep incisional SSI

Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation *and* infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision *and* at least *one* of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site.
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: fever (>38°C), localized pain, or tenderness, unless site is culture-negative.
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician.

Notes:

1. Report infection that involves both superficial and deep incision sites as deep incisional SSI.
2. Report an organ/space SSI that drains through the incision as a deep incisional SSI.

Organ/space SSI

Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation *and* infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation *and* at least *one* of the following:

1. Purulent drainage from a drain that is placed through a stab wound‡ into the organ/space.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space.
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of an organ/space SSI by a surgeon or attending physician.

of diagnosis with variable identification of less virulent organisms (Collins et al. 2008; Schoenfeld et al. 2011). A good example of the variation in incidence and the role of pathology and complexity is within the pediatric scoliosis population – the incidence of SSI for routine AIS correction is in the order of 0.5%, while correction of complex syndromic and neuromuscular scoliosis has a far higher incidence in the order of 20–25% (Mistovich et al. 2017).

Etiology

The understanding of SSI in the spine continues to evolve and the differences in pathophysiology between organisms and processes likely accounts for some of the different presentations observed in the patient clinically. It must be stressed that the etiology is different to that observed in primary spinal infection. Surgical site infections can be sub grouped into temporal (i.e., acute < 3 weeks, subacute 3 weeks–3 months, and chronic > 3 months) and physical characteristics (superficial and deep). The most common organism isolated is *staph. aureus* followed by *coagulase negative staphylococci* with *staph. Epidermidis, Pseudomonas aeruginosa, E. Coli, Proteus,* and *P. Acnes* all relatively common (Abdul-Jabbar et al. 2013).

Superficial infection (superficial to fascia) as in other areas of the body relates to the favorability of the healing environment at the level of the superficial integument: the genetics and immune system of the host, physical tension, wound oxygen tension, vascularity, dead space, apposition of layers, amount of foreign material, and local bacteria all have a role here. Assuming a truly no fascial breach, either local wound care and antibiotics or simple drainage/aspiration of any abscess with antibiotics may resolve the situation.

Deep infection, however, is a different entity not dissimilar to that seen in deep infection of extremity orthopedic implants. Unlike primary spinal infections, SSI is more commonly a result

Table 1 Criteria for Defining a Surgical Site Infection (SSI)*

Superficial incisional SSI
Infection occurs within 30 days after the operation *and* infection involves only skin or subcutaneous tissue of the incision *and* at least *one* of the following:
1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. At least one of the following signs or symptoms of infection: Pain or tenderness, localized swelling, redness, or heat *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture-negative
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician
Do *not* report the following conditions as SSI:
1. Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration)
2. Infection of an episiotomy or newborn circumcision site
3. Infected burn wound
4. Incisional SSI that extends into the fascial and muscle layers (see deep incisional SSI)
Note: Specific criteria are used for identifying infected episiotomy and circumcision sites and burn wounds[433]
Deep Incisional SSI
Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation *and* infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision *and* at least *one* of the following:
1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: Fever (>38 °C), localized pain, or tenderness, unless site is culture-negative
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician
Notes:
1. Report infection that involves both superficial and deep incision sites as deep incisional SSI
2. Report an organ/space SSI that drains through the incision as a deep incisional SSI
Organ/Space SSI
Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation *and* infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation *and* at least *one* of the following:
1. Purulent drainage from a drain that is placed through a stab wound‡ into the organ/space
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of an organ/space SSI by a surgeon or attending physician

∗ Horan TC et al.

† National Nosocomial Infection Surveillance definition: a nonhuman-derived implantable foreign body (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during surgery.

‡ If the area around a stab wound becomes infected, it is not an SSI. It is considered a skin or soft tissue infection, depending on its depth.

of direct inoculation during the surgical procedure, although early postoperative contamination (e.g., getting early postoperative wound wet) and hematogenous spread remains a possibility; this is particularly so if gram-negative organisms are isolated (Chahoud et al. 2014). Whatever the cause, the concern in deep infection is biofilm, which is difficult to control without metal removal. There is then the difficult balance and so-called race between fusion and progression of infection where the natural history is unpredictable. Bacteria embedded in biofilms have been shown to develop and colonize on inert surfaces of many spinal implants and

electron microscopy of samples taken from implant surfaces have shown biofilms to be the foci of device-related infection for "typical" biofilm forming bacteria such as staphylococci and streptococci (Tofuku et al. 2012). The bacteria within biofilms are protected against host defense mechanisms as there is no native blood supply and antibiotic therapy alone is ineffective because activated phagocytes cannot kill bacteria in biofilms. This is as antibodies released from sessile bacterial cells and antibiotics fail to penetrate biofilms and phagocytosis cannot be achieved (Tofuku et al. 2012). Interestingly, stainless steel implants are particularly vulnerable to biofilm compared to titanium implants. Further development of the use of materials or coatings that release antibiotics in concentrations that kill planktonic bacterial cells around the implant may have a role here. Until then, the only reliable way to disrupt the biofilm is surgical (Chahoud et al. 2014).

There is emerging interest in the atypical presentation of spinal infection, particularly in association with *propionibacterium acnes.* This organism, previously thought to be a contaminant, often causes no fever and a low-grade response with indolent failure of the implant construct. It is notoriously difficult to isolate and culture and, as such, should be sought for with PCR and extended cultures when implant constructs fail without a clear pyogenic presentation (Chahoud et al. 2014; Collins et al. 2008).

Risk Factors

Several papers, including those from large databases, have assessed the risk factors for spinal SSI but are limited in their identification of risk factors by methodology (Van Middendorp et al. 2012). From this viewpoint, several risk factors have been repeatedly identified and should be regarded as established while others have associated conflicting data and should be regarded as relative. Established risk factors include the comorbidities of type II diabetes mellitus, obesity, multiple spinal operations, and previous SSI with surgical factors being length of open operation $\geq$ 5 h, $\geq$ one liter blood loss and multilevel constructs. Subpopulations identified as high risk of spinal SSIs compared to population norms include oncology patients, syndromic or neuromuscular deformity patients, patients with inflammatory arthritis, and immunosuppressed patients, e.g., HIV/AIDS (Chahoud et al. 2014; Pull Ter Gunne and Cohen 2009).

Relative risk factors which have been variably reported or not robustly studied include several patient and surgical factors. Patient factors include female gender, advanced age, fecal or bladder incontinence, atherosclerotic vascular disease, hypertension, smoking, alcohol, malnutrition, corticosteroids, and multiple operations. Comorbidities such as the above are thought to be compounding and additional to the risk inherent in any spinal procedure (Chan et al. 2014; Oichi et al. 2015; Quan et al. 2011; Walid and Robinson 2011). MRSA carriage is a controversial risk factor in its implications for screening, prevention, and treatment (Catanzano et al. 2014; Mehta et al. 2013; Molinari et al. 2012).

Relative surgical risk factors that have limited or conflicting data include the approach (higher prevalence with posterior and non-same day staged 360° fusions), "invasiveness" of the approach (higher in open compared to minimally invasive for multilevel procedures) (McGirt et al. 2011; Smith et al. 2011), visceral injury (e.g., bowel for lumbar; esophageal for cervical) (Kang et al. 2009; Pichelmann and Dekutoski 2011), thoracic procedures (Smith et al. 2011), instrumented procedures (Smith et al. 2011) particularly stainless steel, transfusion use intraoperatively and use of surgical drains (Kawabata et al. 2017).

The implication of identifying situations of high SSI risk is to optimize the situation for the patient so as to minimize the risk of infection and also to counsel the patient regarding their relative risk for planned surgery. It is self-evident that the relative risk discussion with a

patient with minimal comorbidities undergoing a single-level procedure would be different to an elderly, obese, diabetic patient planned for a multilevel reconstruction. Optimizing the patient may then also have benefits with regard to minimizing anesthesia-related comorbidity and reaching the therapeutic goal (e.g., increasing likelihood of fusion of a painful motion segment). Several comorbidity-derived calculators may be useful for this purpose, including screening with the Charlson comorbidity index calculator (Walid and Robinson 2011). At present, while infection risk calculators such as the standardized infected ratio exist, no validated long-term data is available for any spinal specific scoring system (Fukuda et al. 2013).

Prevention of Spinal SSIs

Prevention and treatment of spinal SSIs must be viewed through a truly multifaceted manner. To regard prevention of infections with a narrow focus such as concentrating on patient selection, on which prophylactic antibiotic to administer or on which surgical skin preparation to use misses the very broad range of factors that can be successfully addressed with a holistic approach and a multidisciplinary team. In identifying SSIs postoperatively, a search for factors that have led to the SSI and how they can be prevented in future should be prompted, ideally, in a collaborative audit setting. Involvement of physicians, infection control personnel, and specialty nurses may uncover previously unrecognized factors in the patient care that, if unabated, could lead to continued high incidence of SSIs. These include changes which may seem trivial or banal in patient preoperative skin care, theatre equipment sterilizsation, theatre environment such as laminar flow and cleaning, and in ward care such as showering and wound dressing protocols. However, these are changes which the surgeon may not immediately consider or be aware of in their busy routine of daily practice. With the insight and knowledge of other key allied health personnel involved in the hospital facility and the patient's perioperative journey, such factors are imminently amenable to prevention of further infection episodes. From this viewpoint, below are points considered important and best practice to avoid SSI in our practice.

Preoperative

Prehospital

Patient

- Assess and manage patient-related risk factors as detailed above including diabetic, blood pressure and weight control, cessation of smoking and alcoholism, and optimizing nutrition.
- Educate the patient regarding optimal nutrition and hygiene in planned surgical sites. For example, topical benzoyl peroxide may be useful in decolonizing adolescent patients prior to posterior spinal surgery who would otherwise be at risk of *p. acnes* infection.
- Ensure the patient is free of any intercurrent treatable infections. Although controversial, screening the urine for asymptomatic infection may be appropriate in selected populations.
- Depending on regional prevalence of MRSA and VRE coverage, consider adoption of a screening and eradication program, e.g., Nasal screening, washes, and intranasal mupirocin.
- Referral to or involvement of a dermatologist preoperatively should be considered in selected cases. For example, adolescent patients with widespread dorsal acne planned for scoliosis correction or patients with eczema/dermatitis that may require treatment.
- Involvement of an infectious diseases physician in selected cases. For example in patients with immunodeficiency due to HIV/AIDS or tuberculosis.
- For oncology patients, close collaboration with oncology colleagues regarding the patient's immune status and any radiotherapy or chemotherapy interventions perioperatively.
- Liaison with rheumatologist regarding antirheumatic and immune modulating drugs for patients with inflammatory arthritis and whether they should be discontinued perioperatively.

In Hospital

Theatre

- Robust infection control protocols and procedures including audit of theatre and ward cleanliness and sterilization effectiveness.
- Meticulous hand hygiene of all those in contact with the patient.
- Ensure access to large and clean theatres with laminar flow or clean filters (Gruenberg et al. 2004).
- Properly sterilized equipment available.
- Trays, staff, personnel, and theatre traffic managed by team in a way that minimizes potential for contamination and particulate agitation. Signage that open surgery is in progress to minimize traffic.
- Insist on mask donning and appropriate hair coverage at time of tray opening for all personnel and minimize unnecessary equipment movement, e.g., II.
- Meticulous draping technique and patient warming.
- There are mixed reports regarding efficacy of surgical isolation hoods and ultraviolet light (Cheng et al. 2005).

Patient

- Preincision antibiotics, most commonly cephalosporins in the low-risk population, with appropriate cover of skin organisms (Petignat et al. 2008)
- Clipping of excess hair at the surgical site
- Pre-incision cleaning and scrubbing
- Sterile insertion of any drains or invasive monitoring

Intraoperative, in Hospital

- Minimize soft tissue trauma and retraction times where possible. Where surgery is prolonged, consider release of retraction momentarily to prevent prolonged ischemia. Consider use of minimally invasive muscle sparing techniques if appropriate for pathology and adequate training/skillset.
- Utilization of a "no touch" technique where possible and regular glove changes after heavy soiling.
- Adequate hemostasis given that residual hematoma likely to be nidus for infection.
- Minimizing the repetition of steps and adhering to efficient completion of the operative case to minimize any unnecessary delays in achieving sterile wound closure.
- Intermittent saline bathing of tissues to prevent desiccation and lavage of wounds prior to closure (Brown et al. 2004). Diluted betadine has also been shown to be effective for prevention of infection but its effects on tissue fibroblasts need to also be considered (Cheng et al. 2005).
- Consider use of topical vancomycin powder. Some authors advocate for routine usage in spinal surgery as has been shown in some literature reviews to be effective for prevention of deep SSI (Devin et al. 2015; Godil et al. 2013; Schroeder et al. 2016).
- Apposition of skin edges without excessive tension. Dressings that allow removal of excess moisture on the wound and vapor exchange.

Postoperative, in Hospital

- Prophylactic antibiotics according to local guidelines
- Meticulous hand hygiene and environmental cleaning of the patient's surrounds. Adequate signage and control of visitors if the patient has additional resistant organisms or visitors are found to be unwell.
- Mobilization of the patient with physiotherapy and regular positioning and appropriate mattress selection to offload pressure from skin. Regular pulmonary toilet to prevent respiratory collapse and infection.
- Optimal nutrition with diet on ward having adequate protein, vitamins, and minerals to support healing.
- Regular aperients and encouraging elimination to minimize risk of bowel stasis and urinary tract infection.

- Maintaining adequate perfusion with good hydration and consideration for transfusion if levels critically low, e.g., ≤9 g/dL. Perioperative physician care to support the patient in the postoperative period is valuable.
- Preference for mechanical deep vein thrombosis prophylaxis over chemical, where possible, to reduce risk of wound ooze
- Wound changes to be kept to a minimum and performed only where necessary (contaminated wound or excessive fluid).
- Removal of any drains and indwelling devices as soon as practicable to prevent device-related infections

Postoperative, Following Hospital Admission

Patient

- Education and provision of appropriate wound care and hygiene instructions, including washing.
- Maintenance of optimal health and avoiding toxins, e.g., excessive alcohol and tobacco.
- Early review of wound as outpatient and early and aggressive management if infection diagnosed.

Hospital and Surgical Unit

- Hospital infection control and regional infectious disease monitoring to assess local organisms and antibiotic sensitivities.
- Regular auditing and surveillance to correct any unexpected infections or unusual organisms and change practice accordingly. For example, contaminated theatres or malfunctioning sterilization machines.
- Participation in morbidity and mortality meetings and self-reflection on own practice SSI incidence.

Diagnosis of SSI

The diagnosis of SSI can be challenging and a low index of suspicion for infection must be held. With this mentality, neither the "obvious" pyogenic infections heralded by febrile patients with painful and purulent wounds nor the patients who present in an insidious way with persistent low-grade pain and malaise should be missed. This is particularly important with emerging evidence of previously difficult to diagnose organisms affecting instrumented spinal cases (Collins et al. 2008). Figure 1 shown previously provides objective criteria for superficial, deep, and organ space SSIs.

Clinical Presentation

A presentation of a wound issue, such as a discharging, swollen, purulent, erythematous, or discharging wound, should always be a cause for concern for surgeons and staff alike of a SSI. Systemic symptoms such as lethargy, malaise, loss of appetite, and, in more severe cases, fevers, rigors, and sweats should alarm staff that there is not only a local issue in the spine and its surroundings but potentially a systemic response that, if unabated, could lead to a septic syndrome. The sequelae of this can be heralded by hemodynamic dysfunction and metabolic dysfunction before multiorgan failure ensues.

In fact, the most common presenting complaint of patients later diagnosed with infection is less dramatic in the form of back pain. This presents a quandary for the clinician, where postoperative back pain may have a myriad of causes including residual pathology and "normal" postoperative tissue response in the first month. The onset tends to be insidious and persistent (Collins et al. 2008). The usual duration between procedure and discernible features of infection ranges from 2–30 days and varies depending on the behavior of the organism (Chahoud et al. 2014).

The more dramatic presentation of the unwell patient who is septic is becoming increasingly concerning with different resistant strains of staphylococci identified that have the potential to incite a violent systemic response. However, as an increasingly aging and comorbid population come to spinal surgery, there must be an index of suspicion for hematogenous seeding of implants with

the increased incidence of intercurrent infections that can mask an implant infection.

Ancillary investigations that support this diagnosis include blood serology testing, microbiology, and imaging. This also includes evaluation of other potential sites of infection such as the urine, heart, abdomen, and chest with urinalysis, echocardiogram, and radiographs, if the history and physical examination indicates it. Elevated CRP is nonspecific postoperatively but very high levels and levels that do not come down after the early postoperative period is concerning. Likewise, WCC has fair sensitivity for spinal infection only but lacks specificity. ESR can be useful when adjusted for age and sex in the subacute and chronic settings and is concerning if raised but is, again, nonspecific. Novel technologies that are emerging include serology such as serum amyloid and synovial procalcitonin and alpha defensin but these require further validation in the spinal setting (Chen et al. 2017).

Microbiological identification of the causative organism with accurate and careful handling and preparation of sample tissues is critical. It is important, if possible, to avoid the temptation to treat the patient with antibiotics prior to microbiological identification of an organism empirically (unless they are septic) in the cases where a specimen can be obtained. Correct organism identification is paramount to appropriately targeting and tailoring antibiotics to the organism and understanding its behavior. In the case of the septic patient who is progressing to extremis or the patient with probable epidural abscess-related neurological deterioration, blood cultures should at least be obtained prior to commencing empirical antibiotics. Should the patient have inadvertently been given antibiotics then delaying an aspiration for 1 week may be advisable to increase yield. Wound swabs are of mixed value, particularly as they are hard to interpret in the presence of skin colonized by commensals and their often polymicrobial growths. Histopathological examination as an adjunct is useful in assessing for typical pyogenic changes as opposed to granulomatous change or unexpected neoplasm. DNA microarrays and PCR molecular amplification techniques are likely to become the standard of care and offer high sensitivity and specificity (Chahoud et al. 2014).

Imaging can help define and localize the infection and helps to exclude other causes for the patient's presentation. Nuclear medicine, unlike in primary spine infections, have a limited role in SSI given the extent of uptake expected from surgical intervention albeit that continued improvements in technology may make this a more specific and reliable tool in identifying SSI accurately (Cornett et al. 2016). Specimens obtained under sterile conditions either operatively or under image guidance (ultrasound, fluoroscopy or CT) will likely yield the causative organism. In the setting of a spinal SSI, it is important to assess whether there is a collection or any clearly pathological tissue which to target for culture before proceeding with the intervention and it is also important to use a wide-bore cutting needle to maximize tissue yield through a core biopsy (Garg et al. 2016). Imaging here either with MRI, CT (with metal suppression if implants present), or a combination can allow evaluation of the bony and soft tissues in the surgical site and evaluate for evidence of infection as opposed to postoperative edema, hematoma, or pseudomeningocele. For example, if the MRI diagnoses pyomositis and deep soft tissue abscesses around the surgical site, then these present a clear target for diagnostic yield sonographically and likewise suspected vertebral osteomyelitis can be identified readily with CT guided biopsy. While this technique may be useful in trying to avoid the morbidity of addressing a deep SSI, image guided biopsy does not have such a strong indication for superficial infections and when compared to open sampling their diagnostic yield is inferior in the order of 40–60% (Chahoud et al. 2014).

However, there are situations where suspected infected areas are not safely or easily amenable to percutaneous techniques for a diagnostic sample. An example of this is an infection following a decompression procedure that involves an epidural abscess. While some situations allow for safe percutaneous sampling of the abscess, a surgeon must be prepared to perform open sampling with or without drainage of the abscess, depending on

the presence of phlegmon and dural adhesions. Infection around pedicle screws and cross links in the absence of a discernible abscess may have limited yield with percutaneous techniques due to difficulty sampling around the metal and fusion mass. In this setting, where the diagnosis of infection is strongly suspected from the patient history, clinical presentation, and supportive serology, the surgeon must consider the role of an open operative biopsy with or without metal exchange. The advantage of metal exchange, other than to reduce the potential for a nidus and debride the involved spinal tissue is to allow sonification of the spinal implants which can greatly improve yield. Again, one should consider PCR and extended cultures for *p. acnes* or staining for fungi or *mycobacterium* if there is an atypical presentation.

Management

Once the diagnosis of a spinal SSI is made, the approach should generally be aggressive. The exception to this is a cellulitis or suture abscess where a more conservative approach with dressings and antibiotics may be advisable. Where the potential for clinical deterioration, instability, and neurological compromise exists that will likely be difficult to control with medical therapy, early and judicious intervention is recommended (Cornett et al. 2016).

Superficial infections should be managed surgically with either wound excision or incision and drainage depending on its size and localization, followed by debridement and lavage of the area. An assessment should then be made on suitability for primary versus delayed primary closure depending on the patient and the extent of wound infection. This can then reverse a potentially catastrophic complication of deep-space involvement with the relatively simple measure of rapid superficial wound treatment. The difficulty in this scenario is often knowing when to intervene when the patient is systemically well, and markers of infection are equivocal but there is a slow-to-settle or oozing wound. Judgment is required here to ensure that wounds progress towards healing and, if this is not the case, then a return to theatre to achieve a clean and sealed wound is advisable (Cornett et al. 2016).

Deep infections present difficulty not just diagnostically but in deciding on the amount of treatment that should be offered to the individual patient. In an ideal world, infection should be treated in accordance with oncological principles achieving wide local clearance and adequate systemic therapy; however, this is not always possible due to the frailty of the patient or the locale of the infection, e.g., on the spinal cord. The intervention also varies depending on which approach the previous operation used and whether it involved instrumentation. In certain circumstances, where there has been very complex surgery, neurological injury, the need for reuse of potentially dangerous approach (e.g., anterior lumbar) or in a physiologically vulnerable patient then nonoperative treatment with suppression may be reasonable if the patient is stable systemically and neurologically. If there is clear infection and the patient is suitable for an intervention, then the surgeon must decide if it is a situation where the natural history will allow for likely resolution of the infection. The un-instrumented patient with a deep infection may be suitable for antibiotics only or in the instrumented complex multilevel posterior case for temporary suppression and later removal of implants (e.g., when arthrodesis or fracture united).

We favor a more aggressive approach for management of SSI when feasible and safe:

- For posterior instrumentation, this would typically involve exchange of any posterior metalwork, washout, grafting, and vancomycin powder application.
- For posterior abscesses in uninstrumented cases, then drainage and washout is recommended provided there is no direct infection with phlegmon on the neural elements, where careful partial de-bulking may be more appropriate.
- For anterior cervical cases (rare), utmost care must be taken given difficulty in reestablishing planes in the revision setting. Assessment for any esophageal breach should be undertaken as a deep cervical infection anteriorly is unusual.

Again, removal of implants and replacement with graft and vancomycin is advisable.

- For posterior cervical and thoracic decompression cases, care must be taken with washout and debridement due to risk to the spinal cord. Gentle lavage and partial de-bulking only along with vancomycin powder is advised for an epidural collection.
- Anterior column infection complicating interbody cage or disc prosthesis insertion requires a considered approach as to whether an anterior or lateral approach is feasible and, generally, either a vertebrectomy or revision with graft and a titanium cage would be preferable depending on the extent of osteomyelitis and post-debridement bony defect.
- In the rare case of exposed metal or large areas of devitalized soft tissue (usually after posterior wound debridement), then a plastic surgeon may be consulted to provide vascularized coverage to the implants.
- In the rare case of an "open space" SSI related to anterior cervical or lumbar fusion, it is advisable to provisionally diagnose the organ (s) which the infection involves and enlist the assistance of a relevant surgical colleague, for example, otorhinolaryngologist for organ involvement in the anterior neck and a vascular or general surgeon for assistance with organ or vessel infection in the abdomen.

Once a sample is taken or the organism is identified, we commence empirical antibiotics transitioning to tailored antibiotics as soon as practicable. Again, the patient should be optimized and cared for in the standard postoperative manner as detailed above. However, the length and course of the antibiotics will be different and should be discussed with a physician so that consensus over the most effective course for eradicating the infection can be achieved. Close follow-up must then be instituted to confirm successful remission and eradication of infection, including in the medium term. This should be undertaken clinically as well as with serology and imaging, such as CT scans, to verify the absence of any implant loosening or compromise.

Conclusions

SSIs represent a significant morbidity associated with spinal surgery and warrant a multidisciplinary approach to management. Early and aggressive treatment can lead to macroscopic eradication and salvage of the situation. A holistic and considered approach to prevention, diagnosis, management, and follow-up is likely to yield a lower incidence of SSI and improve patient outcomes.

Abstract

Lumbar interbody fusion is an established surgical technique for a variety of conditions affecting the lumbar spine. A large number of interbody fusion devices made of differing materials are now available for use. Approaches for interbody fusion include anterior lumbar interbody fusion, oblique lumbar interbody fusion, lateral lumbar interbody fusion, axial lumbar interbody fusion, transforaminal lumbar interbody fusion, and posterior lumbar interbody fusion. This chapter discusses the biomechanics of lumbar interbody fusion devices and approaches and the clinical rationale and the clinical results of each approach. The advantages and disadvantages of each approach are compared and contrasted. The importance of an appropriate preoperative assessment to determine the best approach for interbody fusion is emphasized, taking into account the condition being treated, sagittal balance, bone quality, and contraindications to a specific approach. The best approach to lumbar interbody fusion by indication and surgical level(s) is discussed.

Keywords

Lumbar interbody fusion · ALIF · OLIF · LLIF · AxiaLIF · TLIF · PLIF · Sagittal balance

Introduction

As with any operation in spinal surgery, the ultimate goal of interbody fusion is to decrease pain and increase function in the patients we treat. The specific technical goals of interbody fusion are to achieve a solid, stable arthrodesis of spinal segments that is able to sustain physiological loads while maintaining disc height and maintaining or restoring sagittal alignment. Any associated neural compression should be addressed as part of the fusion procedure. Maintenance of disc height and lordosis is necessary to preserve the natural alignment of the spine and the dimensions of the neural foramen, thus avoiding compression of the exiting nerve roots.

Spinal fusion has been used for many decades to treat a variety of spinal disorders. Instrumented spinal fusion was introduced to allow surgeons to alter the position of the spine, increase the rate of successful fusion, and allow earlier patient mobilization and recovery. To decrease failure rates of posterior instrumentation, the concept of anterior column interbody support was introduced.

Interbody fusion was originally performed using autograft iliac crest or allograft bone alone (Cloward 1953). The donor site morbidity associated with harvesting large amounts of iliac crest autograft and the inferior mechanical and biological properties of allograft bone were of concern. A significant incidence of collapse and pseudarthrosis was observed. Therefore interbody fusion devices were developed to provide mechanical support, while fusion takes place, thus increasing the rate of successful fusion and maintaining disc height and sagittal alignment while the fusion process occurs.

There are now many devices available for interbody fusion that vary in their material properties and route of implantation. In the lumbar spine, options include anterior lumbar interbody fusion (ALIF), oblique lumbar interbody fusion (OLIF), lateral lumbar interbody fusion (LLIF), posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF), and axial interbody fusion (AxiaLIF).

In determining which approach and device to use for interbody fusion, the surgeon must take into account the specific aims of the surgery in each individual patient. The interbody fusion

device itself is only one of many factors in achieving clinical success for the patient. Appropriate patient selection for surgery and technical expertise in performing the surgery are of vital importance. This chapter will discuss the biomechanics of interbody fusion, the various approaches and devices available, the clinical results of interbody fusion, and "when to use what" in various clinical scenarios.

Historical Perspective

Early techniques of interbody fusion using autograft or allograft without instrumentation were associated with a high rate of clinical failure and pseudarthrosis. Stauffer and Coventry (1972) reported a 44% rate of poor clinical outcomes and a 44% rate of pseudarthrosis in 83 patients who underwent anterior interbody arthrodesis. A number of other studies reported similar results. The need for interbody devices to provide mechanical support while fusion occurs was thus established.

Bagby (1988) developed the first interbody fusion cage, "the Bagby basket," a stainless steel basket that was packed with local autograft bone and used in horses undergoing ACDF for wobbler syndrome, a type of spondylytic myelopathy. Bagby and Kuslich developed the first stand-alone threaded intervertebral cages which were a modified version of the Bagby basket made of titanium alloy and FDA approved in 1996 (Kuslich et al. 1998) (see Figs. 1 and 2). The BAK cage (Sulzer Spine-Tech, Minneapolis, Minnesota) was closely followed by the Ray threaded fusion cage (US Surgical, Norwalk, Connecticut), the threaded interbody fusion device (TIBFD, Medtronic Sofamor-Danek Group, Memphis, Tennessee), the Harms titanium mesh cage (DePuy-Acromed, Cleveland, Ohio), and the Brantigan rectangular and rounded cages (DePuy-Acromed). The cages were designed to stabilize a segment through distraction and tensioning of the annular and ligamentous structures; by partially reaming the end plates, cancellous bone would be exposed for arthrodesis.

Second-generation lumbar cages such as the LT cage (Medtronic, Minneapolis, Minnesota) were designed to be end plate sparing and able to obtain lordosis by threading a wedge-shaped device into the disc space. Since the design of these original devices, the field of interbody fusion technology has advanced significantly with multiple designs now available. The majority of interbody fusion devices are currently made from titanium alloy or polyetheretherketone (PEEK). Other materials include tantalum, carbon fiber, carbon fiber reinforced PEEK (CFRP), and more recently hybrid cages such as those made of titanium-coated PEEK. Emerging technologies include expandable cage technology and 3-D printed cages.

Biomechanics of Interbody Fusion

Interbody fusion offers several biomechanical advantages over posterolateral fusion. The interbody space offers a relatively large area for grafting with excellent vascularity, and the graft is placed under compression further enhancing

Copyright 2018 by Elsevier)

fusion. As 80% of axial compression forces are transferred through the anterior spinal column, the resulting arthrodesis is biomechanically superior to posterolateral fusion (Cunningham and Polly 2002). Interbody fusion also allows better maintenance or restoration of disc height and segmental lordosis and overall sagittal balance when compared to posterolateral fusion. This is associated with improved outcomes and a reduced rate of adjacent segment degeneration and disease (Rothenfluh et al. 2015).

When choosing a fusion device, the surgeon must consider the biomechanical properties of the device, in particular the implant stiffness which is determined by the material modulus of elasticity (Young's modulus) and the implant design (see Fig. 3). The implant design is in turn determined by the strength of the material used; a stronger material can have a more open architecture for bone graft and vascularization. An implant with a stiffness close to that of bone will allow load sharing between the device and the graft material, thus optimizing the biomechanics for fusion. An implant with a stiffness much higher than bone will load bear, therefore, stress shielding the graft material which can lead to resorption and pseudarthrosis.

When performing interbody fusion, the surgeon must consider the biomechanics of the vertebral end plates. Grant et al. (2002) conducted a biomechanical study assessing regional differences in end plate rigidity and found the posterior part was stronger than the anterior and that the periphery was stronger than the center. The strongest part was the posterolateral area, just in front of the pedicles. The superior end plate was much weaker than the inferior end plate. These findings have implications for implant design and placement when performing interbody fusion. A large footprint cage sitting on the peripheral end plate will be less likely to subside.

Early biomechanical studies suggested that threaded lumbar intervertebral cages were potentially stable enough to be used as stand-alone devices. Brodke et al. (1997) showed that two threaded BAK cages placed from a posterior approach resulted in greater stability in a bovine spine motion segment than a PLIF bone graft alone and equivalent stability to a PLIF bone graft and pedicle screw construct. Kettler et al. (2000) found that posteriorly placed intervertebral cages stabilized the spine in flexion and lateral bending but not extension and rotation and reduced stability under cyclical loading conditions was observed. Similarly, Oxland et al. (2000) found that anteriorly placed threaded cylindrical cages enhanced motion segment stability in all directions except extension and that supplementary translaminar facet screw fixation provided additional stability in extension. Rathonyi et al. (1998) also found that translaminar facet screw fixation greatly improved the stability of anterior threaded cylindrical cages in extension and rotation.

Kanayama et al. (2000) investigated the stability and stress-shielding effect of various lumbar interbody fusion devices; 11 different cages were tested, either threaded cages, non-threaded cages or allograft. No statistical differences were observed in construct stiffness among threaded and non-threaded devices in most of the testing modalities. Threaded cages demonstrated significantly lower intra-cage pressures compared with non-threaded cages and structural

allograft, suggesting a stress shielding effect with threaded cages.

Initial threaded cage stability is dependent on achieving adequate disc space distraction with resultant annular tensioning and is also dependent on compressive preload generated by muscle forces across the disc space. Phillips et al. (2004) found that under low preload conditions such as supine posture, BAK cages were less effective at stabilizing the motion segment in extension, whereas higher compressive preloads such as in sitting or standing led to stability of the motion segment in all motion planes. Supplementary translaminar facet screws provided a significant stabilizing advantage during low preload conditions.

ALIF

Further biomechanical testing of ALIF constructs has defined the relative stability of various stand-alone configurations (usually with integrated fixation) and anterior cage-plate constructs compared to the "gold standard" of ALIF with supplementary bilateral pedicle screw fixation.

Tsantrizos et al. (2000) compared the biomechanical stability of five stand-alone ALIF cages and found that all cage constructs reduced range of motion (ROM) but no cage construct managed to reduce the neutral zone (NZ), in fact the NZ was seen to increase with all constructs suggesting an initial segmental instability. Anteroposterior and mediolateral cage dimensions, cage height, and cage angle all influenced initial stability. Cages with teeth had higher pullout strength. They concluded that stand-alone cages reduced ROM effectively, but the residual ROM present indicated micromotion at the cage-end plate interface which may influence fusion.

Gerber et al. (2006) conducted a human cadaveric biomechanical assessment of ALIF with an anterior plate and screws compared to ALIF with supplementary pedicle screw fixation. ALIF was performed with two INTER FIX cages (Medtronic Sofamor Danek, Memphis Tennessee). Compared to stand-alone cages, supplementary anterior plate and screws reduced ROM by a mean of 41%, and compared to stand-alone cages, supplementary pedicle screw fixation reduced ROM by 61%. Similarly, Beaubien et al. (2005) in another human cadaveric study found that, although not as rigid as pedicle screws or translaminar screws, anterior lumbar plating does add significant stability to an ALIF construct.

A biomechanical evaluation of a stand-alone PEEK ALIF cage (Brigade NuVasive, Inc., San Diego, California) found that the cage alone was significantly more rigid than the intact

state in flexion-extension and lateral bending. The addition of three integrated screws was significantly more rigid than the cage alone in all loading directions. The addition of a fourth screw did not significantly increase stability over three screws. The cage with integrated screws allowed more flexion-extension motion than the cage with anterior plate fixation or pedicle screw fixation. Adding a spinous process plate to the 3-screw cage provided the most rigid construct in flexion-extension, providing more stability than the anterior plate and equivalent stability to the pedicle screw construct. Pedicle screw fixation provided the most rigidity in lateral bending and axial rotation although the later was not significant (Kornblum et al. 2013).

Similarly, a comparative biomechanical analysis of a PEEK ALIF cage with integrated fixation anchors (Solus, Alphatec Spine, Carlsbad, California) compared to a standard PEEK cage (ALS, Alphatec Spine), combined with various posterior fixation constructs found that the Solus cage in combination with all posterior constructs provided significant fixation compared to the intact spine. The ALS cage combined with screw-based posterior constructs also provided significant fixation, but the ALS cage combined with an interspinous process clamp showed a significant reduction in stability for lateral bending and axial torsion (Yeager et al. 2015).

Chen et al. (2013) conducted a biomechanical comparison of three different designs of stand-alone ALIF cages using three-dimensional finite element analysis. The cages differed in their method of integrated fixation. All three designs were compared to the "gold standard" of ALIF cage (SynCageOpen, Synthes Spine, Inc., Pennsylvania) with bilateral pedicle screw fixation. The three cages tested were the Latero system (Latero, A-Spine Asia, Taipei, Taiwan) (trapezoidal cage with integrated lateral plate), the Synfix system (Synfix, Synthes Spine Inc., Pennsylvania) (four integrated screws), and the Stabilis system (Stabilis, Stryker, Michigan) (a central threaded cylinder). At the surgical level, the SynCageOpen with bilateral pedicle screws decreased ROM (>76%) in all directions. The Synfix and Latero systems also decreased ROM in all motions compared to the intact model. However, the Stabilis model only decreased ROM slightly in extension, lateral bending, and axial rotation. At the adjacent levels, there was no obvious differences in ROM or annulus stress among all instrumented models. The authors concluded that the Synfix and Latero systems provided adequate stability for clinical use without additional posterior fixation, but the Stabilis cage would require additional fixation. This highlights the importance of biomechanical testing of different cage designs to determine relative stability.

In summary, biomechanical testing suggests that the use of stand-alone ALIF devices without integrated fixation may not offer enough stability to allow fusion to reliably occur. In patients with good bone quality, if an appropriately sized ALIF cage can be placed, then a stand-alone construct with integrated fixation or a cage-plate construct appears to provide adequate stability (see Fig. 4). In a biomechanically challenging environment such as patients with poor bone quality and multilevel surgery or in the setting of sagittal imbalance, the addition of supplementary screw-based posterior fixation provides the most robust biomechanical construct.

OLIF and ATP

First described by Mayer in 1997, there is a paucity of published biomechanical data on OLIF and ATP constructs although in clinical studies the vast majority of OLIF procedures are supplemented with posterior pedicle screw-rod fixation (Sorian-Baron et al. 2017).

The biomechanics of OLIF can be considered similar to LLIF between L1–L2 and L4–L5. At L5–S1 with release of the ALL, the biomechanics are likely more similar to ALIF.

LLIF

The lateral transpsoas approach was developed as a minimally invasive alternative to access the anterior column and places a large surface area interbody device without mobilization of the great

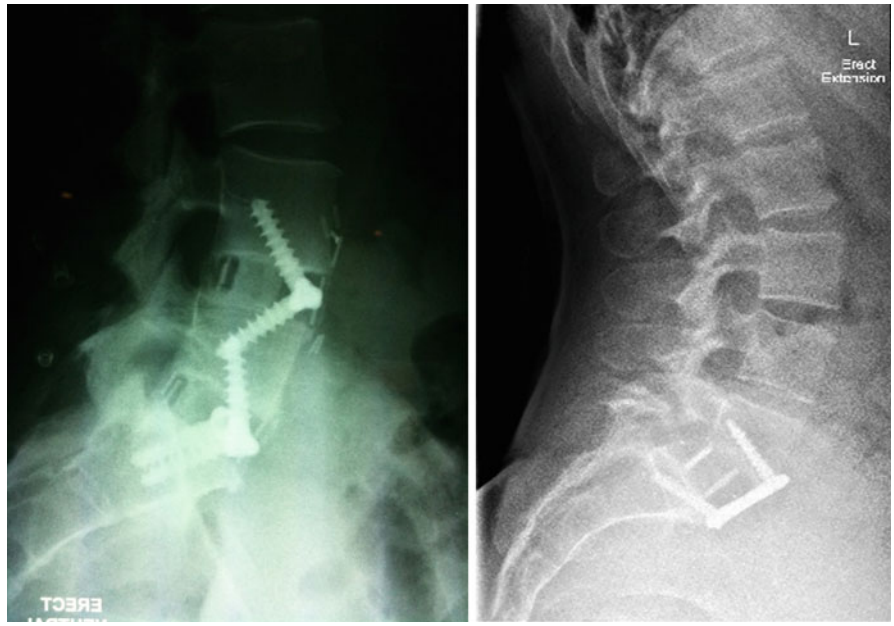

Fig. 4 Examples of stand-alone ALIF cage with integrated fixation, left, and a stand-alone ALIF cage-plate construct, right

vessels. Early biomechanical studies of LLIF have investigated the stability of LLIF compared to ALIF as well as the stability of stand-alone LLIF constructs to the stability of constructs with supplementary lateral plate or posterior fixation.

Laws et al. (2012) performed a human cadaveric biomechanical study to determine the biomechanical differences between ALIF and LLIF with and without supplementary instrumentation. Testing was performed in the intact state, with ALIF or LLIF cage, with cage plus stabilizing plate, with cage plus unilateral pedicle screw fixation, and with cage plus bilateral pedicle screw fixation. The cages used were PEEK cages (Cougar, De Puy Spine, Raynham, Massachusetts). Compared to the intact state, stand-alone LLIF significantly reduced ROM in flexion, extension, and lateral bending, which was not seen with stand-alone ALIF. Addition of a plate increased ALIF group stiffness by 211% in extension and 256% in axial rotation. Compared with stand-alone cages, supplementing with bilateral pedicle screws increased ALIF motion segmental stiffness significantly in flexion (455%) and lateral bending (317%) and LLIF stiffness significantly in flexion (350%) and extension (222%). When bilateral pedicle screws supplemented fusion, ALIF and LLIF were biomechanically equivalent.

Fogel et al. (2014) investigated the biomechanics of lateral lumbar interbody fusion constructs with lateral and interspinous plate fixation and compared these constructs with supplementary bilateral pedicle screw fixation. They found that a stand-alone lateral cage significantly reduced ROM with respect to the intact state in flexion-extension, lateral bending, and axial rotation. Addition of a lateral plate did not alter flexion-extension ROM but significantly reduced lateral bending and axial rotation. Cage with lateral plate was not statistically different from bilateral pedicle screws in lateral bending. Supplementary fixation with a spinous process plate was not statistically different from bilateral pedicle screws in flexion-extension. A combination of lateral plate and spinous process plate was not statistically different from cage with bilateral pedicle screws in all loading modes.

Similarly Reis et al. (2016) found that a stand-alone lateral cage significantly decreased ROM in

all directions, with the addition of a lateral plate improving stability in lateral bending, and the addition of an interspinous plate improved stability in flexion-extension; a combination of lateral cage, lateral plate, and interspinous plate was biomechanically equivalent to a lateral cage with bilateral pedicle screws.

One potential disadvantage of LLIF is that, without release of the anterior longitudinal ligament (ALL), there is limited ability to restore segmental lordosis. Thus the LLIF technique has evolved to sometimes include release of the ALL if correction of lordosis is required; this has been termed anterior column realignment (ACR) (Saigal et al. 2016; Berjano et al. 2015).

Melikian et al. (2016) examined the effect of cage angle and surgical technique on segmental lordosis achieved during lateral interbody fusion. They found that insertion of a parallel or 10 ° cage had little effect on lordosis and even insertion of a 30 ° cage with ALL release only led to a modest increase in lordosis (10.5 °s). The addition of spinous process resection and facetectomy was needed to obtain a larger amount of correction (26 °s). None of the cages, including the hyperlordotic cage, caused a decrease in posterior disc height, suggesting hyperlordotic cages do not cause foraminal stenosis.

A cadaveric biomechanical study examining the effect of anterior longitudinal ligament resection on lordosis correction during LLIF found that an 8 mm parallel spacer with an intact ALL provided the greatest stability relative to the intact state but did little to restore lordosis (1.44 ° increase). Conversely, ALL release led to significant improvement in lordosis correction (6.4 ° increase with 8 mm cage and 11 ° increase with 13 mm cage) but significantly destabilized the spine relative to the intact state. Addition of integrated screws to the fusion cage following ALL resection improved stability back to the level of the intact spine (Kim et al. 2017).

There does not appear to be any biomechanical advantage of expandable lateral cages over static lateral cages. Human cadaveric biomechanical testing showed comparable stability between static and expandable lateral stand-alone cages with the most stable construct being a static cage with bilateral pedicle screws. The authors cautioned that there was minimal feedback when expanding the expandable cage which may lead to over-distraction of the disc space and end plate failure (Gonzalez-Blohm et al. 2014).

In summary, a purely stand-alone LLIF cage appears to have more inherent stability than a stand-alone ALIF cage due to preservation of the ALL; however this is at the expense of the ability to effectively restore lordosis. Addition of supplementary lateral or posterior fixation adds further to stability. Release of the ALL significantly destabilizes the motion segment, and much like ALIF, supplementary fixation with integrated screws, lateral plate, or posterior constructs is required to restore stability.

PLIF and TLIF

The biomechanical considerations of posteriorly placed interbody fusion cages differ significantly from ALIF and LLIF. As the ALL is not resected, a ° of inherent stability is retained; however restoration of anterior disc height and lordosis may be somewhat limited. Lordosis can be achieved with compression across a pedicle screw-rod construct with or without osteotomy of the facet joints. This is feasible with an open PLIF or TLIF procedure but difficult to achieve with a MIS-TLIF procedure due to the limited exposure. The interbody fusion devices placed with PLIF or TLIF are typically a lot smaller than those placed for ALIF or LLIF as exposure of the disc space is limited by the neural elements. End plate coverage by the interbody cages is therefore limited and subsidence much more likely if used in a stand-alone fashion. Therefore, in general, PLIF and TLIF cages are supplemented with posterior screw-rod constructs to increase stability and reduce the chances of subsidence.

Brodke et al. (1997) used a calf lumbar spine model to compare PLIF using structural autograft to BAK cages with or without supplementary pedicle screw fixation. PLIF with bone graft alone was the least stiff construct, less stiff than the normal spine. BAK cages alone were similar in stiffness to bone graft with pedicle screw

fixation which were both significantly stiffer than the normal spine. BAK cages with pedicle screw fixation were significantly stiffer than all other constructs.

In regard to device material, Xiao et al. (2012) used finite element analysis to compare the biomechanics of PLIF with autogenous iliac bone, PEEK cages, and titanium cages. The lowest stresses on the bone graft and the highest stresses on the end plates were seen with titanium cages, whereas the PEEK cages showed significant stresses on the bone graft and less stresses on surrounding ligaments. The authors concluded that the titanium cage was inferior to the other two models with potentially an increased risk of subsidence due to high end plate stresses and increased risk of pseudarthrosis due to stress shielding of the bone graft.

Vadapalli et al. (2006) also investigated the biomechanics of PEEK and titanium PLIF cages with supplementary pedicle screw fixation. Stresses through the bone graft increased by at least ninefold with the PEEK spacers compared to the titanium spacers. Conversely, end plate stresses increased by at least 2.4-fold with titanium spacers compared to PEEK spacers. There was no difference in stability between the two constructs. Again they concluded that PEEK was superior to titanium in a PLIF construct with similar stability but more graft loading and less chance of subsidence into the end plates.

Slucky et al. (2006) investigated the biomechanics of TLIF with either unilateral or bilateral pedicle screw fixation or unilateral pedicle screws with a contralateral facet screw construct. After TLIF, the unilateral pedicle screw construct provided only half of the improvement in stiffness compared with the other two constructs and allowed for significant off-axis rotational motions.

Similarly, Chen et al. (2012) performed a finite element analysis of unilateral and bilateral pedicle screw fixation for TLIF after decompressive surgery. Finite element analysis was performed for TLIF with a single moon-shaped PEEK cage in the anterior or middle portion of the vertebral bodies and TLIF with a left diagonally placed oval-shaped PEEK cage, all with both unilateral and bilateral pedicle screw fixation. All TLIFs with bilateral pedicle screws appeared biomechanically stable; however TLIF cages with unilateral pedicle screws on the same side showed increased ROM and annular stress in extension, contralateral lateral bending, and contralateral axial rotation. This was particularly pronounced with the diagonal TLIF cage. The authors cautioned against performing TLIF with unilateral pedicle screws, especially if a diagonal cage is used.

Ames et al. (2005) performed a biomechanical comparison of PLIF and TLIF performed at one and two levels. There was no statistically significant difference in flexion-extension, axial rotation, or lateral bending after either PLIF or TLIF at one level compared to the intact condition. The addition of pedicle screws significantly increased the rigidity for both PLIF and TLIF. Similar findings were seen in the two-level constructs. They concluded that posterior fixation with a pedicle screw-rod construct is suggested for single-level PLIF or TLIF and is necessary to achieve stability with a two-level PLIF or TLIF.

In summary, there is biomechanical evidence supporting the use of PEEK over titanium cages when performing PLIF/TLIF surgery. There is also good evidence suggesting that all PLIF/TLIF constructs should be supplemented with a posterior bilateral screw-rod construct to enhance stability.

AxiaLIF

Biomechanical studies with single-level and two-level AxiaLIF constructs have been performed. In a cadaveric study looking at single-level constructs, ROM was reduced by 40% with a stand-alone trans-sacral rod. Augmentation with facet or pedicle screws reduced ROM between 70% and 90% (Akesen et al. 2008). In two-level stand-alone constructs, ROM decreased by greater than 42% at L4–L5 and 66% at L5–S1. Supplementary pedicle or facet screws further reduced motion (Erkan et al. 2009). Both studies recommended supplementary posterior fixation to provide greater construct stability. In ROM studies, single-level AxiaLIF was shown to be comparable to other fusion types (Ledet et al. 2005).

Clinical Rationale

Anterior Lumbar Interbody Fusion (ALIF)

ALIF is indicated for the treatment of degenerative disc disease (DDD), spondylolisthesis, recurrent disc herniation, and pseudarthrosis, for deformity correction including long fusions to the sacrum/pelvis, and for treatment of adjacent segment degeneration above a previous posterior fusion. It can also be used for debridement and stabilization in cases of infective discitis.

ALIF can be performed via either a retroperitoneal or transperitoneal approach with subsequent mobilization of the great vessels to expose the anterior aspect of the disc. The approach is predominantly used to approach L4–L5 and L5–S1. Access to higher lumbar levels is possible, often involving a transperitoneal approach and the assistance of a vascular surgeon. Renal vein anatomy may preclude accessing L1–L2 and L2–L3 and should be assessed preoperatively if access to the higher lumbar levels is contemplated.

The approach provides extensive exposure of the disc space allowing release of the ALL, thorough discectomy and release of the posterior annulus, excellent end plate preparation, appropriate restoration of disc height and lordosis, and insertion of a large footprint implant. ALIF avoids injury to the paraspinal muscles and direct mobilization of the neural elements.

ALIF is a preferred approach for the treatment of discogenic pain as it allows thorough removal of the pain generator and excellent stabilization of the motion segment. Several studies have shown ALIF to be superior to PLF for the treatment of discogenic pain (Derby et al. 1999; Weatherley et al. 1986).

ALIF is particularly advantageous in patients with severe disc space collapse and spondylolisthesis as it allows a direct and thorough release of the disc space, restoration of disc height and lordosis, and reduction of spondylolisthesis. Restoration of disc height and spondylolisthesis reduction indirectly decompresses the neural foramen.

The biggest driver of disability in adult spinal deformity is loss of lumbar lordosis and sagittal balance. In these patients ALIF is an effective way to release the disc space and correct disc height and lordosis. ALIF is also useful in correcting large coronal plane deformities, especially in rigid curves. In cases where two or more levels are involved, ALIF may be a more efficient strategy than multilevel PLIF or TLIF. In long fusions to the sacrum (L1 or above), ALIF at L4–L5 and L5–S1 has been shown to lower pseudarthrosis rates (Farcy et al. 1992; Kostuik and Hall 1983).

ALIF is the technique of choice in patients who are at high risk of pseudarthrosis such as smokers and in patients with established pseudarthrosis or ongoing discogenic pain after previous posterolateral fusion.

ALIF is also useful in the management of adjacent segment disease after previous posterior fusion as it avoids reoperating through previous scarring, reinjury to the paraspinal muscles, as well as the need for removal and extension of previously placed posterior instrumentation.

ALIF has several potential disadvantages. Many surgeons are unfamiliar with the anterior approach to the lumbar spine, and a volume performance threshold likely exists. Direct decompression and visualization of the neural elements are not possible, and stenosis due to facet joint and ligamentum flavum hypertrophy is not directly addressed.

Anterior approach-related complications can occur. These include vascular and visceral injury, ileus, sympathetic dysfunction, and, in male patients, retrograde ejaculation. Relative contraindications to ALIF include significant obesity, multiple previous abdominal surgeries, significant vascular calcification, and vascular anatomy precluding safe exposure of the disc space.

Oblique Lumbar Interbody Fusion (OLIF)

The OLIF or anterior to psoas approach (ATP) is designed to access the disc space anterior to the psoas muscle (thus avoiding potential injury to the lumbar plexus) without the requirement

for mobilization of the great vessels. The indications for OLIF are the same as for ALIF, excepting cases of high-grade spondylolisthesis.

The surgery is performed with the patient in the lateral position either left or right side up, depending on surgeon preference and the pathology being treated. The spine can be accessed from L1–S1 using this technique. Like ALIF, OLIF allows good restoration of disc height and lordosis, although, similar to lateral interbody fusion, adequate release of the ALL is required to achieve significant lordosis correction.

Advantages of OLIF include the minimally invasive approach, facilitating faster patient recovery, and the ability to perform extensive disc space clearance and insert a large interbody implant, thus promoting high fusion rates. The approach is useful in obese patients as the lateral positioning allows the abdomen to fall forward out of the operative field.

As with any minimally invasive retroperitoneal approach, the potential disadvantage is major vascular injury that cannot be easily controlled due to lack of a wide exposure. Sympathetic dysfunction is also a potential complication.

Lateral Lumbar Interbody Fusion (LLIF)

The LLIF technique was pioneered by Pimenta who subsequently first published the technique in the literature with Ozgur et al. (2006). The disc space is accessed via a retroperitoneal transpsoas corridor where no direct mobilization of the vessels is undertaken. The technique allows access from T12–L1 to L4–L5. The L5–S1 level cannot be accessed due to the iliac crest obstructing access.

The patient is positioned laterally either left or right side up depending on surgeon preference and the pathology being treated. A small lateral incision is made followed by placement of a guide wire through the psoas under image intensifier guidance. Serial dilation through the muscle is then undertaken before retractor blades are placed flush on the lateral annulus. Neuromonitoring is essential to avoid injury to the lumbar plexus which courses through the psoas muscle. The plexus is more at risk at the lower lumbar levels where it courses more anteriorly in the psoas muscle.

LLIF allows good restoration of disc height via a minimally invasive approach. If significant lordosis restoration is required, ALL release can be performed before insertion of a hyperlordotic cage. LLIF also allows excellent correction of coronal plane deformity (Arnold et al. 2012) and is a useful approach in obese patents as the abdomen falls forward "out of the way."

LLIF has limited ability to decompress severe central and lateral recess stenosis, and the approach is difficult in high-grade spondylolisthesis (Malham et al. 2015). In general supplementary posterior instrumentation is used, especially in cases with instability and deformity, adjacent to a previous fusion, multiple-level LLIF, and in patients with osteoporosis.

LLIF is contraindicated in patients with prior retroperitoneal surgery and abnormal vascular anatomy. "Flying" or "Mickey Mouse ears" psoas muscles are also a relative contraindication as the lumbar plexus is put at significant risk due to anterior position. The axial MRI should be reviewed preoperatively to assess this.

Complications of LLIF include bowel injury, lumbar plexus injury (particularly at L4–L5), and postoperative lower limb dysesthesia on the side of the approach which is quite common and may last for many months. Quadriceps palsy is a rarer complication but devastating functionally for the patient. Like OLIF, if vascular or bowel injury occurs, it may be difficult to control due to lack of a wide exposure for repair.

Transforaminal Lumbar Interbody Fusion (TLIF)

TLIF allows access to the disc space unilaterally via the neural foramen and can be performed via an open procedure or MIS technique. Indications for TLIF include degenerative disc disease, spondylolisthesis, recurrent disc herniation, spinal stenosis, and degenerative scoliosis. It is useful in patients requiring an interbody fusion who have had previous anterior surgery or who have

contraindications to an anterior or lateral approach. In young male patients, it avoids the potential complication of retrograde ejaculation which can occur with an anterior approach. The approach requires less neural retraction than a PLIF procedure.

The patient is positioned prone and a midline or bilateral paramedian incisions used. The disc space is accessed via a unilateral laminectomy and facetectomy. The approach can be used for all lumbar levels.

Advantages of TLIF include direct access and decompression of the neural elements unilaterally and the ability to perform a "circumferential" fusion via a posterior only approach. The approach-related complications of anterior and lateral approaches are avoided. The midline ligamentous structures are preserved due to use of muscle-splitting approaches, thus aiding postoperative stability (Park et al. 2005).

Disadvantages include iatrogenic injury to the paraspinal muscles and limited ability to restore disc height, lordosis, and coronal balance (especially with MIS procedures) (Sakeb and Ahsan 2013; McAfee et al. 2005). If significant lordosis correction is required, then a bilateral open TLIF with complete facetectomies and posterior compression across a pedicle screw-rod construct is an option.

Complications include dural tear/CSF leak, nerve injury, epidural fibrosis, end plate damage with cage subsidence, pseudarthrosis, and iatrogenic injury to the supradjacent facet joint.

Contraindications include severe segmental kyphosis, epidural scarring, conjoined nerve roots, and osteoporosis where a fusion device with a larger footprint (ALIF, OLIF, LLIF) is preferred.

Posterior Lumbar Interbody Fusion (PLIF)

In the PLIF technique, the disc space is accessed posteriorly after laminectomy, facetectomy, and contralateral retraction of the neural elements; traditionally it is performed as a bilateral procedure with supplementary pedicle screw stabilization. The patient is positioned prone, and the procedure performed via an open midline approach or in an MIS fashion via paramedian muscle-splitting incisions. The indications for PLIF are the same as for TLIF.

PLIF has several advantages including direct visualization and decompression of the neural elements and restoration of disc height with preservation of the facet joints, thus aiding in postoperative stability (Lestini et al. 1994). PLIF allows bilateral circumferential fusion through a single incision. Like TLIF, PLIF is useful in patients with contraindications to an anterior or lateral approach. In young males, the risk of retrograde ejaculation is eliminated.

Disadvantages of PLIF include iatrogenic injury to the paraspinal muscles from prolonged retraction (Fan et al. 2010). It may be difficultly to correct coronal imbalance and restore lordosis. The procedure requires significant retraction of the nerve roots which may lead to fibrosis and chronic radiculopathy (Zhang et al. 2014). Other potential complications include dural tear or nerve root injury risking arachnoiditis.

Contraindications include previous posterior surgery, extensive epidural scarring, and arachnoiditis. PLIF is not recommended above L2–L3 as retraction of the conus medullaris can lead to paralysis.

Axial Lumbar Interbody Fusion (AxiaLIF)

Introduced in 2004 and described by Marotta et al. (2006), the AxiaLIF approach was designed to allow distraction and fusion of the L5–S1 disc space through a minimally invasive trans-sacral approach that preserves the anterior and posterior longitudinal ligaments. It is also possible to extend the fusion construct up to include the L4–L5 disc space. AxiaLIF is indicated for degenerative disc disease, low-grade spondylolisthesis, and pseudarthrosis at L5–S1 or L4–L5 and L5–S1.

The patient is positioned prone with care taken to maintain lumbar lordosis. A 2 cm incision is made midline or just left of the paracoccygeal

notch, and blunt finger dissection is used to displace the rectum away from the sacrum. The presacral space is developed using blunt dissection followed by docking of a guide pin at the S1–S2 level. The guide pin is advanced into the L5–S1 disc space, followed by over-reaming to create a 10 mm channel and preparation of the disc space using rotating shavers. The disc space is then packed with local autograft +/− other grafting materials. A channel is then drilled into L5, and an interbody screw with a differential thread is then inserted that allows distraction of the disc space as it is inserted.

The advantages of AxiaLIF include its minimally invasive nature using an avascular and aneural corridor, with preservation of the ALL and PLL, thus aiding in initial stability of the construct. AxiaLIF avoids the approach-related complications of anterior, lateral, and posterior interbody fusion techniques.

Although AxiaLIF has some ability to restore disc height, there is little ability to restore lordosis if required, as the ALL is not released. As the disc space is not directly visualized, the quality and quantity of discectomy may be suboptimal. No direct decompression of neural elements is possible. Only the L5–S1 +/− the L4–L5 levels can be accessed. In some patients the procedure is not possible due to the sacrococcygeal morphology. Complications of AxiaLIF include infection, rectal injury, pseudarthrosis, retroperitoneal hematoma, and subsidence/loss of distraction across the disc space.

Clinical Results

ALIF

Early Studies

In one of the first studies comparing fusion to non-operative treatment for DDD, Fritzell et al. (2002) conducted a prospective multicenter randomized trial comparing three lumbar fusion techniques and non-operative treatment in patients with DDD. Two hundred ninety-four patients were randomized; in the interbody fusion group, 56 patients received ALIF using autologous tricortical bone blocks (19 patients received a PLIF) with additional PLF using pedicle screws and plates. The mean age in this group was 42 years. VAS back pain improved from 65.6 pre-op to 45.7 at 2 years, and ODI improved from 47.3 pre-op to 38.5 at 2 years. The fusion rate was 91% at 2 years. As the biomechanical advantages of graft packed interbody cages over graft alone became apparent, multiple early studies confirmed the clinical effectiveness of the ALIF technique utilizing these devices.

Burkus et al. (2003) reported on 254 patients treated with ALIF using the LT cage device with rhBMP-2 (Medtronic Sofamor Danek, Memphis, Tennessee) and noted a mean 29.3-point improvement in ODI and a 13.5-point improvement in SF-36 PCS. Further follow-up of 146 patients at 6 years (Burkus et al. 2009) was undertaken. The fusion rate was 98%. The ODI improved from 52 pre-op to 20.7 at 6 years. Back pain (using a 20-point scale) improved from 15.4 to 6.9, leg pain improved from 11.6 to 4.8, and SF-36 PCS improved from 27.9 to 43.1 at 6-year follow-up.

Madan and Boeree (2003) conducted a prospective study comparing ALIF, with circumferential fusion through a posterior approach (PLIF and PLF) in patients with degenerative disc disease (DDD). There were 39 patients (47 fusion levels) in the ALIF group. The ALIF procedure was performed using the Hartshill horseshoe cage along with tricortical and cancellous iliac crest autograft. Minimum follow-up was 2 years. Using the subjective score assessment, there was a satisfactory outcome in 71.8% of patients in the ALIF group, and assessment of ODI showed a satisfactory outcome in 79.5% of patients. 64% of patients saw an improvement in their working ability.

Sasso et al. (2004) conducted a prospective randomized controlled trial comparing a cylindrical threaded titanium cage (INTER FIX device, Medtronic Sofamor Danek) to a control group using femoral ring allograft for ALIF. There were 78 patients in the cage group; all had autogenous iliac crest inserted in the cage and had a single-level stand-alone ALIF performed at L4–L5 or L5–S1 for DDD. The fusion rate in the cage group was 97% at 12 months (40% in the

control group). ODI improved from 51.1 pre-op to 23.7 at 48 months. SF-36 PCS improved from 28.3 pre-op to 39.8 at 24 months.

Glassman et al. (2006) conducted a multicenter retrospective review of prospectively collected data analyzing clinical outcomes after single-level and two-level lumbar fusion. A total of 497 patients were included in the study; 125 patients underwent ALIF. The ALIF group had a mean age of 42 years. At 2 years post-op, SF-36 improved 13.8 points. Mean improvement in ODI was 27 points at 2 years.

The results of these four relatively early studies of ALIF fusion devices are very similar, with high fusion rates and clinically and statistically significant improvements in ODI and SF-36 scores.

ALIF Using Femoral Ring Allograft

With the advent of rhBMP-2 and other biologics to enhance fusion, a number of studies revisited the use of femoral ring allograft for use in ALIF. Freudenberger et al. (2009) conducted a retrospective review of 59 patients with single-level or two-level lumbar DDD who underwent ALIF with anterior tension band plating or PLIF with pedicle screw instrumentation. ALIF (29 patients) was performed with an allograft bone spacer, BMP, and an anterior tension band plate. In the ALIF group, median estimated blood loss was 112.5 ml and median surgical time 104 min. At 6–9 months post-op, partial to solid fusion was seen in 92% of patients. ODI improved from 24.3 pre-op to 16.0 at 12–18 months post-op. Complications occurred in four patients in the ALIF group (two intra-op common iliac vein injuries, one post-op thrombosis, and one ileus). Compared to the PLIF group, the ALIF group had similar clinical outcomes but with significantly shorter surgical time and decreased blood loss.

Anderson et al. (2011) retrospectively reviewed 50 patients who underwent ALIF using femoral ring allograft and rhBMP-2 with supplementary percutaneous pedicle screws for degenerative lumbar pathology. Twenty-four patients had a single-level fusion and 26 a two-level fusion. Operating time was 131 min anteriorly and 102 min posteriorly. Mean EBL was 288 ml. Follow-up was 12 months. 61% were "definitely fused" and 31% "probably fused." VAS back pain improved from 8 to 3, VAS leg pain improved from 6 to 2. ODI improved from 47 to 28. The overall complication rate was 12%. No intraoperative complications occurred.

ALIF can also be combined with open posterolateral fusion in a true circumferential fusion construct. Zigler and Delamarter (2013) investigated 75 patients treated with 360 ° lumbar fusion as the control group in a prospective randomized FDA IDE trial of the pro-disc lumbar disc arthroplasty. The fusion patients were treated with femoral ring allograft and DBM for the interbody fusion and open posterolateral fusion. The follow-up rate was 75% at 5 years. VAS improved from 74.9 preoperatively to 40 at 5 years. ODI improved from a mean of 62.7 preoperatively to 36.2, and SF-36 improved from 30.9 preoperatively to 40.1. The fusion rate was 95.6%.

Degenerative Disc Disease

Further studies have examined the role of stand-alone ALIF cages with rhBMP-2 or other biologics in the management of DDD. Gornet et al. (2011) investigated 172 patients undergoing stand-alone ALIF as the control group in a randomized controlled multicenter IDE study of lumbar disc arthroplasty (Maverick). Follow-up was to 24 months. ALIF was performed with tapered fusion cages and rhBMP-2. Mean patient age was 40.2 years. Operative time was 1.4 h and blood loss 95.2 ml. ODI improved from 54.5 pre-op to 24.8 at 24 months. Mean improvement in low back pain was 49 points and mean improvement in leg pain was 23.1 points. The fusion rate was 100%.

Lammli et al. (2014) conducted a retrospective chart review of a consecutive series of patients with DDD treated with single-level or two-level stand-alone ALIF using either a cage and anterior plate or an integrated cage/plate device packed with autograft and rhBMP-2. One hundred eighteen patients were included in the study. The average patient age was 43 years; follow-up was 2 years. VAS score improved from 6.35 to 3.02. Average improvement in ODI was 17%.

Allain et al. (2014) conducted a prospective study involving 65 patients who underwent ALIF using a PEEK cage with integrated intracorporeal anchoring plates (ROI-A, LDR Medical, Troyes, France) in the treatment of lumbar DDD. The average age was 57 years. In 91% of patients, autologous bone and rhBMP-2 were used within the cage. The mean duration of surgery was 133 min and the mean blood loss was 205.8 ml. At 12-month follow-up, the fusion rate was 96.3%. Statistically significant improvements in back and leg pain were seen by 6 weeks and maintained at 12 months. ODI improved by 26.6 points at 12 months post-op. 88.7% of patients were very satisfied or satisfied with their outcome.

Siepe et al. (2015) reported on 71 patients who underwent stand-alone ALIF at L5–S1 for DDD. ALIF was performed using the Synfix-LR cage (DePuy Synthes, Wet Chester, PA) and rhBMP-2 in the vast majority. The mean follow-up was 35.1 months. Statistically significant and clinically relevant improvements in VAS and ODI were seen at all time points from 3 months postoperatively. The fusion rate was 97.3% at a mean of 27.7 months. Segmental lordosis increased from 16.1 °s to 26.7 °s.

Mobbs et al. (2014) reported on 110 patients who underwent single-level or multilevel ALIF for DDD. Surgery was performed using a stand-alone PEEK cage (Synfix, Synthes) packed with i-FACTOR. Mean follow-up was 24 months. The fusion rate was 93.6% for the whole cohort (98% for single-level fusion and 82% for two-level fusion). SF-12 improved from 68.57 to 92.99. ODI improved from 61.02 to 28.42, and VAS score improved from 7.38 to 2.65. 85.3% of patients reported good to excellent outcomes. They concluded that stand-alone ALIF with i-FACTOR was a viable treatment option for DDD with clinical and radiographic results comparable to ALIF with autograft or rhBMP-2.

Giang et al. (2017) conducted a systematic review of outcomes of stand-alone ALIF. Seventeen studies were included. Mean age of all included patients was 48.5 years. ODI improved by a mean of 26.7 points, VAS back pain improved by 4.1, VAS leg pain improved by 3.3, and SF-36 PCS improved by 12.7. The pooled fusion rate was 79.8%. These studies highlight that in the treatment of DDD, stand-alone ALIF can be expected to give clinically significant improvements in both pain and function with a high fusion rate and patient satisfaction.

Ohtori et al. (2011) also provided level I evidence for ALIF in the treatment of confirmed discogenic low back pain patients without leg pain in a small randomized study of 41 patients. Compared to the non-operative treatment patients, patients who underwent ALIF had reduced ODI and VAS scores.

Spondylolisthesis

ALIF can also be used successfully in the treatment of single-level or multilevel spondylolisthesis.

Kim et al. (2010) compared ALIF and percutaneous pedicle screws with circumferential fusion (ALIF with open instrumented PSF) for adult low-grade isthmic spondylolisthesis. Forty-three patients underwent ALIF and 32 circumferential fusion. ALIF was performed with a stand-alone cage with integrated screws packed with allograft chips. Percutaneous pedicle screws were then inserted. Operative time averaged 189.9 min and blood loss averaged 300 ml. The mean follow-up in the ALIF group was 41.1 months. Significant improvements in segmental lordosis, whole lumbar lordosis, and percentage listhesis were seen. Fusion was seen in 42/43 patients. VAS back pain improved from 7.6 to 2.1, VAS leg pain improved from 7.5 to 2.0, and ODI improved from 49.3 to 13.7.

Hsieh et al. (2017) reported on 23 consecutive patients who underwent ALIF with supplementary percutaneous pedicle screws for multilevel isthmic spondylolisthesis. Twenty-one patients had two-level spondylolisthesis and two patients had three-level slips. The mean follow-up was 22.26 months. Mean operating time was 251.1 min and mean estimated blood loss 346.8 ml. ODI improved from 56.2 to 14.9, VAS back from 8 to 1.7, and VAS leg 7.6 to 1.1. Segmental lordosis improved from 22.7 to 32.7, and total lumbar lordosis improved from 45.8 to 53.1. Successful fusion was seen in all patients.

Adult Spinal Deformity

ALIF has also been used successfully in the treatment of spinal deformity and sagittal imbalance and is an effective way to restore lumbar lordosis (see Fig. 5). Saville et al. (2016) assessed the segmental correction obtained using 20 ° and 30 ° hyperlordotic cages for ALIF in staged anterior-posterior fusions in adults with degenerative pathology and spinal deformity. The authors assessed 69 levels in 41 patients with a mean age 55 years. The average follow-up was 10 months. The cages used were made of either PEEK or carbon fiber reinforced polymer. For 30 ° cages, the mean segmental lordosis achieved was 29 °s; in the presence of spondylolisthesis, this reduced to 19 °s. For 20 ° cages, the mean segmental lordosis achieved was 19 °s. The mean lumbar lordosis increased from 39 °s to 59 °s. The mean SVA reduced from 113 mm to 43 mm. Six cages (9%) displayed a loss of segmental lordosis during follow-up, on average 4.5 °s.

Rao et al. (2015) in a prospective study of 125 patients compared the clinical and radiological outcomes of ALIF based on surgical indication. The mean follow-up was 20 months. Patients with DDD (with or without radiculopathy), spondylolisthesis, and scoliosis had the best clinical response to ALIF with statistically and clinically significant improvement in SF-12, ODI, and VAS scores. The favorable results can be partly explained by the powerful ability of ALIF to obtain lordosis which is vital to at least maintain in the aforementioned indications, where mild deformities can coexist. Failed posterior fusion and adjacent segment disease also showed significant improvement although the mean changes were lower. The overall radiological fusion rate was 94.4%.

Fig. 5 Preoperative (EOS™) and postoperative standing lateral radiographs of a combined anterior-posterior correction for severe unbalanced kyphoscoliosis utilizing multiple ALIF for anterior column support

In summary, ALIF is an established approach for interbody fusion that can be used successfully to treat DDD, spondylolisthesis, and deformity. ALIF leads to clinically significant improvements in pain and function in appropriately selected patients. The technique is particularly effective at restoring disc height and lordosis, thus maintaining or restoring sagittal balance. Good clinical outcomes are reported for femoral allograft, stand-alone devices with integrated fixation, cage-plate constructs, and circumferential instrumentation.

OLIF

Mayer (1997) were the first to describe the modern OLIF approach in 20/25 patients with DDD, degenerative spondylolisthesis, isthmic spondylolisthesis, or failed back surgery syndrome.

Segments between L2–L3 and L4–L5 were accessed through a retroperitoneal "OLIF" approach and L5–S1 through a traditional transperitoneal ALIF approach. Patients had undergone posterior decompression and pedicle screw fixation 1–2 weeks prior. OLIF was performed using autologous iliac bone graft. The mean follow-up was 10.6 months. For the OLIF approach, mean operating time was 111 min; mean blood loss was 67.8 ml. The fusion rate was 100%.

Lin et al. (2010) presented the results of a prospective clinical study of single-level or two-level OLIF in 46 patients with DDD, low-grade spondylolisthesis, or pseudarthrosis. The mean follow-up was 15 months. OLIF was performed using a titanium cage and plate and autograft bone. The fusion rate was 94.2%. VAS improved from 9.13 to 2.33 and RMDQ improved from 18.58 to 5.43. Good to excellent outcomes were reported in 87% of patients.

Mehren et al. (2016) conducted a chart review of patients who had undergone OLIF over a 12-year period at a single center, specifically focussing on complications. Eight hundred twelve patients with a median age of 63 years were investigated. Patients predominantly suffered from DDD or spondylolisthesis. OLIF was performed using tricortical iliac crest bone graft early in the series, and titanium or PEEK cages filled with autograft, tricalcium phosphate, or rhBMP-2 later in the series. 98% of cases were combined with posterior instrumentation. 62% of patients underwent single-level surgery. The average operating time for OLIF was 110 min. An inhospital complication occurred in 3.7% of patients. The superficial infection rate was 0.24% and deep infection rate 0.37%. There were three intraoperative vascular injuries (0.37%). Nine patients experienced a neurologic injury (1.1%), six of these were meralgia paresthetica due to iliac crest bone harvesting.

Molloy et al. (2016) conducted a prospective cohort study of 64 patients who underwent OLIF using porous tantalum cages for degenerative spine pathology. All patients had additional pedicle screw fixation. The mean follow-up was 1.8 years. VAS back pain improved from 7.5 preoperatively to 1.4, and ODI improved from 64.3 preoperatively to 6.7 at 12 months postoperatively. Radiographic analysis confirmed improvement in multiple lumbopelvic parameters (including pelvic tilt, sacral slope, lumbar lordosis) and the SVA.

Li et al. (2017) conducted a systemic search of the literature to assess operative outcomes and complications of the OLIF procedure. Sixteen studies were included for review, representing 2364 operated levels in 1571 patients. The average follow-up was 22.3 months. The mean blood loss was 109.9 ml, operating time 95.2 min, and postoperative hospital stay 6.3 days. Fusion was achieved in 93% of operated levels. Intraoperative complications occurred in 1.5% and postoperative complications in 9.9% of patients.

In summary, OLIF is a relatively new approach to lumbar interbody fusion that is currently gaining popularity. Initial clinical studies suggest that OLIF is a relatively safe technique that can be used effectively in the treatment of DDD and spondylolisthesis. High fusion rates and the ability to restore lordosis and sagittal balance have been reported in the literature.

LLIF

Ozgur et al. (2006) reported on the first described cases of LLIF, termed XLIF in their series. All procedures were supplemented with percutaneous pedicle screw fixation. Thirteen patients were reported on at short-term follow-up with no early complications noted.

Youssef et al. (2010) conducted a retrospective review of patients treated with LLIF for multiple clinical indications. Single-level, two-level, and three-level procedures were performed using the CoRoent implant (NuVasive, Inc., San Diego, CA). A total of 84 patients were included in the study (15 stand-alone LLIF, 31 with addition of a lateral plate, 38 with supplemental PSF). The mean operating time was 199 min, mean estimated blood loss was 155 ml, and length of hospital stay averaged 2.6 days. The perioperative complication rate was 2.4% and the postoperative complication rate 6.1%. The mean follow-up was 15.7 months. Solid fusion was seen in 68/84 patients (81%). At 1 year postoperatively, VAS improved from 58.9 to 13.7 and ODI improved from 39.7 to 17.3.

Ahmadian et al. (2015) also reported their experience with stand-alone LLIF for the treatment of DDD, spondylolisthesis, and adult degenerative scoliosis. Follow-up was up to 12 months. Fifty-nine patients were included in the study: average age 60 years. Diagnoses were DDD in 63%, degenerative spondylolisthesis in 7%, and ADS in 30%. Surgery was performed using a 10 ° lordotic, 8–12 mm height PEEK cage packed with allograft (and BMP in 19 patients). The fusion rate was 93% at 12 months. VAS improved from 69.1 to 37.8. ODI improved from 51.8 to 31.8. Grade I–II subsidence was seen in 30% of patients. The authors advised that to consider a stand-alone construct, patients should be sagittally balanced, have a coronal Cobb angle less than 30 °s, and be evaluated for osteoporosis preoperatively.

Spondylolisthesis

Ahmadian et al. (2013) reported on the results of LLIF for treatment of L4–L5 spondylolisthesis. Thirty-one patients were included in the study. All patients were treated with LLIF and supplementary percutaneous pedicle screw fixation. The mean follow-up was 18.2 months. Average age of the patients was 61.5 years. Mean blood loss was 94 ml. ODI improved from 50.4 to 30.9, VAS improved from 69.9 to 38.7, and SF-36 improved from 38.1 to 59.5 at latest follow-up. No motor weakness or permanent deficits were noted. Transient anterior thigh numbness was reported in 22.5% of patients. All patients had improvement in spondylolisthesis classification.

Adult Spinal Deformity

Phillips et al. (2013) conducted a prospective multicenter study to evaluate the clinical and radiographic results of patients undergoing LLIF for the treatment of degenerative scoliosis. A total of 107 patients were included in the study. Follow-up was at 24 months. The mean patient age was 68 years. An average of three levels were treated with LLIF at surgery (range: 1–6). ODI, VAS back, VAS leg, and SF-36 PCS scores all improved significantly. Patient satisfaction was 85%. In hypolordotic patients, lumbar lordosis was corrected from a mean of 27.7 °s pre-op to 33.6 °s at 24 months.

Anand et al. (2013) conducted a retrospective review of 2- to 5-year clinical and functional outcomes of minimally invasive surgery for adult scoliosis. Seventy-one patients were included in the study. All underwent a combination of LLIF, AxiaLIF, and posterior instrumentation. LLIF was performed using a PEEK cage filled with rhBMP-2 and Grafton putty. The mean patient age was 64 years and average follow-up was 39 months. On average, patients were sagittally balanced preoperatively and remained that way at latest follow-up. VAS improved from 6.43 to 2.35 and ODI improved from 50.3 to 41 at latest follow-up.

Tempel et al. (2014) reported on 26 patients who underwent combined LLIF and open PSF for the treatment of adult degenerative scoliosis. Patients were aged between 40 and 77 years. LLIF was performed with a 10 ° lordotic PEEK cage 10–12 mm in height packed with DBM. One-year follow-up results were reported. Statistically significant improvement in regional coronal angles

and segmental coronal angulation at all operative levels was seen. Coronal Cobb angle improved from a mean of 41.1 °s to 12 °s at latest follow-up. Mean PI-LL mismatch improved from 15 °s to 6.92 °s, and SVA improved from 59.5 mm preoperatively to 34.2 mm at latest follow-up. Significant improvements in clinical outcomes were also observed. VAS back pain improved from 7.5 to 4.3, VAS leg pain improved from 5.8 to 3.1, ODI from 48 to 38, and SF-36 PCS from 27.5 to 35. Three major and 10 minor complications were reported.

Costanzo et al. (2014) conducted a literature review focussing on sagittal balance restoration in adult degenerative scoliosis with the LLIF approach. Fourteen studies were identified representing 476 patients and 1266 operated levels. Only two studies measured global sagittal alignment. They concluded that LLIF was particularly effective when the lumbar lordosis correction goal was less than 10 °s and the sagittal balance correction goal was less than 5 cm.

Phan et al. (2015b) conducted a systematic review to assess the safety and clinical and radiological outcomes of LLIF for the treatment of degenerative spinal deformity. Twenty-one studies were included for review (948 patients, 1920 levels). The median follow-up was 14 months. Mean VAS improved from 6.8 to 2.9 and mean ODI improved from 44.5 to 20.5. Regional lumbar lordosis significantly improved from 35.8 °s to 43.3 °s. Sagittal alignment was unchanged (SVA 34 mm vs. 35.1 mm).

Saigal et al. (2016) performed a literature review of the anterior column realignment (ACR) procedure for sagittal deformity correction. ACR generally involves a LLIF with sectioning of the anterior longitudinal ligament (ALL) and placement of a hyperlordotic cage. ACR usually also involves a second stage posterior column osteotomy. Twelve papers met the inclusion criteria. Segmental lordosis between 10 and 27 °s was reported with use of hyperlordotic cages. A 19 ° increase in mean intradiscal angle was reported when ACR was combined with posterior column osteotomy, 13 °s more than is reported for LLIF alone without a hyperlordotic implant. Complication rates ranged between 18% and 47%. Transient hip flexion weakness was reported in 9.3% and transient paresthesia/dysesthesia in 12%. Motor deficit was reported in 11/75 cases, lower than typically reported for three-column osteotomy procedures.

Berjano et al. (2015) assessed the use of the LLIF-based anterior column reconstruction technique for correcting major sagittal deformity in 11 patients. A mean value of 27 °s lordosis was restored at a single ACR level but two major complications occurred, being a bowel perforation and a postoperative infection requiring posterior debridement. Nevertheless, the authors stated that the ACR technique could provide similar correction to a pedicle subtraction osteotomy with comparable complication profile.°

Complications

Rodgers et al. (2010) reported a prospective analysis of 600 LLIF cases; the paper focussed on intraoperative and perioperative complications. Seven hundred forty-one levels were treated; 99.2% included supplementary internal fixation. The overall incidence of perioperative complications (intraoperative out to 6 weeks postoperative) was 6.2%. Complications were statistically more common at the L4–L5 level. VAS improved from 8.82 preoperatively to 3.12 at 1 year post-op. The patient satisfaction rate was 86.7%.

Lykissas et al. (2014) performed a retrospective analysis of 919 LLIF procedures to identify risk factors for lumbosacral plexus injuries. Four hundred fifty-one patients were included in the study (919 levels). Immediately postoperatively 38.5% of patients reported anterior thigh/groin pain. Sensory deficits were recorded in 38% and motor deficits in 23.9%. At last follow-up, 4.8% of patients reported anterior thigh/groin pain, whereas sensory and motor deficits were recorded in 24.1% and 17.3% of patients, respectively. When patients with preoperative neural deficits were excluded, persistent surgery-related sensory and motor deficits were noted in 9.3% and 3.2% of the patients, respectively. Increased risk of neurological deficit was associated with surgery at the more caudal lumbar levels. The use of rhBMP-2 was associated with persistent motor deficits.

In summary, LLIF is now an established interbody fusion technique with good results reported in the treatment of DDD, spondylolisthesis, and deformity. Supplementary pedicle screw instrumentation is recommended in the majority of cases. To achieve significant lordosis correction, additional release of the ALL is required as part of the procedure. A high incidence of temporary postoperative lower limb neurological symptoms is expected due to the transpsoas approach, particularly at the L4–L5 level. The rate of permanent neurological deficit is low.

TLIF

Despite the popularity of the TLIF procedure, there is a relative paucity of robust published literature regarding the clinical outcomes of the technique. Lowe and Tahernia (2002) conducted a prospective analysis of 40 patients treated with TLIF for degenerative disease of the lumbar spine. TLIF was performed using autograft bone and titanium mesh cages. Bilateral posterolateral fusion and contralateral facet fusion were also performed. The mean follow-up was 3.4 years. The fusion rate was 90% and segmental lordosis was increased in all patients. VAS improved from a mean of 8.3 pre-op to 3.2 at latest follow-up. 85% of patients reported a good to excellent result.

Spondylolisthesis

Rosenberg and Mummaneni (2001) described their early experience with TLIF for the treatment of grade I or II spondylolisthesis. They retrospectively reviewed 22 patients, all presenting with low back pain, the majority with associated radiculopathy. TLIF was performed using Pyramesh titanium cages and iliac crest autograft with supplementary pedicle screw fixation. At a mean follow-up of 5.3 months, low back pain was completely resolved in 16 patients, moderate relief was achieved in 5 patients, and pain was unchanged in 1 patient. One intraoperative durotomy occurred, two postoperative wound infections developed, and one patient had a mild postoperative L5 motor palsy that resolved quickly.

Hackenberg et al. (2005) reported their minimum 3-year follow-up of 52 consecutive patients treated with TLIF for isthmic spondylolisthesis (22 patients) and lumbar degenerative disorders (30 patients). Thirty-nine cases were single-level, 11 cases were two-level, and 2 cases were three-level fusions. Operating time averaged 173 min for single-level cases and 238 min for multiple-level fusions. TLIF was performed using a curved titanium cage and autograft iliac crest. Four major complications occurred: one deep wound infection, one persistent radiculopathy, one contralateral disc herniation, and one pseudarthrosis. The fusion rate was 89%. VAS and ODI both improved significantly by 3 months postoperatively and remained significantly better than preoperative scores through follow-up.

Lauber et al. (2006) conducted a prospective clinical study evaluating the 2–4-year clinical and radiographic results of TLIF for the treatment of grade I–II degenerative and isthmic spondylolisthesis. Nineteen degenerative, 19 isthmic, and 1 dysplastic spondylolisthesis were treated. Fusion was performed using a curved titanium cage (Micomed Ortho AG, Switzerland) and autograft bone. Minimum follow-up was 24 months, with a mean clinical follow-up of 50 months and mean radiographic follow-up of 35 months. Mean ODI suggested mild to moderate disability preoperatively, but significant improvements were seen postoperatively (23.5 pre-op to 13.5 postoperatively). Significant improvements in VAS were also observed postoperatively. Both VAS and ODI scores began to deteriorate at the 4-year postoperative follow-up. Better results for both VAS and ODI were seen in the isthmic patients compared to degenerative patients, possibly due to the patients being significantly younger. The radiographic fusion rate was 94.8%. There were three serious postoperative complications requiring a return to theatre.

Open Versus Minimally Invasive TLIF

Since these early reports of the open TLIF procedure (O-TLIF), the technique has been modified into the now widely used minimally invasive

TLIF procedure (MI-TLIF). A number of systemic reviews and meta-analyses have been performed comparing the open and minimally invasive procedures.

Khan et al. (2015) performed a systemic review and meta-analysis to investigate early and late outcomes of MI-TLIF in comparison with O-TLIF. Thirty studies were included in the meta-analysis. MI-TLIF was associated with reduced blood loss, length of stay, and complications but increased radiation exposure. Fusion rates and operative times were comparable between the two groups. There were no differences in early and late ODI or early VAS back pain scores, but a (statistically significant but clinically insignificant) decrease in late VAS back pain scores was noted in the MI-TLIF group.

Goldstein et al. (2016) conducted a systematic review and meta-analysis to compare the clinical effectiveness and adverse event rates of MI-TLIF versus O-TLIF. Twenty-six studies met the inclusion criteria; of note, all were of low to very low quality. Overall, there were 856 patients in the MI-TLIF cohort and 806 patients in the O-TLIF cohort. Estimated blood loss, time to ambulation, and length of stay were all in favor of MI-TLIF. Operative times did not differ significantly. There was no difference found in surgical adverse events, but medical adverse events were significantly less likely in the MI-TLIF group. No differences in non-union or reoperation rates were observed. Mean ODI scores were slightly better in the MI-TLIF group at a median follow-up time of 24 months (3.32-point difference). There was no difference observed in VAS back and leg pain scores at 24-month follow-up.

Phan et al. (2015a) conducted a systemic review and meta-analysis of the relative benefits and risks of MI-TLIF and O-TLIF. Twenty-one studies were included in the analysis, representing 966 patients undergoing MI-TLIF and 863 patients undergoing O-TLIF. No significant difference in operating time was noted between the two groups. The median intraoperative blood loss was significantly less in the MI-TLIF group (177 vs. 461 ml). Length of hospital stay was shorter in the MI-TLIF group (4.7 days vs. 8 days). Infection rates were significantly lower in the MI-TLIF cohort (1.2% vs. 4.6%). There was no difference between the groups in overall complication and reoperation rates. VAS back pain scores and ODI were also slightly lower in the MI-TLIF group, reaching statistical significance but likely not clinically relevant.

Bevevino et al. (2014) conducted a systematic review and meta-analysis to investigate fusion rates of MI-TLIF performed without posterolateral bone grafting. Seven studies with a total of 408 patients were assessed. Average radiographic follow-up was 15.6 months. TLIF was performed using PEEK cages or allograft interbody cages with local autograft bone. In four studies, rhBMP-2 was also used. The overall fusion rate was 94.7% on CT scan, suggesting MI-TLIF without posterolateral bone grafting has similar fusion rates to O-TLIF or MI-TLIF with posterolateral grafting.

In summary, the available literature reports good results for open TLIF in the treatment of degenerative disease of the lumbar spine including spondylolisthesis. Clinically significant improvements in pain and function and a high fusion rate can be expected. In comparison to O-TLIF, MI-TLIF reduces blood loss and hospital stay but does not appear to improve the fusion rate or the clinical outcomes beyond the immediate postoperative period. Restoration of lordosis is possible with O-TLIF but limited with MI-TLIF.

PLIF

In one of the earliest published studies of posterior lumbar interbody fusion, Steffee and Sitkowski (1988) described their experience with PLIF in conjunction with pedicle screws and segmental spine plates. Allograft was used for the PLIF procedure. Thirty-six patients were included in the study with follow-up of 6–12 months. 33/36 had significant improvement in their pain. The fusion rate was reported as 100%.

Degenerative Disc Disease

Barnes et al. (2001) reported their experience with the PLIF procedure for DDD using allograft threaded cortical bone dowels for interbody

fusion. Thirty-five patients with a mean age of 46 years were included in the study. Twenty-three patients underwent a PLIF procedure and 12 patients underwent ALIF. All PLIFs except one were backed up with pedicle screws and rods without posterolateral grafting. ALIFs were performed as a stand-alone procedure. Twenty-eight patients were followed up at a mean of 12.3 months. Satisfactory outcomes were reported in 70% of the PLIF patients. The fusion rate in the PLIF group was 95%. Barnes et al. (2002) also conducted a study comparing the use of allograft cylindrical threaded dowels and allograft impacted wedges for PLIF. There was a 13.6% rate of permanent nerve injury in the threaded dowel group versus 0% in the impacted wedge group. There was no significant difference in fusion rate (95.4% vs. 88.9%). There was a significantly higher rate of satisfactory outcomes in the impacted wedge group.

Chitnavis et al. (2001) reported their experience of PLIF using carbon fiber cages for revision of previous disc surgery. Surgery was performed on patients who had undergone previous discectomy surgery and had ongoing or recurrent low back pain and sciatica with compatible MRI findings. Fifty patients were included in the study; in 40 patients (80%), supplementary pedicle screws were not used. PLIF was performed using paired carbon fiber Brantigan cages packed with autograft bone (iliac crest or spinous process). Symptoms improved in 46 patients (92%) after surgery. Two thirds of patients experienced good to excellent outcomes at early and late follow-up. There was no difference in clinical outcome between those in whom pedicle screws were used or were not used. The fusion rate at 2 years postoperatively was 95%.

Molinari and Gerlinger (2001) reported the functional outcomes of instrumented PLIF in active duty US serviceman and compared these with non-operative management in a non-randomized study. Twenty-nine consecutive patients with single-level lumbar disc degeneration were treated; 15 were treated with instrumented PLIF, and 14 refused surgery and were treated with spinal extensor muscle strengthening, medications, and restricted duty. PLIF was performed using Brantigan or Harms cages, autogenous iliac crest, and pedicle screw-rod fixation. Average follow-up time was 14 months. Only 5/14 soldiers in the non-operative group returned to full unrestricted military duty. In the PLIF group, 12/15 soldiers were able to return to full duty. Outcomes with respect to posttreatment pain, function, and satisfaction were higher in patients treated with instrumented PLIF.

Haid et al. (2004) published their results of PLIF using rhBMP-2 with cylindrical interbody cages in patients with single-level lumbar DDD. The study was a prospective randomized multicenter study comparing iliac crest autograft and rhBMP-2 in paired cylindrical threaded titanium fusion cages (INTER FIX cages). No supplementary pedicle screw fixation was used. Sixty-seven patients were assigned to one of the two groups. There was no significant difference in operative time or blood loss. The fusion rate at 24 months was 92.3% in the rhBMP-2 group and 77.8% in the autograft group. At all postoperative intervals, mean ODI, VAS back and leg pain, and SF-36 PCS improved in both groups compared to preoperative scores.

Hioki et al. (2005) conducted a retrospective review of 19 patients who underwent two-level PLIF for DDD. PLIF was performed using various interbody cage devices and local autograft bone, with supplementary pedicle screw instrumentation. The mean follow-up was 3.6 years. Lumbar lordosis improved from 25.2 °s preoperatively to 36.6 °s at 6 months postoperatively. Segmental lordosis at the fused levels increased from 12.5 °s preoperatively to 18.7 °s at final follow-up. The fusion rate was 100%. Mean JOA score increased from 12.9 preoperatively to 21.3 at final follow-up. There was a positive correlation between increase in lordotic angle and increase in JOA score. Dural tear occurred intraoperatively in two cases. Postoperatively there were one case of displacement of an interbody spacer, two cases of L3 radiculopathy, and one case of pulmonary embolism.

Spondylolisthesis

Wang et al. (2017) conducted a retrospective analysis of the outcomes of autograft alone versus

PEEK + autograft PLIF in the treatment of adult isthmic spondylolisthesis. Eighty-four patients were included in the study: 44 patients had interbody fusion performed with local autograft alone and 40 patients with autograft + 2 PEEK cages. All cases had supplementary pedicle screw instrumentation. The minimum follow-up was 24 months. At last follow-up, there was no difference between the two groups in clinical outcomes (VAS back and leg pain, ODI, and patient satisfaction). The PEEK + autograft group showed better maintenance of disc height, but this did not reach statistical significance. The fusion rate was 90.9% in the autograft alone group and 92.5% in the autograft + PEEK group.

Sears (2005a) published results of PLIF for lytic spondylolisthesis using insert-and-rotate interbody spacers. The study was a prospective observational study of 18 consecutive patients with lytic spondylolisthesis grades I to IV. The mean age of patients was 50.2 years; the majority of patients presented with predominant radicular symptoms. The mean follow-up was 17.3 months. Intervertebral disc space spreaders and pedicle screw instrumentation were used to reduce the spondylolisthesis. PLIF was then performed using carbon fiber, titanium mesh or PEEK fusion cages, and local and iliac crest autograft bone. VAS improved from 5.0 preoperatively to 2.9 postoperatively. Good to excellent results were reported in 83.3% of patients. Mean preoperative slip reduced from 30.2% to 6.2%. Mean focal lordosis improved from 10.6 °s to 18.1 °s. Total lumbar lordosis did not change, but the lordosis over the lumbar segments above the fusion reduced from 46.8 °s to 34.9 °s.

Sears (2005b) also published results of the same PLIF technique for degenerative spondylolisthesis. Thirty-four patients, mean age 65.1 years, were assessed with the majority presenting with predominantly radicular pain. The mean follow-up was 21.2 months. VAS improved from 5.3 pre-op to 2.2 at last follow-up. 31/34 patients rated their outcome as good to excellent. The mean preoperative slip reduced from 20.2% to 1.7%. The mean focal lordosis increased from 13.1 °s to 16.1 °s.

In summary, PLIF is also a well-established technique for interbody fusion, with good clinical results reported for the treatment of DDD and spondylolisthesis. With appropriate surgical technique, appropriate restoration of segmental lordosis is achievable. A high fusion rate is expected with the procedure.

AxiaLIF

Bohinski et al. (2010) reported on the clinical outcomes, complications, and fusion rate of the AxiaLIF procedure at L5–S1 and L4–S1 in 50 patients presenting with low back pain and radiculopathy due to DDD (37 patients) and spondylolisthesis (6 patients) and in 7 patients with ongoing or recurrent symptoms after previous discectomy. Follow-up was out to 1 year. The procedure was performed at L5–S1 in 35 patients and L4–S1 in 15 patients. Supplementary pedicle screw fixation was used in 45 patients. At 1-year follow-up, VAS score improved by 49% (77 to 39) and ODI by 50% (56 to 28). Fusion was assessed by CT scan and was seen in 44 (88%) patients. One case of bowel perforation occurred.

Bradley et al. (2012) conducted a retrospective review of 41 patients who underwent AxiaLIF at L5–S1 for DDD, the majority combined with posterior fusion. Mean follow-up was 22.2 months. VAS back pain improved from 7.1 to 4.2 and VAS leg pain improved from 6.0 to 3.0. ODI improved from 45.5 to 32.6. Fusion was seen in 26/41 (63.4%) patients. There were four (9.7%) reoperations directly related to the AxiaLIF procedure.

Zeilstra et al. (2017) evaluated the mid- and long-term results of AxiaLIF performed for DDD in 164 patients. Additional facet screw fixation was used in 95 patients. Average follow-up was 54 months with longest follow-up out to 10 years. No intraoperative or perioperative complications were reported. VAS back pain improved from 80 to 34, and VAS leg pain improved from 43 to 24. ODI decreased from 46 to 19. The fusion rate was 89.4%. Female sex, work status (still working), lower BMI, and absence of Modic type II changes were correlated with a good result.

Melgar et al. (2014) measured changes in segmental and global lordosis in patients treated with L4–S1 AxiaLIF and posterior instrumentation. A retrospective multicenter review of 58 patients was performed. The majority of patients suffered from DDD. Mean follow-up was 29 months. VAS back pain improved from 7.8 to 3.3. ODI improved from 60 to 34. Fusion was seen in 96% of treated levels. Maintenance of lordosis was identified in 84% of patients at L4–S1 and 81% of patients at L1–S1. Spino-pelvic parameters and sagittal balance were not assessed.

Schroeder et al. (2015) conducted a systemic review investigating the fusion rate and safety profile of L5–S1 AxiaLIF. Fifteen studies were included in the review. The overall pseudarthrosis rate was 6.9% and the rate of all other complications was 12.9%. The reoperation rate was 14.4% and the infection rate was 5.4%. Deformity studies reported a significantly higher rate of complications (46.3%).

In summary, the published literature suggests that AxiaLIF is a relatively safe procedure with good clinical outcomes in the treatment of DDD (predominantly at L5–S1). The fusion rate of AxiaLIF is comparable with other interbody fusion approaches. However it has a limited role in the treatment of spondylolisthesis and deformity, as fusion is performed "in situ" with little in the way of restoration of disc height or lordosis.

Comparative Studies

Humphreys et al. (2001) conducted a prospective study comparing their early experiences with TLIF to the already established PLIF procedure. Forty TLIFs were compared to 34 PLIFs. TLIF was performed using a Harm's titanium mesh cage packed with iliac crest autograft. Of the 40 TLIF procedures, 17 were single-level, 23 were two-level, and 1 was a three-level fusion. For the single-level fusions, no significant difference in blood loss, operative time, and hospital stay was seen between the TLIF and PLIF groups. Significantly less blood loss occurred in the two-level TLIF group compared to the two-level PLIF group. No complications were seen with the TLIF approach, whereas multiple complications were seen in the PLIF group (four cases of radiculitis, one case of broken hardware, one screw loosening, two cases of screw removal, one superficial infection, and one pseudarthrosis).

Lee et al. (2017b) compared the outcomes of ALIF, PLIF, and TLIF at L5–S1 for the treatment of lumbar degenerative spinal disease in 77 patients. Thirty-four patients were diagnosed with isthmic spondylolisthesis at L5–S1 and the rest with degenerative lumbar spinal stenosis at L5–S1. Specific indications for surgery differed between groups. ALIF was associated with better restoration of segmental lordosis. The fusion rate based on X-ray and CT scan did not differ between the three groups. TLIF was associated with a better postoperative VAS back pain score. PLIF showed the lowest cage subsidence rate.

Lee et al. (2017a) investigated which approach (ALIF, LLIF, or PLIF) is advantageous in preventing development of adjacent segment disease after fusion for L4–L5 spondylolisthesis. Eighty-two patients were included in the study. The mean follow-up was 25 months. ASD was seen in 37% of the ALIF group, 41.7% of the LLIF group, and 64.5% of the PLIF group. The ALIF and LLIF group had significantly increased disc height and foraminal height compared to the PLIF group. The ALIF group had significantly improved lordosis compared to the PLIF and LLIF groups. There was no difference in clinical outcomes (VAS and ODI). This suggests that sagittal profile and avoidance of damage to the posterior spinal structures may help prevent adjacent segment disease.

Phan et al. (2015c) conducted a systematic review and meta-analysis of ALIF versus TLIF. Twelve articles were included in the meta-analysis with a total of 609 ALIF and 631 TLIF patients. Fusion rates and clinical outcomes were comparable between ALIF and TLIF. ALIF was associated with better restoration of disc height, segmental lordosis, and total lumbar lordosis. ALIF was associated with longer hospitalization and, as expected, a lower rate of dural injury and a higher rate of vascular injury.

Dorward et al. (2013) conducted a matched cohort analysis of ALIF versus TLIF in long deformity constructs. There were 42 patients in each group. The average age was 54 years and the number of instrumented vertebrae averaged 13.6 levels. TLIF was associated with less operative time but greater blood loss. Overall complications and neurological complications did not differ. The ALIF group had greater improvement in SRS scores. ODI scores improved similarly in both groups. Segmental lordosis at L4–L5 and L5–S1 as well as regional lordosis (L3–S1) was greater in the ALIF group. TLIF allowed greater correction of coronal plane deformity.

Jiang et al. (2012) conducted a systematic review comparing ALIF and TLIF in the treatment of lumbar spondylosis. Nine studies were included in the review, all retrospective comparative studies. Blood loss and operative time were greater in the ALIF cohort. There was no significant difference in complication rates between ALIF and TLIF. The restoration of disc height, segmental lordosis, and total lumbar lordosis in ALIF was superior to TLIF. Clinical outcomes and fusion rate were not significantly different, but radiological alignment and adjacent segment disease were not outcomes uniformly assessed.

Similarly, Hsieh et al. (2007) compared ALIF and TLIF in regard to restoration of foraminal height, disc angle, lumbar lordosis, and sagittal balance. A retrospective radiographic and clinical analysis was completed, with 32 patients in the ALIF group and 25 patients in the TLIF group. There was no difference in improvement in VAS scores. ALIF was superior to TLIF in its capacity to restore foraminal height, local disc angle, and lumbar lordosis. ALIF increased foraminal height by 18.5%, whereas TLIF decreased it by 0.4%. ALIF increased the local disc angle by 8.3 °s and lumbar lordosis by 6.2 °s, whereas TLIF decreased local disc angle by 0.1 °s and lumbar lordosis by 2.1 °s. They concluded that ALIF may lead to better long-term outcomes compared to TLIF due to better restoration of sagittal balance.

Hoff et al. (2016) conducted a prospective randomized trial comparing the lumbar hybrid procedure (stand-alone ALIF L5–S1 and total disc replacement L4–L5) with two-level TLIF for the treatment of two-level DDD. Sixty-two patients were enrolled, 31 in each arm. TLIF was performed using a PEEK cage, local autograft bone, and pedicle screws. ALIF was performed using a stand-alone PEEK cage with integrated screws. The TDR used was the Maverick™. The mean follow-up was 37 months. Hybrid patients had significantly lower VAS scores immediately postoperatively and at final follow-up compared to fusion patients. There was also a trend for lower ODI scores in the hybrid group although this did not reach statistical significance. Complication rates were low and similar between groups. Lumbar lordosis increased at the operative levels in the hybrid group but not in the TLIF group with a compensatory increase in lordosis at the supradjacent levels. ROM at L3–L4 was significantly higher in fusion patients compared to hybrid patients at final follow-up.

Joseph et al. (2015) conducted a systematic review comparing and contrasting the complication rates of MI-TLIF and LLIF. Fifty-four studies were included for analysis of MI-TLIF, and 42 studies were included for analysis of LLIF. In total 9714 (5454 MI-TLIF and 4260 LLIF) patients were assessed with 13,230 levels fused (6040 MI-TLIF and 7190 LLIF). The total complication rate per patient was 19.2% in the MI-TLIF group and 31.4% in the LLIF group. The rate of sensory deficits, temporary neurological deficits, and permanent neurological deficits in the MI-TLIF group was 20.16%, 2.22%, and 1.01%, respectively. In the LLIF group, the rates were 27.08%, 9.4%, and 2.46%, respectively. Rates of intraoperative and wound complications were 3.57% and 1.63% in the MI-TLIF group compared to 1.93% and 0.8% for the LLIF group, respectively. No significant differences were noted for medical complications or reoperations.

In summary, comparing posterior interbody fusion procedures, TLIF is associated with a lower complication rate than PLIF. ALIF achieves better restoration of disc height and lordosis than TLIF and LLIF (without ALL release). Anterior interbody fusion procedures (ALIF and LLIF) are associated with a lower rate of adjacent segment disease than posterior interbody fusion

procedures (PLIF and TLIF). The short-term to midterm clinical outcomes and overall complication rates are similar between anterior and posterior interbody fusion approaches.

Lumbar Interbody Fusion: When to Use What?

When deciding which interbody fusion approach and device to use in each individual patient, the specific goals of lumbar interbody fusion must be kept in mind. These are:

1. Decompression of neural elements, if required
2. Appropriate maintenance or restoration of segmental disc height and lordosis
3. Placement of an interbody fusion device that is able to stabilize the motion segment in the correct position while fusion occurs
4. The use of bone graft and/or other biologic agents to enhance and achieve fusion
5. Avoidance of complications and "collateral damage" from the approach

Decompression of the neural elements can often be achieved indirectly. Restoration of posterior disc height increases foraminal volume allowing decompression of the exiting nerve roots. Restoration of posterior disc height also achieves a ° of central and lateral recess decompression by uncoupling the facet joints and reversing buckling of the ligamentum flavum and posterior disc bulging. In cases of severe lateral recess and central stenosis due to facet arthropathy and ligamentum flavum hypertrophy or a disc protrusion/extrusion, a direct decompressive procedure may still be required. Direct decompression occurs as part of the procedure during PLIF and TLIF procedures. It is also possible to remove disc protrusions/extrusions during an ALIF or LLIF procedure by utilizing rents in the posterior longitudinal ligament to remove the disc fragments. ALIF and LLIF procedures can be combined with a laminectomy if direct decompression is required in addition to the indirect decompression achieved with the procedure.

Increasingly, the importance of maintaining or restoring disc height and lordosis at the time of interbody fusion is being recognized. Fusion of the lumbar spine in appropriate segmental lordosis and sagittal balance leads to a reduced rate of adjacent segment degeneration and disease and therefore a lower incidence of reoperation and superior long-term clinical outcomes (Rothenfluh et al. 2015). With the advent of modern spinal instrumentation and biologics such as rhBMP-2, achieving fusion is no longer a significant issue. Fusion rates for all the approaches to lumbar interbody fusion are high, and as a result the short-term clinical outcomes are fairly similar between the approaches. A high fusion rate and good short-term clinical outcomes should not necessarily be considered a "success" in modern spine surgery, if appropriate segmental lordosis and sagittal balance are not achieved.

As discussed earlier in this chapter, modern interbody device constructs (combined with supplementary pedicle screw-rod fixation when appropriate) are able to achieve a biomechanically stable environment for fusion to occur. In general, a device with a larger footprint is preferred as it provides a larger surface area for fusion to occur and avoids "point loading" and "fish mouthing" through the vertebral end plates, thus reducing the risk of end plate failure and device subsidence. This is of particular importance in osteoporotic bone. The appropriate interbody fusion device combined with bone graft and/or a biologic agent such as rhBMP-2 can be expected to give a high fusion rate, of $>90\%$ in most recent published studies.

Avoiding complications and reducing approach-related "collateral damage" rely on appropriate preoperative planning and meticulous surgical technique. Anticipation of approach-related complications preoperatively is vital as it allows modification of the approach or the selection of a different approach for interbody fusion. For example, significant obesity or aortoiliac vascular calcification may preclude performing ALIF. A "flying" or "Mickey Mouse" psoas pattern or large iliolumbar vein at L4–L5 may prevent LLIF at that level. Multiple previous posterior decompressive procedures with epidural

scarring may prevent PLIF or TLIF being performed safely. Intraoperatively, each approach for lumbar interbody fusion is associated with its own unique set of approach-related complications which have been discussed earlier in this chapter. Meticulous technique at the time of surgery is required to minimize "collateral damage."

With the above goals of lumbar interbody fusion kept in mind, a number of important factors must be considered preoperatively when planning an interbody fusion.

1. **Are there any absolute or relative contraindications to interbody fusion via a particular approach?**

   An appropriate history, physical examination, and review of imaging studies will determine which approaches are feasible in each individual patient. Contraindications to the various approaches for lumbar interbody fusion have been discussed earlier in the chapter.

2. **What are the patient's lumbopelvic parameters? Is there loss of lumbar lordosis segmentally and globally? Is there sagittal imbalance?**

   In the authors' opinion, every patient who is being worked up for a lumbar interbody fusion should have a preoperative standing full spine X-ray including the pelvis and hips or an EOS scan to assess pelvic parameters (pelvic incidence, sacral slope, pelvic tilt), lumbar lordosis (including where in the lumbar spine it is occurring), and sagittal balance. This is not only appropriate for cases of spondylolisthesis or adult spinal deformity but also in all cases of degenerative disc disease where subtle loss of lumbar lordosis and sagittal balance can occur. When assessing preoperative lumbar lordosis, it is important to assess the relative contribution of each segment to total lumbar lordosis.

   Two thirds of lumbar lordosis occurs between L4 and S1, and it is these levels that are most commonly affected by DDD and spondylolisthesis. A lack of lordosis through the lower lumbar segments can be compensated for by increased lordosis through the upper lumbar segments. Therefore although total lumbar lordosis and sagittal balance may be normal in a patient about to undergo an interbody fusion, it should not be assumed that no increase in lordosis is required as part of the interbody fusion procedure. It is well accepted that fusion of a segment of the lumbar spine in kyphosis increases stresses on the adjacent levels and leads to an accelerated rate of adjacent segment degeneration and disease, even if total lumbar lordosis is normal.

   In general, three patterns are seen when assessing these preoperative images.

(A) Total lumbar lordosis, segmental lordosis, and sagittal balance are all normal.

   This pattern is usually seen in patients with internal disc disruption or early-stage DDD where disc height and lordosis at the involved segment(s) are still relatively well preserved. Interbody fusion must maintain the lordosis of the operative segment(s) to minimize the rate of adjacent segment disease and thus improve long-term outcomes.

(B) Total lumbar lordosis and sagittal balance are normal, but there is loss of segmental lordosis at the operative level(s).

   This pattern is usually seen in the more advanced stages of DDD where loss of disc height and lordosis occurs. It is also commonly seen in low-grade spondylolisthesis. A compensatory increase in lordosis of the unaffected levels normalizes total lumbar lordosis. In these patients the lack of segmental lordosis should be corrected at the time of interbody fusion to minimize the rate of later adjacent segment disease. While the patent may have a good short-term clinical outcome from successful fusion of a segment in kyphosis, the long-term clinical outcome is dubious.

(C) There is loss of both segmental and total lumbar lordosis. Sagittal balance may be maintained by compensatory pelvic retroversion or knee flexion, or there may be loss of sagittal balance.

This pattern is seen in the advanced stages of DDD, spondylolisthesis, and adult spinal deformity. Surgery should plan to correct segmental and global lumbar lordosis and restore sagittal balance. Failure to restore lumbar lordosis and sagittal balance is associated with poor clinical outcomes in both the short and long term.

3. **Does the patient have osteoporosis?**

As osteoporosis affects cancellous bone more than cortical bone, the vertebral bodies are more affected by this disease than the posterior elements. Therefore the presence of osteoporosis is important to consider when planning interbody fusion. Assessment of osteoporosis in the spine can be difficult. DEXA scans through the lumbar spine are performed in cross section and therefore give an "average" of the often osteoporotic vertebral body cancellous bone and the more sclerotic bone of the posterior elements which can give false "normal" readings. The bone density of the femoral neck is a more accurate predictor of vertebral body bone density. Other factors predictive of spinal osteoporosis include a history of osteoporotic fracture elsewhere in the body (femoral neck or distal radius), a family history of osteoporosis and vitamin D deficiency, and a prolonged period of relative inactivity due to the spinal condition or other conditions. Postmenopausal women should be assumed to have spinal osteoporosis until proven otherwise.

Especially in the setting of adult spinal deformity/sagittal imbalance, confirmation of osteoporosis should prompt referral to an endocrinologist for assessment and treatment preoperatively to optimize bone quality which often takes months.

At the time of surgery, patients with osteoporosis are at increased risk of vertebral body end plate failure and subsidence of the interbody device. This can occur either intraoperatively or postoperatively as the patient begins to mobilize and weight bear through the spine. The consequences of subsidence include pseudarthrosis, recurrent foraminal nerve compression, and loss of correction of segmental lordosis. The combination of significant osteoporosis and a very collapsed disc space is especially problematic at the time of surgery as an attempt to increase disc height and place interbody fusion devices without appropriate release of the anterior and posterior longitudinal ligaments will likely result in acute end plate failure.

Strategies to combat osteoporosis at the time of interbody fusion include appropriate (usually circumferential) release of the disc space as noted above and placement of an interbody fusion device with a large surface area that sits on the harder bone of the peripheral end plate ring apophyses. In this regard, ALIF and LLIF are favored over PLIF and TLIF constructs. A device with a relatively low modulus of elasticity (see Fig. 3) is also less likely to subside; therefore PEEK cages are theoretically more appropriate than titanium cages in the setting of osteoporosis. Supplementary pedicle screw-rod fixation is advisable in the setting of osteoporosis. If osteoporosis is severe, cement augmentation of the pedicle screws or vertebroplasty (either delivered directly from an anterior approach into the body or transpedicular) can be used.

4. **Can neural decompression be achieved indirectly or is direct decompression required?**

As discussed above, neural decompression can often be achieved indirectly via anterior interbody fusion approaches (ALIF/OLIF/LLIF). If a direct decompression is required, a posterior interbody fusion approach may be preferred (TLIF/PLIF); however if segmental lordosis needs to be restored also, an anterior approach with supplementary laminectomy will likely achieve this more effectively.

5. **Will supplementary fixation be required?**

Supplementary fixation is often required in biomechanically challenging environments such as in patients with osteoporotic bone, multilevel fusions, large corrections of sagittal imbalance, and spondylolisthesis. In general, due to the smaller footprint of the interbody device used, PLIF and TLIF are supplemented with pedicle screw fixation. Depending on the

patient's bone quality and the condition being treated, anterior interbody fusions (ALIF, OLIF, LLIF) may also require supplementary fixation.

Approach by Indication and Level(s) Requiring Interbody Fusion

The decision about which approach to use for interbody fusion is multifactorial and depends on the patient and the condition being treated, the relative advantages and disadvantages of each approach, and the training and experience of the treating surgeon. However based on the biomechanical and clinical literature available, some general recommendations can be made.

Degenerative Disc Disease

ALIF is the preferred approach for management of DDD. The approach avoids iatrogenic injury to the paraspinal muscles and psoas muscles and retraction of the neural elements. With ALIF the pain generator can be almost entirely removed, and the approach allows appropriate restoration of disc height and lordosis with a high fusion rate achieved. DDD typically affects L5–S1 and L4–L5. LLIF cannot be performed at L5–S1 and has a higher complication rate at L4–L5. TLIF and PLIF are options for treatment of DDD with good results published in the literature; however some ° of iatrogenic injury to the paraspinal muscles is expected, and it may be hard to restore disc height and lordosis appropriately. Both these factors likely lead to a higher rate of adjacent segment disease.

Isthmic Spondylolisthesis

Both ALIF and TLIF/PLIF are reasonable treatment options for isthmic spondylolisthesis. Again, this condition is usually seen in the caudal two lumbar levels, limiting the use of LLIF in this condition. ALIF achieves better restoration of disc height and lordosis than TLIF/PLIF.

Supplementary percutaneous pedicle screws of posterior spinal fusion are often required. Care must be taken when performing ALIF for a high-grade L5–S1 spondylolisthesis as L5 nerve injury can occur. Posterior decompression and a pedicle screw-based reduction can be performed prior to ALIF in this setting.

Degenerative Spondylolisthesis

Degenerative spondylolisthesis is often accompanied by some ° of lateral recess stenosis due to facet joint and ligamentum flavum hypertrophy; therefore a posterior approach (TLIF/PLIF) is attractive as it allows both direct and indirect neural decompression and fusion through the one approach. However anterior approaches (ALIF/LLIF) are able to better achieve restoration of disc height and lordosis and as a result achieve significant indirect neural decompression. Each patient should be assessed individually regarding the benefits and risks of an anterior versus posterior approach. If both significant correction of disc height/lordosis and direct neural decompression are required, then ALIF/LLIF can be combined with laminectomy.

Adult Spinal Deformity

ALIF, LLIF/ACR, and TLIF/PLIF are all reasonable options for interbody fusion in the setting of adult spinal deformity, and different approaches can be combined in the same operation if required. ASD is almost always characterized by some ° of sagittal imbalance, and ALIF/ACR are favored over LLIF without ALL release or TLIF/PLIF for correction of sagittal balance. Effective anterior interbody fusion may avoid the need for posterior three-column osteotomy to restore sagittal balance, a procedure associated with a high complication rate, often in elderly comorbid patients. Surgical treatment of ASD generally involves interbody and posterolateral fusion, often up into the thoracic spine. TLIF/PLIF avoids the need for a staged anterior-posterior procedure and allows direct decompression of any associated nerve compression. Each patient should be assessed individually regarding the relative merits of each approach.

Adjacent Segment Disease

There is a paucity of literature to define the best approach for treatment of adjacent segment

disease after lumbar fusion. Intuitively, choosing a different interbody approach for the treatment of adjacent segment disease will avoid scarring from the initial surgery and lower the rate of approach-related complications. For example, after a previous L5–S1 ALIF, adjacent segment disease at L4–L5 may be approached using LLIF or TLIF to avoid mobilization of the great vessels in an area of scarring. Conversely, after a previous L5–S1 TLIF, L4–L5 ALIF is a good choice as operating in an area of potential epidural scarring is avoided. Sagittal balance and segment lordosis should be assessed carefully preoperatively, as, if the original fusion was performed in kyphosis, more lordosis will be required when treating the adjacent level.

Pseudarthrosis

Pseudarthrosis after PSF or PLIF/TLIF is best managed with an ALIF as this avoids reinjury to the paraspinal muscles and operating through epidural scarring. Interbody cages previously placed posteriorly can be removed during the ALIF procedure. Previously placed pedicle screws may have to be removed prior to the ALIF if further restoration of disc height/lordosis is required. Pseudarthrosis after a previous ALIF or LLIF procedure is best managed with an open PSF. Re-exposure anteriorly in an attempt to remove the interbody device carries a high risk of vascular, bowel or ureteric injury.

L5–S1

ALIF is the preferred method of interbody fusion for DDD at L5–S1. It allows excellent release of the disc space, restoration of disc height and lordosis, and placement of a large footprint interbody device for fusion (Lee et al. 2016). Male patients who still plan to have children should be warned of the small risk of retrograde ejaculation, and sperm banking can be performed preoperatively or an alternate approach used if deemed an unacceptable risk by the patient. OLIF is also a reasonable option at this level. LLIF is not possible at L5–S1. Open PLIF and TLIF can be considered especially in the setting of associated lateral recess stenosis or recurrent disc herniation; however iatrogenic injury to the paraspinal muscles is of concern, and restoration of segmental lordosis may be limited. MI-TLIF has no ability to effectively restore segmental lordosis and may not even maintain preoperative lordosis and, therefore, is not a good option at L5–S1 where at least maintaining segmental lordosis is critical for overall lumbar lordosis. AxiaLIF similarly has limited to no ability to restore segmental lordosis.

ALIF can also be used effectively in the treatment of degenerative and low-grade lytic spondylolisthesis, usually combined with supplementary pedicle screw fixation. It can also be used in high-grade lytic spondylolisthesis although a posterior decompression may be required first to avoid L5 nerve injury as the slip is reduced. In these cases, open PLIF/TLIF also is a reasonable treatment option as direct decompression, reduction, and stabilization can all be performed through the one approach. Placement of the interbody cages anteriorly within the disc space, and compression across a posterior pedicle screw-rod construct can help achieve segmental lordosis.

L4–L5

ALIF or OLIF are excellent treatment options for DDD, as disc height and lordosis can be restored effectively and iatrogenic injury to the paraspinal muscles is avoided. The favorability of the vascular anatomy around the bifurcation will dictate which of these two approaches is preferable. LLIF is also a reasonable treatment option for DDD; however a higher rate of lumbar plexus injury is seen with LLIF at L4–L5 compared to higher lumbar levels. PLIF/TLIF can also be considered at L4–L5; however if significant restoration of segmental lordosis is required, ALIF, OLIF, and LLIF with or without ALL release are preferred.

Both anterior interbody approaches (ALIF, OLIF, and LLIF) and posterior interbody approaches (TLIF/LLIF) can also be used effectively to treat L4–L5 spondylolisthesis. If associated spinal stenosis requires direct decompression, then PLIF/TLIF may be preferred. If lordosis restoration is required, then anterior approaches are preferred.

L3–L4 and L2–L3

Exposure for ALIF becomes difficult above L4–L5, and in general, requirement for restoration of segmental lordosis is not as great in the higher lumbar levels. OLIF or LLIF and TLIF/PLIF are therefore good options for DDD and spondylolisthesis of the higher lumbar levels.

L1–L2 and T12–L1

ALIF is not feasible and TLIF/PLIF risk retraction injury to the conus, while OLIF/ATP risks injury to renal vessels and higher retroperitoneal structures. LLIF is, therefore, a good option at these levels.

Multilevel/Deformity Correction

A combination of anterior/lateral and posterior techniques can be used depending on the specific goals of the surgery. Anterior/lateral approaches are preferred if significant correction of sagittal alignment is required, but usually supplementary posterior instrumentation is required necessitating a staged procedure (either same day or delayed).

Conclusion

Interbody fusion is a well-established technique in the treatment of various lumbar pathologies including degenerative disc disease, spondylolisthesis, adult spinal deformity, adjacent segment disease, and pseudarthrosis. Multiple approaches to lumbar interbody fusion exist including ALIF, OLIF, LLIF, TLIF, PLIF, and AxiaLIF with biomechanical and clinical data supporting their use in various contexts. In deciding which approach for interbody fusion is most appropriate in each individual patient, the surgeon must take into account their own skill and experience, the pathology being treated, sagittal balance parameters, bone quality, associated neural compression, and any specific contraindications that may preclude a particular approach. With comprehensive preoperative assessment, appropriate surgical decision-making, and strict surgical technique, lumbar interbody fusion can be expected to yield good to excellent clinical outcomes in both the short-term and long-term with a low complication rate and a high rate of fusion.

Stand-Alone Interbody Devices: Static Versus Dynamic

55

Abstract

Disc degeneration in the lumbar spine accounts for the vast majority of non-acute spine pathology. Progressive loss of disc height leads to a cascade of biomechanical and morphological changes locally in the functional spinal unit (FSU), which in turn may affect the adjacent segments. Loss of disc height may lead to neural compression, facet joint arthropathy, and progressive instability. Multilevel disc degeneration may affect the global spinal biomechanics and alignment resulting in degenerative kyphoscoliosis.

Treatment of degenerative disc disease (DDD) aims to remove the pain generator (degenerative disc), restore disc height and lordosis, and decompress the neural elements (directly or indirectly). The treatment should take into account the alignment (lordosis) of the FSU and also the global alignment of the spine.

Restoring the disc height is achieved by inserting an interbody device to restore the disc height and lordosis. The interbody device could be static which aims at fusing the spinal segment and stopping the painful movement of the disc and the facets, or dynamic, which maintains full or partial controlled movement of the spinal segment as close as possible to the physiological movement (close to the axis of rotation of the disc). The aim of this chapter is to explore the methods of restoring the disc height with either static or dynamic devices and also by combining the two methods depending on the stage of disc degeneration.

The ideal treatment of DDD is to match the pathology with the technology, taking

Introduction

Degeneration of the lumbar intervertebral disc is multifactorial and includes genetic and environmental factors. Disc degeneration is associated with changes in the concentration and fragmentation of the matrix molecules (Singh et al. 2009). Also loss of water content within the nucleus leads to progressive changes in the viscoelastic behavior of the disc (Panagiotacopulos et al. 1987a, b). Similarly, changes in the ratio of collagen contents affect the biomechanical properties of the disc (Melrose and Ghosh 1988; Roberts et al. 1989). Loss of the structural properties of the disc leads to a change in the center of rotation of the disc and instantaneous centers of rotations change from a tightly clustered zone to a long random shape (Gertzbein et al. 1985). Progressive loss of disc height and lordosis leads to a cascade of changes of segmental and global spine biomechanics and alignment. The cascade starts with an internal disc disruption (IDD) and may progress to degenerative kyphoscoliosis affecting the global coronal and sagittal balance.

IDD is the first stage of disc degeneration, and patients usually present with discogenic back pain with a "normal" magnetic resonance imaging (MRI) scan. IDD is diagnosed by performing a provocative discogram, followed by a computed tomography (CT) discogram to confirm the diagnosis. Progression of disc degeneration leads to progressive loss of lumbar disc height resulting in neuroforaminal stenosis in addition to central canal stenosis. At this stage, patients usually present with back and/or leg pain. An MRI scan confirms the degeneration and neural compression. Further disc degeneration results in facet joint arthropathy and further neural compression. Fritzell et al. (2001) showed that surgical treatment for DDD is superior to nonsurgical treatment. The surgical group had a 33% reduction in back pain score and a 25% decrease in disability, measured using the Oswestry Disability Index (ODI), whereas the nonsurgical group had 7% and 6% reductions, respectively.

The art of treating DDD involves obtaining a precision diagnosis, then removal of the pain generator (degenerative disc and the sinuvertebral nerve), and restoration of the disc height, by replacing the disc with a device which either prohibits movement (fusion or static) or maintains it (dynamic or total disc replacement, TDR). Restoring the disc height indirectly decompresses the neuroforamen and the spinal canal. Complete removal of the disc is best achieved by an anterior approach to the lumbar or cervical spine as this allows complete removal of the nucleus pulposus and the cartilaginous end plate. The anterior approach to the spine allows a stand-alone device to be used to replace the disc without the necessary requirement of supplementation with posterior pedicle screws, which would be required if removal of the disc was performed using posterior (or transforaminal) lumbar interbody fusion, for example.

The indications and contraindications for TDR and fusion are discussed in this chapter, as well as the advantages and disadvantages.

Anterior Lumbar Interbody Fusion

Stand-alone anterior lumbar interbody fusion (ALIF) has been performed for many decades in the treatment of DDD with good outcomes (Greenough et al. 1994). It is performed through an anterior approach to the lumbar spine at L2-S1 levels. Anterior approach to the lumbar spine is most commonly performed through a retroperitoneal approach (left or right) to the lumbar spine or transperitoneal approach. Using an appropriate retractor that the surgeon is familiar with is crucial. An example of an anterior retractor is shown in Fig. 1.

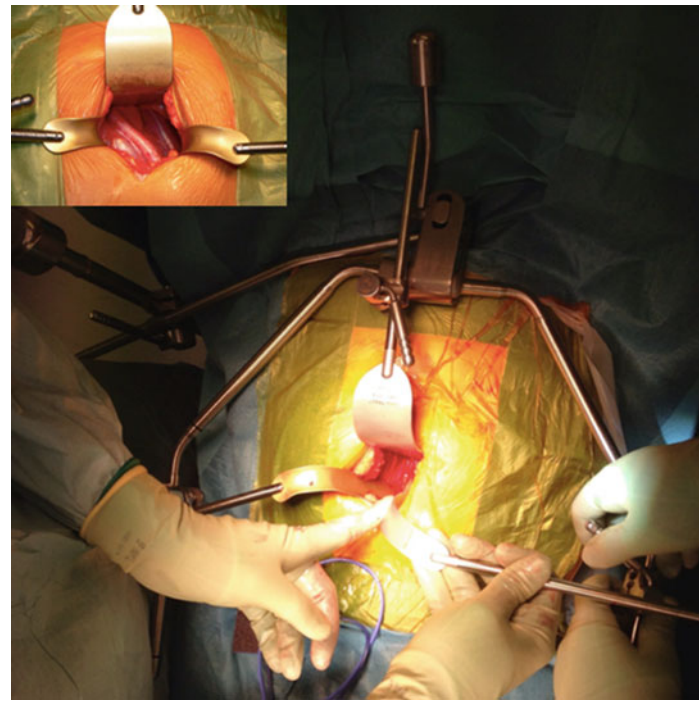

Fig. 1 The Integra Omni-Tract® retractor used during an anterior approach to the lumbar spine

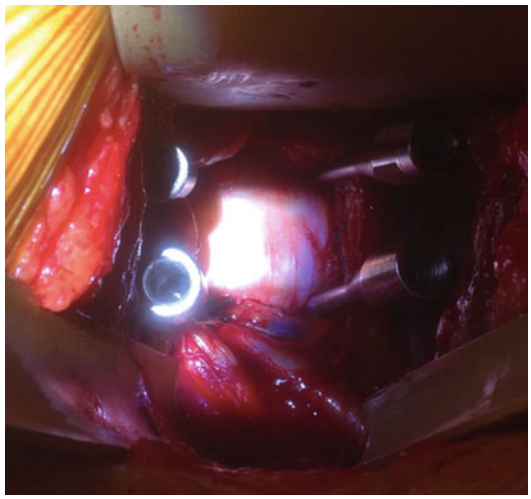

Fig. 2 Modified Steinman pins (OZ pins) are used to hold the vessels while performing the ALIF

Additional retractors are useful during ALIF procedures. In our units (Wansbeck General Hospital and Nuffield Hospital, Newcastle-upon-Tyne, UK), we have adopted the same technique used by Associate Professor Matthew Scott-Young in the Gold Coast Spine practice in Queensland, Australia. Steinman pin retractors are used to hold the vessels after mobilization while performing the ALIF (Fig. 2). Maintaining the anterior annulus and using it as a retractor allows a safe corridor to the disc space and is useful in protecting the surrounding soft tissues and the vessels. This is achieved by performing an H-shaped incision in the annulus and using a stay suture for each arm of the H-shape. This also allows closure of the annulus by suturing the two stay sutures together (Fig. 3).

Anterior approach allows a radical discectomy, removal of the cartilaginous end plate, and the insertion of the interbody cage which contains a bone graft. This allows restoration of the disc height and also restoration of the sagittal and coronal balance (Siepe et al. 2015). Fusion is performed by inserting a cage with or without a bone graft. Cages of various footprint sizes, height, and lordotic angles are available to permit restoration of the appropriate disc height and alignment. Sound interbody fusion is obtained by achieving stability, viability, and proximity of the bone graft to both end plates. This is achieved through meticulous surgical preparation of the end plates, internal fixation, and a good quality

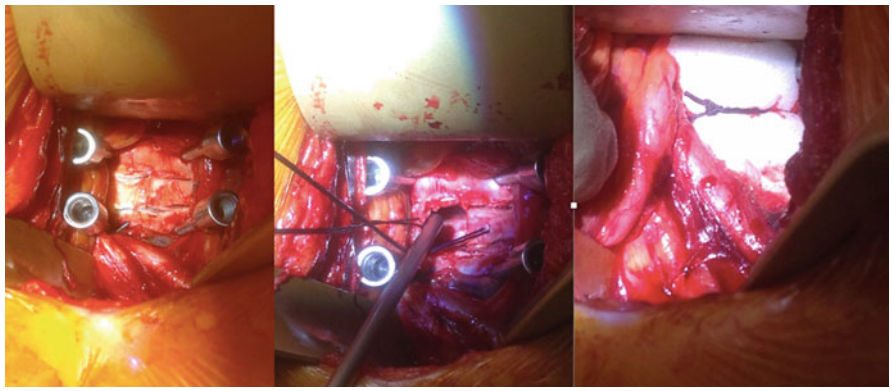

Fig. 3 H-shaped incision in the annulus and suturing the stay sutures to close the annulus on a Spongostan™ as a barrier between the plate and vessels at the end of the procedure

Fig. 4 Comparison between anterior cages (black) of different sizes (small, medium, and large) and a large cage inserted through a posterior approach (white)

bone graft. Inserting the interbody device through an anterior approach places the graft under compression with a large surface area for bony union and with a uniform load transfer. The footprint of an anterior cage is much larger than that of a cage inserted through a posterior approach and allows cross-sectional support on the peripheral ring apophysis (Fig. 4).

Bone graft choice is vital in achieving fusion. The choices for bone graft include autograft, allograft, and synthetic bone graft (Lechner et al. 2017). Combining bone grafts is also an option to improve the fusion rate. Bone morphogenetic protein (BMP-2) has become more popular in recent years (Burkus et al. 2002). Combining allograft (cancellous bone obtained from a femoral head) with BMP-2 INFUSE® is a technique used in Gold Coast Spine, which allows containment of an osteo-inductive bone graft (BMP-2) inside an osteo-conductive allograft-cage construct by drilling holes inside the allograft to host the BMP-2 (Fig. 5). We modified the technique in our unit by inserting a core of autograft (obtained through a vertebral biopsy 10 gauge needle from the iliac crest) inside the allograft. This was used due to the shortage of BMP-2 in Europe in 2016 (Fig. 6).

In our unit, we retrospectively reviewed and compared 50 consecutive patients who underwent ALIF using the bone graft technique described in Fig. 5 with 50 consecutive patient using the technique in Fig. 6. All patients had a CT scan at 5–6 months postoperatively, and the CT scans were reviewed by an independent consultant radiologist. The fusion rate in both groups was identical at 98%.

Fixation of a stand-alone cage is performed either through screws integrated into the cage or through the application of a plate with screws in both vertebral bodies. The aim of the fixation is to stabilize the cage especially in extension which might cause anterior kickout of the cage. Also, fixation limits rotation and flexion. When axial loading is applied through the cage/plate construct, the construct resists axial loading by virtue of its intrinsic cantilever beam with fixed moment arm characteristics.

Gerber et al. (2006) showed that a stand-alone anterior interbody device supplemented by anterior fixation using a plate carries similar stability to a stand-alone cage supplemented by posterior

Fig. 5 Combining BMP-2 and femoral head allograft

Fig. 6 Combining autograft with allograft

screw fixation. Both were more stable in all ranges of movement compared to a stand-alone cage with no fixation (Fig. 7).

Treating loss of disc height using the ALIF procedure obtains indirect decompression by increasing the neuroforaminal height and indirectly decompressing the neural elements (Fig. 8). This was proven by an MRI study by Choi et al. (2014).

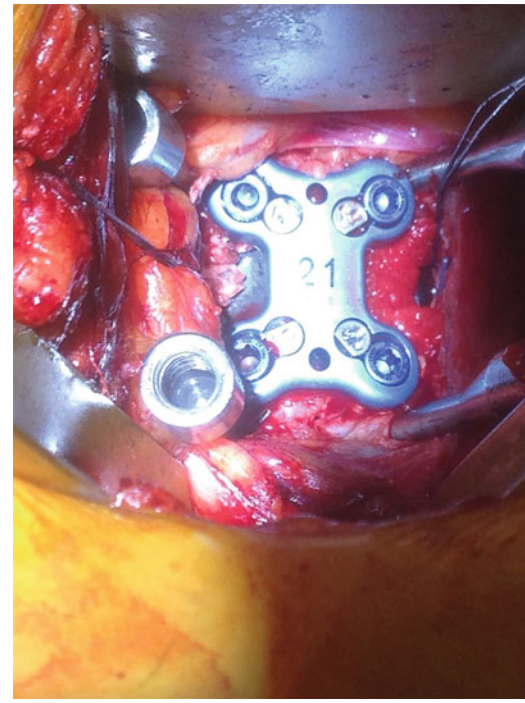

Fig. 7 AEGIS® (DePuy Synthes, Raynham, MA, USA) Anterior Lumbar Plate System. Example of anterior fixation using a plate and four screws with a cam locking mechanism

The indications for ALIF include symptomatic disc pathology which varies from IDD (Blumenthal et al. 1988), DDD, spondylolisthesis, failed prior posterior spine surgery (recurrence/residual disc prolapse (Choi et al. 2005; Vishteh and Dickman 2001) and non-union of posterior fusion (Lee et al. 2006)), and spine deformity. In the absence of spinal instability and deformity, disc degeneration could be treated with stand-alone ALIF. We recommend obtaining a standing lateral and flexion/extension radiograph of the lumbar spine to rule out instability before considering an ALIF procedure (Fig. 9).

Specific complications following an ALIF procedure could be approach-related complications (vascular injury (Fantini et al. 2007; Rajaraman et al. 1999), bowel and ureteric injury, and retrograde ejaculation) or long-term complications such as non-union, metalware complications, and adjacent segment degeneration. Venous thromboembolic (VTE) events are a recognized

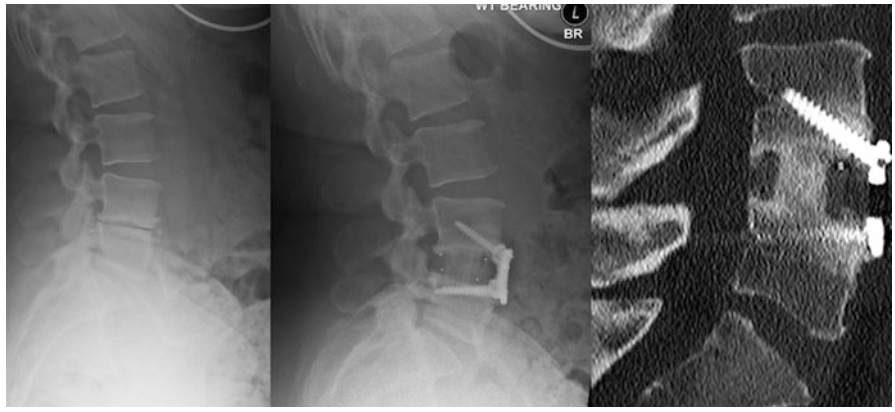

Fig. 8 An example of indirect neuroforaminal decompression obtained by restoring the disc height and a CT scan showing solid fusion at 4 months

Fig. 9 An example of treating failed posterior surgery using ALIF. A 45-year-old patient who had two-level discectomy at L4/5 and L5/S1 with the insertion of an interspinous spacer. Patient had a two-level ALIF to remove the recurrent disc at L4/5, indirectly decompressing the foramen of L5/S1 and restoring the lordosis

complication after abdominal surgery, and ALIF is no exception since it is done through a mini-laparotomy approach with vessel mobilization. Our unit has adopted a thromboprophylactic regime utilizing physical and chemical prophylactic techniques. This entails TED stockings and compressive calf pumps during surgery and the 24 hours following. The calf pumps are then removed and the TED stockings maintained on the patient for 3 weeks until outpatient review. Postoperatively we use low molecular weight heparin (tinzaparin) 4500 units subcutaneously on the evening before surgery and then daily for 3 to 5 days (while an inpatient) and then Aspirin orally 150 mg daily for 4 weeks after surgery with proton pump inhibitor (PPI) cover. Our unit conducted a study on 160 consecutive patients who underwent ALIF by reviewing their records and also by contacting the patients. There were no symptomatic VTE events in any of the 160 patients. There was no incidence of wound hematomas or bleeding and no symptomatic retroperitoneal hematomas requiring intervention.

Graft migration is often related to the surgical technique and is a difficult management problem in that it involves revision anterior surgery. This is challenging in inexperienced hands and associated with high complication rates. Ideally a CT angiogram and insertion of a ureteric stent should be performed before revision of an anterior approach. Non-union due to patient factors, poor bone quality, or lack of meticulous surgical

preparation is also challenging and could be treated through a revision anterior approach or through a posterior approach.

Failure of an ALIF procedure is often due to failure of indication and/or failure of technique. Volume performance threshold and fellowship training is of great importance in performing anterior approach to the lumbar spine in order to reduce the complication rate and improve patient outcomes (Regan et al. 2006).

The aim of ALIF in addition to restoring the disc height is to fuse the spinal segment and eliminate any movement between the two vertebrae. This may change the biomechanics of the adjacent segments resulting in a theoretical increase in the load of the adjacent segment and accelerated degeneration. The effects of post-fusion biomechanics upon adjacent segment disease (ASD) and the role of different approaches remain controversial.

Tang and Meng (2011) showed that restoring disc space height and spinal segmental lordosis is important for preventing ASD by using an anterior cage with appropriate height and lordotic angle. Horsting et al. (2012) followed up 25 patients (minimum 10 year follow-up) who underwent ALIF and posterior fixation for chronic low back pain. The incidence of ASD was 12% above and 20% below the index level. There was significant improvement in patient pain and function up to 2 years with some deterioration at 4 years which was stable at 10 years, but this was not related to the ASD. Kanamori et al. (2012) followed up 20 patients for a minimum of 10 years who had ALIF procedure for degenerative spondylolisthesis and showed progressive ASD. Choi et al. (2014) followed up 49 patients (minimum 10 years) who underwent ALIF for isthmic spondylolisthesis with CT and MRI at 5 and 10 years. The incidence of radiographic ASD was 38.8%, symptomatic ASD was 12.2%, and 4.1% of the patients underwent revision surgery. Also, patients with ASD had more advanced pre-existing facet degeneration compared to those without ASD ($p = 0.01$). They concluded that radiographic ASD is common, while revision for symptomatic ASD is rare, with a risk factor being pre-existing facet joint arthropathy. However, despite the reported incidence of ASD after ALIF procedures, it is reported to be comparatively much less than the incidence of ASD following posterior surgery (Tsuji et al. 2016).

Lumbar TDR

Preventing (or reducing) the incidence of ASD is challenging and has been a subject of debate between surgeons aiming at neural decompression and surgeons aiming at spinal reconstruction. This debate goes back to ASD following knee and hip fusion, which led to the innovation of total hip and total knee replacements and later, ankle and other joint replacements. Similarly in spine, the concept of movement preservation was first introduced in 1966 by Fernström (1966); however the long-term results were disappointing. It was not until 1984 that Schellnack and Buttner-Janz updated this concept by introducing the SB Charité total disc replacement (Buttner-Janz and Schellnack 1990; Buttner-Janz et al. 1987, 1989). Since then the TDR has undergone various modifications in its biomechanics and design.

Based on its biomechanics, the lumbar TDR is classified either as an unconstrained device (Charité III® and In-motion®), as a semi-constrained device (Prodisc®, Maverick®, and Flexicore®), or as a constrained device (the visco-elastic lumbar disc prosthesis-elastic spine pad, LP-ESP®). A mobile core prosthesis (In-motion®) allows uncoupled rotation/translation, while a fixed core prosthesis allows coupled rotation/translation (Fig. 10).

The learning curve of performing lumbar TDR is a steeper curve than that of ALIF (Regan et al. 2006). Inserting the TDR in the midline in the coronal plane is essential, especially when using an unconstrained device. In the sagittal plane, the center of rotation should be at the middle of the end plate or posterior to it (1–3 mm). Correct patient selection for TDR is vital. The condition of the facet joints should be investigated before considering TDR and the type of TDR used. Advanced facet joint arthropathy is a contraindication for performing TDR. Similarly, instability is a contraindication for using unconstrained

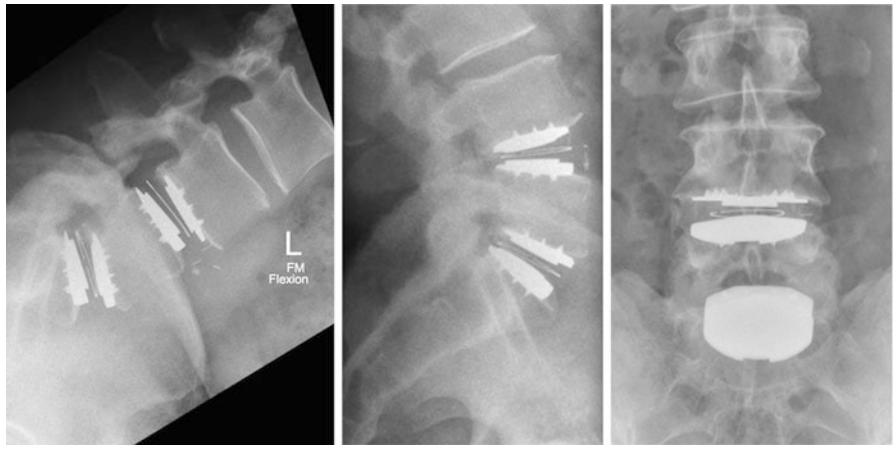

Fig. 10 An example of two-level In-motion TDR for a patient with two-level DDD. (Courtesy of Associate Professor Scott-Young, Gold Coast Spine, Queensland)

Fig. 11 Using the Charité retractor in the intervertebral space to clear the posterior part of the nucleus and the disc allowing assessment of the disc space

TDR. One key factor when performing lumbar TDR is the way the posterior annulus is handled. Ensuring that the posterior annulus is mobile and assessing the symmetry of disc movement is important during preparation of the disc space. This can be achieved by using a Charité or David retractor, for example, which allows symmetrical distraction of both end plates, and the surgeon can then assess the movement of the disc and its suitability for a TDR (Fig. 11).

Great care should be taken when performing multilevel lumbar TDR as it is essential to obtain near perfect alignment in the coronal and sagittal planes. Eccentric positioning of the TDR leads to

suboptimal biomechanical restoration and increased incidence of subsidence and may increase the wear rate. The surgeon should strive to insert the prosthesis with the largest footprint possible to reduce the risk of subsidence. Scott-Young et al. (2012) presented their results, reporting good outcomes of two-level TDR with a minimum follow-up of 4 years.

Lumbar TDR maintains movements of the spinal segment allowing controlled dynamic stability while maintaining near normal disc biomechanics. Maintaining near physiological range of movement reduces the stress on the adjacent segments, and this in turn reduces (and may prevent) ASD and the reoperation rate. Scott-Young et al. (2016) showed a significant reduction of ASD following TDR. In a systematic review, Hiratzka et al. (2015) demonstrated a relative risk of reoperation of 1.7 in the fusion group compared with lumbar TDR, although this risk decreased to 1.1 at 5-year follow-up.

Lumbar TDR is indicated in patients with proven discogenic back pain due to IDD or DDD (with or without disc herniation). Contraindications to lumbar TDR include infection, osteoporosis, scoliosis greater than 20°, spondylolisthesis, failed back surgery syndrome, inflammatory arthropathy, advanced facet joint degeneration, and pregnancy. Adherence to the indication is essential for a good outcome after TDR. Bertagnoli and Kumar (2002) defined criteria for TDR enabling classification of patients as prime, good, borderline, and poor candidates for the procedure. Holt et al. (2007) showed that the incidence of perioperative and postoperative complications for lumbar TDR was similar to that of ALIF, and they recommended that vigilance is necessary with respect to patient indications, training, and correct surgical technique to maintain TDR complications at the levels experienced in the investigational device exemption (IDE) study.

There is robust evidence from class one Food and Drug Administration (FDA) studies of good results achieved using TDR to treat DDD in improvement of both leg and back pain (Delamarter et al. 2011; Gornet et al. 2011; Zigler et al. 2007; Blumenthal et al. 2005). Jacobs et al. (2012) in a systematic literature review found that the TDR had a statistically significant clinical improvement over other methods of treating DDD including fusion; however, they suggested that the differences in clinical improvement were not beyond generally accepted boundaries for clinical relevance.

Combining TDR and Fusion (the Lumbar Hybrid Procedure)

Surgical management of patients presenting with multilevel DDD in various stages of degeneration is challenging. Fusion of multilevel segments increases the risk of ASD (Hiratzka et al. 2015). A good outcome is achieved by matching the technology with the pathology. ALIF could be performed at the symptomatic level if there is significant loss of disc height, facet joint arthropathy, or instability. This allows stabilization of the level, restoring the disc height and treating the facet joint arthropathy. In the level with early stages of DDD, TDR could be performed to maintain movement and reduce the stress on the adjacent segment (Fig. 12).

Aunoble et al. (2010) reported on 42 patients who underwent hybrid lumbar reconstruction with a median follow-up of 26.3 months. The mean improvement of ODI was 53% at 2 years. The visual analogue score improvement for the back pain was 64.6%. Scott-Young et al. (2017) reported that improvements in both back and leg pain and function can be achieved using the hybrid lumbar reconstructive technique and the improvements were maintained at 96 months postoperatively. They reported the largest series in the literature (617 patients) and showed that both statistically and clinically significant ($p < 0.005$) reductions were seen in back and leg pain, which were sustained for at least 8 years post-surgery. In addition, significant improvements ($p < 0.001$) in self-rated disability and function were also maintained for at least 8 years. Patient satisfaction was rated as good or excellent in >90% of cases. Hoff et al. (2016) showed good results of the hybrid procedure in 23 patients in a prospective randomized trial

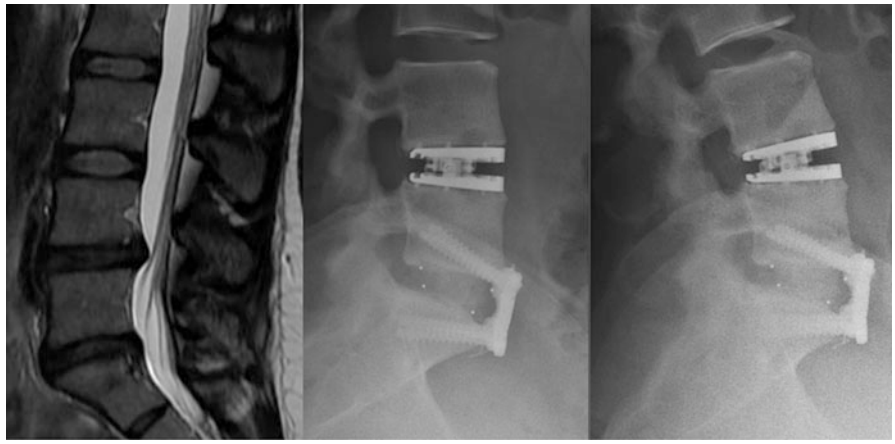

Fig. 12 A 47-year-old patient with two-level DDD, disc prolapse at L4/5 (mobile level) and L5/S1 DDD with facet joint arthropathy who underwent TDR at L4/5 and ALIF at L5/S1

compared with two-level transforaminal lumbar interbody fusion. Yue and Bertagnoli (2006) also showed good results using the hybrid procedure. Chen et al. (2016) showed that hybrid fusion is a valid and viable alternative to ALIF, with at least equal if not better clinical outcomes in terms of survivorship, back pain, and disability scores.

Conclusions

Obtaining a precision diagnosis is paramount to good clinical outcomes in spine surgery. Both ALIF and TDR are valid options in treating DDD; however strict criteria should be met before considering TDR. These include patient factors, surgical training, and also the degree of degeneration. Matching the technology with the pathology is where the art of spine surgery lies.

Allograft Use in Modern Spinal Surgery

56

Matthew N. Scott-Young and Mario G. T. Zotti

Contents

Abstract

Allograft use continues to be important in modern spinal surgery due to its abundant supply, ability to customize to shape, and avoidance of donor site morbidity. However, surgeons must be aware of the limitations of the grafts when used in isolation and how to obtain bony healing. These limitations include subsidence from altered mechanical properties, a lack of osteoinduction and risk of

immunogenicity. Optimal healing can be achieved through optimizing the host, selecting the correct graft for the bony environment where the healing is required, and optimizing local graft site biology and stability. Tissue engineering in arthrodesis through obtaining a stable mechanical construct, use of an appropriate structural allograft, and placement of a biologic component (e.g., BMP-2) has shown to be a reliable means to obtain union and achieved satisfactory outcomes. Novel biological agents show promise and will continue to mature in their clinical application.

Introduction

It is estimated that the number of people aged 65 and older globally will grow from an estimated 524 million in 2010 to nearly 1.5 billion in 2050 with most of the increase occurring in developed countries. Many individuals will suffer from chronic conditions such as hypertension, hypercholesterolemia, osteoarthritis, diabetes, heart disease, cancer, dementia, and congestive cardiac failure. It is thought that heart disease, stroke, and cancer will be the leading chronic conditions that have the greatest impact on the ageing population. However, also to be considered is that a significant number of these individuals will require oncologic surgery, corrective surgery for trauma, revision arthroplasty surgery, and spinal reconstructive surgery which all require bone grafting. At present, it is estimated that there are over two million bone graft procedures performed in the world in a given year. Bone grafting is indeed the second most frequent tissue transplantation worldwide, after blood transfusion. It is estimated that the global bone graft and substitute market accounts for $3.02 billion in 2014 and, it is expected to rise in excess of $4 billion by 2022, growing at a rate of approximately 5% per year.

The use of bone graft and substitutes in the spinal market has increased significantly in conjunction with the aging population and the demand for better standards of health care outcomes. North America is sharing the largest market revenue but Asia-Pacific accounts for the highest growth rate led by the vast ageing population. As a result of the change in demographics, there has been a surge in bone- and joint-related disorders and diseases. Because of this demand, a wide range of products have become available in the market place. These include allograft-based bone graft substitutes, factor-based bone graft substitutes, cell-based bone graft substitutes, ceramic-based bone graft substitutes, and polymer bone graft substitutes. Combining this with the fact that there are limitations associated with autograft, the use of bone graft substitutes has dramatically increased over the last decade. This is due to their ease of use and handling, improved safety profiles, intraoperative cost and time advantages, and adaptability to a variety of clinical challenges.

There are currently over 200 different bone grafts available for surgeons to choose from. This number continues to grow year on year; representing an ever-changing overabundance of options with respect to bone grafting options. Currently, over 90% of reconstructive spinal procedures still utilize autograft and allograft tissue. The current *gold standard* is autogenously sourced bone harvested for reconstructive surgery from the patient. This usually requires an additional surgery from the donor site (usually the pelvis) and has complications such as inflammation, blood loss, infection, and chronic site pain. However, the autogenous bone graft possesses all the necessary characteristics for new bone growth: osteoconductivity, osteogenicity, and osteoinductivity. The ideal synthetic bone graft substitute material would be osteoinductive, osteoconductive, able to bear weight, be resorbable and biologically acceptable, and have a proven safety profile with no adverse local or systemic effects. As yet, the perfect material does not exist, although many materials address one or more of these features.

Basic Process of Bone Formation and Union

In order to achieve solid arthrodesis in the spine, it is a prerequisite to understand the process of bone formation and healing.

Bone is a regenerative organ and maintains this capability in adult life. There is periodic remodeling of the skeleton throughout life and this unique quality allows for fractures to heal and bone grafts to incorporate. The complex and coordinated pathway of bone healing requires an understanding of biomechanical principles, physiological mechanisms, molecular factors, and genetic expression that involves spatial and temporal events. This provides solutions to improve fracture healing or bone grafting and subsequent regeneration. Much of the basic science related to bony union comes from the study of extremity fractures and, as such, the following section talks of union in a spinal (e.g., vertebral body fracture or interbody arthrodesis) as well as an extremity fracture context.

During bone repair, the osteogenic process (under the influence of bone-derived bioactive factors) commences after the inflammatory phase and is initiated by precursor cells from the periosteum adjacent to the fracture site. This generates hard callus by intramembranous bone formation. An autologous bone graft or bone substitute is often required to assist in the healing of an extensive traumatic or postsurgical bone defect and of osseous congenital deformities. The majority of bone formation, however, is by endochondral ossification of the soft callus that appears after infiltrated mesenchyme cells are induced to chondrogenesis. This improved understanding of repair and regeneration has helped with the development of orthopedic tissue engineering.

Understanding the complicated process of bone healing is essential knowledge for a spine surgeon. The primary goal of achieving a successful fusion requires extensive knowledge of bone generation and union and implies a thorough understanding of molecular, physiological, and biomechanical principles. Selection of graft material depends on its properties, the biological status of the patient, comorbidities, mechanical environment, supplemental fixation, availability, cost, efficacy, and the patient's expectations. Inserting materials expecting union or arthrodesis without appreciation of what the role of that material is in bony healing in that particular patient will likely lead to suboptimal results.

Selection of a graft is complex and the three important biological prerequisites need to be considered: osteogenicity, osteoinduction, and osteoconduction. This triangular shaped complex has been extensively studied; however, a fourth element (see Fig. 1 below) should be given the same recognition in terms of significance: mechanical stability. Mechanical stability is a critical factor for bone healing. Progressive maturation of the callus from woven to lamellar bone requires stability. The AO group popularized open reduction and internal fixation techniques to improve union rates. They recognized the role parameters such as fracture rigidity, fracture contact and gap healing, inter-fragmentary strain, and significant role of the soft tissue envelope and vascular environment at the fracture site and coined "The Diamond Concept" (see Fig. 1) (Giannoudis et al. 2007).

To understand new concepts and strategies to enhance the healing of a spinal arthrodesis, a basic summary of the current knowledge on the repair process is required. There are several pathways in which bone can repair, and these are discussed below. One needs to consider that achieving a spinal arthrodesis is a form of tissue regeneration and if fibrous scars form instead then a pseudoarthrosis has developed.

Direct Bony Healing

Direct healing does not commonly occur in the natural process of bone healing. It refers to a direct attempt of the cortical cells to reestablish structural continuity, which requires anatomical reduction of the fragment ends without any gap formation and a stable fixation. This is the primary goal of open reduction and internal fixation surgery. It is also an important type of healing process that occurs when structural allografts are placed under compression in the anterior spine.

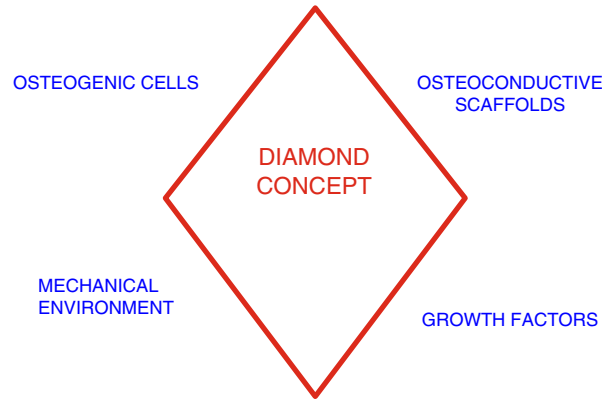

Fig. 1 The diamond concept of bony healing. Reprinted with permission from Fracture healing: The diamond concept, by P. V. Giannoudis; *Injury* 2007 (supp 4; S3–6). (Copyright 2007 by Elsevier)

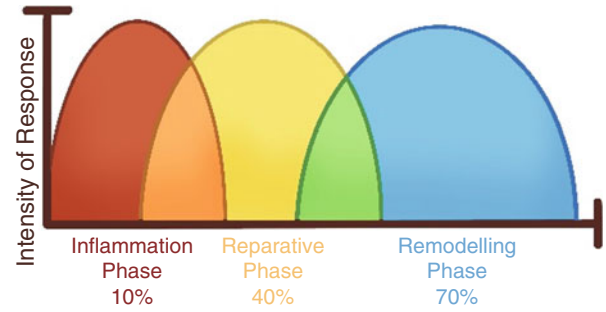

Fig. 2 The overlapping phases of bone healing and relative intensities of response over different time points with display of the relative contribution of the three phases to the overall time taken to heal

Table 1 Phases of bone formation

The acute inflammatory response	Necrotic debris stimulates release of signaling molecules
MSC recruitment	Multipotent mesenchymal stem cells are recruited and transformation to osteoblasts occurs
Vasculogenesis and neoangiogenesis	Stimulation of osteoblast and osteoclast function
Cartilage reabsorption and mineralization	Bone forms around the new scaffold
Remodeling	Continual process occurs for years

Direct bone healing can now occur by direct remodeling of lamellar bone, the Haversian canals, and blood vessels. Complete healing takes several months to a year and progresses through overlapping phases (see Fig. 2 and Table 1). Although time honored, the old dogmatic mnemonic of "coapt coplanar large cross-sectional cancellous surfaces under compression" still holds wisdom.

Contact Healing

To directly reestablish an anatomically correct and biomechanically competent lamellar bone structure, primary healing can occur through contact or gap healing. If bone on one side of the interface is to unite with bone on the other side of the interface there must be anatomic restoration of the bone fragment surfaces and rigid fixation. This will result in a favorable biomechanical environment that will reduce the inter-fragmentary strain (Shapiro 1988). With gaps less than 0.01 mm, the inter-fragmentary strain is less than 2%, thus the vertebral bodies will unite by contact healing (Rahn 2002). Cutting cones consisting of osteoclasts cross the fracture at a rate of 50–100 μm/day. Osteoblasts then occupy the cavity at the end of the cutting cones (Einhorn 2005). This results in simultaneous generation of a bony union and

the restoration of Haversian systems formed in an axial direction (Bais et al. 2009). The reestablished Haversian systems allow for penetration of blood vessels carrying osteoblastic precursors and, with that, complete remodeling ensues in an axial direction (Einhorn 2005).

Gap Healing

If conditions are stable, an anatomical reduction is achieved and the gap is less than 800 μm to 1 mm, gap healing can occur. This differs from contact healing in that the bony union and Haversian remodeling do not occur simultaneously. In this process, the fracture site is primarily filled by lamellar bone oriented perpendicular to the long axis (Dimitriou et al. 2005). This is then replaced by longitudinal revascularized osteons carrying undifferentiated multipotent mesenchyme stem cells (MSC). These MSC differentiate into osteoblasts and produce lamellar bone on each surface of the gap (Shapiro 1988). This lamellar bone, however, is laid down perpendicular to the long axis and is mechanically weak. A secondary remodeling resembling the contact-healing cascade with cutting cones now takes place.

Indirect Fracture Healing

Secondary or indirect fracture healing is the most common form of fracture healing. It involves intramembranous and endochondral ossification leading to callus formation and bone healing (Gerstenfeld et al. 2006). Anatomical reduction or rigid stability is not required. Micro-motion and load bearing enhance the healing process. Excessive load and motion can result in delayed healing or even non-union (Green et al. 2005). Secondary bone healing occurs in the fracture site in non-operative fracture treatment and in operative treatments such as intramedullary nailing, external fixation, or internal fixation of comminuted fractures.

The Acute Inflammatory Response

When a fracture occurs, there is formation of a hematoma and an associated inflammatory response. This consists of cells from both peripheral and intramedullary blood as well as bone marrow cells. The injury initiates an inflammatory response, causing the hematoma to coagulate in between and around the fracture ends as well as within the medulla, forming a template for callus formation (Gerstenfeld et al. 2003). Many local and systemic regulatory factors, hormones, and cytokines work in conjunction with the extracellular osteoconductive matrix producing various cell types and are the first step in the repair process (Gerstenfeld et al. 2003). The acute inflammatory response peaks within the first 24 h and is complete after 7 days. This fracture hematoma produces signaling molecules such as tumor necrosis factor-α (TNF-α); interleukin-1 (IL-1), IL-6, IL-11, and IL-18; fibroblastic growth factor (FGF); insulin-like growth factor(IGF); vascular endothelial growth factor (VEGF); and transforming growth factor-beta (TGFB) that induce a cascade of cellular events that initiate healing (Gerstenfeld et al. 2003). These factors recruit inflammatory cells and promote angiogenesis (Sfeir et al. 2005). The TNF-α concentration has been shown to peak at 24 h and to return to baseline within 72 h post trauma. These factors are secreted by macrophages, MSCs, platelets, chondrocytes, osteoblasts, and other inflammatory cells, and it is believed to mediate an effect by inducing secondary inflammatory signals and act as a chemotactic agent to recruit the necessary cells (Lee and Lorenzo 2006). Differentiation of MSCs down the osteoblastic line is induced by TNF-α. These effects are mediated by activation of the two receptors TNFR1 and TNFR2, which are expressed on both osteoblasts and osteoclasts (Balga et al. 2006).

Interleukins, IL-1 and IL-6, are believed to be most important for fracture healing. There is an overlapping biphasic mode of expression of IL-6 and TNF-α. IL-1 is produced by macrophages in the acute phase of inflammation and induces production of IL-6 in osteoblasts, facilitating the production of the primary cartilaginous callus and angiogenesis at the injured site. IL-6 is produced during the acute phase and stimulates angiogenesis, VEGF production, and the differentiation of osteoblasts and osteoclasts (Lee et al. 2006).

MSC Recruitment

Bone regeneration requires mesenchyme stem cells (MSCs) to be recruited, proliferate, and differentiate into osteogenic cells. MSCs are derived from surrounding soft tissues and bone marrow; there is evidence that a systemic recruitment of circulating MSCs to the injured site might be of great importance for an optimal healing response (Granero-Molto et al. 2009). Which molecular events mediate this recruitment is still under debate. BMP-2 has an important role in this recruitment, but other BMPs such as BMP-7 may play a more important role in the recruitment of progenitor cells (Rahn 2002).

Vasculogenesis and Angiogenesis

There is a greater understanding of the molecular mechanisms controlling callus vascularization. Bony healing requires a blood supply to the healing site, and revascularization is essential. New blood vessels form most commonly, by angiogenesis as well as by vasculogenesis (endothelial progenitor cells, EGC). The vascularization process is mainly regulated by two molecular pathways, an angiopoietin-dependent pathway, and a vascular endothelial growth factor (VEGF)-dependent pathway (Tsiridis et al. 2007). The primarily angiopoetin-1 and 2 are vascular morphogenetic proteins. They are induced early in the healing cascade, promoting vascular in-growth from existing vessels in the periosteal tissues. The VEGF pathway is considered to be the key regulator of vascular regeneration. High levels of VEGF are expressed by chondrocytes and osteoblasts, promoting the penetration of blood vessels and transforming the avascular cartilaginous matrix into a vascularized osseous tissue. VEGF plays a critical role in the neoangiogenesis and revascularization by promoting vasculogenesis (aggregation and proliferation of EGC) and angiogenesis (growth of new vessels from already existing ones). It has been observed that blocking VEGF signaling with antibodies demonstrates that intramembranous bone formation during distraction osteogenesis is dependent on VEGF signaling. The blocking of VEGF-receptors inhibits vascular in-growth and delays or disrupts the regenerative process (Keramaris et al. 2008). Other factors promote neoangiogenesis and vasculogenesis such as the synergistic interactions of the BMPs with VEGF.

Cartilage Resorption and Mineralization

Bony healing is a combination of cellular proliferation and differentiation, increasing cellular volume, and increasing matrix deposition. As fracture callus chondrocytes proliferate, they become hypertrophic and the extracellular matrix becomes calcified (Breur et al. 1991). The primary soft cartilaginous callus needs to be resorbed and replaced by a hard bony callus. Resorption of this mineralized cartilage is initiated by osteoprotegerin (OPG) and TNF-α, macrophage colony stimulating factor (M-CSF), and receptor activator of nuclear kappa factor ligand (RANKL) also known as the RANKL-OPG pathway (Gerstenfeld et al. 2003). These molecules mediate and recruit bone cells and osteoclasts to form woven bone. TNF-α further promotes the recruitment of MSCs and has an important role in initiating chondrocyte apoptosis. The mitochondria accumulate calcium-containing granules, which are transported into the extracellular matrix where they precipitate with phosphate. This becomes a nidus for the formation of apatite crystals. The hard callus formation progresses and the calcified cartilage is replaced with woven bone, the callus becomes more solid and mechanically rigid.

Remodeling of Bone

Hard callus provides biomechanical stability but does not fully restore the biomechanical properties of normal bone. The fracture-healing cascade initiates a second resorptive phase, remodeling hard callus into a lamellar bone structure with a central medullary cavity. This phase is characterized by temporal changes in signaling molecules. IL-1 and TNF-α show high expression levels during this stage, as opposed to most members of the TGF-β family, which has diminished in expression (Ai-Aql et al. 2008). BMP2 is also involved in this phase with reasonably high expression levels (Marsell and Einhorn 2009).

The remodeling process occurs through a combination of resorption by osteoclasts, and lamellar

bone deposition by osteoblasts. The remodeling may take years to be completed to achieve a fully regenerated bone structure. There are many factors which affect the speed and efficiency of the healing process, such as the production of electrical polarity created when pressure is applied in a crystalline environment. This in turn affects the bone modeling. The creation of one electropositive convex surface, and one electronegative concave surface, caused by axial loading, activates osteoclastic and osteoblastic activity. The external callus is gradually replaced by a lamellar bone structure, whereas the internal callus remodeling reestablishes the medullary cavity.

The process of bone healing involves osteogenesis, osteoinduction, and osteoconduction. For bone remodeling to be successful, an adequate blood supply and a gradual increase in mechanical stability is crucial (Gerstenfeld et al. 2003). This is clearly demonstrated in cases where neither is achieved, resulting in the development of an atrophic fibrous non-union. However, in cases where there is good vascularity but unstable fixation, the healing process progresses to form a cartilaginous callus resulting in a hypertrophic non-union or a pseudoarthrosis.

Bone Graft Classification System

Autologous bone represents the *gold standard* source whenever a skeletal deficiency needs to be grafted. It is osteoconductive, osteoinductive, and osteogenic. It has the passive ability of a scaffold to be progressively substituted by viable bone; the capacity to stimulate the osteoblastic differentiation of local and systemic mesenchymal stem cells through specific growth factors, such as bone morphogenetic proteins (BMPs); and the ability to form new bone from the living osteoblasts and MSCs present within the graft material.

Autograft is non-immunogenic and cannot transmit infectious agents unless contaminated during donor site harvesting. It represents the first choice in several procedures such as fracture non-union surgery, spinal fusion, and orthopedic reconstructive surgery (Kannan et al. 2015). Autografts provide the best replacement tissue to a defect site. However, autografts from the donor site require an additional surgery. This can result in complications such as inflammation, lengthening of surgical time, infection, blood loss, hematoma formation, and chronic local pain, especially in older patients who are common candidates for primary and revision spine surgery. This donor-site morbidity occurs in approximately 20% of all cases (Perry 1999). In addition, the volumetric supply limitations reduce its desirability. The quality of the bone in the elderly as a source for grafting is questionable in many cases and the osteoinductive potential may be variable in patients.

As a consequence of the donor issues, market forces have developed scaffolds as bone graft **extenders** (or expanders), which are mixed with the bone graft to augment its volume; bone graft **substitutes**, that may be used alone in place of the bone graft; and bone graft **enhancers**, that are adjuvant therapies aimed at improving the biological performance of the bone grafts by adding cells or growth factors.

There are several categories of bone graft substitutes encompassing varied materials, material sources, and origin (natural vs. synthetic). A bone graft classification system has been developed that describes these groups based on their material makeup (Laurencin and Khan 2013) (see Table 2).

A brief discussion on each group is appropriate on the basis it will provide a basic understanding of each group, advantages and disadvantages, as well as knowledge of when, where, and which product to apply to achieve stability and, ultimately, a solid fusion mass.

Allograft-Based Grafts

Allograft bone refers to bone that is harvested from cadavers and donors. Initially, it was primarily used as a substitute for autografts in large defect sites. Its use has expanded as a result of the absence of autograft donor morbidity, the expansion of bone grafting procedures, and the evolution of bone banks. The coordination of bone bank regulations resulted in donor

Table 2 Different classes of bone graft substitutes

Class	Description
Allograft-based	Allograft bone used alone or with other materials
Factor-based	Natural and recombinant growth factors used alone or in combination with other materials
Cell-based	Cells used to generate new tissue alone or seeded into a support matrix
Ceramic-based	Includes calcium phosphate, calcium sulfate, and bioactive glasses used alone or in combination
Polymer-based	Degradable and nondegradable polymers used alone or combined

screening, tissue processing techniques, and reduction in the risk of disease transmission. This resulted in the acceptance of allographic tissues as a source of grafting and an emergence of allographic materials. A variety of allograft forms are available, including osteochondral, cortical, cancellous, and processed bone derivatives such as demineralized bone matrix (DBM). The processing of allograft ensures there are no viable cells, and consequently, these grafts themselves are not osteogenic. Allograft is osteoconductive and, sometimes, mildly osteoinductive.

Factor-Based Grafts

Growth factors have been extensively researched and have been proven to regulate cellular activity. Proteins and/or growth factors bind to cell receptor sites and stimulate the transcription of messenger RNA that leads to formation of proteins that regulate intra- and extracellular homeostasis. These factors include platelet-derived growth factors (PDGFs), IL-1, IL-3, IL-6, macrophage colony-stimulating factors, the transforming growth factor-β family (TGF-β), BMPs, insulin-like growth factors (IGFs), and vascular endothelial growth factor (VEGF). These factors act in a coordinated manner and influence inflammation, cellular migration and differentiation, angiogenesis, and cellular proliferation. They have both paracrine and autocrine capabilities. Recent approaches have focused on using a combination of factors so as to evoke a synergistic response in the healing of non-union fractures (Kempen et al. 2010). These combinations are delivered in a manner such that they artificially recreate the native microenvironment of healing bone. The use of single factors requires supraphysiological doses to obtain desirable effects. Such high dosages have led to complications such as ectopic bone, osteolysis, and immunological reactions. Multiple growth factor delivery is advantageous because of its ability to promote two or more diverse functions such as mineralization and angiogenesis. This approach requires study on growth factor combinations dosage, temporal events, and release kinetics. Few studies have been performed in this direction, and the delivery or scaffolds to house and release these factors at the appropriate time have yet to be proven.

Cell-Based Grafts

In significant breakthrough in 2006, Takahashi and Yamanaka discovered how mature cells treated with the right factors could be engineered back to a pluripotent stem cell state capable of producing any cell in the body (Takahashi and Yamanaka 2006). Various stem cells are now available for use in conjunction with bone graft substitutes including mesenchymal stem cells (MSCs), adipose-derived stem cells (ADSCs), induced pluripotent stem cells (iPSCs), and embryonic stem cells (ESC).

MSCs are more primitive than ESCs, consequently in the presence of TGF-b and BMP-2, −4, and −7 to culture media can be differentiated down the osteogenic line. ESCs' somatic cell differentiation requires more steps. ESCs are characterized by their unlimited proliferation and ability to differentiate to any somatic cell type, which makes them a great cell source for tissue regeneration.

ADSCs are an attractive source of stem cells because supply limitations and ease of harvesting is less of a problem given the ready access of adipose tissue deposits found under the dermal layers. These cells induced back to an earlier lineage became known as iPSCs. Stem cell technological advances lead to a greater understanding

about the interaction between stem cells and their potential use in bone graft substitutes for clinically relevant applications.

Ceramic-Based Grafts

Ceramics are highly crystalline structures formed by heating non-metallic mineral salts to high temperatures in a process known as sintering. Many ceramics are used in various orthopedic applications (White and Shors 1986). There are resorbable ceramics such as tricalcium phosphate (TCP) and ceramics with highly reactive surfaces such as bioactive glasses and calcium phosphates. The least reactive ceramics are in use in hip arthroplasty (zirconia).

Currently available bone graft substitutes contain ceramics, including calcium sulfate, bioactive glass, and calcium phosphates. Ceramics contain calcium hydroxyapatite (HA), a subset of the calcium phosphate group, which is the primary inorganic component of bone. Calcium phosphates can come close to mimicking the natural matrix of bones, depending on the porosity and structure hence the widespread use of bone graft substitutes that contain HA-based biomaterials.

Calcium phosphates are also osteoconductive, osteointegrative, and, in some instances, can be osteoinductive by the addition of MSCs (Urist and Strates 1970). The structure and crystallinity can influence osteoblastic proliferation and differentiation when in contact with calcium phosphate. The crystallinity of the HA can vary the spatiotemporal proliferation of osteoblasts, and therefore the biological repair activity. The manufacturing of ceramics requires exposure to high temperatures. This complicates the addition of biological molecules. They also tend to be brittle, making them challenging in certain bone graft applications. They are frequently combined with other materials to form a composite.

Polymer-Based Grafts

Polymers are chemical compounds or mixtures of compounds formed by polymerization and consist of repeating structural units. They are classified into natural polymers and synthetic polymers, which can be divided further into degradable and nondegradable. Natural polymers, such collagen, are derived from living sources, whereas synthetic polymers are manufactured.

Synthetic polymers can be used in a wide variety of medical applications. The polymerization process can achieve an extraordinary range of physical and chemical properties. They can be utilized because of their structural and mechanical properties that allow for complex shapes. Polylactideco-glycolide (PLGA) is an example of a synthetic, degradable polymer for bone graft applications. With the addition of water, it can break down to lactic acid and glycolic acid, which are natural human metabolites.

Natural polymers, such as collagen hydrogels, are used in scaffolds in tissue engineering as cells adhere and grow on the collagen fibers within the hydrogel.

Due to their carbon-based chemistry, polymers are closer to biological tissue than inorganic materials. This can be used for targeted interaction between the material and the body. As with ceramics, the functionality of polymers can be enhanced if used in combination with other materials, such as ceramics, to form composites.

Allografts

Introduction

Bone grafting is an essential component of spinal surgery. The need commonly arises in spinal fusion (Takaso et al. 2011) and is utilized in trauma, infection, and tumor resection (Finkemeier 2002), where bony defects can arise. These defects can be filled with autograft, which is generally preferred as it is osteoconductive and osteoinductive. However, harvesting for autograft creates donor morbidity, extended operating time, and may be contaminated by systemic processes (e.g., sepsis, metastases) (Aro and Aho 1993). In addition, autografts are limited in number, shape, size, and volume to which allografts are not constrained.

Consequently, the need for bone banks arose. Currently bone is a commonly transplanted tissue, second only to blood.

Therefore allografts supplied by a bone bank are commonly used instead of autografts because of their immediate availability and unlimited volume. The use of allograft bone eliminates the operative time required for harvesting and associated donor morbidity. Virtually any shape or size can be fashioned and are often combined with other enhancers, extenders, and substitutes to achieve union. Allogenic bone has osteoconductive activity; it serves as an acellular mineralized frame against which newly formed bone gets deposited. It is, however, variably and weakly osteoinductive (depending on source and processing) and is not osteogenic.

The obvious disadvantages of allografts are the potential for disease transmission, host incompatibility, and infection from contaminated tissue.

The Food and Drug Administration (FDA) has established guidelines that all bone and tissue banks must adhere to. The American Association of Tissue Banks (AATB) established guidelines that accredited banks must follow, which have set the industry standards. These guidelines include training and certification of employees as well as regular inspections of the facility through to assessing documentation and auditing.

The AATB is a not for profit organization that regulates and monitors the safety, consistency and availability of allografts across the United States. The AATB ensures and accreditates tissue banks to ensure their compliance with the FDA guidelines. Governments have imposed the standardization of bone bank operations to ensure the safety of transplanted tissues. The performance of a bone bank depends on its organization, donor selection and procurement, documentation, storage and processing, and implementation.

There are two types of donor of homologous tissues: live donors, consisting mainly of donations of femoral heads after fractures and total hip arthroplasty and cadaver donors, from which much greater quantities of tissues can be harvested, from any segment of the skeleton. Cadaveric donors are usually younger and have better bone quality.

Allograft Safety

The aggregate risk of disease transmission with allograft is a reflection of the rigor of the screening and testing of donors and the type of allogenic tissue that is transplanted. The risk of transmission of viral diseases (human immunodeficiency virus (HIV), hepatitis B (HBV), hepatitis C (HCV)) depends on the product type and its preparation. Regulatory guidelines in Europe, the United States, and Australia have developed critical pathways for manufacturers of biological products to follow. Simply stated, these involve screening tissues for infectious agents (viral/bacterial), processing techniques to ensure sterilization (ethylene oxide/radiation), and follow up mechanisms to track the patient and product. By AATB standards, serologic testing is used including for hepatitis B surface antigen, hepatitis B core antibody, hepatitis C antibody, syphilis, human T-lymphotrophic virus-1 antibody, HIV 1 and 11 antibodies, and HIV P24 antigen. All tissue and blood samples are tested for infectious diseases, including for AIDS with Nucleic Acid Testing (NAT by TMA), HCV, HIV-1, HIV-2, HTLV-1, HTLV-11, HB Core, RPR, HCV-Ab, HBs Ag, HIV-1 NAT, and HCV-NAT.

Mroz et al. (2009) performed a retrospective review of data analyzing 54,476 allograft specimens recalled by the FDA. They found that despite the large number of allograft recalls in the USA, there was only one documented case of disease transmission (HIV) in spine surgery. The review found no reports of bacterial transmission from the use of allograft. They admitted that the precise incidence of disease transmission linked to tissue allografts was unknown. They concluded that there appears to be no overt risk associated with the use of allograft bone in spine surgery.

Bone Banking Overview

The presence of microorganisms on processed tissues is inevitable and unavoidable. In order to prevent disease transmission the appropriate donor selection process, proper tissue processing,

and adequate sterilization is of paramount importance.

The most valuable method for determination of suitability is the donor's medical history. In general, there should no history of infectious, malignant, neurological, and autoimmune diseases. In addition, there should be no metabolic bone disease, drug abuse, or exposures to radiation and toxic substances present in the history. Essentially, any condition in which there is the possibility of disease transmission or where the quality of the bone may be compromised could warrant exclusion from donation.

The procurement and processing of allograft has to be performed with a sterile and hygienic technique. Grafts may be harvested from two sources. Bone is procured aseptically or cleanly. The first is from live donors where femoral heads are typically collected aseptically in the operating room by a surgeon in the course of a hip replacement. The second source is cadaver bone which can also be procured under aseptic conditions in the operating room. Removal of bone should take place within 12 h of death or within 24 h if the body has been refrigerated at 4 °C to reduce bacterial growth and bone autolysis. Standard sterile draping of the cadaver and sterile gowning of all trained procurement personnel are essential.

A sterilization process that has a high inactivation process prevents the transmission of diseases from donor to recipient. Various techniques are utilized such as ethylene oxide (Dziedzic-Goclawska 2005), irradiation (Nguyen et al. 2007), thermo disinfection (Folsch et al. 2015), and other techniques such as antibiotic soaks. Ethylene oxide sterilization is of limited use because of limited tissue penetration and can cause an inflammatory reaction to ethylene chlorohydrin, a by-product formed from ethylene oxide. Gamma irradiation has bactericidal and viricidal properties and has been proven to be successful in sterilizing medical products. The concept of sterility assurance level (SAL) is derived from studies on bacteria, fungi, and spores where a sterilization dose is high enough that the probability of an organism surviving is no greater than one in one million units tested. The dosage of 25 kGy has been the recommended for terminal sterilization of allograft tissues. This is 40% above the minimum dose required to kill resistant microorganisms. Research has shown dose-dependent reductions in biomechanical properties of allografts at high levels of gamma irradiation (>30 kGy). This prompted bone banks to employ lower doses that are efficient at deactivating microorganisms, while protecting the biomechanical properties of bone allograft. Several bone and tissue banks around the world utilize minimum doses to achieve sterility with dosages as low as 11 kGy. The radiation process is a cold sterilization process and therefore preserves the properties and characteristics of tissues (Singh et al. 2016).

Gamma irradiation of allografts is a safe and highly effective sterilization method and offers a clear advantage in terms of safety compared with other sterilization techniques. There is no substitute for donor screening and rigorous tissue processing procurement techniques and, when combined with gamma irradiation, the sterile product is safe for clinical use.

Types of Bone Allograft

There are three commonly used forms: fresh frozen allograft, freeze dried allograft and demineralized bone matrix (DBM).

Allografts are either fresh or processed. Fresh allografts are sometimes utilized because they are alive. However the immunologic reaction and the risk of disease transmission has led to most allografts being processed.

Fresh frozen allograft has improved osteoinductive and biomechanical properties relative to irradiated materials. After harvest, the allograft is cleaned by a high-pressure lavage and antibiotic solutions. The removal of marrow elements removes a significant antigenic cell population. After cleaning, the tissue is cultured and if sterile the graft is then frozen and released for implantation in due course. The grafts are packaged without solution and frozen to −70 °C to −80 °C. The stored life of sterile fresh frozen allograft is 3–5 years. Fresh frozen graft has the greatest strength of any type of structural allograft, however carries the risk of disease

transmission, which can be reduced by donor screening and sterile harvesting techniques. Any grafts that have positive cultures after processing are secondarily sterilized. This secondary sterilization process occurs with either gamma irradiation or ethylene oxide.

Freeze-dried allograft is prepared by tissue water being replaced with alcohol to a moisture level of 5% with the alcohol, then being removed under vacuum. Freeze-dried grafts can be stored at room temperature for 3–5 years and are therefore easier to maintain. The graft requires a 30 min period of rehydration prior to implantation. The risk of disease transmission is also reduced with no cases of HIV transmission being reported. It is estimated the risk is 1 in 2.8 billion compared to fresh frozen allograft risk of 1 in 1.6 million (Costain et al. 2000). Freeze drying does not eliminate the HIV virus, however it does reduce the immunogenicity. The effect of freeze-drying on the mechanical characteristics of the graft is dependent on the method and rate of rehydration. Compared with fresh frozen bone, it has been found that the process results in a small but significant reduction in stress (18%) and stiffness (20.2%) (Cornu et al. 2000). A study comparing the compressive strengths of fresh frozen, freeze dried and ethylene oxide treated allograft showed no significant differences (Brantigan et al. 1993). The effect of irradiation on freeze-dried allograft has been shown to reduce graft strength further (Hamer et al. 1996). As well as the mechanical stability reduction, irradiation results in the denaturing of endogenous BMPs eliminating much of its osteoinductive capacity.

The discovery of osteoinductive proteins within demineralized bone matrix has resulted in the widespread use of DBM in grafting procedures (Urist et al. 1967). The production of DBM is a multistep process commencing with cortical bone being cleaned followed by machining into small particles. Acid is then applied to reduce the calcium content while maintaining the organic matrix and growth factors. The demineralization process releases these cytokines that participate in the complex cascade of events leading to bone repair. This renders DBM weakly osteoinductive. Approximately 93% is collagen and 5% are growth factors, a portion of which is BMPs. There is variability in the osteoinductivity depending on the donor, the site of the harvest and the method of processing. This variability resulted in different osteoinductive capabilities between different manufacturers and within a single manufacturer's product (Wang et al. 2007). The end product is a powder and therefore the handling characteristics were problematic. If placed in a cavity the product could be easily displaced from its desired location by blood and other fluids. Hence, most DBMs are placed in carriers such as putty or glycerol. DBMs have been found to be useful as graft extenders for both local bone and iliac crest bone graft (Schizas et al. 2008). The literature supports the utility of DBMs as enhancers and extenders but not as bone substitutes in isolation.

It is important to select an allograft product that is applicable to the clinical situation. In addition, surgeons should be familiar with the bone bank and its regulations, the products and their preparation, the biologic activity and biomechanical characteristics, as well as cost, safety, and efficacy of the product.

Allograft Use in Spine Surgery

It is clear that there are four essential elements of bone grafts for successful bone regeneration. Osteoconductivity, osteoinductivity, osteogenicity, and the mechanical environment is the diamond concept and all aspects need to be considered when selecting an allograft in a particular operation to fulfill a particular role.

Osteoconductivity is the ability of a material to provide a three-dimensional structure for the ingrowth of host capillaries, perivascular tissue, and osteoprogenitor cells.

Osteoinductivity is defined as the ability of a material to stimulate primitive, undifferentiated, and pluripotent cells to develop into the bone-forming cell lineage with the capacity to form new bone.

Osteogenicity implies that a bone grafting material has the intrinsic capacity to stimulate

bone healing by the presence of mesenchymal stem cells (MSCs) or osteoprogenitors cells.

The mechanical environment in which the allograft is placed is critical to the success: the construct needs to be rigid, the graft under compression and the recipient vascular bed viable.

The choice of bone graft for achieving an arthrodesis or reconstruction in the spine should be made on the evidence available from the literature and not from a salesman in a suit or a glossy brochure. The primary goal is to achieve an interbody arthrodesis, therefore, many factors need to be taken into account. Less commonly, graft is used to recreate and restore anatomy in the case of spinal deformities. For example, remodeled endplates can be recreated in cases of high grade dysplastic spondylolisthesis to support an interbody cage/graft and anterior fixation. The recipient's biological status, age, comorbidities, graft harvest site, the vascularity and local tissue viability, the mechanical environment and the use of supplemental fixation influences the environment for bone healing to occur. In selecting a graft, one needs to take into account the diamond concept: osteoinductivity, osteoconductivity, osteogenicity and the mechanical environment.

Although iliac crest bone graft is the gold standard, there are numerous reports on the success of alternate approaches, especially in combinations. For example, with large or segmental bone defects, the healing process is impaired; thus the use of tissue engineering techniques becomes a necessity. To mimic the natural bone healing process, three major components are required: a mechanically stable graft, a suitable cell source and the presence of chemical and biological factors. Extensive research has been done in all three components mentioned above; however, we are still at the laboratory bench stage, in which biomaterials, growth factors, and cell sources are being examined and optimized for the regeneration of bone. In addition new efforts by several major orthopedic companies have expanded the role of allografts by tailoring them for specific surgical procedures. For example, dowels and wedges can be utilized in spinal fusions and DBMs with carriers to provide better handling and performance characteristics.

Allografts are now manufactured in a variety of forms and consequently offer versatility to meet the requirements of an ideal graft. They can be processed to offer mechanical support in load bearing environments, provide the ability to incorporate and remodel, to be biocompatible, to be osteoinductive when demineralized and to provide a high level of safety. As mentioned earlier factor, cellular, ceramic and polymer based bone enhancers, extenders and substitutes are used singularly or in combinations to enhance the role of allografts in spinal fusion. As new technologies are developed, tissue engineering and gene therapies are likely to add to the biological characteristics already available with allografts.

Allograft in the Anterior Column

Multiple studies on the radiographic success of allograft in the anterior column of the cervical spine have been reported. Few studies have studied the clinical efficacy. Generally, the use of allografts is supported for use in anterior column support (level I-IV evidence). The utilization of supplemental fixation, such as cages and plates, has resulted in a substantial increase in fusion rate as well as maintenance of lordosis, which in turn appears to reduce adjacent motion segment degeneration (AMSD) and improves the clinical efficacy. Many options exist for the usage of allograft in the anterior column: these include cortical or cortico-cancellous allograft, with or without supplemental cage or plate fixation, and DBM, which always requires supplemental fixation. It should be noted that allograft alone with BMP-2 leads to high union rates but is prone to subsidence (Vaidya et al. 2007) and, as such, additional measures to improve the biomechanical environment such as cage support and/or plate/posterior fixation is important (Slosar et al. 2007).

The Cervical Spine

Allograft has been shown to be at least equivalent to autograft when used for anterior cervical procedures with the exception of multilevel constructs. Tuchman et al. (2017), in a systemic review compared the effectiveness and safety

between iliac crest bone graft (ICBG), non-ICBG autologous bone, and allograft in cervical spine fusion. The review identified 13 comparative studies: 2 prospective cohort and 11 retrospective cohort studies. Twelve cohort studies compared allograft with ICBG autograft during anterior cervical fusion and demonstrated with a low evidence level of support that there are no differences in fusion percentages, pain scores, or functional results. There was insufficient evidence comparing patients receiving allograft with non-ICBG autograft for fusion, pain, revision, and functional and safety outcomes.

The FDA IDE studies on disc replacement have provided information on allograft fusion in the anterior cervical spine (Coric et al. 2018; Gornet et al. 2017). These studies have provided valuable information on the control group in regards to the incidence of fusion, reoperation, non-union and data on the patient-reported outcome measures (PROM) and have generally found high fusion rates and acceptable outcomes. These, along with other studies with single level allograft constructs supported with internal fixation show that meticulous surgical technique could result in fusion and improvement in PROMs irrespective of graft choice (Yeh et al. 2017; Fraser and Härtl 2007).

ACDF using allografts have in general shown clinical and radiological success. Muzević et al. (2018) investigated clinical parameters of ACDF treatment and outcomes using osseous allografts in different age groups, studying the postoperative results of restoration of lordosis and evaluating the utility of bone allografts for ACDF, including graft subsidence. Fifty-two patients had disc herniation and 102 had spondylosis. Surgery was performed on a total of 313 levels. The median duration of follow-up was 24 months, and no patients were lost to follow-up. Human cortical allografts were used in 51 segments (16.3%), and corticocancellous allografts were used in 262 segments (83.7%). Solid fusion was achieved in 97.92% of patients and 98.37% of levels at a mean follow-up of 5.97 $\pm$ 2.86 months. Graft sizes ranged from 8 mm to 15 mm. The most frequently used graft size for fusion was 11 mm (119 levels; 38%), followed by 10 mm (72 levels; 23%) and 12 mm (70 levels; 22.4%). Anterior cervical plates and screws were used in all patients. The importance of a plate in load sharing is recognized, especially in patients with a kyphotic cervical spine. Treatment outcomes achieved excellent or good outcomes in more than 80% of patients, regardless of age. Yeh et al. (2017) retrospectively collected preoperative and postoperative radiographic and clinical data of 50 patients from 2005 to 2009, with a diagnosis of multilevel cervical spondolytic myelopathy (MCSM), who received 2-level anterior cervical corpectomy and fusion (ACCF) with a fresh frozen cortical strut allograft (FFCSA) fibular shaft and an anterior dynamic plate (see Fig. 3). The cervical curvature lordosis improved and the neurogenic function recovered well postoperatively. The VAS-neck and NDI scores both decreased after 12 and 48 months following surgery. The Japanese Orthopaedic Association score recovery rate at postoperative 4 years was 87.5%. Fusion rates achieved were 100% at 12 months. They stated the results were satisfying and the complication rate was low. The authors emphasized meticulous graft preparation on both the donor bone ends and the recipient endplates so the graft could be inserted with a press fit technique.

Evidence for the efficacy regarding the use of allograft in multi-level anterior cases is mixed. A study by Park et al. (2017) demonstrated similar clinical and radiologic outcomes between patients treated with corticocancellous composite allograft or autograft for ACDF, with a decreased subsidence rate in the corticocancellous composite allograft group. They utilized freeze dried, fully machined corticocancellous composite allograft cages. APS was utilized for primary fixation. Corticocancellous composite allograft is composed of cortical lateral walls with a cancellous centre. The cortical portion provides structural support for the disc space, while the cancellous portion provides a scaffold for bone in-growth that can minimize graft subsidence with an enhanced fusion rate. The authors stated the allograft group took longer to fuse and in multi level cases, may result in hardware failure. Peppers et al. (2017) reported on the results of a prospective multicentre clinical trial assessing the safety

Fig. 3 Example of corpectomy and fibular strut allograft with plate/screw stabilization for reconstruction of the anterior column

and effectiveness of the viable cellular bone allograft in combination with a polyetheretherketone (PEEK) interbody spacer in two-level ACDF using patient reported and radiological outcome measures. The per subject fusion rate increased over time and was determined to be 65.7% of subjects fused at 6 months and 89.4% at 12 months. This study did not have a control group and thus treatment was not directly compared to autograft or non-cellular allograft treatments. Samartzis et al. (2003) however found equivalent and high rates of fusion (in the order of 97–98%) with rigid plating emphasizing that mechanical stability may be a factor influencing the difference between autograft and allograft in older studies without rigid fixation.

A near 100% union rate is achievable with the addition of BMP to allograft but the side effects related to dosage require caution. Burkus et al. (2017) reported on a prospective study evaluating the safety and efficacy of BMP-2 with allograft for ACDF in single level degenerative disc disease (DDD). The investigational group had 0.6 mg of BMP-2 inside a PEEK cage/APS with a fusion rate of 99.4% versus a control group treated with allograft spacer/APS with a fusion rate of 87.2%. A higher rate of adverse events such as swelling, dysphagia and oropharyngeal pain was noted. Butterman (2008) similarly found high rates of union but increased incidence of neck swelling and higher cost of allograft with BMP-2 compared to iliac crest autograft for ACDF. Higher dosage has also been linked with increased osteoclastic activity via the RANKL-OPG pathway and osteolysis (Gerstenfeld et al. 2003) that can lead to subsidence of implants.

While allograft and autograft showed near equivalence in the literature for the cervical spine, the same cannot be said for synthetic bone graft. Buser et al. (2016) reviewed the efficacy and safety of synthetic bone graft substitutes versus autograft or allograft for the treatment of cervical degenerative disc disease. Data from 8 comparative studies were included: 4 RCTs and 4 cohort studies (1 prospective and 3 retrospective studies). Synthetic grafts included HA, β-TCP/HA, PMMA, and biocompatible osteoconductive polymer (BOP). The PMMA and BOP grafts led to lower fusion rates, and PMMA, HA, and BOP had greater risks of graft fragmentation, settling, and instrumentation problems compared with iliac crest bone graft. The authors stated that conclusions regarding the efficacy and effectiveness of these products are low and insufficient. Most of these studies were sponsored and the sample size inadequate, therefore with the potential for bias. The use of bone substitutes, extenders and enhancers has escalated rapidly and of course buyers are being charged a premium without clinical evidence to support the use of such products. In this review, synthetic grafts performed similarly or worse than autologous grafts in achieving fusion. A detailed review of the level of evidence, safety, and efficacy is required.

It should be discussed briefly also that allografts play a role in providing structural integrity or bridging significant bone loss in certain circumstances in the anterior cervical spine. This includes structural allograft for vertebrectomy cases anteriorly in the setting of metastatic tumor or systemic infection or significant traumatic bony comminution in a burst fracture where the patient's autograft may be less

desirable for reasons of contamination, healing problems or increased morbidity.

In summary, the evidence suggests that ICBG and allograft demonstrated clinical equipoise in terms of fusion rates, pain scores, and functional outcomes following anterior cervical fusion. Recognition about patient factors and surgical techniques play a significant role in the outcome of anterior cervical fusion surgery. Age, osteoporosis, the number of levels and tobacco use can affect the fusion rate. In addition, surgeon factors such as graft doweling, endplate preparation and the use of supplemental fixation can also affect fusion rates.

Allograft utilization removes donor site complications. While the preparation and sterilization reduce or eliminate transmission of disease, it also reduces or eliminates osteoinductive capabilities and can mechanically alter the graft and the ability to withstand compressive and torsional loads. This can result in longer fusion times, subsidence, and loss of correction.

The Lumbar Spine

A large variety of devices have been developed and used for structural support of the spine in the anterior and middle columns. These structural deficits arise from anterior discectomies, trauma, tumor resections and following osteotomies for correction of deformity. The anterior lumbar spine is similar to the cervical spine in that, following disc resection or vertebrectomy, the graft is placed under compression. An additional advantage is the larger cross sectional area of the lumbar spine vertebral body on which to seat the allograft. The loads are mainly axial compression, although some rotational stresses are also applied. The two most commonly used allografts in the anterior spine are femoral ring allografts (FRA) and tricortical iliac crest. Mechanical testing of the vertebral body and FRAs has revealed compressive strength of 8000n and 25000n, respectively (Voor et al. 1998). These biomechanical tests revealed the importance of placement, surface area coverage, and the importance of endplate preservation.

Clinically, studies of allograft use in the lumbar spine for degenerative disc disease and deformity have reported favorable outcomes in use with an anterior approach (ALIF). Burkus et al., in a randomized controlled trial of 131 patients used ALIF threaded cortical allograft dowels and BMP equivalent rates to autograft without additional morbidity (Burkus et al. 2005). In fact, some other multicenter studies have even reported superior results compared with allograft (Burkus et al. 2003).

Regarding tumor and deformity, allograft has been a useful tool in the surgeon's armamentarium. Bridwell et al. (1995) reported in a prospective study of 24 patients with kyphosis or anterior column defects treated with fresh frozen allograft and posterior instrumentation and autogenous grafting. Only two patients showed some subsidence and the other 22 maintained the correction. Bridwell (Bridwell et al. 1995) also found that deformity correction using anterior allograft support was effective on the proviso it was combined with rigid posterior fixation and autograft. Janssen et al. (2005) reported on the clinical and radiographic outcomes of 137 patients who were treated with a FRA allograft packed with ICBG ($n = 117$) and DBM ($n = 13$) and supplemental posterior fixation. They were able to achieve a 94% fusion rate.

Systemic review and consensus of expert opinion in the setting of reconstructions following en bloc tumor resection have recommended cages packed with morcelized allograft and suitable autograft for single level vertebrectomies with strut bone grafting used in the thoracic spine (Glennie et al. 2016).

Other interbody approaches have had variable success. Generally, PLIF studies have reported inferior outcomes from the use of allograft compared with autograft alone (Jorgenson et al. 1994), be it with or without instrumentation (Brantigan 1994). Anand et al. (2006) in a study of allograft laden TLIF cages have been more favorable with regard to fusion at 99% and satisfaction 96%. The literature on interbody fusion via lateral and oblique approaches utilizing allograft is limited so an inference as to their efficacy cannot currently be drawn.

It is important that one is aware of the potential for allograft resorption when used in isolation with BMP-2 (Pradhan et al. 2006). An anterior cage-allograft-BMP-2 combination may provide the best synergy in terms of initial support,

Fig. 4 Solid arthrodesis achieved in the lumbar anterior column as demonstrated across a coronal CT plane through a tissue engineering construct of plate-PEEK cage-femoral allograft and BMP-2

scaffolding and growth factor stimulus combining to support effective arthrodesis. The cage (usually with supplemental screw fixation within or extraneous to the cage) provides the mechanical stability, the cancellous structural graft the osteoconductive matrix and the BMP-2 the osteoinductive protein (see Fig. 4). This is effectively tissue engineering. There is good evidence for the utility of spinal allografts for structural reconstruction in the anterior spine. They have the advantage of immediate strength, are under compression and have comparable fusion rates with autograft if combined with anterior and/or posterior instrumentation.

Posterior Elements

Cervical

There is limited literature on use of allograft for fusion of the posterior elements of the cervical spine as most studies relate to anterior cervical reconstructions. However, studies do highlight their utility with regard to availability of shape and size in more complex anatomy. For example, posterior interventions including occipitocervical and C1–2 posterior based fusions can benefit from access to spanning shaped segmental support (Nockers et al. 2007; Aryan et al. 2008).

Thoracolumbar

Posterior correction of scoliosis is a particularly important clinical situation requiring large amounts and surface area of bone graft to achieve a solid posterior fusion. In the most common cases of either adolescent idiopathic or pediatric neuromuscular scoliosis, adequate quantity and quality of autograft bone may not result from simple local bone grafting alone. In this instance, the choice of graft(s) is important in minimizing further blood loss and morbidity from an already invasive procedure for the child. To this end, freeze-dried allograft chips have been employed with high success in some literature with the advantage of reduced blood loss and morbidity (Blanco et al. 1997; Montgomery et al. 1990) but some studies have reported inferior outcomes when compared to autograft only or composite autograft-demineralized bone matrix combinations (Price et al. 2003).

Regarding fusion of the posterior elements in posterolateral fusion (PLF), studies are mixed on the efficacy of allograft bone making it difficult to recommend for or against for posterior fusion, e.g., in a 360° fusion strategy. An and colleagues reported inferior clinical and radiological results of allografts compared to autografts in PLF (An et al. 1995). However, in a randomized controlled trial instrumented allograft use in PLF without BMP has been found to have equivalent fusion rates and outcomes scores to autograft (Gibson et al. 2002). In general, there is little or no evidence for any utilization of structural allograft in the posterior spine except at the occipital-cervical junction. There is some evidence for cancellous allograft chips being used as an extender in PLF. There is evidence for the use of DBM as an extender and possibly as an enhancer in the posterior spine.

Conclusions

There is a wide range of osseous allografts available for use in spinal surgery. Allograft has gained popularity because of its abundant supply and absence of donor site morbidity. The goal is to produce comparable or superior outcomes when

used as a substitute for autograft. The surgeon needs to take into account the type of procedure and therefore the graft best suited for that environment.

The ideal bone replacement material should be osteoinductive or conductive, non-pathogenic, minimally antigenic and mechanically stable. Compared with autografts, allografts show delayed vascularization and remodeling of the fusion mass. Allogenous bone has limited osteoinductive properties and carries the risk of subsidence due to delayed union or non-union. Currently, several modified allograft cages have been introduced to enhance union rate and structural stability, including corticocancellous composite allograft. Despite these facts, allografts are in plentiful supply, have a proven track record, and are an effective adjunct when used in the correct clinical situation.

There are many patients who may not have enough available bone for the prescribed procedure and any additional surgery may result in added blood loss, pain, infection, contamination and an increased hospital stay. Therefore, allogeneic bone from cadaver donors or live donors has been used successfully for a number of procedures and has several advantages including long-term storage, large available quantities, and specific types and sizes of bone.

Regenerative engineering is emerging at a rapid rate. More is now understood about material science, stem cells, signaling molecules, growth factors, and the strategies available to integrate these components to produce the functional biological system we regard as bone. One can envisage a time when structural allografts will be composites of minerals and signaling molecules with growth factors in their structure that will facilitate bone union.

Abstract

The traditional open approach to the thoracolumbar spine remains one of the most powerful and widely practiced approaches in all of spine surgery. Over the past 2 decades or so, minimally invasive options have gained increasing traction and have been associated with reduced blood loss, paraspinal musculature disruption, infection rates, and length of stay, as well as hospitalization costs, without compromising clinical outcomes or radiographic fusion rates. The minimally invasive approach is not necessarily appropriate for all patients and pathologies, and the two approaches are not mutually exclusive. Currently an array of open and minimally invasive options exist for posterior thoracolumbar fusion, including midline and paramedian approaches, conventional and tubular retractors, posterior and transforaminal interbody as well as posterolateral fusion options, static and expandable cages, and various fixation systems, including pedicle (both open and percutaneous) and cortical bone trajectory screws. More recently, endoscopic spine surgery has garnered growing attention as an ultra minimally invasive alternative and may yet play a significant role in neural decompression and spinal fusion. Furthermore, advances in navigation, robotics, osteobiologics, and perioperative protocols will hopefully translate into increased safety, efficacy, and reproducibility for posterior thoracolumbar fusion procedures.

Thoracolumbar fusion · Open · Minimally invasive · Posterior lumbar interbody fusion · Transforaminal lumbar interbody fusion · Tubular retractor · Percutaneous pedicle screw · Cortical bone trajectory screw · Endoscopy

Introduction

The posterior approach to the thoracolumbar spine is one of the most powerful tools in the spine surgeon's armamentarium. This approach is the oldest, and most widely practiced and accepted technique in all spinal surgery (Knoeller and Seifried 2000). It affords the surgeon access to all three columns of the spine through a single stand-alone approach, obviating the need for patient repositioning and staged procedures. It enables direct decompression of the common thecal sac and nerve roots and provides an avenue for fixation and fusion and therefore correction of instability and deformity.

Despite these advantages, the traditional open approach to the thoracolumbar spine is associated with significant iatrogenic disruption of normal surrounding tissue, in particular collateral damage to the paraspinal musculature, leading to devascularization, pain, atrophy, and disability (Fan et al. 2010; Kim et al. 2005). Minimally invasive spine surgery (MISS) has gained much popularity in recent years owing to the reductions

in patient morbidity, length of hospital stay, and costs. This has been supported by advances in technology, including access, instrumentation, neuromonitoring, biologics, navigation, and robotics (Yoon and Wang 2019).

In this chapter, we will address the history of lumbar instrumentation and fusion, and the increasing adoption of minimally invasive techniques. We will also address current trends in spinal procedures performed in Australia and outline the common indications for lumbar fusion, including reviewing the most contemporaneous literature on the subject. Rather than exhaustively detailing each step involved in common thoracolumbar fusion operations, we will endeavor to share with our reader specific nuances accumulated through our surgical experience.

Brief History of Open and Minimally Invasive Spinal Fusion

Harrington in the 1950s is credited with the birth of spinal instrumentation (Harrington 1962). He revolutionized the treatment of pediatric scoliosis with his stainless-steel rod construct. While these were effective in correcting coronal deformities, it created a generation of patients with flat back deformities. The next major revolution in instrumentation came in the form of segmental transpedicular screw fixation, and while described a few decades earlier (Knoeller and Seifried 2000), Roy Camille is often credited with their popularization in the 1970s (Roy-Camille et al. 1976). While Hibbs had harvested iliac crest bone graft in the 1910s for posterolateral graft (Hibbs 1911), Cloward in the 1940s was the first to describe its placement in the interbody space (Cloward 1952), now considered the first iteration of the posterior lumbar interbody fusion (PLIF). To mitigate the forceful retraction applied to the traversing nerve root and thecal sac, Harms (Harms and Rolinger 1982) modified this technique in the 1980s to a more lateral approach, now termed transforaminal lumbar interbody fusion (TLIF) involving total facetectomy and entrance through a corridor referred to as Kambin's triangle (Kambin and Zhou 1996), formed by the obliquely oriented exiting nerve as its hypotenuse, the longitudinally oriented traversing nerve root medially, and the transversely oriented disc space and vertebral endplates inferiorly. Following the lead of our general surgical colleagues and their widespread adoption of laparoscopic techniques over traditional open laparotomies, the search for less invasive approaches to the spine had started to gain momentum. Magerl's percutaneous adaptation of the pedicle screw in the 1980s (Magerl 1982) and Foley's introduction of the tubular retractor[7] a decade later are often considered two of the most significant landmarks in MISS. Kambin, in addition to his eponymous anatomical triangle, is also credited with the development of percutaneous and later endoscopic approaches to the intervertebral space (Kambin and Zhou 1996), and thus spinal endoscopy was born.

Regional and Global Trends in Spinal Fusion

The World Health Organization estimated that low back pain (LBP) affects approximately two-thirds of people in industrialized countries at some point in their lives (Duthey 2013). Epidemiological studies have ranked LBP as the second commonest cause of disability in adults (Prevalence and most common causes 2009), and number one in Years Lived with Disability (Hoy et al. 2014). In parallel to the growing disability incurred by spinal pathology, the number of spinal surgeries performed has also increased, particularly fusion procedures. In Australia, where we practice, the number of simple spinal fusion procedures doubled between 2003 and 2013, while complex fusion procedures quadrupled (Machado et al. 2017). Similar trends have been demonstrated in the United States, with the fastest increases seen in the over 65 age group (Martin et al. 2019). Over a similar epoch, MISS has also gained increasing traction. According to a recent global survey of nearly 300 spinal surgeons, most respondents (71%) regarded MISS as mainstream, while the majority (86%) practiced some form of

MISS (Lewandrowski et al. 2020). In parallel with this trend, based on patient surveys, most patients (80%) prefer MIS over open surgery, provided that long-term outcomes and complication risk are comparable (Narain et al. 2018).

Selected Indications and Evidence for Spinal Fusion

Most spine surgeons would support the addition of fixation and fusion in patients with evidence of instability, classically manifesting as spondylolisthesis with abnormal movement on dynamic radiographs, although indirect signs such as sagittally oriented facets, intra-articular effusions, and synovial cysts may sway a surgeon toward fusion out of concern for creating iatrogenic instability following decompression (Blumenthal et al. 2013). Furthermore, the predominance of mechanical LBP in patients with neurogenic claudication or radiculopathy significantly reduces probability of improvement following decompression alone and may provide further impetus to fusion (Pearson et al. 2011). More recently, our growing understanding of spinal deformity and the negative impact of sagittal imbalance and spinopelvic mismatch on outcomes following spine surgery (Glassman et al. 2005; Schwab et al. 2013) has contemporized our understanding of the longitudinal impact of segmental fusion upon regional and global spinal alignment, as well as the potential benefits and pitfalls of long segment fusion, strategic placement of interbody devices and osteotomies, and deformity correction.

Spondylolisthesis

The rate of *fusions* around the world has more than doubled from the start of the twenty-first century and is only continuing to *increase* from *year* to *year* (Makanji et al. 2018). Despite this, evidence from large randomized controlled trials remains either lacking or conflicting. Certainly, the as-treated results from the spondylolisthesis arm of the Spine Patient Outcomes Research Trial (SPORT) supported surgery over conservative management for patients with degenerative spondylolisthesis (Abdu et al. 2018). However, the significant crossover rate mitigated the benefits of randomization, and the heterogeneity in surgical methods prevented any firm conclusions regarding whether fusion afforded additional benefit to decompression alone.

The two recent randomized controlled trials published in the New England Journal of Medicine addressing whether the addition of fusion to decompression in patients with low-grade degenerative spondylolisthesis raised more questions than they answered. The Swedish study (SSSS) randomized more patients (Försth et al. 2016), around 250, but only half had spondylolisthesis, and important patient characteristics such as dynamic instability and relative contributions of mechanical LBP versus leg pain were not addressed. They concluded that fusion was no better than laminectomy alone in all outcome measures and resulted in longer length of stay and higher costs. The North American study (SLIP) compared the addition of fusion to laminectomy alone in approximately 60 patients (Ghogawala et al. 2016). Patients with mechanical LBP and dynamic instability, generally considered relative indications for fusion, were excluded, potentially reducing the applicability of their patient population to real-world practice. Their results suggested a small but statistically significant improvement in the physical component of the 36-item Short Form Health Survey (SF-36). Neither trial was able to explore the nuances in decision-making spine surgeons face every day in this diverse patient population, and both largely used a surgical strategy, instrumented posterolateral fusion with autologous iliac crest bone graft without interbody that some would consider outdated today. Certainly, no minimally invasive techniques were utilized. Some evidence does also exist supporting the use of interbody over posterolateral fusion with respect to fusion and reoperation rates (Liu et al. 2014). Furthermore, interbody graft provides additional potential benefits of anterior column support and load sharing, fusion under compression and over a shorter distance, as well as indirect foraminal

decompression and restoration of segmental lordosis.

Axial Back Pain

Fusion specifically for LBP has remained a subject of contention for many years. The reduced efficacy of surgery in patients with back-pain predominant symptomatology (Pearson et al. 2011), coupled with difficulties in localizing a specific pain generator in these patients (Brusko et al. 2019), who often possess significant psychological overlay and covert secondary gain, has made this field one of the most controversial in all of spine surgery. The initially positive Swedish trial (Fritzell et al. 2001) on fusion for intractable LBP was later rebutted by the Norwegian trial (Brox et al. 2003), which showed no benefit for fusion over rehabilitation with a cognitive behavioral component. True structured rehabilitation is, however, a scarce commodity in a lot of countries, including Australia, often with lengthy wait times. The latest American Association of Neurological Surgeons (AANS) and Congress of Neurological Surgeons (CNS) guidelines support at least consideration for fusion surgery in the setting of persistent mechanical LBP once all reasonable conservative alternatives have been exhausted (Eck et al. 2014).

Thoracolumbar Burst Fractures

Trials on surgery versus nonoperative management for thoracolumbar burst fractures in neurologically intact patients have shown similarly conflicting results (Abudou et al. 2013), although contemporary minimally invasive methods have not yet been rigorously studied. Certainly, patients with unstable thoracolumbar fractures without need for direct decompression may serve as an ideal cohort for percutaneous fixation to facilitate pain control, mobilization, and fracture union, with minimal collateral soft tissue disruption (Court and Vincent 2012). The instrumentation can often be removed following fracture union to remobilize the involved segment of the spine and prevent long-term adjacent segment issues (Court and Vincent 2012). Similarly, percutaneous instrumentation has an established role in providing supplemental fixation in the context of interbody fusion approached via a lateral route (Alvi et al. 2018) and holds promise in the realm of spinal infection (Deininger et al. 2009), with minimization of communication with infected tissue, and preservation of paraspinal musculovasculature and viability.

MISS Fusion

With an aging population and associated frailty, coupled with increasing emphasis on healthcare economics, there is growing demand for less invasive surgical options. The benefits of MISS have been clearly demonstrated in other subspecialties, such as laparoscopic abdominal surgery and endovascular neurosurgery. There is now a growing body of evidence that MISS fusion provides similar outcomes and fusion rates as traditional open methods. Our meta-analysis on MISS TLIF versus open TLIF showed less blood loss and lower incidence of infection with at least comparable clinical outcomes with regard to axial pain and disability (Phan et al. 2015a). Other studies have consistently shown shorter length of stay (Goldstein et al. 2014), reduced complications (Khan et al. 2015), less disruption of paraspinal musculature (Fan et al. 2010; Kim et al. 2005), less postoperative narcotic use, and earlier return to work (Adogwa et al. 2011), as well as decreased overall costs (Wang et al. 2012). Concerns around increased fluoroscopic exposure to the surgical team (Khan et al. 2015) have been counteracted by advances in navigation and robotic technology, which have also resulted in improved fixation accuracy (Kosmopoulos and Schizas 2007). The initial steep learning curve has been overcome to some extent by widespread dissemination of techniques, and opportunities to learn and practice at cadaveric workshops. The unique challenges raised by patients at risk for nonunion, including osteoporosis (Benglis et al. 2008), have led to strategies such as augmenting pedicle screws with cement to increase pull-out strength, and bone morphogenetic protein (BMP) to improve

fusion (Mccoy et al. 2019). Understanding the dose-dependent properties of BMP, and risks of radiculitis, heterotopic ossification, and osteolysis (Fu et al. 2013), has led to more controlled application of smaller doses in carefully selected patients without malignancy to areas without exposed dura or nerve root, or endplate violation.

The classic tenets of MISS involving small incisions and tubular retractors have shifted toward an overarching paradigm of minimizing collateral tissue disruption to reduce disability, and a greater appreciation for the importance of multidisciplinary teams in enhancing recovery after surgery (ERAS). (Dietz et al. 2019) Patient selection remains key, and while indications for minimally invasive approaches have expanded, there remain pathologies, including but not limited to severe adult spinal deformity, especially if concomitantly rigid, which may be better suited to an open approach (Mummaneni et al. 2019).

Open Lumbar Fusion

There are several variations on the traditional open PLIF technique. We prefer to decompress then instrument to allow us to palpate and visualize the pedicular walls, although the opposite sequence is equally valid. This guides our pedicle screw trajectory both in the craniocaudal as well as medio-lateral planes, thereby minimizing risk of breaching. We also remove most if not the entire facet, comparable to a traditional Ponte osteotomy or Schwab grade 2 osteotomy (Schwab et al. 2014) and affording a similar lateral trajectory as TLIF. Not only does this minimize the amount of nerve root retraction necessary, it also increases the amount of autologous bone available for fusion, and mobilizes the spine to facilitate interbody insertion, foraminal height restoration, spondylolisthesis reduction, and deformity correction. Topical hemostatic agents such as thrombin and gelatin are essential to minimize blood loss, and cell saver technology should be considered if available. Retractors are intermittently released throughout the case to minimize muscle ischemic time. In closing, the muscle is approximated to obliterate dead space, but not so tightly as to risk ischemia. The fascia is closed tightly, particularly if there has been incidental durotomy. We prefer to do this is in an interrupted fashion so that suture line integrity is not reliant on a single knot at each end. We often place an epidural catheter for narcotic infusion (Klatt et al. 2013) postoperatively in addition to a wound drain. There is also some evidence to suggest that topical vancomycin placed in the wound may reduce the incidence of postoperative infection, particularly following instrumentation (Khan et al. 2014). Loupe magnification with headlight illumination is used to enhance visualization.

Positioning

Following appropriate timeout, intravenous antibiosis, and application of mechanical lower limb antithrombotic devices, the patient is positioned prone on the operating table. Particular emphasis is paid to the position of the arms to avoid undue traction on the brachial plexus, padding of all potential pressure areas, sufficient room for the abdomen so as to not impede venous return, and slight reverse Trendelenburg position and avoidance of any direct pressure on the globes to prevent ischemic optic neuropathy.

Laminectomy

In exposing the spine, it is critical to avoid, if possible, violating the capsules of the facet joints of uninvolved levels, particularly at the upper-instrumented vertebra, to minimize acceleration of adjacent segment disease (ASD). Furthermore, clear delineation of bone and bony edges is paramount and facilitates surgeon orientation, particularly in revision cases where the anatomy may be distorted. Laminectomy is performed with a combination of Leksell bone nibblers, high-speed drill, and Kerrison punches. There is usually a deficiency in the midline where ligamentum flavum attaches to the undersurface of the lamina, where epidural fat is encountered, heralding entrance into the spinal canal. The thinner the bone is egg-shelled, the easier it is to enter the

canal with rongeurs. Significant dural adhesions may be encountered, especially in revision cases, which require careful separation with blunt dissectors such as curettes. Not all epidural adhesions or scar tissue require excision, provided the necessary neural elements have been detethered and decompressed.

Facetectomy

Following laminectomy, attention is turned to the facetectomy. The inferior articular process (IAP) is disarticulated by drilling or osteotomizing across the pars interarticularis, allowing it to be removed en bloc and saved as graft. Care must be taken to avoid violating the superior pedicle. The naked articular surface of the superior articular process (SAP) is then exposed. The SAP can be similarly removed en bloc by first palpating the superior border of the inferior pedicle with a blunt dissecting instrument such as the Woodson elevator. This defines the inferior limit of drilling or osteotomy (Fig. 1). The pars artery (Macnab and Dall 1971) is often encountered during these maneuvers and must be secured for hemostasis. In excising both the IAP and SAP en bloc, it is important that bony leverage occurs in the upward direction to avoid neural injury. Alternatively, Kerrison punches can be used to skeletonize the medial and superior borders of the inferior pedicle until sufficient space is created for interbody insertion. Care is taken superiorly and laterally in the foramen to avoid injury to the exiting nerve root. Foraminal ligament can be preserved as a protective barrier over the exiting nerve root if satisfactory direct and indirect decompression has otherwise been achieved.

Interbody

The epidural veins are cauterized with the bipolar tips parallel to the traversing nerve root to avoid inadvertent thermal injury, and divided to avoid neural traction. In cases where the disc is severely collapsed, it may be difficult to gain entrance into the disc space with traditional interbody instruments. It may be effective in these situations to enter the space with a smaller blunt tipped instrument, such as a pedicle probe, under lateral fluoroscopic guidance. Gradual distraction can then be achieved by sequentially upsizing spacers placed contralateral to the side that discectomy and endplate preparation is occurring if bilateral interbody devices are planned. Alternatively, laminar spreaders or ones anchored to pedicle screw heads can be used. Aggressive distraction must be avoided in the latter instance to avoid pedicular fracture, particularly in patients with osteoporosis.

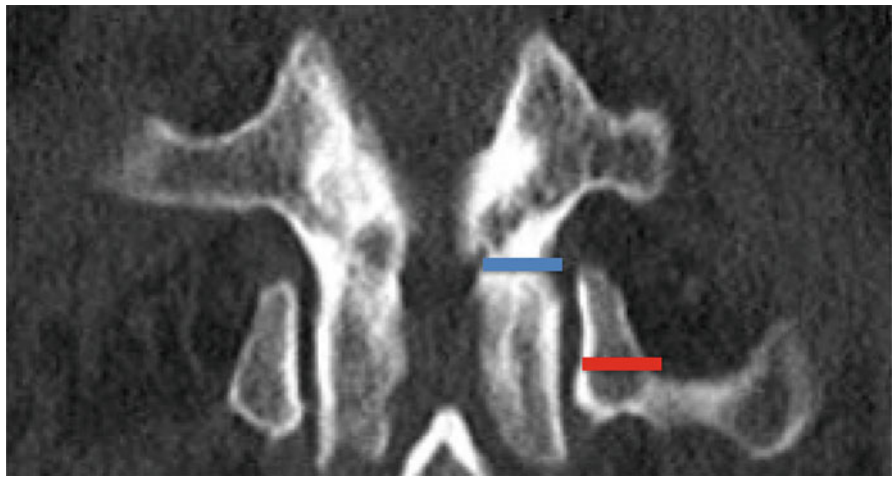

Fig. 1 Coronal lumbar spine computed tomography (CT) demonstrating the relationship of the IAP and SAP. The osteotomies performed are indicated by the blue (IAP) and red (SAP) lines, taking care not to violate the cranial and caudal pedicles

Similarly, care must be taken to avoid violating the bony endplate with forceful use of oversized shavers. The final implant is then inserted and impacted as ventrally as possible to take advantage of the strong apophyseal ring as well as maximize segmental lordosis. However, care must be taken to avoid breaching the anterior longitudinal ligament, as ventrally displaced cages are notoriously difficult to retrieve (Murase et al. 2017). Autogenous bone, supplemental allograft and BMP, if necessary, is packed into the disc space to enhance fusion (ventral to the implant in the case of BMP to prevent predural seroma and radiculitis), as implants themselves often contain very little space to accommodate graft. Traditionally, polyetheretherketone (PEEK) cages have been used, although titanium technologies are gaining popularity due to their osteo-integrative potential (Rao et al. 2014), at the cost of possibly increased risk of subsidence due to higher modulus of elasticity (Seaman et al. 2017), radio-opacity, and difficulties visualizing fusion mass. Insert and rotate devices (Sears 2005), as well as expandable cages (Fig. 2), offer further options in disc height and segmental lordosis restoration (Boktor et al. 2018). Autologous iliac crest bone graft, the gold standard to which other interbody devices and biologics have historically been compared, has been used with decreasing frequency due to the morbidity associated with its procurement (Banwart et al. 1995).

Pedicle Screw Placement

There are several methods for placing pedicle screws, including free hand and fluoroscopic techniques. Advances in navigation and robotics have improved placement accuracy (Kosmopoulos and Schizas 2007). We do not routinely use neuromonitoring due to its expense, lack of availability at our institution, and lack of substantive evidence demonstrating efficacy in preventing neurological harm outside of deformity, lateral transpsoas, and intramedullary tumor surgery (Fehlings et al. 2010). The safety of the freehand method is enhanced by intimate understanding of anatomy, visualization and palpation of the pedicular walls, tactile feedback, and subtle adjustments made based on detailed study of

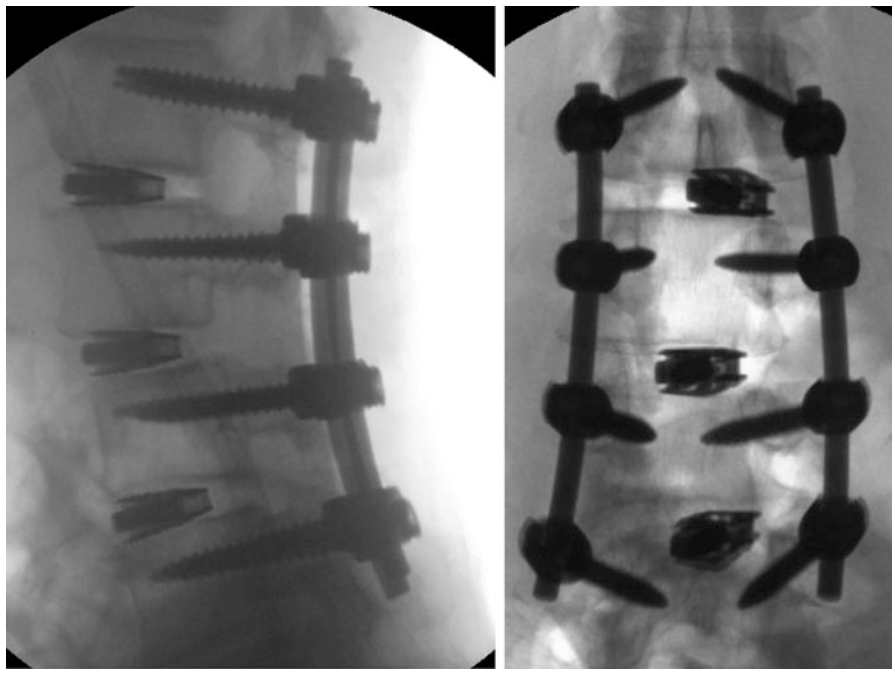

Fig. 2 Intraoperative lateral and AP x-rays demonstrating open L2–5 pedicle screw fixation and interbody fusion with expandable cages to restore foraminal height as well as segmental lordosis

preoperative imaging. Aiming perpendicularly toward the floor in the craniocaudal plane at L4 and adding approximately 5° of medialization per level to a baseline of 10° at L1 serve as useful additional guides.

The entry point is at the junction between the SAP and the bisected transverse process, where the mammillary process may be visualized (Fig. 3). To identify the entry point, it is often necessary to remove the lateral overhang of hypertrophic facets. This also serves to create sufficient room to house the head of the screw. Entry points can be customized to facilitate easier rod passage, particularly if multiple levels are instrumented. Furthermore, the trajectory of open pedicle screws is usually less medialized than their percutaneous counterparts due to the significantly increased amount of tissue dissection necessary in order to achieve a sufficiently lateral starting point, and the hindrance of both paraspinal musculature and retractors to medialization.

In probing the pedicle, tactile feedback is provided by the crunchiness of cancellous bone (in contrast to the hardness of cortical bone), and visual feedback by the marrow blush of the cancellous bone. It is critical that the screw goes down the same tapped hole, and can be aided by marking the trajectory on the skin edge, and to avoid forcefully tightening the screw against the facet, losing its poly-axiality and potentially stripping the screw. Screw symmetry can be achieved by leaving the handle on the contralateral screw as a guide or using fluoroscopic control. Pull-out strength is improved by using the longest screw possible with the widest diameter and augmenting with cement in osteoporotic patients. Given the largely cancellous nature of S1, it may be desirable to achieve bicortical purchase through the sacral promontory (the most corticated part of the vertebra) at this level. Compression and reduction are achieved against a final tightened screw if necessary, aided by extension tabs on the screw head, lordotically contoured rods, and cantilever maneuvers, although a significant degree of reduction is often already accomplished through the interbody work.

One must also be adept at managing breaches of the pedicular wall. While medial and inferior breaches have classically been associated with injury to the traversing and exiting nerve roots, respectively, lateral breaches can be equally undesirable, with potential injury to the adjacent intrapsoas lumbar plexus, as well as lumbosacral trunk at the caudalmost levels. While existing pilot holes can sometimes be rescued by redirecting the pedicle probe, including using ones with curved tips, it is often easier to fashion

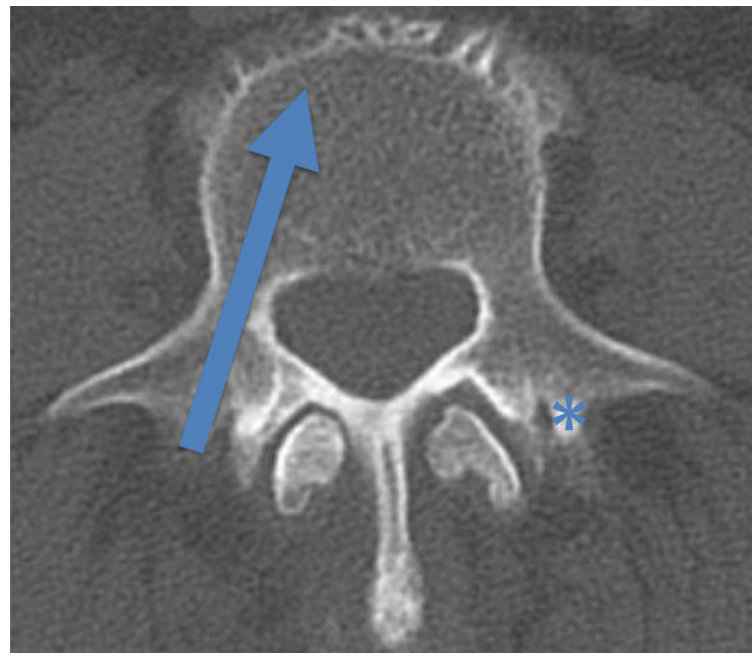

Fig. 3 Axial CT demonstrating the typical latero-medial trajectory of a lumbar pedicle screw (asterisk represents the mammillary process, an ideal entry point)

new entry points in order to avoid existing tracts. Careful examination of preoperative imaging can aide in preventing pedicular breach, including accounting for rotational deformities, as well as accounting for narrow, dysmorphic, or sclerotic pedicles, particularly on the concavity of a scoliotic curve in the latter.

Selected Variations in Open Lumbar Fusion

Posterolateral Fusion

We place interbody grafts routinely due to the aforementioned benefits. However, there may be clinical scenarios such as significant disc space collapse, weakened osteoporotic endplates, or minimal neuro-foraminal stenosis, in which interbody fusion may be difficult, inappropriate, or unnecessary. In these cases, posterolateral fusion serves as a reasonable alternative. Equally, posterolateral fusion may serve as a useful adjunct to interbody fusion in patients at risk for nonunion and in revision cases for pseudoarthrosis. It is critical that meticulous decortication of the transverse processes down to bleeding cancellous bone is performed to create an ideal fusion environment, a process that is often neglected. The remaining facet joint may also be decorticated. A cottonoid may be temporarily placed over the thecal sac as a barrier against bone graft inadvertently placed epidurally, preventing iatrogenic stenosis.

Pedicle Screws Via a Wiltse Approach

One of the criticisms of open pedicle screws is the difficulty in achieving the desired medialization due to hindrance by paraspinal muscles and retractors. Idealized exposures often require extensive lateral dissection and lengthy incisions. To mitigate this, bilateral incisions can be made in the lumbodorsal fascia through a single midline skin incision. Dissection is then carried down between the multifidus and longissimus muscles, often through a natural avascular cleavage plane, landing directly onto the junction between the facet joint and transverse process (Wiltse et al. 1968). This plane between the two muscles is measurable from the midline on preoperative imaging (Fig. 4), and often palpable and visible

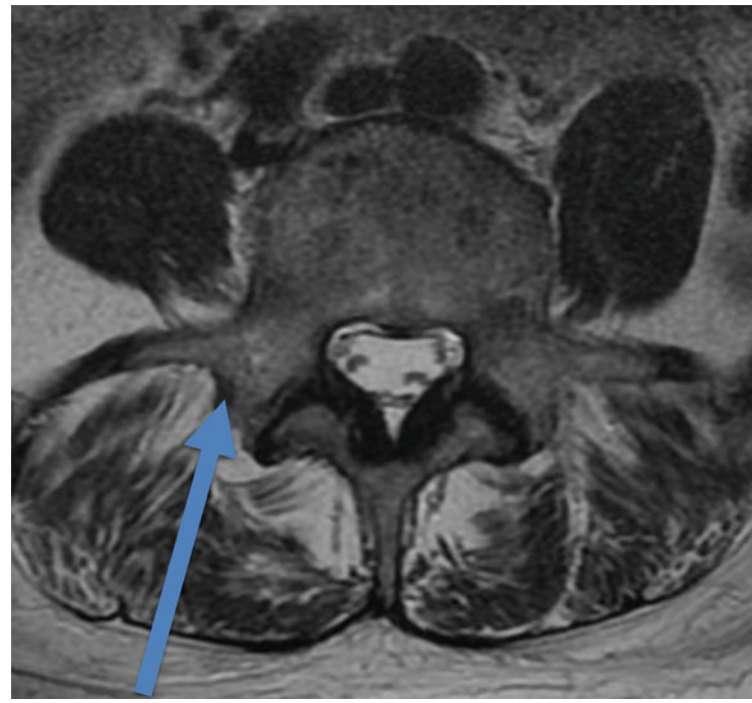

Fig. 4 Axial T2-weighted magnetic resonance imaging (MRI) illustrating the Wiltse paraspinal plane between medial multifidus and lateral longissimus, with a muscle-sparing approach (arrow) landing directly onto the facet-transverse process junction

intraoperatively. Pedicle screw insertion then proceeds in the aforementioned fashion. However, the extensive suprafascial undermining required creates significant dead space, which must be obliterated to prevent postoperative seroma and potential infection.

Cortical Bone Trajectory Screws

Some of the other criticisms of the open approach to pedicle screw placement are the amount of lateral muscular dissection required and the propensity to violate the facet capsule at the upper-instrumented level, thus potentially accelerating adjacent segment degeneration (Sakaura et al. 2019). Furthermore, pedicle screws reside mostly in cancellous bone, which is significantly weaker than cortical bone, an issue accentuated in osteoporotic patients. Within the last decade, a medial to lateral and inferior to superior screw trajectory has been proposed to address these issues, including maximizing purchase into cortical bone (Santoni et al. 2009). The entry point is in the pars, and the upward and outward trajectory is analogous to lateral mass screws in the cervical spine (Fig. 5). The poorer definition on fluoroscopy of the pars on fluoroscopy and the lack of tactile feedback due to the cortical nature of the traversed bone can be mitigated by use of intraoperative navigation. The spinous process navigation clamp, if used, should be placed at the cranial end of the exposure (rather than caudal end in navigated pedicle screws) to ensure that it remains between the surgeon and navigation camera, as well as maximizing the amount of

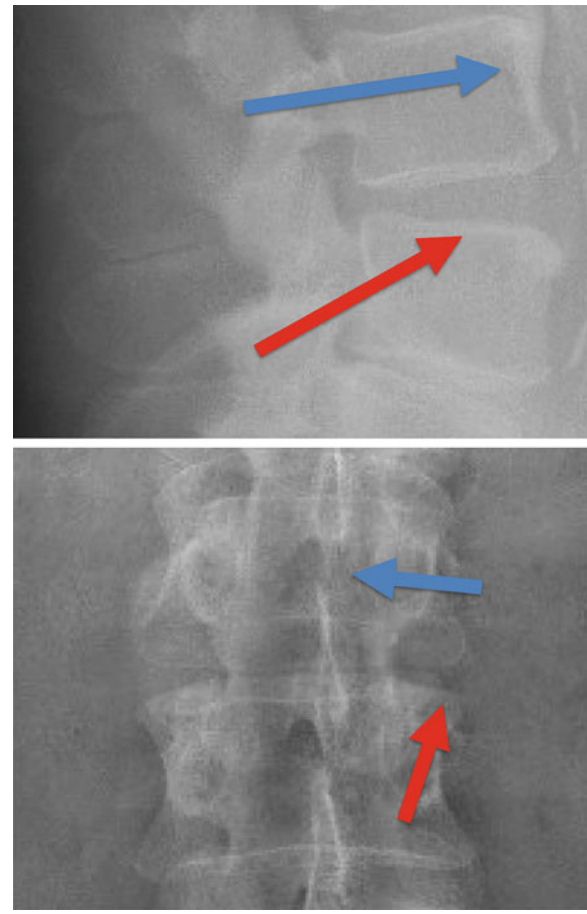

Fig. 5 Lateral and AP radiographs contrasting the latero-medial trajectory of traditional pedicle screws (blue arrows) versus the infero-superior and medio-lateral trajectories of CBT screws (red arrows)

working space given the caudo-cranial trajectory of these screws. The diameter and length of cortical bone trajectory (CBT) screws are typically narrower and shorter. While laboratory studies have demonstrated comparable biomechanical strength and some evidence exists to support similar short-term clinical and radiographic outcomes compared to traditional pedicle screws, long-term follow-up data remains pending (Phan et al. 2015b). The CBT screw certainly represents a less invasive open alternative to traditional pedicle screws, with a potential specific role in osteoporotic patients, although its efficacy in multilevel constructs, high-grade spondylolistheses, and deformity remains unknown.

Hybrid Percutaneous Screws with Miniopen Interbody

A minimally invasive variation on the traditional open PLIF combines percutaneous pedicle screw fixation, described later, with a miniopen midline incision for laminectomy and interbody work (Mobbs et al. 2012). This reduces the amount of lateral muscular dissection required and shortens the midline incision. In these hybrid cases, we prefer transversely oriented stab incisions for pedicle screw placement to longitudinal ones to minimize devascularization of overlying skin and soft tissues. A further variation involves paramedian stab incisions in the fascia through a single midline incision to avoid multiple unsightly skin incisions. The same percutaneous instrumentation can then be used through the fascial incisions. However, this often necessitates a longer incision, such as a traditional open approach, as well as extensive undermining of the skin alluded to previously.

Minimally Invasive Lumbar Fusion

An MISS TLIF is the archetypal MISS fusion procedure. It is often synonymous with tubular retractors and percutaneous pedicle screws, (Foley et al. 2003) although several variations exist. We prefer the miniopen paramedian Wiltse approach on the side of interbody, dissecting between the multifidus and longissimus muscles as this represents a natural cleavage plane, landing the surgeon directly onto the junction between the SAP and transverse process. Critics of the unilateral transforaminal approach cite poor disc clearance and endplate preparation for fusion, comparative biomechanical weakness in lateral bending compared to bilateral PLIF constructs (Sim et al. 2010), and inability to induce significant segmental lordosis (Carlson et al. 2019) as justification against minimally invasive TLIF. However, in cases of immobile facets, or where significant segmental lordosis induction (Jagannathan et al. 2009) or spondylolisthesis reduction is desirable, we often perform bilateral facetectomies for complete segmental mobilization through short bilateral paramedian incisions and muscle splitting Wiltse approaches. Expandable cages can further facilitate induction of segmental lordosis without compromising disc and foraminal height. Percutaneous pedicle screws are inserted through the Wiltse incision on the side of the interbody and small contralateral stab incisions. The MISS transforaminal approach also naturally lends itself to revision cases where florid epidural scar makes reapproaching through the midline technically challenging and potentially hazardous, with heightened risks of durotomy and cerebrospinal fluid leak.

Fluoroscopy Nuances

Once the patient is positioned, prepped, and draped, the C-arm is positioned in the anteroposterior (AP) plane. Kirschner wires are used to identify the desired level, as well as mark out the lateral border of the pedicle in the vertical plane and the bisected pedicle in the transverse plane. It is imperative that a true AP image of the desired vertebra is obtained, with a clearly defined superior endplate without any elliptical shadow, and midline spinous processes (Fig. 6). The C-arm should be locked in this position and any adjustments from the orthogonal plane recorded to ensure ease of return to the same desired position.

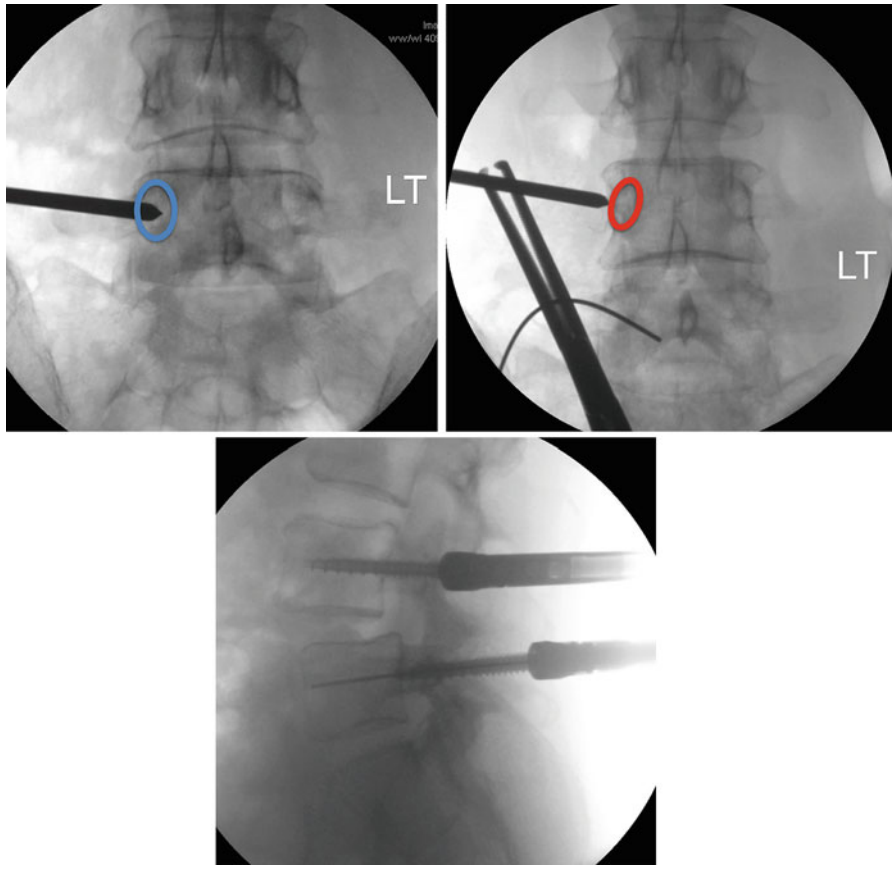

Fig. 6 True AP fluoroscopy with crisp L5 superior endplate (top image) and midline spinous process, demonstrating passage of Jamshidi needle and K-wire through the right L5 pedicle (blue circle, top image), followed by L4 (red circle, middle image), starting at 9 o'clock. At an approximate depth of 2 cm (usually heralding the junction between pedicle and vertebral body), the tip of the needle should not transgress the medial border of the pedicle. Screws are subsequently placed under lateral fluoroscopy (bottom images)

The importance of having a skilled radiographer experienced in the percutaneous workflow cannot be overemphasized. Draping of the C-arm and absolute attention to sterility are also of paramount importance, as any adjustments to the C-arm, particularly switching between AP and lateral views, can desterilize the drape and endanger the operative field.

Jamshidi Needle Advancement

Stab incisions are made approximately 1–2 cm lateral to the outer border of the pedicle, depending on the body habitus of the patient and the depth of intervening soft tissue. The bull's eye technique is used for pedicle cannulation (Fig. 6). The Jamshidi needle is docked at the junction of the SAP and the transverse process. It is often useful to walk the tip of the needle along the superior and inferior borders of the transverse process and the lateral wall of the facet joint for secondary anatomical confirmation. Close examination of preoperative imaging is crucial, as a severely hypertrophied facet joint can significantly alter the desired entry point as well as increase the depth the Jamshidi needle needs to be advanced in order to traverse the pedicle, traditionally considered to be 2 cm in patients without distorted anatomy. Failure to account for this

can lead to complications, including medial pedicular breach, and injury to the traversing nerve root and common thecal sac. The craniocaudal trajectory of the Jamshidi needle should match the degree of tilt or Ferguson on the C-arm.

While fluoroscopic control is critical, a degree of both tactile and aural feedback, similar to traditional open pedicle screw probing, remains possible and serves as secondary confirmation. Tactilely, advancement through crunchy cancellous bone should be relatively unhindered. Resistance often heralds proximity to cortical bone and forewarns against imminent pedicular breach. Similarly, the sound the Jamshidi needle makes against cortical bone when using the mallet is usually lower in frequency and duller in quality. There is often a small amount of toggle within the cancellous part of the pedicle to allow subtle redirections of the Jamshidi needle. Excessive force should, however, be avoided as the needle may bend, making passage of the Kirschner wire and subsequent needle removal from the vertebra difficult. It is critical to be constantly cognizant and wary of the length of the needle that has been advanced. Sclerotic pedicles pose a specific challenge to Jamshidi needle advancement and may necessitate gentle coring out of the pedicle with a high-speed drill to facilitate Kirschner wire passage, both carefully performed under fluoroscopic control but nonetheless often still achievable percutaneously.

Kirshner Wire Management and Screw Placement

The Kirschner wire can often be manually advanced up to 1 cm further into the cancellous bone through the Jamshidi needle without need for the mallet. Tip position within the vertebral body is confirmed if a bottom is palpable, analogous to using the ball tip feeler in open cases. At all stages, including Jamshidi needle removal, tissue dilation, tapping, and screw insertion, care must be taken to avoid inadvertent loss of wire position, including pullout or advancement, and undue twisting and bending. This is achieved both manually with judicious control with the noninstrumenting hand as well as constant attention to fluoroscopy.

Pedicle screws are inserted down the Kirschner wire through the tapped hole under lateral fluoroscopy (Fig. 6). When advancing the pedicle screw, resistance is met once the screw head meets the facet capsule. Further forceful advancement may cause stripping of the screw and loss of poly-axiality of its head. Systems incorporating a sharp-tipped stylet into a self-tapping screw now exist and further streamline the percutaneous workflow (Huang et al. 2020), although possibly at the cost of reduced tactile feedback. Navigation and robotic technologies that marry percutaneous pedicle screw systems also exist, reducing radiation exposure for the surgeon and other operating room staff, while maintaining high rates of placement accuracy (Kochanski et al. 2019).

Interbody

Once the contralateral pedicle screws and ipsilateral Kirschner wires have been placed, the ipsilateral skin and fascial incision are connected, and the facet landed upon by dissecting down through the natural cleavage plane between multifidus and longissimus. This is often accomplishable by spreading the tips of the bipolar forceps, coagulation and division of any small bridging fibers, and gradual retractor advancement. Blunt finger dissection is also often effective. Upon landing on the facet joint, we use a bladed retractor system such as the McCullough, with the short blade medial and long lateral, to maintain exposure. Kirschner wires can often be engaged into the teeth of the retractor blades and kept out of instruments' way. Further medial dissection with electrocautery is carried out, partially exposing the lamina. The steps that follow are like the interbody portion of the open approach detailed earlier, performed either under loupe magnification and headlight illumination, or microscopic visualization. A laminotomy is performed, followed by facetectomy, discectomy, and endplate preparation. Disc removal and fusion bed preparation can be optimized by gradual medialization of interbody instruments and

deployment of forward angled rongeurs. Distraction on the contralateral screws can be performed if necessary, to facilitate entrance into the disc space and maintenance of working corridor. Several interbody options exist, including banana-shaped devices, initially inserted vertically then gradually horizontalized to optimize ventral and medial positioning, maximizing cortical apophyseal ring contact, and potentially inducing lordosis, as well as bulleted and the expandable technologies previously described.

Rod Passage

After interbody and once the pedicle screws have been inserted bilaterally, attention is turned to rod placement. The incision through which the rod is placed may need to be extended to facilitate passage to avoid excessive skin tension. The tip of the rod is inserted initially vertically to engage the screw head and then advanced through each successive tower. This not only ensures subfascial placement, but also minimizes the amount of paraspinal muscle captured, preventing possible compartment syndrome. The rod is maneuvered with subtle movements to engage each tower, including medially or laterally rotating the rod holder. Screw engagement is confirmed if the overlying tower no longer rotates, by dropping a specialized measuring tool down the tower, by direct visualization, or by fluoroscopy. Placing the set screw into the tulip closest to the rod holder first brings the rod beyond the screw head, ensuring sufficient rod proximally. Reduction can be achieved through a variety of means, including rod contouring, extension, and cantilever maneuvers, as well as specialized reduction tools.

Selected Variations in Minimally Invasive Lumbar Fusion

Tubular Retractors

Traditionally, MIS lumbar fusions have been associated with the tubular retractor (Foley and Smith 1997). This requires gradual dilation through the paraspinal musculature and docking of the final tube on the facet joint prior to securement onto a table-mounted arm. Despite gradual dilation, a small amount of muscle is invariably encountered at the depth of the retractor, which then requires excision for exposure. If the tubular system is used, we advise against the use of the initial Kirschner wire due to the risk of inadvertent dural puncture and neural injury. The retractor should be docked onto the facet joint with sufficient exposure of the adjacent lamina, and ideally orthogonal to both the desired disc space as well as the floor to optimize disc access and surgical ergonomics. Given the narrow working corridor, specialized angled and bayonetted instruments are necessary. Similarly, the protected portion of the conventionally straight monopolar tip can be manually bent to facilitate use. Various other retractor systems, including bladed and screw-based assemblies, are also available.

Cross over the Top Decompression for Bilateral Stenosis

If decompression of the contralateral subarticular zone is desired, the retractor can be wanded medially (Fig. 7) or the bed rotated to facilitate over-the-top decompression. In this method, also known as unilateral laminotomy for bilateral decompression (ULBD) or ipsilateral-contralateral approach, the ligamentum is left intact while the base of the spinous process and under surface of the contralateral lamina are drilled to protect the underlying dura. Flavum and contralateral medial facet can subsequently be removed till the hump of the thecal sac drops away and the contralateral traversing nerve root visualized. The dura is at greatest risk of injury when rongeuring medially due to the upward slope of the thecal sac, though the risk of overt cerebrospinal fluid leak is low as the paraspinal muscles remain largely intact and reapproximate following retractor removal, obliterating any dead space. Use of upward angled Kerrison punches can also be useful in this approach to achieve contralateral decompression. The results of this approach are comparable to the traditional midline laminectomy, while largely

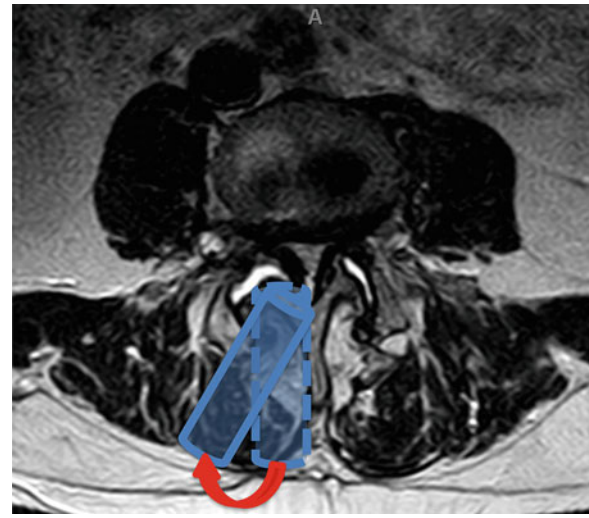

Fig. 7 Axial MRI simulating wanding (red arrow) of the tubular retractor (blue cylinders) to facilitate decompression of the contralateral lateral recess from a unilateral approach

preserving the posterior tension band (Mobbs et al. 2014).

Endoscopy

More recently, endoscopic techniques have been applied to minimally invasive TLIFs, permitting even smaller incisions and less tissue destruction. This has been combined with awake anesthetic techniques, application of long-acting liposomal local anesthetic agents, expandable technologies, biologic materials, and ERAS protocols to treat a range of lumbar spondylotic conditions (Kolcun et al. 2019). The intervertebral disc is accessed via percutaneous transforaminal route through Kambin's triangle using a spinal needle, followed by nitinol wire insertion and sequential dilation and docking of an endoscopic channel, all under constant fluoroscopic control (Fig. 8). Discectomy and endplate preparation are accomplished using specialized endoscopic rongeurs and curettes, and percutaneous reamers, shavers, and stainless-steel brushes, followed by sizing and insertion of an expandable interbody device. The procedure is completed by standard insertion of percutaneous pedicle screws. While long-term and comparative data are eagerly awaited, this technique, representing the least anatomically and physiologically disruptive of all MIS fusion methods, holds promise for elderly and infirm patients who may not otherwise tolerate lengthy prone general anaesthetics (Kolcun et al. 2019).

Thoracic Instrumentation and Selected Variations

A comprehensive description of the multitude of approaches to the thoracic spine is beyond the scope of this chapter. We will, however, endeavor to describe the various options for posterior thoracic instrumentation, both open and minimally invasive. MIS thoracic instrumentation naturally lends itself to scenarios in which direct decompression or fusion is unnecessary, such as burst fractures in patients without neurological compromise, while traditional open methods remain valid, particularly if concomitant direct decompression, fusion, or anterior column reconstruction is required, such as in oncologic pathologies.

The traditional entry point for thoracic pedicle screws is immediately inferior to the intersection between the superior border of the transverse process and the lateral border of the SAP, classically

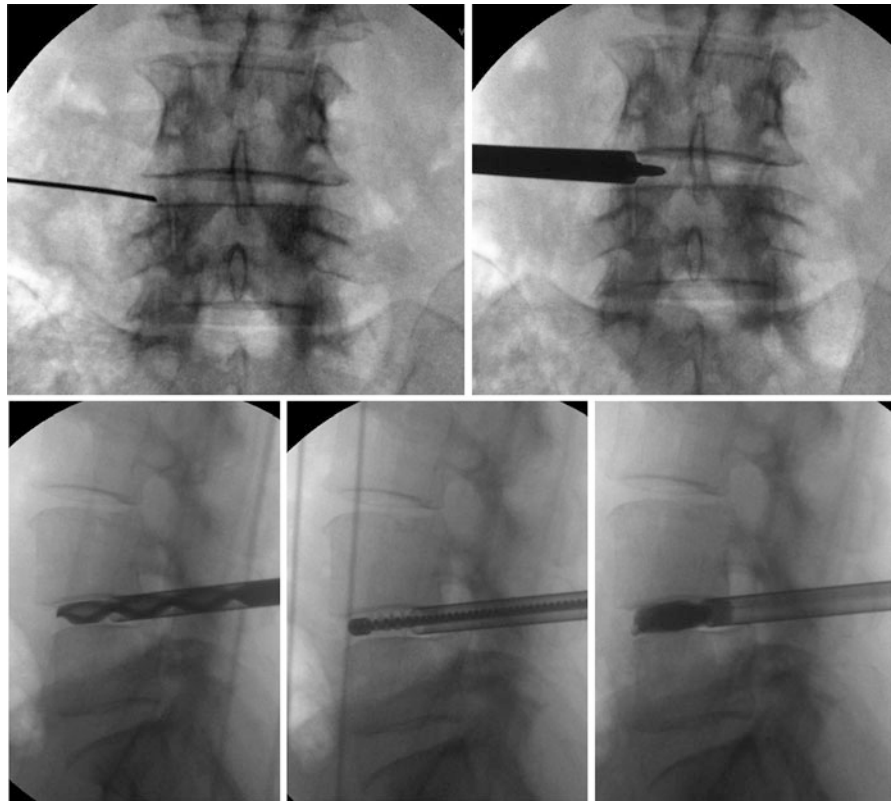

Fig. 8 Intraoperative fluoroscopy demonstrating transforaminal entrance into the L4–5 intervertebral space via Kambin's triangle using a spinal needle (**a**), followed by sequential dilation (**b**), introduction of percutaneous reamer and stainless steel brush (**c** and **d**), and measurement of extent of discectomy and sizing of interbody graft size by inflation of a balloon with radio-opaque contrast (**e**)

described as the junction between the medial two-thirds and lateral one-third of the base of the SAP (Fig. 9) (Chung et al. 2008). The ideal entry point moves slightly laterally and inferiorly as one progresses toward the cranial and caudal ends of the thoracic spine (Kim et al. 2004). Adjustments to the entry point in the axial plane can also be made based on the patient's unique anatomy on preoperative CT. Furthermore, bleeding cancellous pedicular bone can often be exposed by removing the tip of the transverse process, particularly at T12 (Fig. 10). Medialization increases at the superior-most segments of the thoracic spine, while both straight forward and the more caudally directed anatomical trajectories (Fig. 9) in the sagittal plane are acceptable (Puvanesarajah et al. 2014). The in-out-in technique (Fig. 9) with a more lateral entry point along the superior edge of the transverse process to minimize risk of medial breach has also been advocated and may be especially useful in patients with narrow pedicles, particularly in the mid-thoracic spine, enabling the insertion of wider and longer screws with tri-cortical purchase (Jeswani et al. 2014).

Percutaneous thoracic pedicle screw insertion follows the same principles described previously for the lumbar spine. We adopt a strategy of erring on the side of less medialization of the Jamshidi until the pedicle-vertebral body junction is reached to minimize risk of medial breach, followed by subtle toggling of the needle to

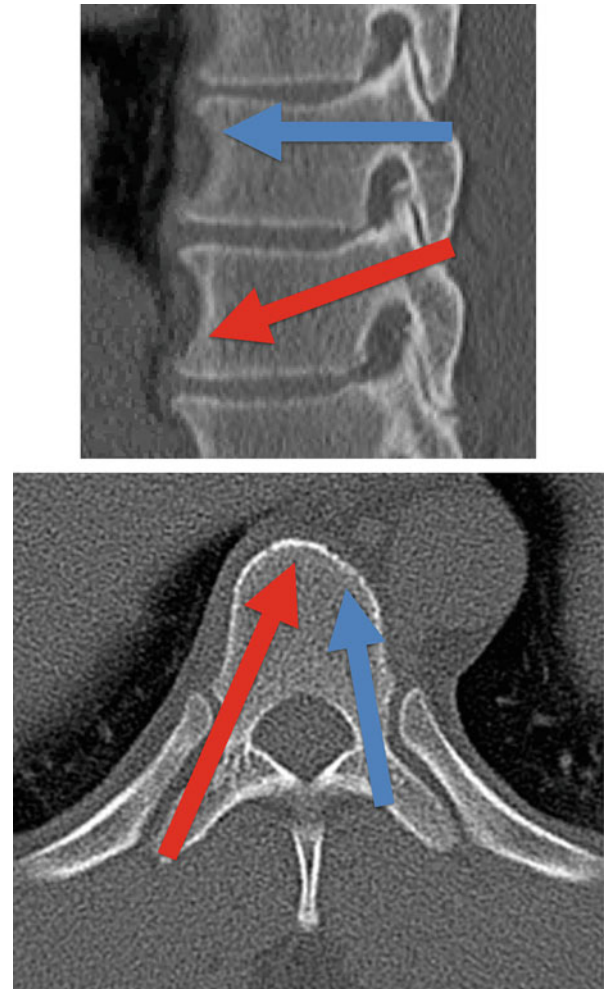

Fig. 9 CT comparing the straight forward (blue arrow) trajectory, parallel to the endplates, with anatomical (red arrow), parallel with the superior and inferior pedicular borders, in the sagittal plane (top image), and traditional intrapedicular (blue arrow) and in-out-in (red arrow) techniques in the axial plane (bottom image)

achieve more medialization to ensure that it remains within the vertebral body. Navigation and robotics may also improve accuracy of thoracic pedicle screw insertion, both open and percutaneous, especially in cases with narrow pedicles or significant deformity (Kochanski et al. 2019).

Conclusion

In summary, the posterior approach to the thoracolumbar spine is a versatile workhorse for the spine surgeon, affording access to all three columns of the spine and enabling the trinity of decompression, instrumentation, and interbody through a single approach. Both open and minimally invasive approaches present valid options, and the modern spine surgeon should be adept at both in order to cater to the needs of different patient populations with contrasting pathologies. Advances in navigation and robotics, biologics, access, instrumentation, and expandable technologies have improved the safety and efficacy of minimally invasive thoracolumbar fusions. These advances, coupled with progress in perioperative protocols and multidisciplinary care, will continue to deliver improvements in posterior thoracolumbar surgery.

Lateral Approach to the Thoracolumbar Junction: Open and MIS Techniques

58

Mario G. T. Zotti, Laurence P. McEntee, John Ferguson, and Matthew N. Scott-Young

Contents

Abstract

The thoracolumbar junction is a site less commonly affected by degenerative disease but disproportionately affected by unstable spinal pathologies such as fractures, infections, and neoplasms. Varying approaches for the treatment of these pathologies have been historically described, but there has been a shift toward more pathology being treated by minimally invasive approaches. While a working knowledge of the open approach and its advantages and disadvantages is important, the MIS approach is favored where feasible due to being less disruptive with reduced cardiovascular, respiratory, muscular, and cosmetic morbidity. The unique anatomy of the thoracolumbar junction is discussed with respect to the separation of and structures relevant to the abdominal and thoracic cavities. Evaluation of and preparation for surgery

Thoracolumbar junction · High lumbar · Lower thoracic · Lateral approach · Lateral interbody fusion · Minimally invasive (MIS) · Open

Introduction

The thoracolumbar junction (TLJ) is a transitional zone between the rigid thoracic spine and relatively mobile lumbar spine, making it a common site for spinal fractures, as well as being afflicted by other diseases including infectious, neoplastic, and degenerative lesions. With the advent of modern instrumentation, pathology and deformity involving the thoracic spine are being increasingly treated via posterior techniques in isolation. However, the sensitivity of the spinal cord to any manipulation, high rates of durotomy, and the limited access afforded by other posterior-based approaches such as costotransversectomy limit the safe and complete treatment of anterior column-based pathology with posterior approaches (Arnold et al. 2012; Malham and Parker 2015). Concurrently, there has been a significant advancement of surgical approaches and techniques to approach the thoracolumbar and lower thoracic vertebrae safely causing a paradigm shift from open thoracotomy-based techniques to thoracoscopic and lateral minimally invasive surgery (MIS) exposures. This development has led to expanding indications for the lateral and anterolateral approaches to treating pathology of the thoracolumbar region such as disc herniation, vertebral body/pedicle tumor, and infection as well as allowing efficient and safe intervertebral space access for interbody anterior column support.

Patient Presentation

Pathology of the TLJ such as tumor, trauma, and infection of the thoracolumbar anterior column will generally present with significant pain with or without radiculopathy or myelopathy. Trauma or systemic malaise in these cases will cause the patient to present for medical investigation where further imaging may reveal a TLJ lesion. Deformity, where utilization of the anterior column of the TLJ may form part of the surgical strategy, may include coronal or sagittal plane deformities and may be idiopathic or syndromic in nature. While many of these deformities will present in childhood, there is an increasing burden of ageing patients presenting for treatment with de novo deformities in middle age and beyond due to pain or deformity.

The degenerate or herniated thoracic disc presents variably. While many thoracic disc lesions are asymptomatic, significantly symptomatic thoracic herniations account for around 1% of disc-related presentations. Anand and Regan (2002) developed a classification system for different presentations of symptomatic thoracic disc herniations and their outcome. These include presentations of axial pain only (28%), thoracic radicular only (5%), axial pain and thoracic radiculopathy (38%), axial pain and lower leg pain (19%), myelopathy (8%), and paralysis (2%). Unlike symptomatic lumbar disc disruption, symptomatic thoracic disc disruption does not tend to respond favorably to nonsurgical measures, and surgery is generally recommended. Arce and Dohrmann (1985) in their series of 280 thoracic discs found that 75% are in the lower thoracic segments (T8–T12).

Indications and Comparison of Approaches

Indications for thoracolumbar spinal surgery include treatment of anterior- and middle column-based tumors or infections (Kawahara et al. 1997; Uribe et al. 2010; Pimenta 2015), as an adjunct in a deformity correction strategy for short segment fusion of focal coronal malalignment

or focal kyphosis (usually with posterior instrumentation) (Good et al. 2010; Min et al. 2012), in the trauma setting for vertebrectomy of burst fractures, and treatment of pseudarthrosis and degenerative lesions. Regarding the latter, disc pathology either herniated nucleus pulposus causing ventral cord compression or significant degenerative disc disease can be treated with microdiscectomy or interbody fusion, respectively. While microdiscectomy has been published with favorable results (Malone and Ogden 2013; Nacar et al. 2013; Oskouian et al. 2002; Otani et al. 1982; Berjano et al. 2014; Roelz et al. 2016), the desire to avoid further approach involving the pleura for the patient in the form of a revision fusion has led some authors to advocate for primary fusion, with satisfactory results (Berjano et al. 2012, 2015; Malham and Parker 2015; Meredith et al. 2013). Posterior-based approaches can be considered for dorsal cord compression, but treatment of anterior-based pathology from a posterior-only approach historically yielded unsatisfactory results, and an example of this is shown in Fig. 1 (Love and Kiefer 1950; Logue 1952; Benson and Byrnes 1975; Perot and Munro 1969).

Complications, regardless of mode of approach, remain significant and include pleural effusion, pneumothorax, intercostal neuralgia, vascular injury, pain associated with chest tube (if required), and diaphragmatic paresis or herniations (if affected) (Boriani et al. 2010). Open procedures, despite being considered "gold standard," were particularly affected by intercostal neuralgia and incisional pain and required a thoracic access surgeon. Open approaches have more classically been either the transthoracic retroperitoneal or lateral retropleural approaches and, more recently, a lateral extensile extracavitary approach. There is significant patient discomfort and pulmonary complications that stem from need for resection of a rib, deflation of ipsilateral lung, and insertion of a chest tube which can all contribute to postoperative pain, atelectasis, and pneumonia (see Fig. 2). Thoracotomy-associated major complications occur in 11% to 11.5% of patients, tend to extend hospitalizations, and augment medical resource use (Faciszewski et al. 1995).

Treatment of thoracolumbar lesions that was once marked by significant morbidity and patient risk that resulted from traditional open techniques has become feasible and technically simpler due

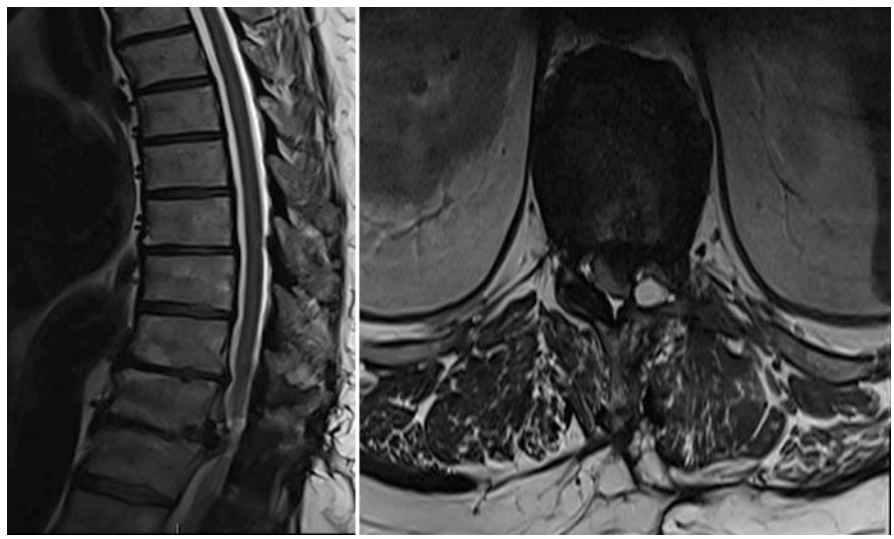

Fig. 1 Ventral cord compression from T11/12 degenerative disc-osteophyte complex causing clinical myelopathy. Posterior decompression failed to improve the patient's symptoms and residual compression and cord signal change is demonstrated

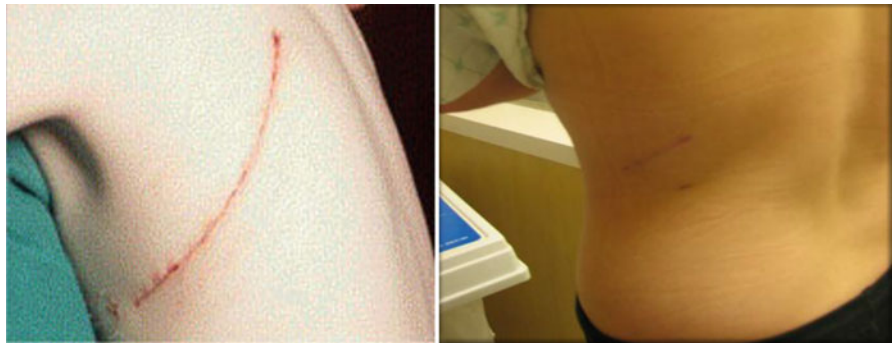

Fig. 2 Significant scar and morbidity from traditional open transthoracic approaches to the thoracic spine (left); MIS incision required to approach limited TLJ levels (right). (Copyright 2009, used with permission from NuVasive. All rights reserved)

to the evolution of surgical techniques stemming from development of MIS approaches to the thoracic spine (Smith and Fessler 2012). The advantage of thoracoscopic and MIS techniques is that they are minimally disruptive (not usually requiring rib resection), deflation of the lung is not routinely required, and there is minimal blood loss, direct visualization, less risk of aortic injury, and typically no requirement for any chest tube. However, circumstances may dictate that such approaches may not be appropriate for the patient despite indicating pathology, e.g., significant thoracic pulmonary injury and hemothorax involving the operative segments for trauma vertebrectomy or a primary bone tumor in the anterior column necessitation open approach to minimize contamination and safely perform spondylectomy (Gandhoke et al. 2015).

Limitations of the thoracoscopic (also known as video-assisted thoracic surgery (VATS) or thoracic endoscopic) technique include a high learning curve, limited visualization compared to direct stereoscopic assessment, and need for lung deflation. VATS had been first reported in 1993 for spinal disease by Mack et al. (1993) VATS allows a significant reduction in chest wall morbidity related to the traditional thoracotomy (Cunningham et al. 1998; Newton et al. 2003). These included a reduction of the postoperative incisional pain and intercostal neuralgia. While thoracoscopy is capable of producing the same exposure as the transthoracic route without the need for a large incision or rib resection, there is, however, still a significant decrease in vital capacity by up to 30% (Faro et al. 2005). This technique provides a greater access to more vertebral levels through smaller incisions, when compared to transthoracic approach, but still presents some complications, such as intercostal neuralgia (7.7%), symptomatic atelectasis (6.4%), excessive (>2000 cc) intraoperative blood loss (2.5–5.5%), pneumonia (1–3%), wound infections (1–3%), chylothorax (1%), tension pneumothorax, long thoracic nerve injury, and pulmonary embolism (Pimenta Journal of Spine 2015). Although this is an effective technique in specialized practices that have sufficient experience and expertise with this skill set, MIS techniques are technically simpler, without a steep learning curve, and arguably safer for spine surgeons not trained in endoscopic surgery, and, as such, we will focus on open and MIS TLJ approaches.

The MIS approach referred to herein is either a direct or extreme lateral approach depending on the proprietary company and is either in the form of a coelomic (transthoracic) or extracoelomic (retropleural) approach, while the lumbar spine requires a retroperitoneal approach (Uribe et al. 2010). Because this approach remains in the retroperitoneal/retropleural space, it can be performed from the right or left side depending on surgeon preference or location of the pathology without interference by the liver, spleen, or other peritoneal structures and theoretically can access from T4 to L5 blocked superiorly by the axilla and inferiorly by the iliac crest (Malham and Parker

2015). Because the approach remains in the extracoelomic space and the diaphragm is not incised, there is no need for any repair of the diaphragm (Pimenta 2015). The MIS approach also can traverse the diaphragm with care, enabling the surgeon to treat low thoracic and high lumbar levels either side of the TLJ by coming from pleural to retroperitoneal through a diaphragmatic incision. Above T12–L1 there is typically no need for dividing the diaphragm. Diaphragmatic incisions need to be biased toward the chest wall and periphery to minimize diaphragmatic innervation disruption and enable a tendinous repair, and regarding incisions, there is evidence that incision <4 cm of the diaphragm heal without suture.

With regard to pitfalls and contraindications to the MIS approach, it is important to understand that there is a long working distance in a relatively narrow working space, and as such, the operative tools typically used may not be long enough to perform the procedure in some patients. Further, retropleural and retroperitoneal dissection may not be feasible after a previous ipsilateral thoracotomy or retroperitoneal approach such as patients who have had osteomyelitis of the spine and spinal metastases, where marked paraspinal pleural reactions with adhesive thickening of the parietal pleura and infiltration of the pleura by tumor or inflamed fibrous tissue can occur (Uribe et al. 2010).

Relevant Anatomy of Thoracolumbar Junction

The complex relationship between the diaphragm, ribs, pleura, and peritoneum poses a notable challenge when surgically approaching the lower thoracic and upper lumbar vertebrae (Pimenta 2015), and the relevant structures at risk to be aware of must be studied and anticipated.

The basic path of MIS approaches is through the rib cage laterally onto the targeted disc space. After incision through the skin and fat, the palpable targeted rib is sought and a plane developed above the rib. This is as the intercostal neurovascular bundle lies directly inferior and deep to the rib. One can do a rib osteotomy for access and graft material but places the neurovascular bundle at risk unless it is explicitly protected. The parietal pleura which is the next layer is plastered over the inner surface of the rib-intercostal complex. This must be penetrated, ideally with blunt dissection, prior to entering the chest cavity. The visceral pleura, on the other hand, overlies the lung parenchyma, and a pneumothorax can result with its injury.

The relevant vascular anatomy includes on the right, the vena cava; on the left, the aorta (variable course); and traversing the field, the segmentals. If approaching on the left-hand side levels T8–L1, it is imperative to assess on preoperative imaging and angiogram for a dominant vascular cord supply in the form of the artery of Adamkewicz, as ligation of this segmental vessel unknowingly may disturb region flow to the cord. Left-sided lateral approaches will require ligation of the segmentals at the level of planned treatment and possibly adjacent levels for safety as they come off the left-side positioned aorta and transmit segmental branches posteriorly which will be encountered in cases of vertebrectomy and plate positioning.

The diaphragm is a complex but important three-dimensional dome-shaped structure to understand, particularly if planning TL approaches as it will be in the surgical access path when approaching levels from T10 to L1. Uncontrolled injuries to the diaphragm can lead to atelectasis, reduced vital capacity, and hypoxemia. It has multiple attachments and separates the thoracic from the abdominal cavity between T12 and L1 with a convex superior thoracic floor and concave inferior abdominal roof. The crura extend along the anterolateral vertebral body on each side with the left crus extending to L2 while the right extends to L3. It is innervated central to peripheral (important for incision and dissection planning) with the phrenic nerve supplies entering medially toward the periphery, formed by the C3-4-5 cervical nerves, more prevalent in its central portion (Joaquim et al. 2012). The peripheral portions of the diaphragm have sensorial afferents from the intercostal nerves (T5–11) and the subcostal nerve (T12) (Joaquim et al. 2012).

Regarding the relationship of the diaphragm to the peritoneum, the posterior portion of the diaphragm is separated from the peritoneum by a fat layer and by the superior aspect of the kidneys and adjacent structures. Posteriorly, the diaphragm forms two ligamentous bands, on either side: the medial and lateral arcuate ligament. The former arises from the tip of the 12th rib and expands around the quadratus lumborum, while the latter spans across the psoas muscles. These ligamentous bands meet on the transverse processes of L1. Also to be aware of are diaphragmatic openings which transmit structures. These are the aortic hiatus (containing the aorta, azygos vein, and thoracic duct between the left and the right crura), the esophageal hiatus (containing the esophagus and anterior and posterior vagal trunks), and the caval hiatus (inferior vena cava and branches of the right phrenic nerve) (Joaquim et al. 2012). Other small openings are also present, especially near the crus (containing the splanchnic nerves and the hemiazygos veins).

Regional wall muscles include the latissimus dorsi, intercostal, transversus abdominis, and external and internal oblique muscles as well as the quadratus lumborum. The superficial nerves such as the subcoastal (T12), Iliohypogastric (L1), and ilioinguinal (L1) nerve can run in the field of dissection and the abdominal wall planes after and be injured if any sharp dissection or diathermy is undertaken between the muscular layers. The position and morphology of the psoas muscle should also be considered for high lumbar procedures given that trans-psoas approaches to L1 and L2 still have the potential to injure the upper lumbar plexus. They generally consist of two main portions in their origins: the anterior and lower edges of the lumbar transverse processes and the lateral vertebral bodies and annuli of the lumbar vertebrae. Slight flexion at the hip in positioning can help to relax each psoas and reduce the tendency for anterior traction on the lumbar plexus.

As the approach goes further caudally to the L1 and L2 levels, the retroperitoneal structures come into play. The lumbar plexus, unless there are vertebral anomalies, does not tend to be at risk unless approach levels at T12 and lower as it is generally formed from ventral roots of L1–L4 (with variable subcostal T12 contribution) and sits in the posterior third of the psoas. Renal vessels and the position of the ureters and bowel must be considered when approaching L2 and caudally, particularly if the approach strays anteriorly. Ventral exiting branches can still be injured by retractors placed too posteriorly, even above the level of the psoas origin, and for this reason, retractor placement in the ventral anterior three quarters of the body is recommended (Arnold et al. 2012).

Operative Considerations

Preoperative Workup

The patient should be assessed from the point of view of fitness for surgery and anesthesia in the perioperative period. Where possible, all acute illness should be dealt with and the patient physiology and nutrition optimized, in a multidisciplinary fashion, before they undergo surgery. Relevant biochemistry, hematological parameters, as well as blood typing for possible transfusion should be assessed and prepared for surgery. Poor nutritional status (preoperative albumin and ferritin), current or recent smoking, and lung parenchymal radiotherapy may be more subtle to patients at risks of pulmonary complications than the obvious patients with morbid obesity and obstructive airway disease.

Pulmonary function tests are particularly relevant in the elective or semi-urgent setting where poor reserve or functional asymmetry of the pulmonological system may warrant delaying the surgery or modifying the side and type of approach.

AP/lateral X-ray erect films are ideal to assess for vertebral body size and alignment (see Fig. 3). EOS standing films, if available, give detailed study of the spine type and alignment which is important when treating lesions that have likely significantly altered the sagittal profile of the patient. CT or MRI assessment of structures at the planned operative level should be undertaken especially looking for calcification, which may cause

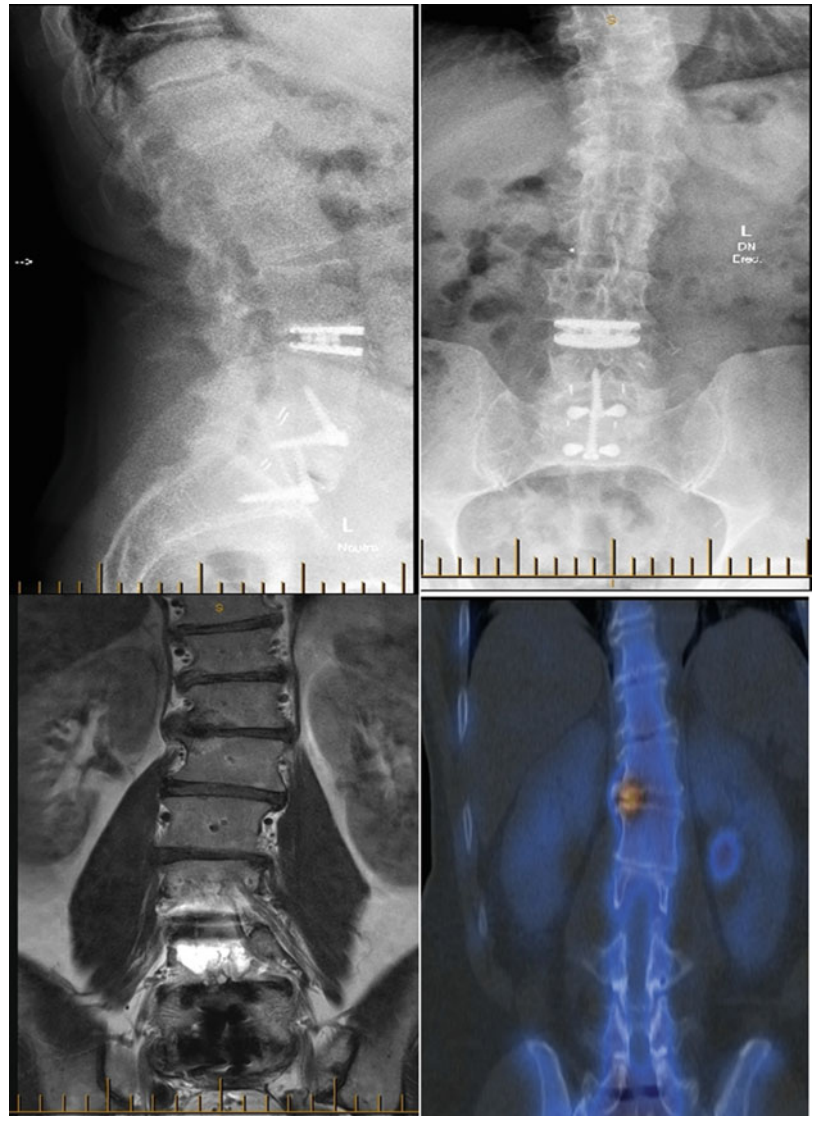

Fig. 3 Erect lateral and anteroposterior films and coronal MRI demonstrating collapsed T12/L1 disc. Note "hot spot" on SPECT scan due to collapse and focal scoliosis

operative difficulty (see Fig. 3). In the case of trauma, it will also assist with non-contiguous injury and evaluate for any posterior element injury or hematoma that may change management. The MRI also allows adequate assessment of the neural elements and position of the conus medullaris.

Neurological studies such as nerve conduction studies and/or electromyography may characterize and reveal any preoperative myelopathy or radiculopathy prior to treatment that may have implications for prognosis and patient expectations.

In the case of suspected neoplastic or infectious lesions, the local and systemic staging followed by biopsy and/or microbiological testing should be instituted to characterize the pathology (Liljenqvist et al. 2008). Diagnosis of thoracic DDD has not been well characterized. Axial ache and stiffness that changes with rest, recumbency, and different positions is suggestive. Extrapolating from lumbar studies, discogram is the gold standard, while combinations of findings on CT/MRI and pain blocks or activity on nuclear medicine scans can support a diagnosis.

Depending on the level(s) to be approached, the position of the aorta, the sympathetic plexus, and renal vessels and their relation to the psoas muscle and the spinal curvature should be studied. Scoliosis may place the aorta in the path of the lateral surgical corridor and may warrant consideration for right- rather than left-sided approach. If there is significant anomalous anatomy, then obtaining an arteriogram and/or venogram may be prudent.

Intraoperative

The procedure is undertaken under general intravenous anesthesia so as not to attenuate motor pathway signals of the neuromonitoring. As to the choice of endotracheal tube, a double lumen tube for selective lung ventilation is utilized above T8 level, whereas below T8 it is not usually necessary for MIS.

Open Lateral Approach to the TLJ

The patient is positioned lateral and commonly left side up with the most common approach to access T10–L2 being the left-sided thoracolumbar junction approach and is described adapted from the retropleural thoracotomy of McCormick (1995). Alternatives include the mini-thoracotomy and transdiaphragmatic, extrapleural (Balasubramaniam et al. 2016; Foreman et al. 2016; Graham et al. 1997; Otani et al. 1988), or left-sided thoracotomy. Pertinently, high thoracic lesions tend to be approached from the right to limit exposure to cardiovascular structures, while more caudal thoracic lesions are best approached from the left to avoid the inferior vena cava and liver.

An oblique incision is centered over the pathological vertebra/disc space as confirmed by image intensifier. The length of the incision will depend upon the number and location of levels to be treated. The incision is made over the rib belonging to the vertebrae 2 levels above the targeted discovertebral space given the caudal sloping of the ribs, e.g., 10th rib for T12. The thoracic muscles over the rib and abdominal muscles distal to the costal cartilage are divided with electrocautery. There is subperiosteal exposure of the rib, and depending whether bone grafting or interbody fusion is planned, it can either be preserved or osteotomized, protecting the caudal neurovascular bundle, for later use. The parietal pleura is opened at the posterior aspect of the wound revealing parenchyma/visceral pleura of the lung and the diaphragmatic attachment to the chest wall anteriorly.

Next, the retroperitoneal space is accessed via splitting the layers of the abdominal wall at the anterior part of the incision, and the peritoneum is peeled off from the inferior surface of the diaphragm down to the crus adjacent to the spine. It is important to leave a small (1–2 cm) cuff for later repair, and marking stay sutures periodically can be useful to aid later approximation. Smooth handheld deep retractors may be used here, but a dedicated table-mounted retraction system allows ease of access and ergonomics in a limited field.

Further steps of the approach depend on the discovertebral level(s) to be accessed as is discussed below (Vialle et al. 2015). If above T12 then the approach converts to a left-sided thoracotomy. If T12/L1 has to be exposed, the diaphragm has to be cut. If L1/2 has to be exposed, the principles of the retroperitoneal lumbar approach should be followed.

For levels T12 and above, a left-sided lung deflation is completed (see Fig. 4) and the deflated lobe retracted anterior to expose the ventral thoracic spine (Shen and Haller 2010). The parietal pleura is incised over the planned operative level (s) at the disc space and then to adjacent levels, being aware that the segmental vessels are in the midline and needing to be isolated and ligated. A subperiosteal exposure from posterior and lateral to anterior is then completed with blunt instruments protecting the great vessels anteriorly. Posterior dissection exposes the rib heads which often have to be osteotomized for adequate disc access.

For access to the TLJ, the diaphragm has to be incised to be able to access either side. As discussed in the anatomy section, the diaphragmatic innervation is from the phrenic nerve near the esophagus. Thus, it is important to incise the diaphragmatic attachments as close as possible to the chest wall as any muscle left in situ after

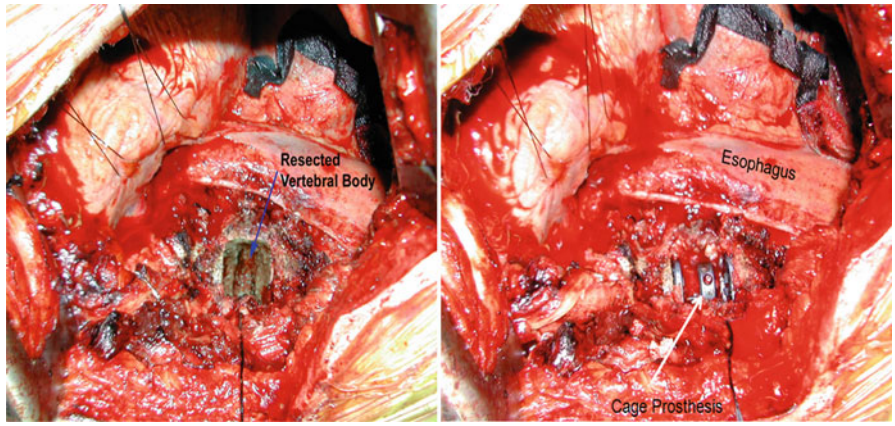

Fig. 4 Visualization via a lateral thoracotomy of low thoracic corpectomy and cage prosthesis insertion for fracture. (Copyright 2008, used with permission from CTSNet (www.ctsnet.org). All rights reserved)

incision in the periphery will undergo denervation. In the case of isolated TLJ approach (T12–L1), the diaphragm can be retracted anteriorly with the lung being retracted with a moist sponge and not requiring selective deflation. The parietal pleura is then incised longitudinally along the lateral aspect of the spine at least one level proximal to the most proximal vertebra to be treated. As in the thoracotomy approach, the segmental vessels are isolated and ligated, and the sympathetic chain is bluntly retracted and the great vessels protected.

For high lumbar levels (L1–2), the peritoneum is retracted along with the sympathetic chain anteriorly after being shifted away from the lateral abdominal wall and the psoas muscle reflected posteriorly after careful dissection on the anterior border of the muscle over the disc space and isolation and ligation of segmental vessels. Care for nearby renal vessels and the nearby great vessels lying anterior to the anterior longitudinal ligament is paramount.

Any approach with pleural breach, as distinct from an extrapleural approach, will require a chest drain insertion. One or two chest tubes are typically inserted in the midaxillary line although some surgeons prefer an anterior drain to extract air from the chest cavity and a posteriorly placed drain for drainage of blood and fluid.

The diaphragm is reattached using interrupted sutures, making sure that the parietal pleura is approximated and preferably closed over the instrumentation. The chest wall muscles that have been divided are then re-approximated.

MIS Approach

The minimally invasive approach to the thoracolumbar spine has been described, publicized, and refined since the first report by Pimenta in 2000 (Pimenta 2015). The patient is positioned in the right lateral decubitus position on a radiolucent table with the hip and knees flexed. Bony prominences and pressure points are padded, arms placed onto table attachments assessing for brachial plexus and ulnar pressure, and the torso secured either with a beanbag or table-mounted bolsters and sports tape (Elastoplast™) is also used. The choice of how to secure the torso and keep the posterior spinal elements exposed to prevent rolling during the procedure will depend on whether supplemental pedicle screws are planned from the same patient position or repositioning or a staged posterior fixation is to take place (see Figs. 5 and 6). They are taped in such a way as to afford good biplanar visualization of the affected levels. The skin can be secured with taping if access to lower lumbar levels is planned and a side bolster or break in the thoracolumbar region can be placed to open up the ipsilateral ribs and operative disc space at the TLJ. Neural monitoring including transcranial motor evoked potentials and somatosensory evoked potentials along with pertinent nerve roots is, we believe, imperative when performing direct lateral approaches.

The acquisition of proper image intensifier (II) images is important for ease of workflow. The II

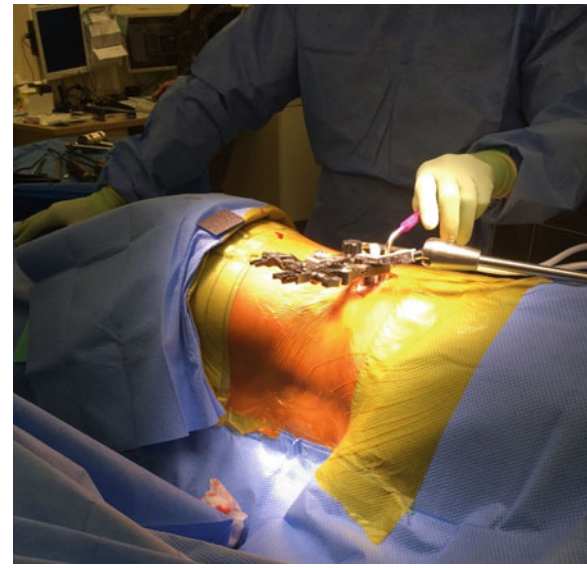

Fig. 5 Setup and retractors in place for direct, left side up lateral approach to the TLJ

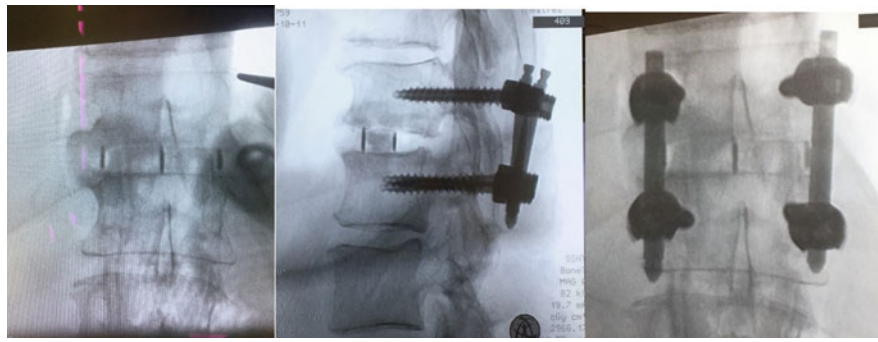

Fig. 6 Interbody insertion at T12/L1 level for same patient as in Fig. 5, followed by posterior instrumentation, all carried out without changing the position of the patient or need for redraping

generally will go over the patient who is in the lateral position and first obtain a true AP of their pedicles, and the table is adjusted until this is achieved. This allows us to correct the rotation of the spine and makes confirmation of endplate alignment in the lateral position easier. Once this correct AP position is confirmed and marked on the II machine, a position 90° orthogonal to this is utilized for the disc space access. Note, it is very important to have a well-trained radiographer for these procedures, and often it is easier to describe the AP view as being a side to side C-arm image and the lateral as being a top to bottom image so as to avoid confusion when conversing with members of the team. Given the relatively limited visual field of standard C-arms, if one cannot see the affected level and the sacrum in a single view, then it is advised to have a metallic marker placed in the affected pedicle under CT guidance prior to surgery.

The patient is then prepped and sterile draped over the shoulder and pelvis. It is important to have a large enough surgical window and imperative to have in mind an extensile approach in the event of significant bleeding occurring through a small incision. Incision planning is undertaken using fluoroscopy for level check and the 12th rib as landmark. One can use the ribs to trace up rib 2 levels above planned thoracic level(s) to choose for resection as a guide. Placement of a Kirschner wire in the spinous process immediately inferior to the pathological thoracic disc/

level has been proposed as a strategy to avoid wrong site surgery (Malham and Parker 2015).

A 4–6-cm-long oblique incision (parallel to and following the trajectory of the rib at the index level) is made at the midaxillary line, 90° lateral to the disc space (Uribe et al. 2010). Sharp dissection is carried to deep fascia, and a small rent is typically made in the deep fascia with the Bovie cautery. Blunt dissection is then carried through the intercostal muscles above the rib. The parietal pleura is then pierced in the same way as one would pass a chest drain in the setting of thoracic trauma. Typically, the right index finger can then be swept down the undersurface of the rib to palpate the transverse process. The blunt dilator can then be passed on the palmar aspect of the finger to the level of the transverse process and walked out onto either the disc or the affected vertebral body (see Figs. 7 and 8). This ensures that no visceral pleura or lung parenchyma is caught by the dilator. The position of the neurovascular bundle under the rib is considered at all times. The dilator is initially directed posteriorly away from the lung parenchyma before being brought anteriorly to the rib head over the target disc space and confirmed by lateral fluoroscopy (see Figs. 8 and 9). It is important to note the reversal of usual retractor blade positions in the thoracic spine, with the posterior blade actually being anterior with the lung retractor blade. Multiple retractors exist for the purpose of this surgery. When crossing to T12 or L1 or lower, to obtain retroperitoneal access, we prefer a tubular retractor such as a NuVasive Maximum Access™ as this allows a smaller hole to be made in the pleura and this retractor is passed through the proximal diaphragmatic attachment at the chest wall and with the dilator passing below apex of the diaphragm (Fig. 10).

Following treatment of the targeted region, provided that there be no visceral injury observed and it is a low thoracic level performed through a direct lateral approach, a drain is seldom required as the small air leak that may result is usually subclinical. Thus far, in our experience, this T12/L1 approach has never necessitated diaphragmatic repair or the passage of a chest drain. Obviously, when removing the retractor, a positive-pressure ventilation, a "bubble test," should be performed prior to definitive closure and a chest X-ray gained prior to waking the patient to ensure no significant pneumo- or hemothorax has occurred.

If the approach is to be made targeting higher lumbar levels, the transversalis fascia is one of the main components that maintain structural integrity of the retroperitoneal space. A 4 cm transverse incision is made along the lateral flank at the midline level of the index vertebral body. The incision should be made parallel to the direction

of the fibers of the external oblique to minimize the possibility of injury to the motor nerves supplying them. This prevents abdominal wall pseudo-hernia formation from loss of tone to these abdominal wall muscles. Blunt dissection with anterior sweeping movements of the retroperitoneal contents is then performed to enable palpation of the psoas muscle and the transverse process of the index vertebra.

Once the operative levels are reached and illuminated retractors are in place, a removal of the rib head via osteotomy over the operative site is typically necessary for adequate access to the disc space (Fig. 11). The operative strategy can then be carried out, whether discectomy, interbody fusion, or corpectomy (Fig. 12). In the case of an interbody fusion, the macroscopic discectomy is carried out first from anterior to posterior disc

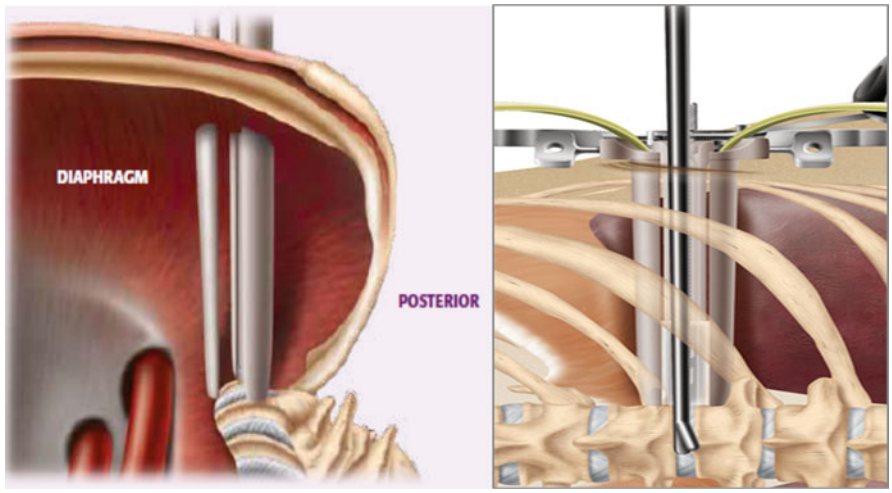

Fig. 10 Crossing of instrumentation through the diaphragm from thoracic to upper lumbar levels through small diaphragmatic incision. space before careful resection of the posterior longitudinal ligament.

Postoperative

A chest radiograph in recovery is recommended if no chest drain has been inserted to assess for any interim pneumothorax development (Fig. 13).

Following a decision for insertion and securing of a chest drain, a chest radiograph should be obtained the first day postoperatively. If the pulmonary sacs remain expanded with no evidence of pneumothorax and the drain continues to "bubble," await approximately 24 h and remove at that time. If there is no re-expansion, then either the drain should be checked (if there is no bubbling or swinging) or a respiratory physician opinion should be obtained (Henry et al. 2003).

The ward care postoperatively will depend on the procedure performed. The common path, however, is for early graduated mobilization and aggressive chest exercises to prevent atelectasis and pneumonia. Analgesia for open thoracotomy approaches will typically be considerably more aggressive than for MIS procedures and may

involve a patient-controlled analgesia setup in an attempt to minimize pain-mediated pulmonary dysfunction. Hemoglobin and electrolytes are assessed routinely and corrected as required. Erect radiographs to verify position and alignment of hardware is arranged as an inpatient when the patient is able to stand.

Once safe and comfortable, the patient is discharged, and follow-up is arranged as an outpatient as postoperative week 2 for a wound review. The patient is encouraged to keep active, but avoidance of heavy lifting and explosive or rotational activities during the first 6–12 weeks is advised. The patient is then followed clinically and radiographically from a fusion perspective if interbody fusion or corpectomy or clinically if a microdiscectomy was performed.

Abstract

In order for surgeons to be able to achieve the best possible outcomes for their patients, it is important that they tailor their treatments to each individual patient and their condition. To achieve this, spinal surgeons in particular must be familiar with a variety of different implants and the various approaches that can be used to access the pathology. Patient positioning and preoperative planning are important, as well as identifying soft tissue corridors, which avoid damage to the numerous neurovascular structures found in close proximity to the axial skeleton.

Focusing on the cervical spine, this chapter provides discussion regarding indications, patient positioning, preparation, practicalities, as well as illustrations of the commonest approaches and surgical procedures. Approaches include the anterior (retropharyngeal, transoral), anterolateral (Smith-Robinson), lateral (Verbiest), and posterior, and for each approach, there is also a discussion of the structures at risk and a review of the literature regarding complications.

Keywords

Cervical spine · Surgical approach · Transoral · Odontoid · Retropharyngeal · Verbiest · Anterolateral · Smith-Robinson · Posterior approach

Introduction

Surgery in the cervical spine can be incredibly rewarding. The pathology at times may be severe, with a high chance of permanent disability if left untreated. Despite this, the outcomes are often

remarkably good. The complications associated with cervical spine surgery are potentially devastating; however, thankfully they are infrequent, and some are avoidable if one takes care to identify anatomy and plan the surgery diligently. This chapter will present approaches commonly, and in some instances less commonly, used to treat pathologies of the cervical spine. This is by no means an exhaustive list; there are several eponymous approaches which are infrequently used and will not be discussed at length as they are excellently described by their creators in the wider literature. This chapter will also explore the practicalities of performing these approaches, including the positioning of the patients, the structures at risk, the procedures themselves including their indications and the complications which may occur.

Anterior Surgery

Up until the 1950s, cervical spine surgery was almost exclusively performed via a posterior approach, including decompression and stabilization. The "workhorse" of cervical spine surgeons was the posterior cervical laminectomy. However, the ability to retrieve the prolapsed intervertebral disc was limited by the unretractable characteristics of the spinal cord through this approach. In 1954, Lahey (Lahey and Warren 1954) described an anterior cervical approach which he used to approach esophageal diverticula. In addition, neurosurgeons such as Dereymaeker from Louvain, Belgium, were discussing the potential of using this approach in spinal surgery. Two years later, Smith and Robinson (Robinson and Smith 1955) were the first to formally describe an anterolateral cervical approach for the purpose of spine surgery. In 1958, Smith and Robinson (1958) went on to publish the results of their first 14 cases of Anterior Cervical Discectomy and Fusion (ACDF) surgery. Popularity for this anterolateral approach grew, as it provided a new safe corridor for surgeons to access the intervertebral disc without having to venture around the spinal cord. New retractor systems were quickly developed to facilitate this approach, and surgeons such as Cloward (1958) began to refine the technique for achieving an interbody fusion. As more surgeons began to favor the anterior cervical approach further developments were seen in the implant materials and designs, including static and dynamic plates, cement and bone block spacers, interbody and corpectomy cages, and arthroplasty devices. Further anterior and lateral approaches to the cervical spine were later developed in order to give better access to the proximal and distal most vertebrae, the neuroforaminal roots and vertebral arteries. These include the transoral approach to the odontoid, the anterior retropharyngeal approach (McAfee et al. 1987) to the C1-3, the lateral (Verbiest) approach (Verbiest 1968), and the transsternal approach to the cervicothoracic junction.

Posterior Surgery

In the late 1970s, led by spinal surgeons in Japan, there was also a drive to further develop the posterior cervical operations. This was still the favored approach for the treatment of certain spinal conditions, such as myelopathy caused by ossification of the Posterior Longitudinal Ligament (OPLL,) which has a higher prevalence in patients of Japanese and Asian heritage. Posterior laminectomy was known to be associated with postoperative segmental instability, kyphosis, perineural adhesions, and late neurological deterioration. Hirabayashi (Hirabayashi et al. 1983) and Kurokawa (Kurokawa et al. 1982) developed the techniques of "open door" and "double door" laminoplasty in an attempt to avoid these problems. Since their inception, there have been several variations on these techniques including the introduction of different "spacer" implants designed to hold open the elevated lamina. Another great advancement was the introduction of the surgical microscope into spine surgery (Yasargil 1977). The superior magnification and light they provided enabled surgical wounds to shrink, thus reducing the damage to surrounding tissues, and led to the introduction of endoscopic surgery. Posterior stabilization of the cervical spine was difficult to achieve as it relied almost entirely upon wiring techniques which were not good at resisting extension, rotation, or lateral

bending forces. The introduction of translaminar, lateral mass and pedicle screws insertion techniques by surgeons such as Roy-Camille (Roy-Camille et al. 1989) and Magerl (Magerl and Seemann 1987) has greatly improved the ability of surgeons to stabilize the cervical spine from a posterior approach.

As surgical approaches to the anterior, lateral, and posterior aspects of the cervical spine have evolved, so too has our understanding of the various pathologies, facilitated through basic science research and the advancements in imaging including computerized tomography (CT) and magnetic resonance imaging (MRI). With the help of these imaging modalities, clinical evaluation, electromyography (EMG), and diagnostic injections, surgeons are now able to be more confident about their diagnoses, and in turn, more likely to select a suitable surgical strategy to achieve the goal of treatment – a good outcome for their patients.

Planning

As with any surgical treatment, it is of paramount importance that the surgeon takes care to plan the procedure fully before entering the operating theater.

Surgical Strategy

Planning starts with identifying the surgical strategy which will be used to address the pathology and achieve the surgical goal. Unfortunately, it is still commonplace to find ill-considered operations being performed on patients, which can fail to help with symptom relief and potentially cause them harm. Surgeons must make every effort to identify the underlying cause of a symptom and formulate a surgical strategy to deal with this cause, as opposed to treating just the symptom. For example, it should come as no surprise that stabilizing a degenerative C5/6 disc in a patient will do little to relieve the neck pain that they have referred up from their arthritic shoulder.

In general, the pathologies requiring treatment in the cervical spine tend to be related to tumor, trauma, infection, degenerative, or inflammatory musculoskeletal and disc disease. The sequelae of these pathologies are often either instability or compression of neural structures, which then gives a target for surgical treatment. Consequently, surgical strategies usually involve decompression, stabilization, or both.

Surgical Approach

Next, the surgeon needs to decide which surgical approach will best enable them to carry out the surgical strategy, whilst also minimizing the risk of complications by avoiding structures at risk. Most pathologies can be addressed with either an anterolateral or posterior approach, although some require both. The lateral, transoral, retropharyngeal, or transsternal approaches are more specialist approaches with narrow indications which will be highlighted within the relevant subsection of this chapter.

Intuitively, pathologies which affect the anterior structures – that is structures lying ventral to the spinal cord and roots – are often best approached from the anterior aspect. This approach enables removal of any compressive material (disc, bone, pus, tumor, or hematoma) with little manipulation of the neural structures, followed by stabilization, fusion or motion preservation, depending on the implants used. Kyphotic deformity is also an indication for an anterior approach as it enables restoration of the normal cervical lordosis by lengthening of the anterior column. Most degenerative pathologies affecting the cervical spine benefit from an anterior approach for these reasons. Trauma, tumor, or infection which compromises the integrity of the anterior column is an absolute indication for an anterior approach to enable reconstruction of the anterior column, preventing a later kyphotic deformity.

Posterior cervical pathologies are often best treated with a posterior approach. These pathologies include cord or neural compression caused by trauma, tumor infection, or degenerative disease

such as osteophytes or an in-folding of the ligamentum flavum. Dissecting through the posterior muscles and stripping them from their boney attachments is more likely to give the patients postoperative pain compared with the anterior intermuscular approach; however, it does enable a more complete decompression of the cord for the entire length of the spine. It is an extensile approach and is, therefore, ideal for treating pathology which is found at the occipito-cervical and cervico-thoracic junctions, or extensive pathology occurring at several different levels in the cervical spine. If stabilization needs to bridge to the occiput or the thoracic spine, then the posterior approach is indicated. The posterior approach is also used if intradural pathology is encountered, or if there is OPLL which is often adherent to the ventral surface of the cord.

Whichever approach is selected by the surgeon to best treat the pathology, it must be one which they are familiar with and can perform competently. There are many pathologies, such as cervical spondylotic myelopathy, where research is ongoing in trying to identify the approach which delivers the best outcomes. It is, therefore, advisable for surgeons to carefully consider all options when planning their surgical approaches.

Surgical Setup

Finally, once the tactics and approach have been confirmed, consideration should then be given to the surgical setup, including patient positioning, operating room layout, instruments and implants, list management, and additional support which may be required. Patient positioning will be covered in more detail later in the chapter. One common setup strategy is to have the cervical spine patient positioned on the operating table with their feet by the anesthetist, and their head at the other end nearer to the surgeon. This is to provide the least obstruction for the surgeon to be able to operate with the microscope and reduces the risk of contamination of the surgical field. It is important to use an operating table which is radiolucent over the areas where intraoperative X-rays may need to be taken. The need for instruments for insertion (and removal) of implants should be anticipated in advance and present before commencement of the anesthetic, along with any support staff such as neurophysiologists for intraoperative cord monitoring. With the advent of navigation and robotic-assisted surgery, spinal operating rooms can easily become cluttered with this additional equipment, implant trays, instrument trollies, microscopes, and image intensifier equipment. It is often worth planning the theater layout with adequate space assigned for all the items with the largest footprints to ensure the operation can go ahead safely. Although we are reluctant to admit it, surgeons do fatigue during the day, and so it is preferable to schedule bigger cases for the morning to reduce the risk of avoidable complications.

Ensuring the key members of the operating room team are fully informed of the preoperative plan is the simplest way of preventing mistakes and negative outcomes when unforeseen events occur in theater.

Anterior Transoral Approach to C1-C2

Indication

The transoral approach (Crockard 1985; Fang and Ong 1962; Menezes and VanGilder 1988) to the cervical spine is ideal for pathology in the anterior midline at the craniocervical junction, such as tumors. Previously, cord compression and instability caused by rheumatoid arthritis were the leading indication; however, this disease is now better treated by medication and hence the overall incidence of transoral surgery to the spine has greatly reduced (Choi and Crockard 2013).

Positioning, Preparation, and Practicalities

Nasopharyngeal bacterial swabs are taken 3 days pre-op along with antiseptic mouth washes (Watkins III 2015b). Intravenous antibiotics are

given at induction and for 7 days post-op. The patient is positioned supine with their head on a Mayfield headrest. A reinforced nasotracheal tube is inserted endoscopically and skull traction (3 kg) applied via a HALO ring. Some surgeons feel a tracheostomy is advisable in order to ensure a patent airway post-op. Antiemetics are given and a nasogastric (NG) tube is passed to reduce the risk of any regurgitation of stomach contents affecting the wound. The NG tube is retained for 5 days post-op to enable feeding as the patient will remain nil by mouth for at least 5 days post-op. A rubber loop is passed down from the un-intubated nostril and hooked round the uvula and pulled cephalad to bring it out of the field of surgery. If this is insufficient, the soft palate can be incised with a curvilinear incision around the uvula in a cephalad direction and the two flaps held clear with stay sutures. A Boyles-Davis mouth gag is then inserted to retract the tongue, being released and reapplied every 30 min to avoid tongue necrosis. The nasopharynx and laryngopharynx are packed to catch any secretions. The oropharynx is prepped with Betadine and the posterior pharyngeal tissues are copiously infiltrated with a lidocaine and 1:200,000 adrenaline solution for hemostasis (Fig. 1).

Approach

The anterior tubercle on the atlas is palpated and confirmed on X-ray. A 3 cm longitudinal midline incision is made – 1 cm cephalad and 2 cm caudal to this tubercle. Incision is made through the posterior pharyngeal mucosa, the constrictor muscles, the prevertebral fascia, and the anterior longitudinal ligament (ALL). Remaining soft tissues are then bluntly dissected off the body of C2 (below the odontoid) and the anterior tubercle of C1. At this stage the blunt dissection can be extended further laterally and longitudinally to expose the lateral masses of C1 and C2. However, one should remember that the vertebral arteries lie a minimum of 2 cm from the anterior tubercle of C1 in the foramen transversarium on either side. There is often venous bleeding just lateral to the base of the odontoid, and sharp dissection may be needed to detach the longus coli muscles from the anterior aspect of C1 and C2.

Procedure

With the C1 and C2 now exposed, the definitive treatment can begin, usually with burring away of the anterior arch of C2 to reveal the odontoid which can also be excised if indicated. The dura should be completely decompressed and if necessary, a durotomy can be performed. Access can be extended proximally to reach the clivus, although this may require further soft palate incision or formal maxillotomy. Depending on stability and the extent of bony excision, a HALO jacket or posterior stabilization may now be required.

Closure

The longus coli muscles, constrictor pharyngeal muscles, and mucosa are all closed as individual layers if possible with absorbable sutures. Any soft plate extensions are closed in one layer with an absorbable suture.

Structures at Risk

The vertebral arteries lie a minimum of 2 cm from the anterior tubercle of C1 in the foramen tranversarium on either side. They are found at the lateral edges of the joints between the C1 and C2 lateral masses, and so care must be taken to use blunt retractors laterally if exposing these joints and stay sutures should not go too deep within the lateral pharangeal wall. Care should be taken to avoid damaging the tongue or the pharyngeal mucosa with the retractors. The spinal cord and dura are located beneath the cruciate ligaments at the back of the odontoid.

Complications

In 2016, Shriver et al. published a meta-analysis of the complications related to 1238 transoral

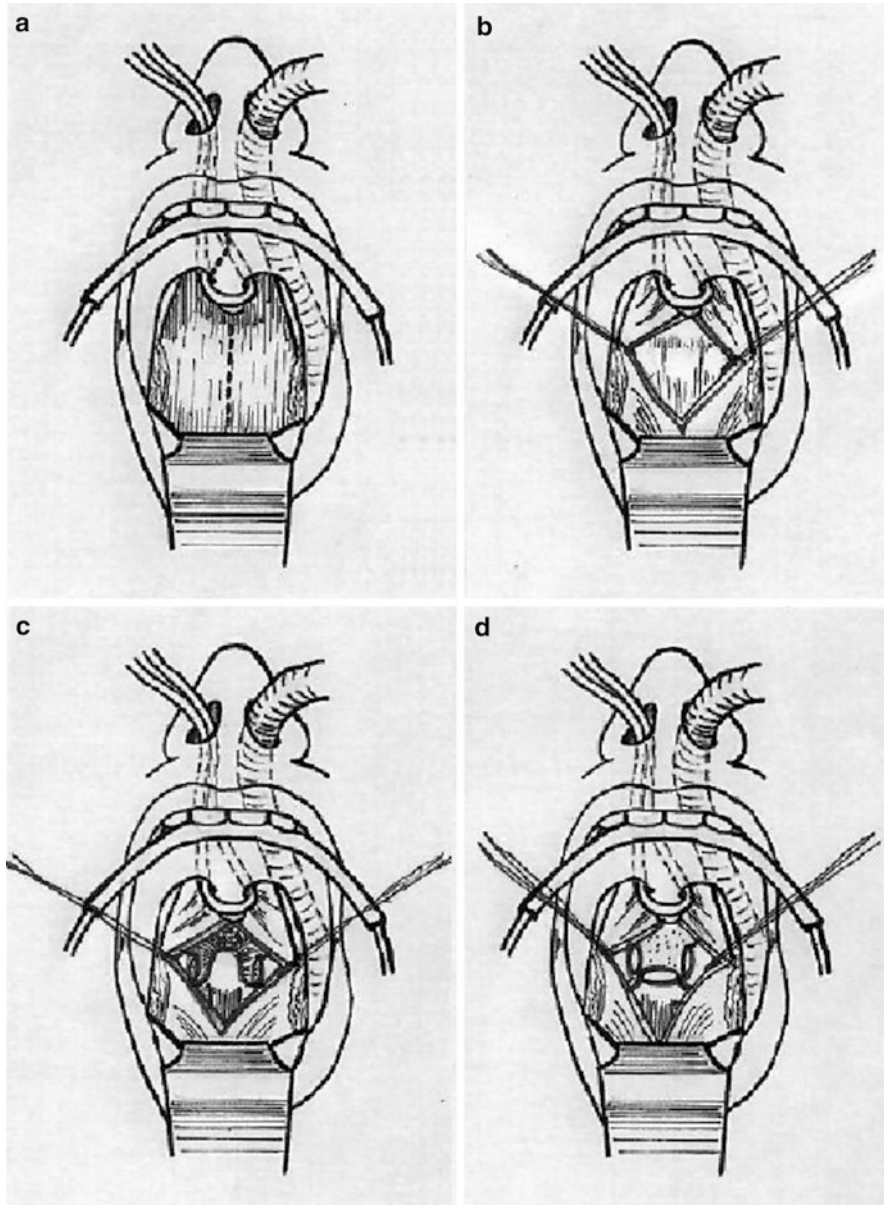

Fig. 1 Anterior transoral approach to C1-C2. (**a**) Transoral incision, including soft palate peri-uvula extension (dotted line), showing vascular loop elevating uvula and McIvor mouth gag exposing the posterior pharyngeal mucosa. (**b**) Pharyngeal mucosa, constrictor muscles, and prevertebral fascia, incised and retracted with stay sutures, exposing the ALL and longus coli muscles over the anterior tubercle of C1 and body of C2. (**c**) Anterior tubercle and arch of C1 removed with high-speed burr to reveal the odontoid process. (**d**) Ondontoidectomy can then be performed carefully with Kerrison rongeurs to decompress the cord

odontoidectomy patients (Shriver et al. 2016). The commonest reported complications were medical complications (13.9%), which were mostly respiratory with some cardiac. The mortality rate at 30 days was 2.9%. Other complications included arterial injury (1.9%), CSF leak (0.8%), meningitis (1%), pharyngeal wound dehiscence (1.7%), dysphagia (3.8%),

velopharyngeal insufficiency (VFI) (3.3%), and tracheostomy (10.8%).

Anterior Retropharyngeal Approach (C1-C3)

Indication

The anterior retropharyngeal approach (De Andrade and Macnab 1969; McAfee et al. 1987) is indicated in tumor, trauma, infection, and instability cases affecting the upper cervical spine, especially where there may be a need to insert bone graft and implants. It also enables the surgeon to extend distally past C3, which is not possible from the transoral approach without splitting the mandible.

Positioning, Preparation, and Practicalities

The patient is positioned supine with their head on a Mayfield headrest, and rotated slightly contralaterally. A reinforced nasotracheal tube is inserted endoscopically to allow better elevation of mandible. Depending upon the pathology skull traction (3 kg) can be applied using Gardener-Wells tongs. Due to the slightly awkward approach angle (cephalad under the mandible) early introduction of the microscope is advised as it serves as an excellent light source. The handheld Cloward retractor facilitates the blunt dissection and approach. The skin around the incision can be pre-infiltrated with a lidocaine and 1:200,000 adrenaline solution to reduce the bleeding from the superficial tissues during the procedure.

Approach

A 2–4 cm skin incision is made below the angle of the mandible from midline to the mid-axis of the sternocleidomastoid muscle, curving up toward the mastoid process (Watkins III 2015a). The platysma and superficial fascia are divided in line with the incision. The subplatysmal plane is developed a little proximally and distally. Care is taken to identify and protect the greater auricular nerve and anterior cervical nerve branches of the ansa cervicalis. These course around from the posterior border of sternocleidomastoid, crossing the proximal end of the muscle on their route up to give sensory distribution to the auricular and mandibular skin. The investing fascia is incised along the deep medial edge of the sternocleidomastoid muscle. The pulsation of the carotid sheath is palpated, and blunt dissection preferably with the index fingers is used to develop a plane medial to the carotid sheath and lateral to the trachea, esophagus, and strap muscles.

The neurovascular structures crossing from lateral to medial, across the carotid triangle (Fig. 2), are found in this layer. Before ligating any of these vessels it is important, at this stage, to identify the hypoglossal nerve. After descending between the internal carotid artery and jugular vein, it turns horizontally and becomes superficial over the proximal external carotid artery, traversing medial-lateral over the proximal carotid triangle, before passing deep to the digastric tendon to supply the muscles of the tongue. A nerve stimulator should be used to confirm correct localization of the hypoglossal nerve. It should then be mobilized from the surrounding tissue to enable gentle cephalad retraction along with the posterior belly of the digastric muscle. If necessary, the digastric (and stylohyoid) muscles can be divided at their tendinous junction and tagged for later repair. Access into the retropharyngeal space is prevented by the lateral-medial traversing branches of the external carotid artery, including the superior thyroid, lingual, and facial arteries. These vessels, along with their accompanying veins, are divided. The submandibular duct can be tied off and the gland removed to facilitate proximal exposure.

The carotid sheath is retracted along with the ligated stumps of the superior thyroid, lingual, and facial vessels laterally. The digastric muscle and hypoglossal nerve are retracted proximally, and the musculovisceral column is retracted medially. Blunt finger dissection is used to locate the ALL and longus coli muscles on anterior cervical spine.

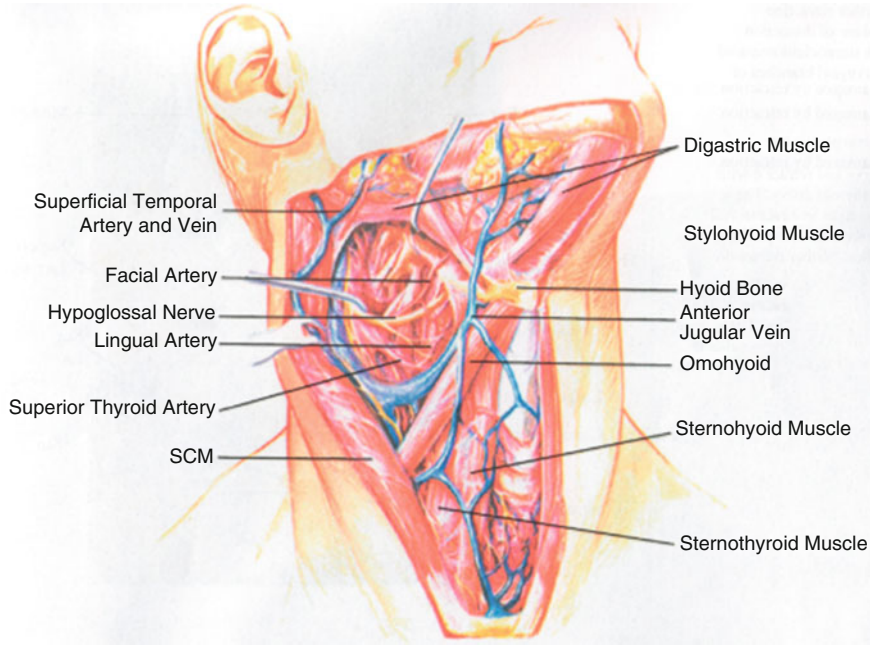

Fig. 2 Anterior retropharyngeal approach with the exposure of the carotid triangle. (From Watkins III 2015a)

The anterior tubercle on the atlas serves as a useful landmark and can be confirmed on X-ray. The prevertebral fascia and longus coli fibers are elevated, and the blunt handheld Cloward retractors are substituted for some sharp, clawed retractor blades under longus coli.

Procedure

Once the desired bony anatomy is identified, a high-speed burr is used to remove the anterior arch of C1 and the odontoid process. The tip of the odontoid process is removed before sectioning of the base to prevent superior retraction of this structure in cases of basilar invagination. The body of the odontoid is drilled, leaving a thin shell of bone posteriorly, which is carefully removed with Kerrison rongeurs. The lateral pillars should be retained as they are the primary load-bearing structures of the atlantoaxial articulation. Following decompression, supplementary stabilization is usually required. This can be accomplished with anterior or posterior instrumentation, or a halo device.

Closure

Deep closure is not required. The digastric muscle tendon is repaired, if it was divided. The platysma muscle is closed over a drain, and then fat and skin are closed in separate layers. Suture/clip removal equipment accompanies the patient during the first 12 h in case an urgent evacuation of hematoma is needed to prevent airway compromise.

Structures at Risk

Take care to identify and protect the greater auricular nerve and anterior cervical nerve branches of the ansa cervicalis crossing over the proximal sternocleidomastoid muscle. Injury to these can cause loss of sensation to the auricular and mandibular skin. When operating in the submandibular triangle, it is important to avoid damaging the marginal mandibular branch of the facial nerve. Ensure the hypoglossal nerve has been correctly identified before ligating any other vessels. Avoid excessive retraction on the stylohyoid muscle as this can injure the facial nerve as it exits the skull

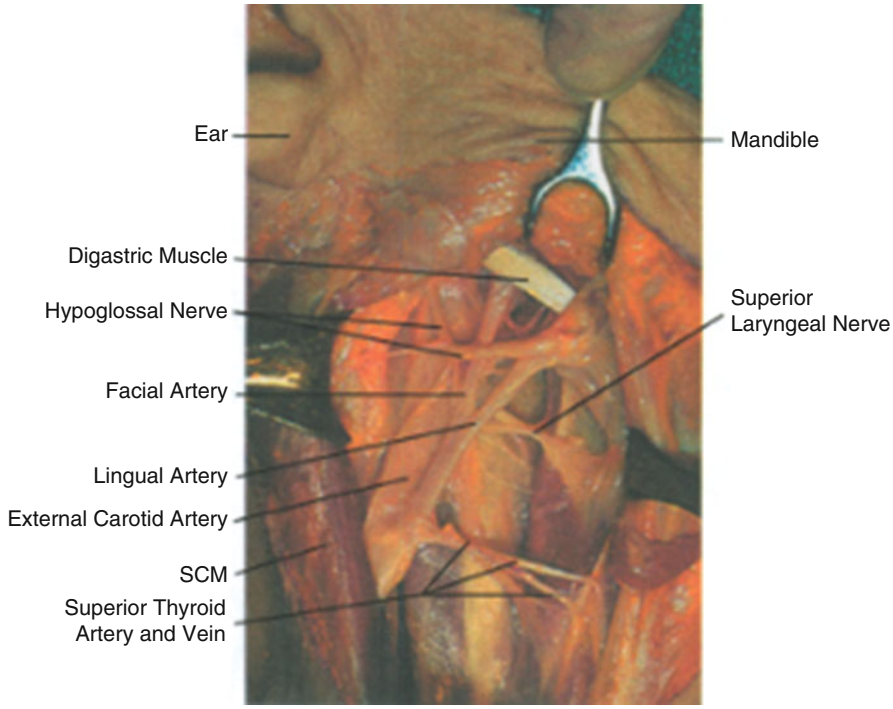

Fig. 3 Note the position of the superior laryngeal nerve, which must be protected. (From Watkins III 2015a)

through the stylomastoid foramen. It is important to identify the superior laryngeal nerves (both internal and external branches) (Fig. 3) as injury to these can lead to increased voice fatiguability, loss of high-pitched notes in singing, or even aspiration pneumonia as a result of reduced laryngeal cough reflex. They are located in the carotid triangle adjacent to the superior thyroid artery and are commonly injured by retractors. The superior laryngeal nerve should be mobilized in order to prevent retraction injury to its internal and external branches.

Complications

The commonest complaint with the retropharyngeal approach is dysphagia. Other complications include facial nerve palsy (9.4%), hypoglossal nerve plasy (4.7%), nonunion/graft displacement (6.3%), infection (1.6%), hypopharynx injuries (3.1%), and a mortality rate of 3.1%.

Lateral Approach (Verbiest)

Indication

The lateral approach to the vertebral artery was described in detail by Henry (1970) and later modified by Verbiest (Verbiest 1968) to enable additional access to the lateral aspects of the cervical vertebral bodies, the neuroforamina, and the portions of the anterior rami of the brachial plexus. Bony spurs compressing the vertebral artery or the cervical nerve roots, and neural tumors can be addressed with this extensile approach (Watkins 2015).

Positioning, Preparation, and Practicalities

The patient is positioned supine with their head on a Mayfield headrest, without any rotation. This is to avoid occlusion of the vertebral artery in cases

of spondylotic compression. The skin around the incision can be pre-infiltrated with a lidocaine and 1:200,000 adrenaline solution to reduce the bleeding from the superficial tissues during the procedure.

Approach

An oblique incision is made along the medial border of the sterncleidomastoid muscle. Skin and subcutaneous tissues are retracted, and the platysma muscle is divided longitudinally in line with its fibers. The investing layer of the cervical fascia is incised to reveal the medial border of sternocleidomastoid muscle. The plane between the muscle and the medial strap muscles is developed with finger dissection. Care is taken to identify and protect the greater auricular nerve and anterior cervical nerve branches of the ansa cervicalis. These course around from the posterior border of sternocleidomastoid, crossing the proximal end of the muscle on their route up to give sensory distribution to the auricular and mandibular skin. The sternocleidomastoid muscle is then retracted laterally and the carotid sheath is identified by its pulsation against a fingertip. The plane between the carotid sheath and sternocleidomastoid (laterally) and the musculovisceral column (medially) is further developed with blunt dissection with a finger and mounted pledgets, down to the anterior tubercle of the transverse process. The sternocleidomastoid can be released from its proximal attachment on the mastoid process if it is required. However, care must be taken to identify and protect the accessory nerve which enters the muscle 4–6 cm from the mastoid tip. After identifying the anterior tubercle of the transverse process, where longus coli, longus capitis, and anterior scalene muscles attach, it is possible to palpate medially to feel the vertebral body and disc. The longitudinal sulcus between the tubercle (laterally) and the body (medially) is the costotransverse lamellae, which forms the roof of the foramen transversarium covering the vertebral artery. Incise the prevertebral fascia longitudinally to expose the longus coli and longus capitis muscles. The longus coli muscle has three parts – two oblique parts lying over one longitudinal part. The longus capitis muscle lies longitudinally over the upper oblique longus coli. The upper vertical longus coli arises from the anterior tubercle of the atlas and then inserts on the body of C4, while the lower stretches from C5 to T3. The oblique parts insert (with the longus capitis) on the anterior tubercles on the transverse processes. The sympathetic chain lies directly anterior to the transverse processes, between the prevertebral fascia and the carotid sheath, sometimes being adherent to the latter. The sympathetic chain, including its superior (at C1) and middle (at C6) cervical ganglions, should be moved as one with the longus coli muscles from lateral to medial to access the underlying structures. In order to achieve this retraction, the muscular attachments of the oblique longus coli and the longus capitis are sharply dissected off the anterior tubercles. The dissector should be working in the acute angle the muscle fibers make with the bone (the stripping angle), which is an inferolateral direction when working on the proximal levels, and a superolateral direction when working on the inferior levels (Fig. 4).

Procedure

The bone of the anterior tubercle is removed with a rongeur, and the proximal and distal margins of the costotransverse lamellae are identified. With a small Kerrison rongeur, the bone of the costotransverse lamellae is carefully removed, and the foramen transversarium is de-roofed. In doing so it is inevitable that venous plexus surrounding the artery will bleed, and this should be controlled with light pressure. The nerve root should now be accessible underneath the mobile vertebral artery. Again, further bleeding may be encountered from the main vertebral veins which may require additional hemostatic products.

Closure

Deep closure is not required. The platysma muscle is closed over a deep drain, and then fat and skin

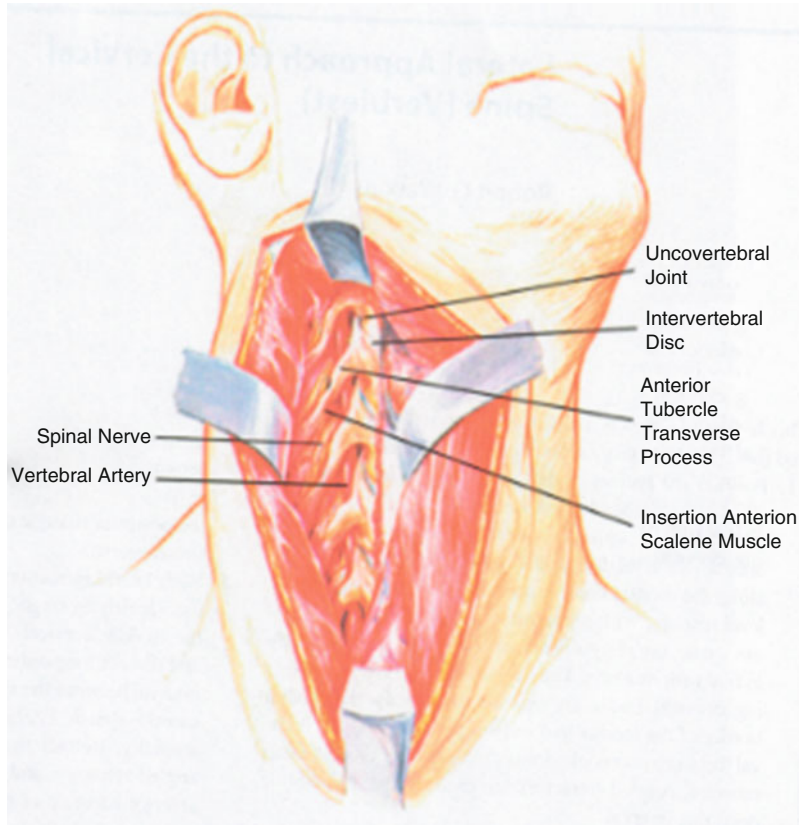

Fig. 4 Lateral approach revealing the vertebral artery running through the foramen transversarium. (From Watkins 2015)

are closed in separate layers. Suture/clip removal equipment accompanies the patient during the first 12 h in case an urgent evacuation of hematoma is needed to prevent airway compromise.

Structures at Risk

Take care to identify and protect the greater auricular nerve and anterior cervical nerve branches of the ansa cervicalis crossing over the proximal sternocleidomastoid muscle. Injury to these can cause loss of sensation to the auricular and mandibular skin. If proximal detachment of the sternocleidomastoid is required, care must be taken to identify and protect the accessory nerve which enters the muscle 4–6 cm from the mastoid tip. The sympathetic chain should be moved as one with the longus coli muscles from lateral to medial to avoid injury and a subsequent Horner's syndrome (partial ptosis, meiosis, and anhidrosis). The vertebral artery is at risk during the longus coli strip and the excision of bony costotransverse lamellae. If the vertebral artery is injured, bleeding may be controlled by a ligature above and below the lesion.

Complications

Due to a lack of published data on lateral-approach cervical surgery, it is not possible to present the complications rates from these procedures.

Anterolateral Approach (Smith-Robinson)

Indication

The anterolateral approach was borne out of the desire of spinal surgeons to treat diseases of cervical discs and the vertebral bodies, without

having to negotiate a path around the immoveable cord and nerve roots. It is indicated primarily for treatment of pathologies which lie ventral to the cord such as neural compression caused by disc, osteophyte, tumor, abscess, or bone. It is also useful in correcting instability and deformities caused by degeneration, trauma, infection, or tumor. Cervical disc arthroplasty is only possible through an anterolateral approach. This approach should enable access from C2-T2, although this range may be reduced to C3-C7 in certain patients where the mandible or the clavicle restricts further access.

Positioning, Preparation, and Practicalities

The patient is positioned supine with their head on a Mayfield headrest, without any rotation (Fig. 5). A small rolled towel, or alternatively a 500 ml bag of iv fluid, is placed between the scapulae approximately at the level of T2 spinous process. This allows for slight extension of the neck and permits the shoulders to drop back toward the table, providing more room for the surgeons' instruments. The head and neck are secured in position with soft tape or, if traction is known to be needed, Gardener-Wells skull traction. If the arms and shoulders need to be pulled caudally to enable a lateral X-ray to be taken, then they can be held in this position with soft tape to facilitate intraoperative X-rays. An inserted nasogastric tube can facilitate identification of the esophagus in difficult revision approaches; however, this is not necessary in primary cervical surgery. Although palpable anatomic landmarks such as the hyoid (C3), thyroid cartilage (C4/5), carotid tubercle (C6), or the cricoid cartilage (C6) can provide fairly reliable indication of incision location (Fig. 6), it is preferable to use a radio-opaque marking stick and an X-ray machine to map out the incision. The skin around the incision can be pre-infiltrated with a lidocaine and 1:200,000 adrenaline solution to reduce the bleeding from the superficial tissues during the procedure.

Historically, the side of the approach has generated much research interest regarding the effect of side of approach on the risk of recurrent laryngeal nerve (RLN) injury. In the original description of the procedure (1955) (Robinson and Smith 1955), the authors suggest an apparent increased traction applied on the RLN when approaching from the right side and hence they recommend a left-sided approach. Another of the earliest users of this technique (Cloward 1958) used the right-sided approach. There has yet to be any conclusive published evidence that a right-sided approach significantly increases the RLN injury rate, although a cadaveric study (Rajabian et al. 2020) does seem to show that below C5 the RLN requires more retraction to keep it from the field of surgery. For ergonomic reasons, many surgeons favor use of the same side as their hand dominance and this is likely to lead to other indirect benefits such as reduced length of surgery and retractor time. It is helpful for the theater team and the anesthetist to know of the side of the approach in advance, as the endotracheal tube may be positioned to the contralateral side and theater layout can be tailored to the advantage of the surgeon.

Approach

A transverse skin-crease incision is made from the midline to the medial border of the sternocleidomastoid at the desired level. The subcutaneous tissues are dissected and then retracted with a Mollinson retractor, exposing the platysma. The platysma is incised in line with the wound, and the subplatysmal plane is only developed proximally and distally if more than one cervical level is to be approached. The investing layer of the cervical fascia, which envelopes the sternocleidomastoid muscle, is incised along the medial muscle border. The medial musculovisceral tissues (thyroid, esophagus, trachea, strap muscles) are retracted medially with the handheld Cloward retractor, while the surgeon's index finger is used to dissect through the pretracheal fascia and palpate for the pulsation of the carotid sheath underneath the sternocleidomastoid. The superior and inferior thyroid vessels may be encountered at C3/4 and C6/7 levels, respectively, and they can either be

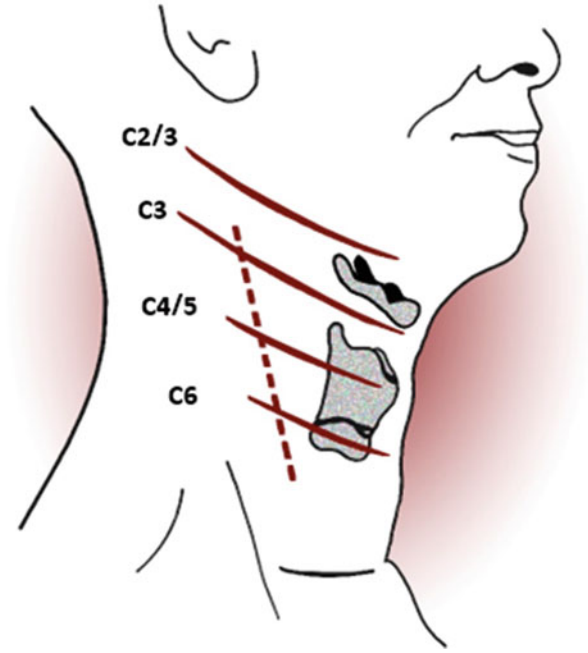

Fig. 5 Incisions related to bony anatomical landmarks including lower border of the mandible (anterior retropharyngeal approach C2/3), hyoid bone (C3), upper aspect of thyroid cartilage (C4/5), cricoid cartilage (C6)

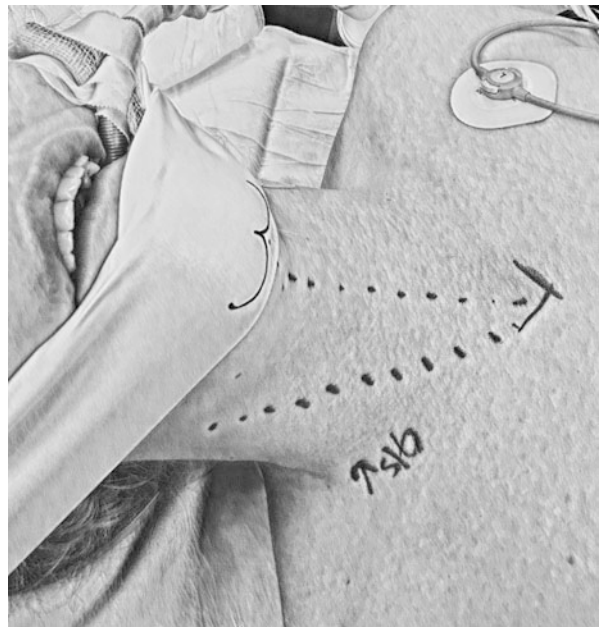

Fig. 6 Anterolateral approach positioning

retracted or ligated if necessary. Omohyoid is often encountered at the level of C6/7, and can also either be retracted or divided laterally. The former option is the author's preferred choice. A plane between the pulsatile carotid sheath and sternocleidomastoid laterally, and the musculovisceral tissues medially is further developed down to the front to the prevertebral fascia (Fig. 7). Through the smooth, white prevertebral fascia it should be easy to palpate the anterior spinal column, made up of alternating ridges and sulci of the intervertebral discs and vertebral

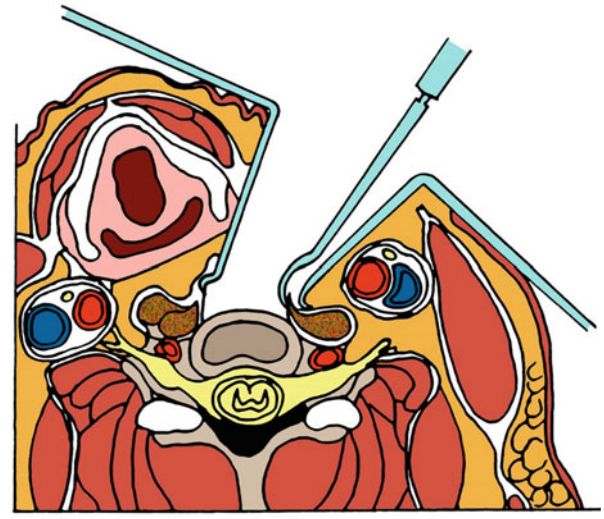

Fig. 7 Cross section of the anterolateral approach at C5/6 showing medial retraction of the thyroid, strap muscles, trachea, and esophagus, and lateral retraction of the sternocleidomastoid and carotid sheath. The longus coli muscle is elevated along its medial border

bodies, respectively. Sweeping the index finger medially and laterally should confirm the location of the midline, between the prominent longus coli and capitis muscles running longitudinally. Using toothed forceps, the prevertebral fascia is lifted at this midline point, and incised proximally and distally to reveal the ALL. A small clip is applied to the ALL and X-ray is used to confirm that the correct level has been approached. The medial borders of longus coli are elevated with insulated diathermy, and toothed retractor blades are inserted under each side (Fig. 8).

Procedure

This approach can be used to gain access to the spine for fracture fixation, such as interfragmentary lag screw fixation of the odontoid process. In this scenario dual image-intensifiers are used to simultaneously obtain anteroposterior and lateral fluoroscopy images of the odontoid. Through a C5/6 anterolateral approach, blunt finger dissection is used to dilate the prevertebral space proximally as far as the C2/3 disc ridge. A curved, radiolucent retractor is inserted into this space, and with the fulcrum of the retractor on the distal C2 body, the anterior musculovisceral tissues of the neck are levered off the anterior spine. This enables two guidewires to be driven up from the anterior inferior rim of the C2 vertebral body, across and perpendicular to the oblique fracture and as far as the subcortical bone of the proximal dens.

The anterolateral approach is invariably followed by one or more discectomies. After the correct level is confirmed on X-ray and retractor blades are secured under the medial boarders of longus coli, diathermy is used to expose the distal half of the cranial vertebra and the proximal half of the caudal vertebra, either side of the disc being removed. The midline can be identified using the midpoint between the two uncovertebral (Luschka's) joints. A scalpel blade is used to make a horizontal rectangular annulotomy, removing the ALL and anterior annulus fibrosus of the disc in one piece. A series of fine curettes are then used to scrape the cartilage from the bony endplates, taking care not to violate the end plates as this is likely to lead to spacer implant subsidence. Once some of the disc and cartilage have been removed, it is possible to increase the space inside the disc by inserting a pin distractor. This may not be necessary if the patient has skull traction already fitted. Two pins are placed in the midline, 3 mm from the edge of cranial and cauda vertebra, taking care to insert them parallel to the endplates. This will enable improved visualization of the deeper structures which are to be carefully removed under microscope guidance with 1–2 mm Kerrison rongeurs and a high-speed burr. Complete discectomy is achieved when the

posterior annulus, posterior longitudinal ligament, sequestrated disc fragments, or compressive osteophytes are removed and both neuroforamen are probed to confirm lack of any compression on the nerve roots. In the event of a corpectomy, it is useful to perform complete discectomy at two adjacent levels, as detailed here. Corpectomy can then be performed, without the risk of violating the cranial or caudal endplates which are needed to support the subsequent corpectomy cage endplates. For ACDF surgery a spacer containing a bone substitute or autologous graft is inserted into the empty disc space and a plate over the cage is optional.

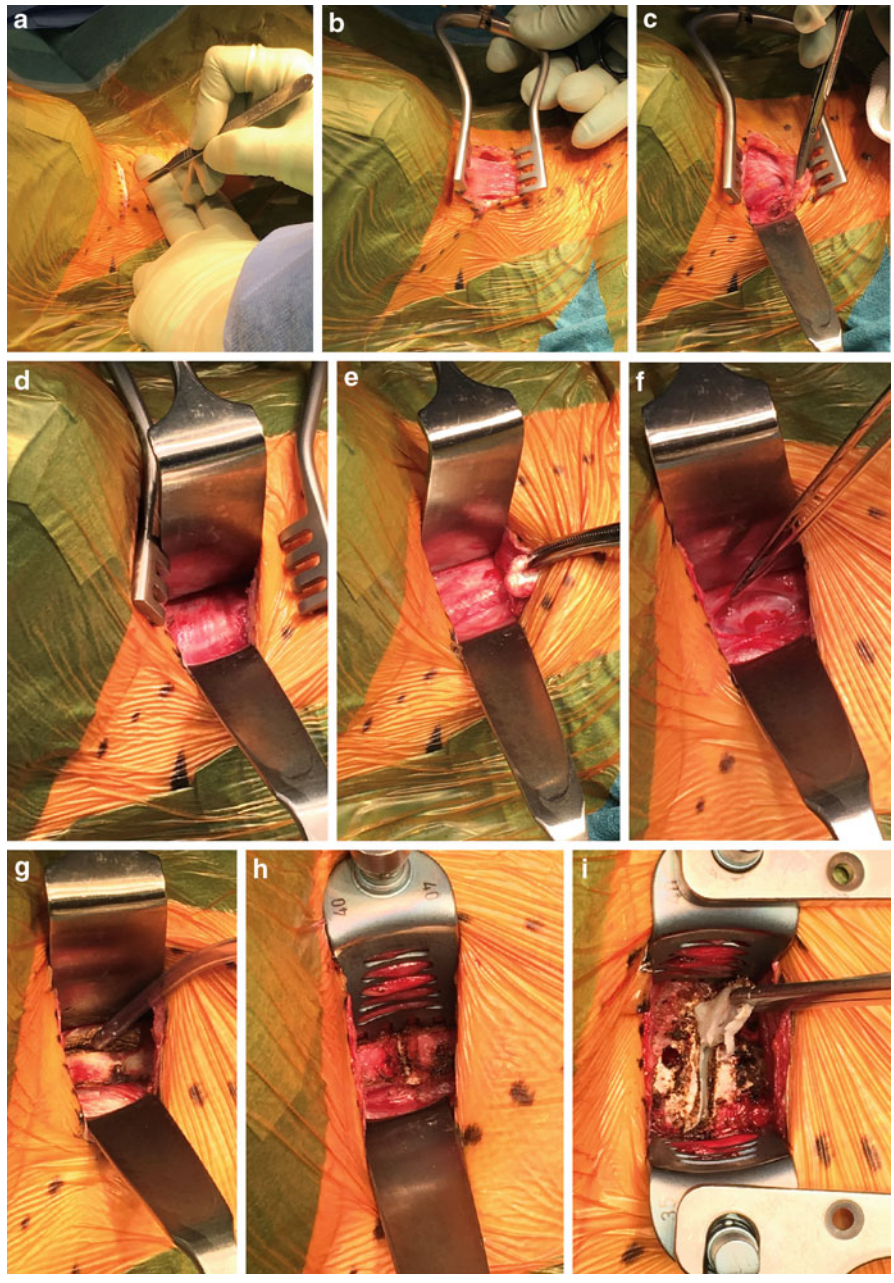

Fig. 8 (continued)

Fig. 8 Anterolateral approach. (**a**) Incision. (**b**) Platysma layer. (**c**) Platysma undermined, revealing the sternocleidomastoid (laterally) and strap muscles (medially). (**d**) Medial retraction of musculovisceral column and lateral retraction of sternocleidomastoid, revealing the carotid sheath (laterally) and pretracheal fascia (medially). (**e**) Medial retraction of the musculovisceral column, and lateral retraction of the carotid sheath, revealing the prevertebral fascia. (**f**) Elevation of the prevertebral fascia and longitudinal incision. (**g**) After the correct level is confirmed on X-ray, the medial edges of longus coli are elevated either side of the disc ridge (covered in ALL, between the longitudinal muscle bellies). (**h**) Toothed retractor blade is carefully tucked in under the longus coli. (**i**) Disc margins are cauterized, annulotomy performed, and disc removed with rongeurs and curettes. (**j**) After complete discectomy and clearance of the posterior longitudinal ligament and osteophytes, an implant is inserted (in this case a cervical disc replacement)

Closure

The platysma muscle is closed over a deep drain, and then fat and skin are closed in separate layers. Suture/clip removal equipment accompanies the patient during the first 12 h in case an urgent evacuation of hematoma is needed to prevent airway compromise.

Structures at Risk

The RLN is at risk during the approach and the time the retractor blades are in situ. It lies in the tracheoesophageal groove and so is not usually encountered during a standard anterolateral approach; it is retracted medially along with the musculovisceral structures and, hence, lies under tension throughout the procedure. The esophagus and pharynx are also at risk, and perforations of either tissue can lead to devastating complications including abscess, tracheoesophageal fistula or mediastinitis. Any abscesses need to be drained and washed out, tears should be repaired, and the patient must remain nil by mouth and receive nasogastric feeds. The sympathetic chain, which lies between the carotid sheath and the longus coli muscle, is at risk from injury if the toothed retractor blades inadvertently slip out from under the longus coli muscles, resulting in Horner's syndrome. The vertebral arteries are at risk as they lie immediately lateral to the uncovertebral joints, which may be opened by either skull traction or segmental pin distractors.

Complications

ACDF is the most commonly performed surgery using the anterolateral approach, with an average of 137,000 ACDF surgeries performed per year in the United States (Epstein 2019). A recent comprehensive review of complications associated with ACDF surgery (Smith and Robinson 1958) has found an overall morbidity rate of 13.2–19.3%. The complications rates are detailed in Table 1. Psueudarthrosis rates rose with the numbers of ACDF levels: 0.4–3% (1 level), 24% (2 level), 42% (3 level), to 56% (4 level).

Table 1 Breakdown of complication rates in ACDF surgery from literature review (1989–2019) (Epstein 2019)

Complication	Rate (%)
Dysphagia	1.7–9.5
Postoperative hematoma	0.4–5.6
Exacerbation of myelopathy	0.2–3.3
Symptomatic RLN palsy	0.9–3.1
Cerebrospinal fluid (CSF) leak	0.5–1.7
Wound infection	0.1–1.6
Worsening of radiculopathy	1.3
Horner's syndrome	0.06–1.1
Respiratory insufficiency	1.1
Esophageal perforation	0.3–0.9
Instrumentation failure	0.1–0.9

Posterior Approach (C3-C7)

Indication

In many respects the posterior approach is more straightforward, and many spine surgeons find it familiar given the large number of posterior lumbar decompressions which are performed each year. This approach is ideally suited to treating any compression of the cord or neural structures caused by posterior structures, such as ligamentum flavum, bone spurs, fracture fragments or hematomas, epidural abscesses, or tumors. Intradural surgery always requires posterior approach and laminectomy. In multilevel stenosis, the posterior approach is often preferred as it enables several levels to be addressed without the morbidity of having prolonged compression on the anterior neurovascular and visceral structures. Posterior approach surgery is also preferred in treating OPLL, large calcified disc prolapse with myelopathy, and as a revision option where anterior approach has already been performed.

Positioning, Preparation, and Practicalities

A neurosurgical head fixation device is fitted to the patient. They are then turned over into a prone position, and the device is fixed to the table (some surgeons prefer to position patients upright). The arms remain by their side on arm supports, and the bed is tilted in slight reverse Trendelenburg position to increase venous drainage and reduce blood loss. The neck is flexed to open the facet joints and to aid the exposure (Fig. 9). Excessive soft tissues around the scapular region can be pulled caudally and taped to the contralateral buttock. The spinous processes of C2 and C7 are usually palpable landmarks. However, it is always advisable to plan the incisions using lateral view X-rays. The skin around the incision should be pre-infiltrated with a lidocaine and 1:200,000 adrenaline solution to reduce the bleeding from the superficial tissues during the procedure.

Approach

A longitudinal midline incision is made in the skin, and sharp dissection down to the ligamentum nuchae. Overzealous stripping of the subcutaneous layer too widely off the ligament should be avoided, as this creates a large dead-space and increases the risk of hematoma and seroma formation. The bifid spinous processes should be palpable through the ligament. The dissection is continued through the ligamentum nuchae in the midline in order to reduce the amount of bleeding. Once the spinous process tip is visible, a small clip is attached to it, and confirmatory lateral fluoroscopic X-rays are obtained. The periosteal dissection is then continued down each spinous process, lamina, and out onto the start of the lateral masses. If posterior instrumentation is to be inserted, the dissection should continue out to the lateral border of the lateral masses. The approach is extensile distally as far as the coccyx, and proximally as far as the occiput (Fig. 10).

Procedure

All or part of the laminae can be removed to enable access to the spinal canal. Care should be taken when inserting the first rongeur or probe through the ligamentum flavum, as at that stage the canal diameter is at its tightest and the cord

Fig. 9 Posterior approach positioning, slight Trendelenburg position with neck flexed

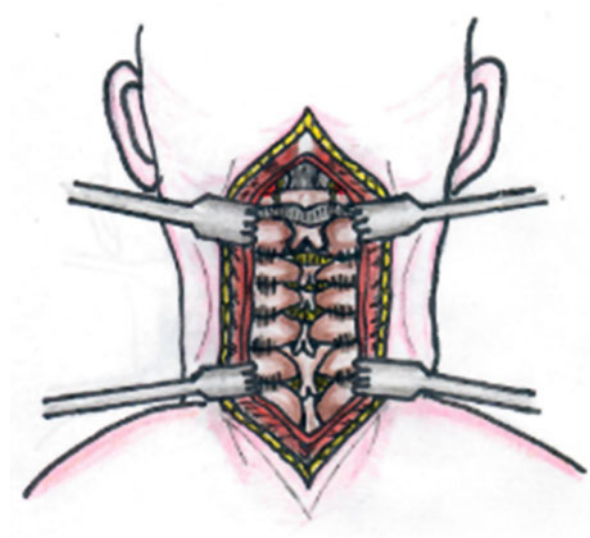

Fig. 10 Posterior cervical approach from external occipital protuberance (inion) to C7 spinous process, out as far as the lateral borders of the lateral masses in preparation for lateral mass screw fixation and fusion

may be vulnerable to injury. The high-speed burr should be used to thin the base of the lamina and only a 1 mm Kerrison rongeur should be used until the canal is mostly decompressed.

If a muscle sparing, lamina-splitting approach was planned, a high-speed burr is used between the bifid spinous process and down through the middle of the lamina. The lateral edges of the

laminae are then thinned with the burr until they can be bent out or detach from the base where they meet the lateral masses. This keeps the external muscular attachments while allowing access to the base of the lamina and then the spinal canal. Decompression can be achieved at two levels through this single split spinous process. Various laminoplasty techniques are also possible, either with or without implants.

If stabilization is required due to the extent of the decompression, the lateral masses are cleared of all remaining facet capsule tissue and the boundaries are clearly defined. The screws are then inserted using the surgeon's choice of technique.

Closure

The ligamentum nuchae is repaired over a drain. Copious infiltration with local anesthetic into the deep and superficial tissues around the wound helps to reduce the need for opiates in the immediate post-op phase of recovery.

Structures at Risk

The vertebral artery is largely shielded from the surgeon by the lateral masses, although it is at risk at the proximal end of the approach at C2, or during instrumentation of the lateral masses. It is advisable to have a 14 mm lateral mass screw loaded and ready to immediately insert, in the event of a vertebral artery injury with the lateral mass drill.

Complications

Post-laminectomy kyphosis is a risk associated with posterior approach surgery due to muscle denervation or excessive decompression. The risk increases with age, increasing numbers of levels being decompressed and if C2 is approached, and it can be as high as 47% in these groups (Nishizawa et al. 2012). Other complications associated with the posterior cervical approach include epidural hematoma (1.3%), wound infection (1.2%), C5 nerve palsy (4.6%), and spinal cord injury (0.18–2.6%) (Cheung and Luk 2016; Nishizawa et al. 2012). Complications relating to lateral mass screws include misplacement (0–7%), vertebral artery injury (1.3–4%), and neural injury (1.3%) (Cheung and Luk 2016; Nishizawa et al. 2012).

Posterior Approach (Occiput-C2)

Indication

The posterior approach to the C1/C2 may be indicated for insertion of C1/2 fixation screws, for reduction and stabilization of a fracture or dislocation, for decompression for degenerative disease, or excision of a tumor. There may be a need to extend the fixation up to the occiput.

Positioning, Preparation, and Practicalities

A neurosurgical head fixation device is fitted to the patient. They are then carefully tuned over into a prone position, and the device is fixed to the table. If the indication is for fracture fixation, a lateral X-ray is obtained to see if adjustments are needed to reduce any displacement which may have occurred during the proning of the patient. The arms remain by their side on arm supports, and the bed is tilted in slight reverse Trendelenburg position to increase venous drainage and reduce blood loss. The neck is flexed under fluoroscopic guidance to allow correct placement of the C1/2 fixation screws. The external occipital protuberance, the first palpable spinous process (C2), and the most prominent spinous process (C7) are usually palpable landmarks. However, it is always advisable to plan the incisions using lateral view X-rays. The skin around the incision should be pre-infiltrated with a lidocaine and 1:200,000 adrenaline solution to reduce the bleeding from the superficial tissues during the procedure.

Approach

A midline incision is made from the external occipital protuberance down to the mid-cervical spine. Overzealous stripping of the subcutaneous layer too widely off the ligament should be avoided, as this creates a large dead-space and increases the risk of hematoma and seroma formation. The bifid spinous processes should be palpable through the ligament, especially those of C2 and C7. The dissection is continued through the ligamentum nuchae in the midline, in order to reduce the amount of bleeding. Once the spinous process tip is visible, a small clip is attached to it, and confirmatory lateral fluoroscopic X-rays are obtained. The periosteal dissection is then continued down the C2 spinous process, lamina, and out onto the lateral masses, and up onto the occiput. The C1 posterior arch is deep between the C2 spinous process and the occiput. The tissues over the posterior arch are carefully dissected outward up to about 1.5 cm from the midline, using either a knife or bipolar diathermy. The vertebral artery runs over the cranial part of the arch and enters the spinal canal behind the lateral mass of atlas (Jeanneret 2015). Only the superior part of the midportion of the posterior C1 arch is prepared. A small sharp elevator is used to identify and subperiosteally clear the cranial surface of the C2 lamina. On sliding along the edge of the lamina, the elevator will meet the isthmus of C2, at which point the soft tissues cranial to the elevator contain the C2 root with its venous plexus. This can be elevated to expose the C1/2 articulation. It can also be ligated leading to occipital numbness but reducing the chance of a painful neuroma caused by constant impingement by a C1 lateral mass screw on a retained C2 nerve root.

Procedure

At this stage either transarticular screws can be passed supplemented with a wired fusion of the spinous process tips. Alternatively, smooth-shank screws can be passed into the lateral masses of C1 and pedicle screws into C2, once again using the fine elevator to feel the trajectory of the C2 pedicles and the C1 lateral masses. The two pairs of polyaxial screws are then connected to the rods to complete the stabilization. If C1 is not to be instrumented, its posterior arch need not be exposed, and rather more exposure of the occiput is required to accommodate the occipital plate. Once fixed to the occiput, the plate can be connected to the cervical screws with two rods bent to 90° to fix the head in a position which will permit a forward gaze.

Closure

The ligamentum nuchae is repaired over a drain. Copious infiltration with local anesthetic into the deep and superficial tissues around the wound helps to reduce the need for opiates in the immediate post-op phase of recovery.

Structures at Risk

The main structure at risk is the vertebral artery. It is most vulnerable to injury during lateral dissection along the posterior arch of the atlas, and one should not attempt to dissect tissues more lateral than the greater occipital nerve (Singh et al. 2011).

Complications

Complications related specifically to upper cervical approaches include adjacent segment disease (7%), pseudoarthrosis (6%) and problems with the occipital plate screws, loosening (4.2–7%), and CSF leak (0–4.2%). As with lower cervical surgery, post-laminectomy kyphosis is a risk associated with posterior approach surgery due to muscle denervation or excessive decompression. The risk increases with age, increasing numbers of levels being decompressed and if C2 is approached, and it can be as high as 47% in these groups (Nishizawa et al. 2012). Other complications associated with the posterior cervical approach include epidural hematoma (1.3%),

wound infection (1.2%), C5 nerve palsy (4.6%), and spinal cord injury (0.18–2.6%) (Cheung and Luk 2016; Memtsoudis et al. 2011; Nishizawa et al. 2012). Complications relating to lateral mass screws include misplacement (0–7%), vertebral artery injury (1.3–4%), and neural injury (1.3%) (Nishizawa et al. 2012).

Conclusions

Preparation for cervical spine surgery commences in the outpatient clinic when a condition is diagnosed based upon symptoms, signs, and investigation findings. Surgeons will then make plans on how best to treat the condition and weigh up the advantages and disadvantages of each treatment option. Eventually, they will arrive upon the approach, which is least invasive for the patient, most likely to achieve the surgical goal, and is within their capabilities – in that order of importance. It is clear from reading this chapter that there are often several options for treating the same conditions, which is fortunate as not all patients suit the same approach for a single condition. For example, a music teacher who leads a choir may reasonably have their radiculopathy treated with a posterior cervical foraminotomy to avoid the rare complication risk of an RLN palsy, whereas their pathology could equally have been treated with an ACDF, and may have resulted in less neck pain afterwards.

Once the surgical plan has been made, it is also important to have contingency plans in place to help the surgeon navigate through unexpected challenges that may be encountered in the operating room.

Knowing the anatomy before performing surgery around the cervical spine is of critical importance given the devastating consequences of the complications which can occur. Hopefully, with a better understanding of the various approaches available and their anatomical detail, the surgeon will be better equipped to select the best options for their patients and deliver their management proficiently.

Abstract

Chronic low back pain is one of the leading causes of adult disability globally. Currently there are no therapeutic options that target the commonest pathophysiology of back pain which is intervertebral disc degeneration. Intradiscal therapeutics aim to treat some aspects of the pathological disease processes, by regenerating or assisting biophysical characteristics of the intervertebral disc. Intradiscal therapies include biological therapy, cell-free implantation, and anti-inflammatory agents and research conducted into these areas will in time elucidate an effective intradiscal therapeutic for disc degeneration. This chapter reviews the horizon of this exciting area of development.

Introduction

Chronic low back pain is one of the most common musculoskeletal diseases worldwide, with 70–85% of adults experiencing back pain at some time in life (Andersson 1999). The accepted leading cause for chronic low back pain is intervertebral disc (IVD) degeneration, with sciatic pain associated with posterior IVD herniation (Luoma et al. 2000). Current treatments such as discectomy or analgesia only target the clinical symptoms of the disease rather than treating the pathological process itself. Intradiscal therapeutics aim to treat aspects of the pathological disease process, by regenerating or assisting (by way of aiding or augmenting) biological processes and thereby physical characteristics of the IVD.

Biological Therapy

Biological therapies function by regenerating an aspect of the IVD. Within early disc degeneration biological therapies involve enhancing anabolic extracellular matrix (ECM) molecules, or to lower the levels of catabolic ECM molecules. Biological therapies focus growth factors to promote anabolic molecule synthesis, either by direct or indirect stimulation (Moriguchi et al. 2016). A presentation of promising and unfavorable results allow insight into which model would be the most appropriate to pursue for bedside therapy.

Bone Morphogenic Protein 7

Bone morphogenic protein 7 (BMP-7), also known as osteogenic protein-1 (OP-1), is part of the bone morphogenic protein (BMP) family which regulates many aspects of embryonic skeletal development, including osteoblast and chondrocyte differentiation, cartilage and bone formation, mesoderm patterning, and craniofacial and limb development (Wan and Cao 2005). OP-1 is used clinically as an adjunct to treatment of fractures and atrophic long bone nonunion. OP-1 has been used within posterolateral lumbar fusion as a substitution for autologous bone. However a large prospective, randomized, multicenter

clinical trial of 295 patients suggested in the 4 year follow-up that autograft appeared to have superiority in bridging bone formation (Hustedt and Blizzard 2014). Hence, it was reasonable to investigate a clinically available molecule as a possible intervertebral disc regenerator rather than a spinal fusion enhancer.

The rationale of OP-1 is to increase anabolic ECM proteins. Within the context of IVD regeneration, OP-1 has been experimented in animal trials involving rats, rabbits, and canines, with the disc degeneration models including needle puncture, nucleus pulposus aspiration, compressive loading, chondroitinase induction, and spontaneous degeneration. Delivery of OP-1 into the IVDs has either been direct OP-1 protein injection or cell-based and viral-based OP-1 gene transfer. OP-1 has been demonstrated to increase disc height and MRI T2 intensities compared to the control, indicating its strong ability to regenerate degenerated discs. OP-1 was found to enhance disc mechanical function, maintain spine stability, and alleviate pain-related behaviors. However, the rabbit and mice models used mostly keep the notochordal cells into adulthood, whereas in humans they disappear before the age of 10 and hence the animal IVDs may contain more regenerative capabilities than the human IVD. Moreover, within humans the natural degeneration is a slow process, whereas within the models the applied degeneration is acute and may not mimic the natural human degenerative process (Li et al. 2017). On the other hand, notochordal cells disappear when degeneration is induced prior to OP-1 or other therapeutic injections. Care should be taken when OP-1 delivery is used to treat human disc degeneration due to the differences between human and animal discs.

Research into human IVD regeneration has undergone in vitro experiments. Within a cadaveric model, human nucleus pulposus (NP) cells grown in a medium containing OP-1upregulated proteoglycan synthesis and accumulation, and prevented a decrease in cell numbers (Imai et al. 2007; Wei et al. 2008). In moderately degenerated lumbar discs, capacitively coupled electric stimulation increased BMP-7-induced upregulation of aggrecan and collagen type II (Wang et al. 2017). However, degenerative human NP cells cultured with OP-1 alone, or released from a slowly degrading biomaterial, had no positive effect on the cell growth (van Dijk et al. 2017).

OP-1 has been effective in halting disc degeneration and regenerating degenerative discs within animal models. However, there has been varying results demonstrated within human NP cell regeneration. A phase 2 study was conducted in late 2000's to evaluate the safety and efficacy of OP-1 as a disc regenerator. The results of this trial are not available in the public domain. Further research is mandatory to assess the efficacy and safety of use of OP-1 into human subjects prior to consideration as an intradiscal therapeutic option for disc degeneration.

Growth and Differentiation Factor 5

Growth and differentiation factor 5 (GDF-5) is part of the BMP family and is also known as BMP-14 and cartilage-derived morphogenic protein 1 (CDMP-1). The function of GDF-5 is primarily chondrogenesis during embryonic development. It is present within the joint regions of skeletal precursors to subdivide the precursor into the individual skeletal elements, and is required in all joints for normal development (Settle et al. 2003). Mutation of the GDF-5 gene results in anomalies of development such as Du Pan syndrome, Hunter–Thomson dysplasia, and lumbar disc degeneration.

GDF-5 has been demonstrated to have some reasonable effects on intervertebral disc regeneration. Within live animal models, GDF-5 has regenerated mouse and rabbit intervertebral discs. GDF-5 has also been demonstrated within human cell experiments to increase cell numbers and matrix proteins, establishing it as a protein that can possibly cause IVD regeneration. Delivery methods of GDF-5 into live animals resulting in positive results include protein injection, viral-based gene transfer, and slow releasing biomaterials.

However, there are some disadvantages presented by GDF-5. Repeated injections of GDF-5 results in inflammation of the IVD, which impedes the biological effect of the growth factor (Walsh et al. 2004). GDF-5 has been shown to function in a dose-dependent manner, with a short

half-life of 20 min, which means repeated injections would be required in human subjects (Cui et al. 2008). The subsequent inflammation may negate any positive effects of GDF-5. A recent clinical trial NCT00813813 has been conducted assessing injections of GDF-5 into the IVD, with results yet to be published. Our center was involved in the escalating dose arm of the phase 2 multicentric outside the US study. While the average reduction in visual analogue scores for pain was good, the variability in individual patient's response and lack of sponsor support led to cessation of the development of the molecule. Finally, Clarke et al. have demonstrated within an in vitro study that GDF-5 lacked the ability to convert stem cells effectively to disc cells when compared to GDF-6 (Clarke et al. 2014).

Growth and Differentiation Factor 6

Growth and differentiation factor 6 (GDF-6) is part of the BMP family and is also known as BMP-13 and CDMP-2. During embryonic development, GDF-6 is expressed strongly in the notochordal cells of the NP, and key extracellular matrix molecules aggrecan and collagen type II coincide with GDF-6 expression (Wei et al. 2016). GDF-6 mutations are related to several disease states including Klippel–Feil syndrome, and age-related macular degeneration.

GDF-6 has had positive results in regeneration of the IVD. GDF-6 was found within mouse mesenchymal stem cell lines to induce anabolic extracellular matrix (ECM) molecules, without causing ossification, validating its possibility as a regenerative therapy. Conversely with GDF-5, the adenoviral vector transmission did not effectively increase anabolic ECM molecules to a significant level (Zhang et al. 2006, 2007). However, direct culturing of NP cells with GDF-6 elicited positive results (Gulati et al. 2015). An ovine annular puncture model with GDF-6 treatment applied simultaneously with the annular injury showed complete restoration of the IVD height after 4 months (Le Maitre et al. 2015). A rabbit annular puncture model with GDF-6 treatment applied 4 weeks after injury demonstrated faster recovery with GDF-6, and some recovery of the IVD height (Miyazaki et al. 2018).

GDF-6 has been demonstrated to be a potential future intradiscal biological therapy for IVD degeneration. There are encouraging results from in vitro and in vivo trials providing some evidence that GDF-6 can regenerate the IVD after injury. However, disadvantages to GDF-6 treatment include its cost, time to manufacture, and lack of human data. Future research would include clinical trials to assess the safety and efficacy of the molecule.

Hepatocyte Growth Factor

Hepatocyte growth factor (HGF) was first identified as a potent mitogen of primary cultured hepatocytes. HGF is essential in mammalian development, as disruption of the HGF gene resulted in impaired organogenesis of the liver and placenta and is incompatible with life. HGF is also involved in formation and trophic support of vital organs such as the kidneys, lungs, heart, and brain. The receptor for HGF was identified as c-met proto-oncogene product (c-Met) and the HGF-c-Met signalling pathway leads to multiple biological responses in a variety of cells including mitogenic, morphogenic, and antiapoptotic activities (Funakoshi and Nakamura 2003; Nakamura et al. 2011)

The therapeutic approaches for HGFwithin animal models have been very effective for the treatment of chronic fibrosis in various disease models, such as liver cirrhosis, chronic kidney disease, dilated cardiomyopathy, and lung fibrosis (Nakamura et al. 2011). There have been few human clinical studies with HGF, however a recent randomized, double-blind, placebo-controlled clinical trial of hepatocyte growth factor plasmid for critical limb ischemia demonstrated the safety and efficacy of HGF treatment using naked plasmid (Shigematsu et al. 2010). There are currently several clinical trials occurring in the context of cardiac therapy for conditions such as acute coronary syndrome, myocardial infarction, and critical limb ischaemic.

For the treatment of intervertebral disc degeneration limited research has been conducted. A rat

tail disc degeneration model was applied, and a slow release biomaterial was used as the vehicle to deliver HGF. The experiment resulted in an increase in T2-weighted signal intensity on MRI, improved histological score, and stronger immunohistochemical responses demonstrating some prevention of IVD degeneration (Zou et al. 2013). In a rabbit cellular in vitro model HGF promoted NP cell proliferation, inhibited apoptosis and inflammatory cytokine expression, however did not affect matrix protein production (Ishibashi et al. 2016). The results suggest that HGF alters matrix catabolism and hence may be used as an adjunct to prevent degeneration. However as there is no improved anabolic effect, HGF alone may not induce IVD regeneration. Further studies within animal models to elucidate the exact expression of HGF and its receptor c-Met within the IVD is required to research the anabolic response elicited. HGF may be a potential adjunct within future intradiscal IVD therapy.

Platelet-Rich Plasma

Platelet-rich-plasma (PRP) is obtained by concentrating platelets and blood products with the use of a centrifuge. PRP can contain up to eight times the products found in blood and includes not only platelets but a variety of growth factors such as epithelial growth factor (EGF), platelet-derived growth factor (PDGF), transforming growth factors (TGF), and vascular endothelial growth factor (VEGF). Many of these growth factors are stored in granular storage compartments within the platelets, which must be activated to release their contents. The concentration of growth factors parallels the increased concentration of platelets. PRP can increase collagen content, accelerate endothelial regeneration, and promote angiogenesis. Whilst the scientific basis remains to be elucidated, due to ease of availability, and no intellectual property disputes, PRP has been used for various applications such as assisting repairs of the common extensor tendon of the elbow, rotator cuff tendons, and knee articular cartilage (Monfett et al. 2016).

PRP contains growth factors which are claimed to be beneficial in regeneration of IVD degeneration. Within in vitro models of both human and animal cells, PRP increased proteoglycan and NP cell proliferation, as well as upregulated ECM synthesis. PRP also downregulates proinflammatory cytokines and reduces their detrimental effect upon the NP cells (Yang et al. 2016). Within rabbit in vivo models, PRP increases the water content present on T2 MRI within the IVD suggesting a restoration of matrix function, and in some studies increased the disc height of the PRP-injected IVDs. Within rat models, there was an increase of water content present within T2 MRI. The animal models suggested PRP to be appropriate for treatment of IVD degeneration (Monfett et al. 2016; Obata et al. 2012). It remains unclear whether a specific factor helps the PRP achieve its intradiscal effect, or it is the cells and associated media.

There have been clinical trials assessing the safety and efficacy of PRP. Autologous blood cells are used, and are activated by calcium chloride, which is advantageous as there is little side effects using this technique. However, a disadvantage with this technique is that there is variability in the concentration of growth factors within the PRP. Another disadvantage is the vehicle of delivery, as injections themselves can induce inflammatory responses. However, there have been encouraging results presented from a double-blinded randomized control trial with 47 patients, with reduced pain and increased function even up to 2 years later (Tuakli-Wosornu et al. 2016). A feasibility trial observed the effects of stromal vascular fraction and PRP, essentially PRP enhanced with adipose-derived stem cells (ADSC), and within 15 patients after 6 months there was decrease in pain, increase in flexion, and no adverse effects (Comella et al. 2017). The trials suggest PRP may have potential to lower back pain.

PRP has encouraging findings particularly within the clinical setting. Future research would involve phase 2 and 3 trials discovering which group of patients would receive the most benefit from the treatment, finding the optimum concentration for PRP, and combining with other biological and stem cell therapy to find the most effective treatment.

Link-N

Link-N, also known as DHLSDNYTLDHDRAIH is the N-terminal peptide of the link protein. The role of Link-N is to stabilize the proteoglycan aggregates, by binding both to aggrecan and hyaluronate. Link-N is generated by the cleavage of human link protein by stromelysins 1 and 2, gelatinase A and B, and collagenase between His(16) and Ile(17) (Mwale et al. 2003). As Link-N is a synthetic peptide, it has the possibility of being financially beneficial as it is cheap to produce.

Link-N has been researched mainly within the context of IVD repair. Link-N functions by binding to the BMP receptor II, which establishes a classical feed-forward circuit converging on SMAD 1/5 activation. The feed-forward loop is the BMP-RII inducing BMP-4/7 synthesis which activates BMP-RI to produce SMAD 1/5, whilst the BMP-RII also itself induces SMAD 1/5 production (Wang et al. 2013). Link-N is proteolytically cleaved by AF cells into a bioactive short form of the peptide (sLink-N), into a residue spanning amino acid residues 1–8.

Link-N has been demonstrated to increase anabolic ECM proteins. Within both animal and human in vitro models, Link-N has been shown to induce the production of collagen type II, aggrecan, and glycosaminoglycan content. Within an in vivo rabbit annular puncture model, Link-N increased the disc height, increased anabolic proteins, and decreased catabolic cytokine levels (Mwale et al. 2011; Wang et al. 2013). Within a human in vitro model, sLink-N increased the levels of collagen type II and aggrecan. However, Link-N has a limited capacity to overcome catabolic and proinflammatory cytokine expression presented within severely degenerated NP cells (AlGarni et al. 2016; Bach et al. 2017).

Link-N has the capability to upregulate anabolic ECM proteins within human IVD cells, however this may be limited within the late stages of degeneration. It may be able to prevent or regenerate early stages of IVD degeneration. As part of the mechanism of Link-N is activating the BMP-4 and BMP-7 pathways, caution should be taken as these are potentially osteogenic growth factors. The safety and efficacy of Link-N is yet to be established, however the promising results and financial benefit lead Link-N to be an attractive molecule for further research for an intradiscal therapeutic for disc degeneration.

Statins

Statins function by inhibiting 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase and are the most efficient agent to reduce blood cholesterol with good tolerance. Statins alter the conformation of the enzyme, making the effect very specific. Statins also have anti-atherosclerosis effects, reducing incidents of coronary events (Stancu and Sima 2001).

Simvastatin activates BMP-2 gene expression, a growth factor which stimulates osteoblast proliferation but inhibits osteoblast differentiation, making it an ideal candidate for stimulation of bone formation (Mundy et al. 1999). However within the human IVD cells, BMP-2 facilitated the chondrogenic gene expression of human IVD cells with no evidence of bone nodule formation, and simvastatin was demonstrated within rat IVD cells to upregulate BMP-2 expression and stimulate the production of anabolic ECM molecules (Zhang and Lin 2008). Simvastatin loaded into a hydrogel carrier, injected into rat tails which had undergone annular needle puncture, increased anabolic ECM molecules, collagen type II, and the density on MRI improved (Zhang et al. 2009). Simvastatin was demonstrated within a rat model to function more effectively if injected within a hydrogel carrier, than a saline model, with improvements within MRI and histology and higher gene expression of anabolic ECM molecules (Than et al. 2014). Simvastatin was demonstrated to suppress several catabolic ECM molecules, suggesting that simvastatin may not only be effective in inducing NP cells to express regenerative ECM molecules, but may also help prevent any further degeneration (Tu et al. 2017).

Lovastatin is very similar to simvastatin, with the same mechanism of action, similar hydrophobicity, and same method of metabolization by cytochrome P450 3A. A difference is in reduction

of LDL-cholesterol. To reduce cholesterol by 25–30%, 10 mg of simvastatin are required, whereas 20 mg of lovastatin is needed for the same effect (Neuvonen et al. 2008). Simvastatin was shown to stimulate BMP-2 production, and as they have a similar mechanism of action, lovastatin was researched. Within human nucleus pulposus cells in vitro lovastatin upregulated collagen type II genes and chondrogenesis gene SOX9 (Hu et al. 2011). Within a discography-induced rat model, lovastatin was shown to increase anabolic ECM molecules, whilst suppressing collagen type I production which leads to fibrotic scar tissue (Hu et al. 2014).

The early research presented has shown statins to have positive results for intervertebral disc regeneration. However, as the statins mechanism of action for intervertebral disc regeneration rely on the BMP-2 pathway, it is appropriate to consider results of trials investigating BMP-2. BMP-2 has positive results, including inducing mitosis and increasing anabolic ECM molecules, however it has also been demonstrated to reduce proteoglycan content, initiate ossification of the annulus fibrosus, and accelerate osteophyte formation (Belykh et al. 2015). Furthermore, there has been no assessment of regeneraion on disc height and whether catabolic molecules have an effect upon statins function. Whilst early findings are promising, more research is required to assess if statins can be a feasible treatment for intradiscal therapy of disc degeneration.

Haematopoietic Stem Cells

Haematopoietic stem cells (HSC) are progenitor cells which have the capability to differentiate into cellular elements of blood and maintain blood cell production throughout an individual's whole life. HSC transplantation was one of the first proven clinical uses of stem cells, and is being researched to be used as a cure for haematological malignancies (Barriga et al. 2012). HSCs were the first cell therapy used with living humans for treatment of IVD diseases (Wu et al. 2018).

There has been very limited research between HSCs and IVD treatments. According to a prospective analysis of 10 patients found after 1 year, intradiscal HSC injections had 0% reduction in their pain (Haufe and Mork 2006). Moreover, a rabbit model of determining the fate of injected human HSC and MSC cells within coccygeal discs discovered no detection of HSC cells after 21 days, whereas the MSC cells survived and differentiated into a chondrocytic phenotype (Wei et al. 2009). These were the only two studies found assessing HSC in the context of IVD degeneration.

Currently there is little evidence to suggest HSCs have the potential to assist in the treatment of IVD diseases. However, there have been very few studies and hence there is a potential for future research to investigate the relationship between HSC and the IVD, including if within cellular contexts HSC can survive in an avascular tissue such as the IVD, and if they can be differentiated into a chondrocytic phenotype. HSCs are currently unsuitable to be an intradiscal therapy for IVD degeneration.

Hypertonic Dextrose

Prolotherapy is a minimally invasive technique where percutaneous delivery of a therapeutic results in influx of macrophages, fibroblasts, and other molecules with the final goal of new collagen formation strengthening the connective tissue, reducing pain, and disability (Linetsky and Manchikanti 2005). Hypertonic dextrose has been used as a prolotherapy agent for a range of chronic pain conditions with positive results. Prolotherapy within the intervertebral disc may result in improvement of discogenic pain due to modulation of chemoreceptors for pain (Miller et al. 2006).

There have been clinical trials assessing the use of hypertonic dextrose within IVD degeneration. Miller et al. studied advanced lumbar disc pain within 76 patients, with 43.4% of patients having a sustained treatment response with an improvement in pain reduction by 71% after 18 months (Miller et al. 2006). Many other trials have been conducted in treating chronic low back pain, however the hypertonic dextrose has been injected into the surrounding soft tissue, or other

areas of the vertebrae including the lamina, spinous process, and vertebral body, with prolotherapy providing significantly greater long-term pain reduction than corticosteroid injection in patients with sacroiliac joint pain (Hauser et al. 2016).

The principle of prolotherapy is introducing a small irritant, to create a low-level inflammatory reaction to induce fibroblasts, growth factors, and other cytokines to induce proliferation and create new connective tissue to strengthen the area (Hauser et al. 2016). Within the intervertebral disc, inflammation induces a degenerative response, and can accelerate degenerative disease (Carragee et al. 2009). Future research into hypertonicdextrose would involve its effect on the IVD, and its long-term safety. Due to the mechanism of prolotherapy theoretically inducing disc degeneration, despite the prospective trial presented having some benefits, it will be with great caution and skepticism that clinicians will assess hypertonic dextrose as a future therapeutic intradiscal treatment for degenerative IVD diseases.

Summary of Biological Therapies

The growth factors BMP-7, GDF-5, and GDF-6 have been demonstrated to be possible sources of future therapy for IVD degeneration, however there is still more research to be conducted. HGF may have a role, but as an adjunct to therapy as an anticatabolic agent. PRP is currently being used in clinical trials, however further results are needed to assess its efficacy. Link-N and statins function through other growth factors which are yet to be established for effective IVD therapy, yet they might bring about possible positive results. HSC and hypertonic dextrose have shown little improvements and probably do not have a role in future intradiscal treatments of IVD degeneration.

Chemonucleolysis

Chemonucleolysis is a percutaneous intradiscal injection to dissolve the nucleus pulposus. This aims to reduce intradiscal pressure, reducing pain within cervical and lumbar disc herniations. Moreover, destruction of the dermal nerve endings which are present in IVD degeneration within the cartilaginous end plate may also result in pain relief. Interestingly, this technique is used within animal models to induce disc degeneration (Norcross et al. 2003). An exploration of chemonucleolysis will elucidate whether it is an effective treatment for pain relief, or an inducer of degeneration.

Chymopapain

Chymopapain is a proteolytic enzyme derived from the latex of papaya (*Carica papaya*). It is a chemonucleolytic agent, which functions by causing dehydration and degradation of nuclear proteoglycans. Chymopapain was first introduced in 1964 and used in the treatment of lumbar disc herniation until the 1980s, with production discontinued in 2003. Chymopapain treatment involved using a minimally invasive injection with local anesthetic.

There were several clinical trials assessing chymopapain's treatment of symptomatic lumbar disc herniations. Two meta-analyses have been completed investigating chymopapain, which have been summarized by Varshney and Chapman (2012; Couto et al. 2007; Gibson and Waddell 2007). The meta-analyses concluded that chymopapain was superior to placebo in the treatment of symptomatic lumbar disc herniations, with fewer patients having subsequent surgery. In comparison with the gold standard of microdiscectomy, despite gross heterogeneity between 12 studies, surgery was found to be superior to chymopapain for treatment and long-term outcomes. Concerning the safety of chymopapain, the anaphylaxis rate was 0.5%, with a total mortality rate of 0.02%. Compared to microdiscectomy mortality rate of 0.1%, it was considered a safer procedure (Nordby et al. 1993).

The FDA maintains chymopapain on its discontinued product list, however not for reasons of effectiveness. Simmons and Fraser suggest several reasons for the loss of popularity and eventual discontinuation of chymopapain, including poor

techniques leading to complications, inappropriate patient selection including patients allergic to papaya, changes in attitude of early rehabilitation after surgery, and use of targeted epidural steroids (Simmons and Fraser 2005). Regarding future research for treatment of degenerated IVDs, chymopapain would not treat the disease state, only causing possible symptomatic relief through chemonucleolysis.

Gelified Ethanol

Pure ethanol is an effective agent to induce chemonucleolysis. However, it is radiopaque and is injected blindly, with a risk of an undetected leak into the epidural space. The leak can damage all components of the IVD, giving rise to severe pain. Gelified ethanol (GE) is pure ethanol enhanced with ethyl cellulose to increase the viscosity of the liquid and regulate its diffusion, thus reducing the risk of epidural leaks, and radiopaque tungsten for visualization (Theron et al. 2007, 2010). GE has advantages over similar techniques as it does not cause the allergic reactions of chymopapain, and it has a more lytic effect than oxygen-ozone.

There have been several trials assessing the safety and efficacy of GE. A preliminary study of 276 patients demonstrated safety of the technique with no pathologic event recorded after 4 years, and patients had an increase in function and reduction in pain (Theron et al. 2007). Thirty-two patients who failed treatment of oxygen-ozone chemonucleolysis therapy were treated with GE, with success within 75% of the patients (Stagni et al. 2012). A further 80 patients with lumbar and cervical disc herniations were treated with GE, and 3 months later 85% of lumbar disc herniation patients and 83% of cervical disc herniations obtained significant improvement in function and reduction of pain (Bellini et al. 2015). Twenty-nine patients with L5-S1 disc herniations with failed conservative treatments were treated with GE, and at the 6–12 month follow-up 66% of patients obtained a 50% relief of pain, with only three patients not experiencing any pain relief from the treatment (Houra et al. 2017).

GE has been demonstrated to be effective at treatment of radicular leg pain, compared with low back pain. The pathophysiological mechanism of radicular pain is most likely a combination of somatic pain from the outer annulus and adjacent ligaments, and neuropathic pain from nerve root compression and chemical inflammatory reaction. GE, by reducing the pressure caused by herniations, serves to reduce this radicular pain. GE's mechanism of action is destruction of the nucleus pulposus, rendering it unsuitable for treatment of degenerative disorders other than disc herniation.

Oxygen-Ozone

Oxygen-ozone (O_2-O_3) is a chemonucleolysis agent which is used in the treatment of lumbar disc herniation. The mechanism of action relies on the chemical properties of both oxygen and ozone. Oxygenation leads to reduced pain due to the oxidization of proinflammatory mediators and improves microcirculation within the compressed areas. Ozone is an unstable allotropic form of oxygen, and reacts with proteoglycan glycosaminoglycans (GAG) to form oxidization products smaller than the original GAGs, reducing the osmotic pressure of the NP, and causing dehydration and shrinking the disc (Murphy et al. 2016; Muto et al. 2004). Empirical studies have demonstrated the optimal concentration of ozone per millimetre of oxygen to be 27 μg (Iliakis et al. 2001).

Several clinical studies have been undertaken assessing O_2-O_3 therapy for treatment of lumbar disc herniation. Intradiscal injections of O_2-O_3 have been demonstrated to reduce pain and improve function after 1 month (Murphy et al. 2015), 6 months (Lehnert et al. 2012), 6 months with an additional paraganglionic injection (Andreula et al. 2003), and after 2 years intradiscal injections alone (Das et al. 2009). Intraformational injections have also been demonstrated to have success after 6 months with about 75% reduction in pain (Bonetti et al. 2005; Perri et al. 2015). And peri radicular with paraganglionic injections have had 80% success after 6 months and 75% at 18 months (Muto et al. 2004).

O_2-O_3 therapy has been demonstrated to be effective in treating the symptoms of disc herniation. However, there are some risks to the therapy, as the dose of ozone must not exceed the capacity of antioxidant enzymes. Excess ozone leads to accumulation of the superoxide anion (O_2-) and hydrogen peroxide (H_2O_2), which can cause cell membrane degradation (Andreula et al. 2003). The injections also present a source of infection, as demonstrated by a case study involving an infection of Achromobacter xylosoxidans following O_2-O_3 therapy (Fort et al. 2014). Similarly, to GE, O_2-O_3 is unsuitable for treatment of IVD disorders other than pain caused by herniation.

Methylene Blue

Methylene blue, also known as methylthioninium chloride, can be used as both medication and a dye. It is part of the WHO Model List of Essential Medicines, particularly as an antidote for poisonings. Methylene blue is an inhibitor of nitric oxide synthase, and guanylate synthase. It has been used in a wide variety of treatments, including improving arterial pressure in septic shock, treatment of methemoglobinemia, neutralization of heparin, and more. Methylene blue has also been used as a dye to locate lesions within parathyroid glands, intestinal lumen, lymph nodes, and as a rapid detection method for Helicobacter pylori on histology. Adverse effects of methylene blue include toxicity in high doses to the renal system, cardiovascular system, and pulmonary system. Contraindications include patients with renal insufficiency, and G6PD-deficient patients (Ginimuge and Jyothi 2010).

Methylene blue has shown to destroy dermal nerve endings. Part of the pathophysiology of pain from intervertebral disc degeneration is ingrowth of new nerve vessels. A pilot study of 72 patients was conducted under the rationale that methylene blue would destroy nerve fibres growing within the annulus, alleviating discogenic pain. The study found after 2 years from treatment, 91.6% of patients were satisfied with their outcome, and 89% of patients had obvious to complete alleviation of pain (Peng et al. 2010). A clinical trial with 33 patients assessed the use of methylene blue injections for low back pain, and had 81% success at 3 months, however after 12 months only 54% of patients had reduced pain and increase in function (van Dijk et al. 2017). A study of 24 patients discovered 87% of patients to have alleviation of back pain, and improvements in physical function after an average of 18 months (Peng et al. 2007). Another study of 20 patients found after 1 year that only 20% of patients had successful alleviation of pain (Kim et al. 2012), and a retrospective case series of 8 patients only identified 1 to have any benefits from methylene blue injections (Gupta et al. 2012).

Methylene blue has been demonstrated within the previous clinical studies to have varying results. There are differences in measurements of pain and assessments of function; however the general trend is that methylene blue is appropriate for reduction of short-term pain, and loses its potency over time. Factors contributing to this may include dissipation of the methylene blue, and regrowth of nerve endings, or a more complex pathophysiological system may be causing the pain. There have been little assessments on the effect of methylene blue on the histology of the intervertebral discs, and future research would identify the exact response of the intervertebral disc to methylene blue. Methylene blue has been shown to have varying degrees of success, however a lack of understanding about its function on disc cells makes its use simply for pain alleviation, and symptom control, but not treating the root cause of the disease state and may be an effective adjunct in finding a cure for disc degeneration.

Summary of Chemonucleolysis

Chemonucleolysis is a destructive tool which can be very effective in the reduction of pain during disc herniation. Chymopapain was found to cause anaphylaxis, due to the papaya content. The other agents have found to provide useful short-term benefits, however long-term outcomes vary. This technique does not treat the cause of the degeneration and is only useful for the treatment of pain caused by herniation of disc content.

Chemonucleolysis may be useful in destruction of the intradiscal nerve endings, however, it will only serve as either a very specific treatment or an adjunct to any future therapy developed.

Cell-Free Intradiscal Implantation

Intradiscal implantations are used either after nucleotomy procedures to mimic the mechanical properties of the IVD, or as a mechanism to repair annular fibrosus defects. They can also become a medium in which the NP cells can migrate into and proliferate within. They are able to be manufactured prior to surgery and then implanted.

Hyaluronate Hydrogel

Injectable hyaluronate hydrogels (HH) are cell-free intradiscal matrix implantations that have been proposed to limit disc degeneration following a nucleotomy procedure. HH have an anti-inflammatory effect within the intervertebral disc, and also provide a growth-permissive environment for NP cells and MSCs (Isa et al. 2015; Priyadarshani et al. 2016).

HH has been investigated within several animal models. Hyaluronic acid alone reduced degeneration on imaging following nucleotomy procedures in nonhuman primate lumbar spines (Pfeiffer et al. 2003). Within a rabbit annular puncture model of IVD degeneration, cross-linked HH and cross-linked chondroitin sulphate hydrogel retained MRI T2 intensity for 3 months, and histologically had increased proteoglycan staining (Nakashima et al. 2009). Within a sheep nucleotomy model, after 6 months HH completely regenerated sheep IVD histologically, biochemically, and radiologically (Benz et al. 2012). However, within a porcine nucleotomy model, HH did not affect the regeneration of the IVD, and caused further annular scarring and localized annular inflammation (Omlor et al. 2012). Within each of these animal models, the exact makeup of the HH is different, with the best results of Benz et al. incorporating autologous serum solution into their injectable HH solution.

HH has been demonstrated to be an effective medium for IVD cells to proliferate. A gel culture with 4% hyaluronan cross-linked with serum albumin was demonstrated to be a viable medium for the culturing of human IVD cells, and chondrogenic MSCs, stimulating the release of anabolic ECM molecules (Benz et al. 2010). Human NP cells cultured for 8 weeks within a HH showed functional matrix accumulation and synthesis, and these results were higher at lower density of NP cells (20 million cells per millilitre) (Kim et al. 2015). A study cross-linking type-II collagen HH with 1-ethyl-3(3-dimethyl aminopropyl) carbodiimide (EDC) was also demonstrated to be a viable growth medium for culturing of NP cells (Priyadarshani et al. 2016). Another hydrogel with chitosan and hyaluronic acid cross-linked with glycerol phosphate promoted ADSC proliferation and nucleus pulposus differentiation (Zhu et al. 2017).

HH is a potential future intradiscal therapy for degenerative IVD disease. Advantages of HH include its versatility and ability to create different cross-linking to find the optimal hydrogel for regeneration of the NP. It also has the capacity to be a growth medium for NP cells and MSCs, potentially improving its regeneration ability. However, as the variability of the animal models demonstrate, not only is there a capacity for HH to cause complete regeneration, there is also the possibility of HH solutions to cause more degeneration. Care must be taken in future research to develop an HH which is both efficacious and safe. HH has the potential to be an effective intradiscal therapy for IVD degeneration.

Fibrin Sealant

Fibrin sealant (FS) can be used within surgery to prevent local haemorrhaging complications. It functions by consisting of two components, factor XII and fibronectin (the sealant) and thrombin and albumin (the catalyst) (Canonico 2003). When the sealant and catalyst are mixed, they create a fibrin monomer, and a stable clot. Fibrin is required for normal wound healing, and factor XII and fibronectin is important for fibroblast proliferation

and adhesion. Within the IVD the fibrin sealant would function to seal annular fissures from proinflammatory substances and facilitate disc healing (Buser et al. 2011).

Fibrin has been shown to be an alternative three-dimensional cell carrier to cultivate porcine and rabbit NP cells in vitro (Sha'Ban et al. 2008; Stern et al. 2000). In vitro FS was demonstrated to decrease proinflammatory cytokine levels in both human and porcine cells (Buser et al. 2014). Within a porcine nucleotomy model FS preserved the disc architecture, reduced section of inflammatory cytokines, and recovered the mechanical properties lost from the nucleotomy. FS also increased proteoglycan synthesis and inhibited progressive fibrosis of the NP (Buser et al. 2011). A prospective clinical trial of 15 patients found improvements in pain relief and function at weeks 15, 26, 52, and 104 with low complication rates (Yin et al. 2014).

Guterl et al. added genipin (Fib-Gen), a plant-based chemical cross-linker with low cytotoxicity, alongside cell adhesion molecules fibronectin and collagen and successfully improved the shear properties of FS (Guterl et al. 2014). Fib-Gen was injected into in vitro bovine IVDs which had undergone nucleotomy, and shown to effectively seal any defects, and prevented IVD height loss from the induced compressive force. Fib-Gen maintained AF cells, and NP cells migrated into the gel (Likhitpanichkul et al. 2014). Fib-Gen has also been demonstrated to be an effective drug carrier, maintaining a constant slow release of infliximab, and more effectively than FS alone (Likhitpanichkul et al. 2015). Long et al. elucidated the biomechanical properties of Fib-Gen, by performing annular injuries on bovine coccygeal IVDs in vitro and repairing the defect with Fib-Gen within a scaffold. Long et al. demonstrates Fib-Gen to reduce disc height loss, had little herniation risk, but could only partially restore disc biomechanical behaviors (Long et al. 2016).

FS is a promising therapy due to its potential for multipurpose action. Whist originally intended to seal annular fissures and prevent ingrowth of nerve vessels leading to pain, the possibility of being loaded with pharmaceuticals allows for optimization of the treatment. Moreover, the creation of Fib-Gen and attempts to biomechanically replicate the NP provide an adjunct treatment to perform alongside discectomy. Cellular migration of NP and AF cells within FS and Fib-Gen also may strengthen the material within in vivo trials. However, care must be taken as there may be fibrin instability and solubility over time, particularly when exposed to cells, and currently it does not provide the same mechanical properties as the IVD (Colombini et al. 2014). FS has the potential to be an effective intradiscal therapeutic, either as an adjunct to pharmacological therapy or as an adjunct to discectomy.

Summary of Cell-Free Intradiscal Implantations

Both HH and FS are promising as they can not only repair or restore some mechanical function of the IVD, but they can also house either NP or stem cells for continued treatment. However, large drawbacks include trying to compare the studies, as each proposes a different formula for the creation of the hydrogel. Another disadvantage is that they cannot fully match the durability and mechanical properties of the IVD, leading to degradation and possible replacement after an unknown period of time. Intradiscal implantations have the potential to be used alongside biological treatments to be an effective intradiscal therapy for IVD degeneration.

Anti-Inflammatory Agents

Anti-inflammatory agents are used to reduce the catabolic ECM molecules within IVD degeneration. They also reduce proinflammatory cytokines which are a source of pain. They achieve this through preventing their synthesis, and directly inhibiting their action upon the cells.

Interleukin-6 Receptor Monoclonal Antibody

Tocilizumab is a recombinant monoclonal IgG1 antihuman interleukin-6 receptor antibody (IL-6R mAB). Also known as Atilizumab, it is an

immunosuppressive drug used within the treatments of disorders such as rheumatoid arthritis, and systemic juvenile idiopathic arthritis (Rosman et al. 2013). IL-6 is an inflammatory cytokine which functions by activating the 130 gp signal transducer, inducing angiogenesis, and amplifying activity of adhesion molecules. Tocilizumab was found to be beneficial and safe for treatment of rheumatoid arthritis in cases of nonresponse to anti-TNF-alpha therapy or when anti-TNF-alpha therapy is contraindicated (Rosman et al. 2013).

IL-6 expression is secreted by intervertebral discs, with raised expression present in herniated discs. IL-6 levels are also upregulated in degenerative IVDs, and upregulates other catabolic cytokines that attribute to intervertebral disc degeneration. IL-6 is also a cause of discogenic pain, as it induces apoptosis of neuronal cells in the dorsal root ganglion, which may contribute to allodynia and hyperalgesia (Risbud and Shapiro 2014).

There have been few experiments concerning IL-6 and IVD regeneration. A mouse degeneration model demonstrated IL-6R mAB to reduce IL-6 expression, and decreased pain-related peptide release within the dorsal root ganglions (Sainoh et al. 2015). A prospective comparative cohort study revealed tocilizumab to provide short-term, 2 weeks, relief of back pain (Sainoh et al. 2016). An in vitro trial elucidated human degenerative annular fibrosus cells induces the expression of IL-6 through the JAK/STAT pathway, and therefore may be causally linked to IVD degeneration (Suzuki et al. 2017).

IL-6 is a catabolic factor which contributes towards IVD degeneration. It is unclear if IL-6 is the principal cytokine involved in the development of IVD degeneration, or functions as an ancillary to other cytokines. Future research is required to clarify this relationship, however IL-6 treatment would only slow the degenerative process, and would not be able to induce regenerative capabilities.

Glucocorticoids

Glucocorticoids are a class of corticosteroids and are created endogenously within the adrenal cortex. The function of glucocorticoids is to reduce the synthesis and release of a variety of inflammatory mediators (Becker 2013). Vertebral degenerative changes at the lumbar spine can be classified into a three-stage system using Modic classification (Modic et al. 1988). Within Modic type 1, the cartilaginous end plates have a high amount of proinflammatory cytokines, and increased vascularity, indicating an inflammatory reaction and Modic type 1 changes are closely associated with chronic lower back pain (Beaudreuil et al. 2012). The rationale of glucocorticoids is to stop the inflammatory process, and provide symptomatic relief and prevent further degeneration.

Clinical trials have illustrated glucocorticoids to have a mixed effect in the treatment of chronic low back pain. Glucocorticoids have a mostly positive effect at reducing pain and improving function within the short term, up to 1 month (Beaudreuil et al. 2012; Benyahya et al. 2004; Buttermann 2004; Fayad et al. 2007; Nguyen et al. 2017) and no effect after 12 months (Khot et al. 2004) with only one paper revealing glucocorticoids to have no effect within early time periods (Simmons et al. 1992). Conversely, Benyahya et al. found after 6 months 43.5% of 67 patients had improvements in pain reduction and function (Benyahya et al. 2004). Long-term results were improved when combined with an alternative therapy such as O_2-O_3, with paraganglionic glucocorticoid injections providing treatment and increased function at 1 month and 6 months (Andreula et al. 2003; Murphy et al. 2015) and combined with a polypeptide, positive results after 3 and 6 months (Cao et al. 2011).

Concerns about glucocorticoids include a risk that it can cause degeneration and primary calcification as demonstrated within a rabbit model (Aoki et al. 1997). Moreover intradiscal procedures can create inflammation (Ulrich et al. 2007) and possibly contribute to IVD degeneration (Carragee et al. 2009), with the potential of glucocorticoids to have a toxic effect on intradiscal cells. Glucocorticoids has been generally very well tolerated within the clinical trials presented. Glucocorticoids may have symptomatic relief for a short time of chronic low back pain, however as its mechanism is only preventing inflammation, future research may reveal it to be a helpful adjunct with other treatments, as opposed

to a cure. As an intradiscal treatment glucocorticoid is currently only appropriate for short-term symptomatic relief, and inappropriate for curative treatment.

Celecoxib

Celecoxib is a nonsteroidal anti-inflammatory drug (NSAID), and was the first cyclooxygenase-2 (COX-2) selective inhibitor introduced into clinical practice. Inhibition of COX-2 results in anti-inflammatory and analgesic effects, with fewer gastrointestinal side effects than NSAIDs. Celecoxib is eliminated by hepatic metabolism involving primarily the CYP2C9 protein, with a half-life of 11 to 16 h (McCormack 2011; Shi and Klotz 2008). COX-2 inhibitors can be effective in reducing back pain and reducing degeneration, as they prevent the formation of proinflammatory cytokines such as prostaglandin E2 (PGE2), which shifts the environment to a catabolic state leading to regeneration. However, systemic delivery of COX-2 at levels high enough to alleviate chronic low back pain is associated with comorbidities and side effects, hence a localized delivery system would provide more effective pain relief with fewer side effects (Tellegen et al. 2018).

Celecoxib does not reduce the rate of nerve growth within the nucleus pulposus (Olmarker 2005). Canine models have demonstrated that separate hydrogels are safe and feasible when loaded with celecoxib, with one study having significant improvement in 9 out of 10 canines, and at 3 months only 3 having recurring back pain, however no changes in %DHI or MRI T2 brightness (Tellegen et al. 2018; van Dijk et al. 2015). Within a bovine NP cellular model replicating herniation, celecoxib reduced PGE2 proving within the intervertebral disc celecoxib is effective in reducing catabolic enzymes (van Dijk et al. 2015). Within a cox-2 knockout mouse experiment (Cox-2 −/−), the deficiency causes delay in the ossification of lumbar vertebral endplates, and plays a role in IVD degeneration by affecting the sonic hedgehog and BMP signaling pathways (Ding et al. 2018).

Celecoxib can reduce the levels of the catabolic molecule PGE2. However, there has been no evidence so far that celecoxib has other effects than in reducing pain, and potentially reducing the rate of degeneration. Future research would involve perfecting the hydrogel to load with celecoxib, and then observing if within humans it can reduce pain levels as demonstrated within canines. Other future research into the relationship between COX-2 and intervertebral disc development may lead to a novel solution to prevent early degenerative disease. However with the current evidence, Celecoxib may be an effective adjunct in preventing pain alongside other intradiscal therapies for disc degeneration.

Summary of Anti-Inflammatory Agents

Intradiscal anti-inflammatory agents have mixed results within the treatment of IVD degeneration. Tocilizumab has promising results, but has not been trialled in clinical practice. Glucocorticoids have been demonstrated to have a positive early response, albeit with negative long-term results, and celecoxib is unknown if it can reduce pain. More evidence is required for the effectiveness of intradiscal applications of anti-inflammatory agents, and at most they might be a useful adjunct with treatments for intradiscal therapies of IVD degeneration.

Summary

The following Table 1 is a summary of the current research of intradiscal therapies.

Conclusion

Biological therapies, intradiscal implantations, and anti-inflammatory agents have been explored as possible future intradiscal therapies for IVD degeneration. The most promising research is within the biological and intradiscal therapies, as they have the possibilities of working in conjunction to halt degeneration, induce regeneration, and

Table 1 A summary of the studies of intradiscal injections and implants. provide support for the recovering IVD. Anti-inflammatory agents may be used as an useful adjunct for therapies, however their efficacy is not yet conclusive. There are currently no intradiscal therapies available, however with the development of so many different avenues of research the promise for treatment being soon available is great.

Abstract

Low back pain is the leading cause of years lived with disability worldwide and thus a significant burden on the economy and healthcare systems. Degenerative changes and/or repetitive abnormal loading in the lumbar spine could lead to structural failures of the intervertebral disc and herniation of the nucleus pulposus, all of which may manifest as chronic back and/or leg pain. Although lumbar discectomy is a clinically beneficial procedure for appropriately selected disc herniation patients, revision discectomy rates range from 2% to 18% within the first decade of the primary discectomy, especially in patients younger than 65 years. Discectomy being a tissue discarding procedure may compromise the biomechanical integrity of the disc and accelerate its degeneration. Nucleus replacement (NR) implants present a promising option to address some of the challenges surrounding lumbar discectomy. An NR implant may be used as an adjunct to discectomy to preserve the biomechanical integrity of the disc and minimize recurrent herniation of the nuclear tissue. Nonetheless, a systematic review of the literature on clinical outcomes for NR implants revealed high rates for endplate remodeling and implant subsidence. A detailed multiscale understanding of the mechanisms of disc herniation and reherniation, closure of the annular defect, and the ability to tailor geometry and material properties for individual patients are needed to develop the next generation of NR implants.

Introduction

Low back pain (LBP) is the leading cause of years lived with disability (YLD) worldwide, contributing approximately 57.6 million years to the total YLDs in 2016 (followed by migraine contributing 45.1 million years) and a lifetime prevalence that exceeds 80% in the industrial world (Connelly et al. 2006; Vos et al. 2017). In the United States alone, the total costs associated with low back pain exceed US$ 100 billion per year, two-thirds of which are a result of lost wages and reduced productivity (Katz 2006). Although the factors leading to LBP are largely unknown, it is frequently due to the defects or failures of the intervertebral disc (IVD) resulting in the herniation of the inner disc (pulposus) material which causes irritation and/or mechanical compression of the spinal cord or the exiting nerves, often resulting in pain, neurologic deficit, or both.

Structure and Function of a Healthy IVD

The IVD is a fibrocartilaginous structure that has a mechanical role of absorbing and transmitting loads acting on the spinal column. Together with the facet joints, the IVD completes the three-joint complex at each motion segment in the spinal column. There are three primary components in an IVD: an inner jellylike material called the nucleus pulposus (NP), an outer tough fibrocartilaginous structure called the annulus fibrosus (AF), and the vertebral endplates (EP) which serve as a transitional zone joining the IVD to the vertebrae above and below (Fig. 1).

The NP is a hydrated mass of gelatinous tissue in the center of the IVD, primarily composed of large amounts of proteoglycans with sparsely arranged collagen fibrils serving as supporting

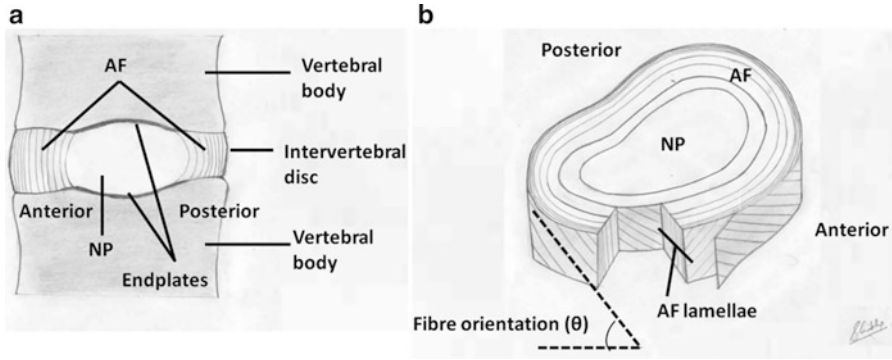

Fig. 1 Schematic representation of an adult intervertebral disc (IVD). (**a**) Midsagittal section of the IVD attached to the vertebral bodies, showing its primary components: nucleus pulposus (NP); annulus fibrosus (AF); and endplates (EP). (**b**) Three-dimensional view of the IVD illustrating the oblique and counter-oblique fiber orientation in adjacent lamellae

matrix. Bottlebrush-shaped proteoglycan molecules contain a protein core and hydrophilic glycosaminoglycan (GAG) chains (Cassinelli and Kang 2000). The high concentration of GAGs increases the osmotic pressure of the NP and allows it to swell and resist large compressive loads (Buckwalter 1995; Kroeber et al. 2002). While proteoglycans make up roughly 50% dry weight of the NP, the NP is also composed of approximately 25% collagen (Cassinelli and Kang 2000; Maroudas et al. 1975; Trout et al. 1982). Collagen type II is highly prevalent in the NP, and its concentration decreases toward the peripheral AF (Cassinelli and Kang 2000). The cells within the NP are sparse and are responsible for the maintenance of the extracellular matrix (Cappello et al. 2006).

The AF is a composite structure comprising ground substance and concentric layers (lamellae) of collagen type I fibers arranged in a regular crisscross pattern and attached circumferentially to the endplates (Hukins 2005). The AF is composed of more than two-thirds collagen, and proteoglycans make up only a small percentage of its composition (Cassinelli and Kang 2000; Maroudas et al. 1975). Within each lamella, the orientation of the fibers varies, alternating at approximately $\pm 20^\circ$ on the ventral side and continuously changing up to $\pm 45^\circ$ toward the dorsal side (Cassidy et al. 1989). The outer lamellae are stiffer and more densely packed than the inner ones (Holzapfel et al. 2005; Mengoni et al. 2015). In addition to axial compression, the AF withstands stresses in the tangential and radial directions. The NP and the inner AF contain only chondrocytes, while the outer AF contains mostly fibrochondrocytes (Melrose et al. 2008).

The top and the bottom of the IVDs are capped with EP (Fig. 1). The EP consists of a bony and a cartilaginous component which serves to balance conflicting biophysical demands. The bony endplates (BEP) provide the strength required to resist mechanical failure, whereas the cartilaginous endplates (CEP) facilitate chemical transport due to their porous nature (Lotz et al. 2013). In the lumbar spine, the cranial BEP is significantly thicker (1.03 ± 0.24 mm) and denser than the caudal BEP (0.78 ± 0.16 mm) (Wang et al. 2011). Within lumbar EPs, regional variation in stiffness exist, with the periphery stronger than the center, posterior stronger than the anterior, and the posterolateral sites in front of the pedicles being the strongest (Grant et al. 2001).

Together, the AF and the EPs serve to contain the NP, and in a healthy IVD, an osmotic pressure gradient provides the flow of nutrients to the NP. The IVD does not contain nerve tissues beyond the outer layers of the AF and the EP (Fagan et al. 2003; Ozawa et al. 2006). With no direct vascular supply, the IVD is the largest avascular component of the human body, relying entirely on diffusion for nutrition as well as the elimination of the waste products.

Degenerative Disc Disease (DDD)

Disc degeneration is one of the many progressive changes in the human body primarily attributable to natural ageing and is not a disease as much as it is a process. Magnetic resonance imaging (MRI) studies have shown that morphologically similar degenerated discs can be symptomatic or asymptomatic, which supports the hypothesis that a painful disc is a result of biochemical rather than morphological changes (Boos et al. 1995; Brinjikji et al. 2015). As early as the first two decades of life, the disc starts undergoing a progressive alteration in biochemical and morphological characteristics, which subsequently alters its biomechanical properties (Haefeli et al. 2006; Vernon-Roberts et al. 2007).

The etiology of disc degeneration is not well understood. One of the primary causes is thought to be the failure of nutrient supply to the disc cells, which may happen due to endplate calcification or other factors that affect the blood supply to the vertebral body such as atherosclerosis (Nachemson et al. 1970). A relationship has been found between loss of cell viability and fall in nutrient transport in scoliotic discs (Urban et al. 2001). Abnormal mechanical loads are also thought to initiate injury that leads to disc degeneration (Lotz et al. 1998; Stokes and Iatridis 2004). Lastly, genetic predisposition has been confirmed in twin studies as well as by reports of an association between disc degeneration and polymorphisms of matrix macromolecules (Paassilta et al. 2001).

Biochemical Changes

The composition and organization of the extracellular matrix in an IVD largely govern its mechanical properties. The balance between synthesis, breakdown, and accumulation of the matrix macromolecules determines the quality and integrity of the matrix and thus the mechanical behavior of the disc itself. The extracellular matrix in an IVD comprises two main macromolecules which have distinct composition, structure, and function. The collagen network, formed mostly of type I and type II collagen fibrils and making up approximately 70% and 20% of the dry weight of the AF and NP, respectively, provides tensile strength to the disc and anchors the tissue to the bone (Eyre and Muir 1977). Aggrecan, the major proteoglycan of the disc, has negatively charged GAG chains which attract water molecules, thereby maintaining tissue hydration and creating an osmotic pressure gradient within the NP (Johnstone and Bayliss 1995).

The most significant change to occur in an IVD with degeneration is the loss of proteoglycan molecules (Lyons et al. 1981). The bigger proteoglycan molecules break down into smaller fragments resulting in a loss of GAG chains, which leads to a gradual loss of hydration in the disc matrix and is primarily responsible for a fall in osmotic pressure within the NP. With degeneration, the collagen population in the disc can alter in type and distribution, but the absolute quantity of collagen does not change significantly. The relatively thin type II collagen in the nucleus is replaced by denser type I collagen with increased cross-linking between the collagen fibrils, making the nucleus more fibrotic, which is thought to further hinder tissue-fluid exchange (Duance et al. 1998). The barriers created by increased cross-linking reduce the rate of turnover and repair of collagen and proteoglycans, altering homeostasis within the IVD and resulting in the retention of damaged macromolecules (Adams and Roughley 2006).

In a normal disc, aggrecans, because of their high concentration and charge, prevent the movement of large uncharged molecules such as serum proteins and cytokines into and through the disc matrix (Maroudas 1975). The fall in concentration of aggrecans could result in an unchecked loss of osmotically active small aggrecan fragments from the disc, and increased penetration of large molecules such as growth factor complexes and cytokines into the disc. The increased vascular and neural ingrowth observed in degenerated discs is likely associated with proteoglycan loss because disc aggrecan has been shown to inhibit neural ingrowth (Melrose et al. 2002).

Hydration of the AF extracellular matrix, which serves to facilitate waste and nutrient exchange, is crucial to imparting viscoelasticity

properties to the disc (Gu et al. 1999; Travascio et al. 2009). Both extra- and intrafibrillar fluids are responsible for the AF hydration. The intrafibrillar fluid that closely adheres to collagen fibers provides long-term AF hydration. The earliest known compositional change in proteoglycan loss reduces both the AF extra- and intrafibrillar fluid capacity and swelling pressure while impairing its overall load-bearing capability (Johannessen and Elliott 2005; Yao et al. 2002). On the other hand, extrafibrillar fluid, which is responsible for nutrient and waste (i.e., lactic acid) transport, moves freely across the AF. Drop in the AF osmotic pressure secondary to the lack of extrafibrillar fluid reduces the efficiency of nutrient-waste exchange and leads to a decrease in pH and consequently lactic acid accumulation (Iatridis et al. 2007; McMillan et al. 1996). Both decrease in pH, which leads to acidity increase, and insufficient nutrition across the AF impair cellular metabolism and increase the risk of disc degeneration (Cassinelli et al. 2001). Therefore, any undesirable changes in the AF extra- and intrafibrillar fluids lead to dehydration, alter osmotic and viscoelastic properties, and may result in disc degeneration (Gu et al. 2014; Murakami et al. 2010).

Morphological Changes

Macroscopic analysis of midsagittal slices of human lumbar IVD of individuals ranging from newborn to senile age has revealed the temporospatial variation of age-related morphological changes in the disc (Haefeli et al. 2006). Degenerative processes in the disc start in the first two decades of life with transformation in the NP, mucous degeneration, AF disorganization, alteration of the EP, and osteophyte formation (Fig. 2). After the initial phase of significant alterations, degenerative changes remain constant over the next two decades before increasing again after the fourth decade (Haefeli et al. 2006).

The initial morphological changes are followed by the appearance of nuclear cleft and subsequent radial and concentric tears in the annulus in the fifth decade of life. Radiating annular tears rarely extend to the outer AF and are thought to be a consequence of clefts originating in the NP (Vernon-Roberts et al. 2007). Rim lesions typically occur independent of annular tears and substantially later in life (Haefeli et al. 2006; Vernon-Roberts et al. 2007). With progressive degeneration, an ingrowth of nerve fibers and blood vessels beyond the outer AF is observed which is often associated with discogenic pain (García-Cosamalón et al. 2010; Stefanakis et al. 2011). Although disc height narrowing with DDD has been reported in some studies, Twomey and Taylor (1987) contradicted this opinion by showing that the average disc height is maintained in old age, with the distance between the anterior and posterior corners of the vertebral bodies decreasing and the IVD expanding centrally to become increasingly convex (Butler et al. 1990; Twomey and Taylor 1987). Nonetheless, in some cases, severe tissue destruction (including cleft and tears formation as well as rim lesions) may occur in the first two decades of life, which presents an enormous challenge for any prophylactic tissue engineering repair attempt.

Disc herniation can be considered as one specific feature of disc degeneration that is much more closely related to mechanical loading (exceeding tissue strength) and pain than other features of degeneration such as signal intensity on MR scans and biochemical changes. Examination of autopsy or surgical specimens suggests that some degenerative changes, such as nuclear desiccation and fragmentation and preexisting tears in the AF, are necessary before a disc can herniate (Moore et al. 1996). In extruded disc tissue material, isolated fragments of AF and EP are much less common than the NP (Moore et al. 1996).

Biomechanical Changes

In healthy conditions, the high water content within the NP creates hydrostatic pressure which contributes to sustaining large loads acting on the spinal column. The compressive spinal loads are uniformly distributed to the AF through hydrostatic pressure, which creates hoop stresses within the AF. The fiber orientation of the AF is suitable

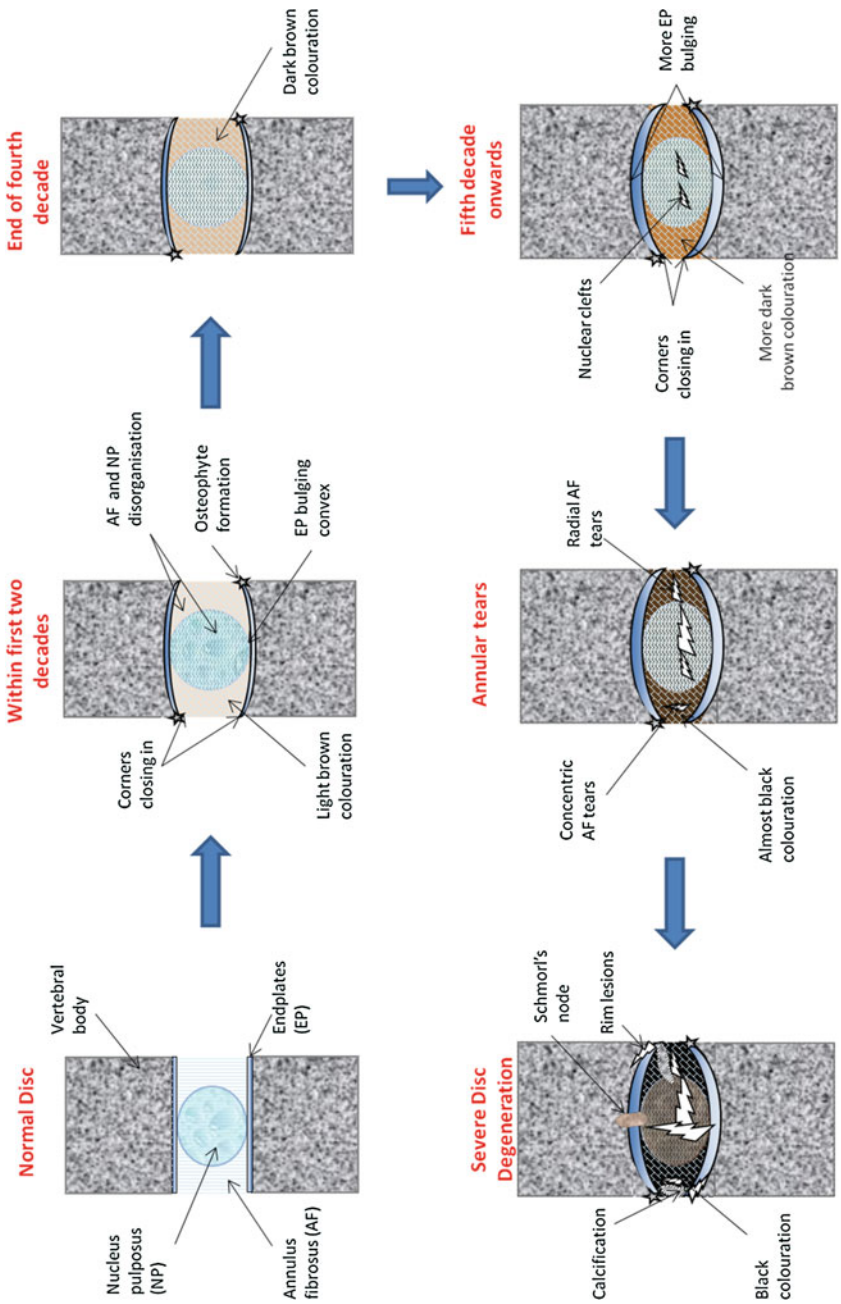

Fig. 2 Schematic representation of the course of macroscopic degeneration in the human lumbar intervertebral discs. Age or degeneration-related structural abnormalities combined with complex repetitive mechanical loading in the disc could result in disc prolapse or herniation (Fig. 3). A disc may, however, herniate without degeneration if loaded severely enough, and the degenerative changes found in the herniated disc material probably occur after herniation has taken place, as a result of tissue swelling, leaching of proteoglycans, and revascularization (Fig. 3d) (Adams and Hutton 1986; Lama et al. 2013)

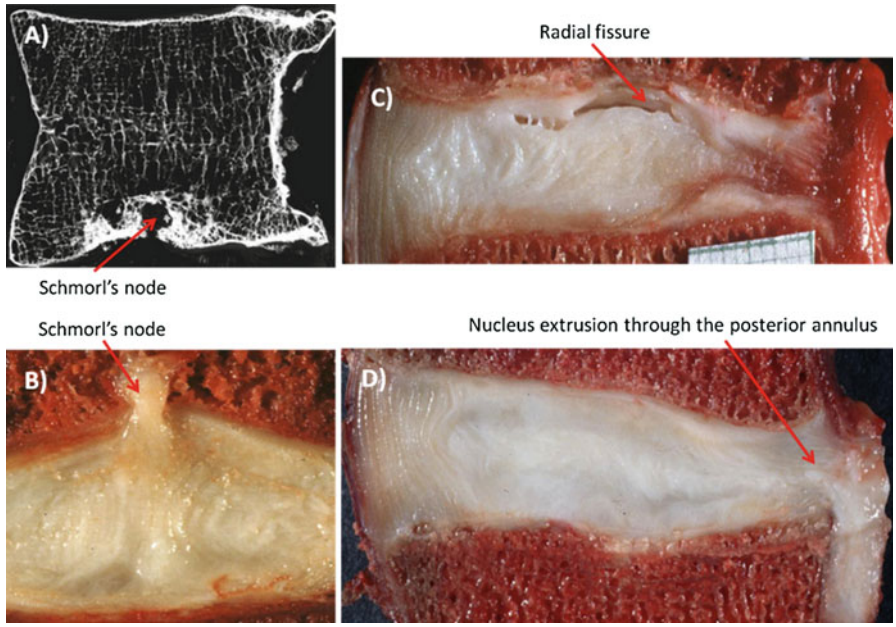

Fig. 3 Structural defects in lumbar intervertebral discs due to degeneration and/or mechanical overloading. (**a**) Microradiograph of a midsagittal slice of a cadaver vertebral body showing Schmorl's node and bone remodeling around it. (**b**) A cadaver disc which has herniated through the endplate in response to compressive loading shows decompressed nucleus and bucking of inner annulus walls. (**c**) A cadaver disc showing a complete radial fissure in the posterior annulus. (**d**) Nucleus extrusion through the posterior annulus due to abnormal bending and compressive loads in an otherwise nondegenerate disc. (Images adapted from Adams and Dolan 2016, with permission)

to resist hoop stresses generated by the hydrostatic pressure.

Degenerative changes in the biomechanical properties of the disc can occur due to changes in either material properties of the individual NP and AF tissues or due to consequent morphological changes in the substructure of the disc. The process is thought to initiate in the NP, with a decrease in its proteoglycan concentration and a gradual change in collagen type, making the nucleus more fibrotic, stiffer, and severely limited in its ability to generate hydrostatic pressure. Degenerated NP tissues have significantly lower swelling stress ($P_{sw} = 0.037 \pm 0.038$ MPa degenerate, $P_{sw} = 0.138 \pm 0.029$ MPa nondegenerate), lower effective aggregate modulus ($H_A^{eff} = 0.44 \pm 0.19$ MPa degenerate, $H_A^{eff} = 1.01 \pm 0.43$ MPa nondegenerate), and a higher permeability ($k_a = 1.4 \pm 0.58 \times 10^{-15}$ m^4/N-s degenerate, $k_a = 0.9 \pm 0.43 \times 10^{-15}$ m^4/N-s nondegenerate) (Johannessen and Elliott 2005). In the degenerate AF, the fiber orientation becomes disorganized, and the nonlinear elastic response also varies consequently (Schollum et al. 2010). The response of the degenerate AF tissue has been shown to be of a twofold increase in the toe-region modulus in tensile testing, which correlated with age, as well as fiber reorientation toward the loading direction (Guerin and Elliott 2006; O'Connell et al. 2009). Although the water content within the AF is not affected by degeneration, material property parameters such as Poisson's ratio, failure stress, and strain energy density are strongly influenced by the level of degeneration (Michalek et al. 2009).

The above changes in biochemical, morphological, and biomechanical properties of the disc combined with complex repetitive loading may result in the structural failure of the disc and present in the form of disc herniation: either protrusion or complete rupture of the AF walls followed by the expulsion of the NP material (extrusion or sequestration). The inflammatory material from the disc (particularly the NP) may

cause chemical irritation and mechanical compression of the cord and the exiting nerves and contribute to radicular back and/or leg pain (Goupille et al. 1998; Omarker and Myers 1998). Therefore, a common approach to the clinical treatment for painful disc herniation is surgical removal of the herniated material to unload the nerves (discectomy) (DeLeo and Winkelstein 2002; Loupasis et al. 1999).

Herniation and discectomy may accelerate disc degeneration. The loss of NP material results in decreased pressure within the disc, progressive loss in disc height, inward buckling of the inner annulus, and an increased bulging of the annulus under compression (Brinckmann and Grootenboer 1991; Frei et al. 2001; Meakin and Hukins 2000). In an in vitro study on human lumbar discs, Brinckmann and Grootenboer (1991) demonstrated that, on average, removal of 1 g of disc tissue resulted in a height decrease of 0.8 mm and a radial bulge increase of 0.2 mm under compressive loads. Removal of 3 g of central disc tissue lowered the intradiscal pressure to approximately 40% of its initial value (Brinckmann and Grootenboer 1991).

Although discectomy provides immediate relief from leg/back pain in most cases, the procedure is a tissue discarding one, in which the most frequent adverse events are the recurrent herniation of the residual nuclear tissue, progressive disc height loss, and reoccurring back/leg pain. An additional risk following discectomy is the loss of disc height which has been linked to the amount of nucleus material removed at the time of surgery (Tibrewal and Pearcy 1985; Yorimitsu et al. 2001). In turn, there is an alteration of the entire spinal column kinematics, and as the more nuclear material is removed from within the disc, the less capable it is of supporting the spinal loads.

Filling the nucleotomized cavity with a biologically inert replacement material has the potential to restore biomechanical characteristics of the disc and mitigate the progressive loss in disc height. Our group has conducted preliminary work to assess biomechanical efficacy of a non-hydrogel silicone-based in situ curing nucleus replacement (NR) implant, the Kunovus Disc Device (KDD, Kunovus Pty Ltd., Australia) in restoring the bending stiffness of a human lumbar motion segment following discectomy. A finite element modelling study to evaluate changes in bending stiffness of a L3–L4 motion segment revealed that compared with the baseline intact state, a complete nucleotomy significantly increases annular bulge (flexion, 0.65 mm; extension, 0.18 mm) and average Von Mises stress in the annulus (flexion, 38%; extension, 6%) (Fig. 4). Although partial filling of the nucleotomized cavity with the KDD was not able to restore the synergistic biomechanical interaction between the AF, EP, remnant NP, and the NR implant; complete filling of the cavity restored the biomechanical characteristics of the motion segment close to the normal intact state levels (Fig. 4).

Nucleus Replacement Implants

Nucleus replacement (NR) implants present a promising option for restoring and preserving the biomechanical integrity of an IVD and address some of the challenges surrounding discectomy procedures. These implants fill the treatment gap between nonsurgical care and invasive surgical procedures such as fusion and total disc replacement (TDR).

Essential Design Criteria

An NR implant must meet five essential criteria to be considered for clinical use:

1. Biocompatible and durable to survive the lifespan of the recipient.
2. Maintain the disc height, stabilize motions across all axes of movement, and restore normal distribution of loads in the motion segment.
3. High conformity in the nucleotomized cavity to avoid device migration and subsidence
4. Optimal stiffness to avoid excessive wear and/or remodeling of the EP. An overly compliant implant will overload the AF and fail to maintain the disc height.

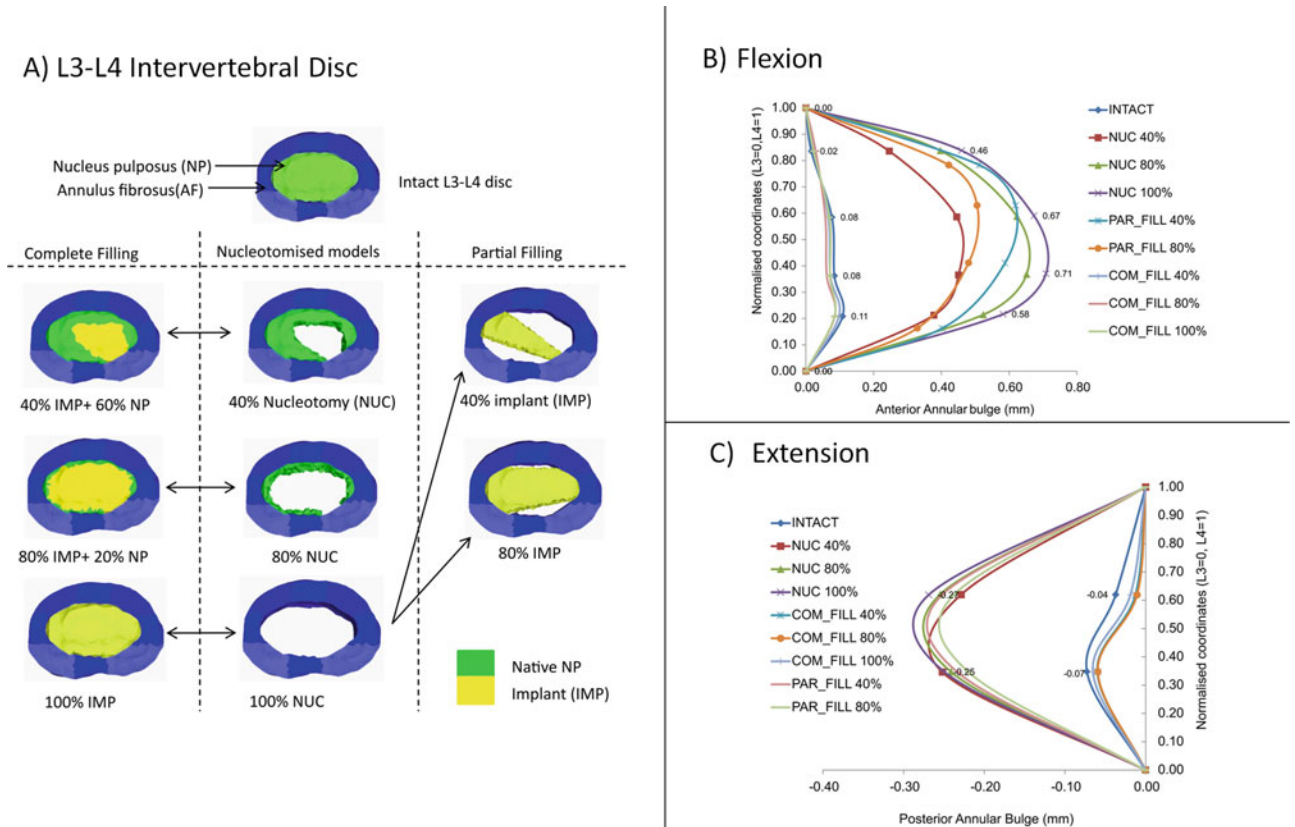

Fig. 4 (**a**) Finite element (FE) models of the L3–L4 intervertebral disc were assembled representing the disc in the intact state, different states of nucleotomy, partial and complete filling with the Kunovus Disc Device (KDD, Kunovus Pty Ltd., Australia). Multisegment FE models of the lumbar spine (L1–L5) were loaded in flexion and extension bending moments (±10 Nm) with the L5 vertebra fixed in space. (**b**) Anterior annulus bulge in the midsagittal plane of the L3–L4 disc in different states during peak flexion loading. (**c**) Posterior annulus bulge in the midsagittal plane of the L3–L4 disc in different states during peak extension loading. Only complete filling of the nucleotomized disc with the KDD implant restored the annular bulge to the intact state levels

5. Easy to implant as an adjunct to discectomy, minimize any additional damage to the AF during implantation. Easy to remove in the instance of any adverse event during or after surgery.

Classification

A number of NR implants have been developed so far, with an unaccounted number of them still under development. Some of these NR implants are at different stages of clinical use, while others have been abandoned. Based on the design principles and materials used, NR implants may be divided into various categories (Fig. 5).

Clinical Outcomes: A Systematic Review of Literature

A systematic literature search into currently available clinical data on NR implants published in various journals and book chapters between January 1988 and March 2017 was conducted using Scopus and Medline online databases. After removing duplicate articles across both the databases, and further screening through reading abstracts, a total of 12 articles were found, which presented short-term ($\leq$1 year), mid-term (1–3 years), and long-term (>3 years) clinical and radiological follow-up data on NR implants. One article reported data on three different NR implants (PDN, NuBac, PNR) (Pimenta et al. 2012). Two articles reported short-term and mid-term clinical results (Ahrens et al. 2009; Balsano et al. 2011). Due to variations in implant designs and materials used, studies were not directly comparable; and therefore, articles were grouped based on the type of implant reported (Table 1).

Preformed Mechanical

NuBac (Pioneer Surgical Technology, Michigan): NuBac is a two-piece prosthesis made from PEEK, with a ball-and-socket-type articulation between the two pieces (Fig. 6). Short-term clinical follow-up data for 49 patients were presented in two separate studies (Alpizar-Aguirre et al. 2008; Balsano et al. 2011). Balsano et al. further presented mid-term clinical data for 166 patients implanted with the NuBac device (Balsano 2014; Balsano et al. 2011). Pimenta et al. (2012) reported long-term follow-up data for 19 patients implanted with the NuBac device. Table 2 presents clinical and radiological follow-up data for the NuBac implant.

Preformed Elastomer

Prosthetic disc nucleus PDN (Raymedica, Minnesota): The PDN implant comprises a special hydrogel pellet core encased in a polyethylene jacket that helps maintain device shape when subjected to heavy spinal loads (Fig. 7). The expanding hydrogel constrained within the jacket is designed to provide the lifting force in the intervertebral disc space to maintain the disc height and remain flexible at the same time. In order to minimize the size of annular opening required for implantation, the device is implanted as two separate units, connected by means of a tethering suture (Klara and Ray 2002).

Among NR implants, clinical data for PDN is most widely reported in the literature. Three separate studies have reported short-term clinical data for a total of 84 patients implanted with PDN (Bertagnoli and Vazquez 2003; Jin et al. 2003; Shim et al. 2003). Four additional studies have reported long-term follow-up data for a total of 199 patients implanted with PDN (Klara and Ray 2002; Pimenta et al. 2012; Selviaridis et al. 2010; Zhang et al. 2009). Table 3 presents clinical and radiological follow-up data for the PDN implant.

In Situ Curing

In situ curing injectable materials have been the recent focus of research in NR implants due to their ability to conform to the shape of the nucleotomized cavity and cure within the disc. These NR implants can be delivered using a minimally invasive surgery and, in principle, are designed to overcome endplate remodeling and

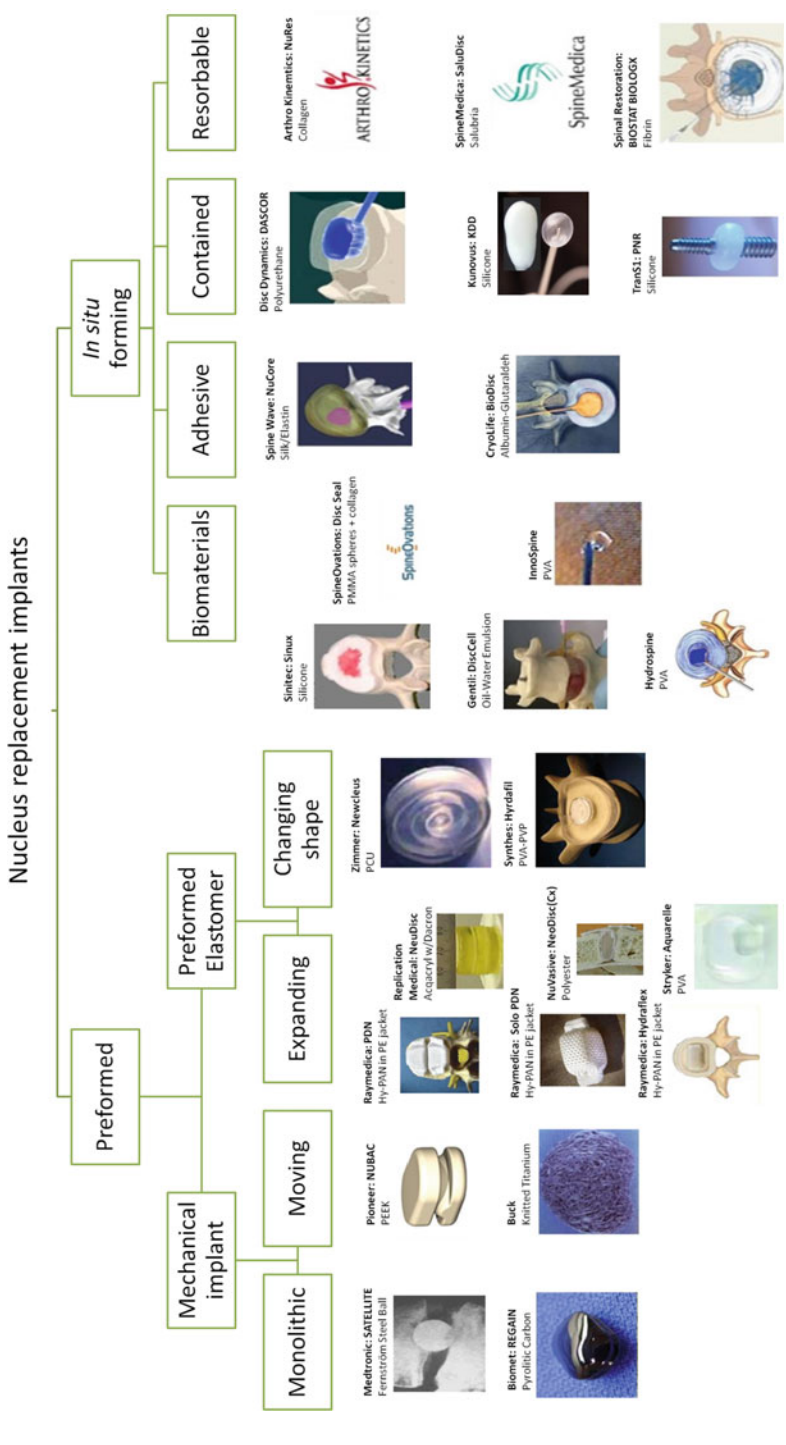

Fig. 5 A broad classification scheme for nucleus replacement implants

Table 1 Medline and Scopus online database search between January 1988 and March 2017 revealed that clinical and radiological follow-up data are available for five nucleus replacement implants

Type of implant	Implant name	Studies with clinical data	Manufacturer	Material
Preformed mechanical	NuBac	2 (short-term), 2(mid-term), 1(long-term)	Pioneer Surgical Technology, Michigan	PEEK
Preformed elastomer	PDN	3(short-term), 4(long-term)	Raymedica, Minnesota	Hydrogel pellet in PE jacket
In situ curing	DASCOR	1(short-term), 1(mid-term)	Disc Dynamics, Minnesota	Polyurethane
	NuCore	1(mid-term)	Spine Wave, Connecticut	Silk and elastin
	PNR	1(long-term)	TranS1, Colorado	Silicone

implant migration issues associated with the preformed NR implants. A number of in situ curing NR implants have been developed using a variety of materials (Fig. 5); however, clinical and radiological follow-up data is only available for the following: DASCOR (Disc Dynamics, Minnesota), NuCore (Spine Wave, Connecticut), and Percutaneous Nucleus Replacement (PNR) (TranS1, Colorado) (Fig. 8).

Ahrens et al. (2009) reported short-term (n = 70, 1 year) and mid-term (n = 41, 2 years) clinical data for 85 patients implanted with the DASCOR device (Ahrens et al. 2009). Berlemann and Schwarzenbach (2009) reported mid-term clinical data for 14 patients implanted with the NuCore device. Pimenta et al. (2012) reported long-term clinical data for 26 patients implanted with the PNR device. Table 4 presents clinical and radiological follow-up data for the above three in situ curing implants.

Lessons Learnt

In all of the above studies, the average age of patients receiving an NR implant was 35–45 years, and therefore the implant was expected to function for five to six decades. The premise behind using an NR implant is to restore mobility and salvage structures in a functionally suboptimal disc which would otherwise be sacrificed in more invasive spine surgeries. Although short-term and mid-term clinical results have been promising (pain scores, functional outcomes, disc height preservation, intra-op, and post-op complication rates), reoperation rates in the long-term remain a matter of serious concern, particularly for the mechanical and preformed NR implants. In 199 patients implanted with PDN and followed for a minimum of 4 years, endplate remodeling rate was 32%, subsidence rate was 26%, and reoperation rate was 27%. For in situ curing implants, although conformity with the shape of the nucleotomized cavity has theoretical advantages in distributing loads to the adjoining structures, there is a dearth of long-term clinical follow-up data to show any translational benefits of this design principle.

A stiff implant in the nucleus space could lead to remodeling of the endplates and result in implant subsidence, whereas a compliant implant (or a nucleotomized cavity) may offload the endplates and overload the annulus, consequently increasing the likelihood of annulus degeneration, implant extrusion, or both. Perhaps, the *one-size-fits-all* philosophy for the material properties of NR implants may not be able to address all the design objectives in individual patients, and future

NR implants will need to provide clinicians with tools to customize material properties and geometry to suit their patient's needs.

While the implant geometry and material properties are important parameters in meeting the design objectives for an NR implant, the clinical success will also rely on the quality of vertebral subchondral bone, extent of endplate calcification, and structural integrity of the AF; and therefore a careful selection of patients is important.

Disc Preservation Following Lumbar Discectomy

Lumbar Discectomy: Clinical Outcomes

Lumbar discectomy in disc herniation patients results in significantly better clinical outcomes when compared with nonsurgically treated patients (Atlas et al. 2005; Weinstein et al.

Table 3 Table summarizing short-term (≤1 year) and long-term (>3 years) clinical and radiological follow-up data (average values) for patients implanted with prosthetic disc nucleus PDN (Raymedica, Minnesota)

2008). Although lumbar discectomy is a clinically beneficial procedure for appropriately selected patients, revision discectomy rates range from 2% to 18% within the first decade of the primary discectomy (Virk et al. 2017; Watters and McGirt 2009). The survivorship rate for first lumbar discectomy is particularly lower for patients younger than 65 years when compared with older patients (Virk et al. 2017).

It remains unknown whether limited discectomy (LD) or aggressive discectomy (AD) provides better clinical outcomes for the treatment of lumbar disc herniation patients with radiculopathy. In a systematic review of 44 studies, the reported incidence of short-term (<2 years) recurrent leg or back pain was similar after LD (mean, 14.5%; range, 7–16%) and AD (mean, 14.1%; range, 6–43%) (McGirt et al. 2009a). In the long-term (>2 years), the reported incidence of recurrent back or leg pain was 2.5-fold less after LD (mean, 11.6%; range, 7–16%) compared with the AD (mean, 27.8%; range, 19–37%). However, the reported incidence of recurrent disc herniation after LD (mean, 7%;

range, 2–18%) was significantly greater than that reported after AD (mean, 3.5%; range, 0–9.5%) (McGirt et al. 2009a).

LD may result in shorter operative time, a quick return to work, and a decreased incidence of long-term recurrent back pain, but at a significantly greater risk of long-term recurrent herniation compared with AD. Aggressive removal of the remanent nucleus is effective at decreasing reherniation but at the cost of significantly poor long-term clinical outcomes and low patient satisfaction (McGirt et al. 2009a).

Various risk factors have been identified for the recurrent herniation of the disc. Smoking and occupational lifting are known to increase the likelihood of recurrent herniation (Miwa et al. 2015). Discectomy patients with preserved disc height postoperatively generally have favorable results, but the risk of recurrent disc herniation is high in this population (Yorimitsu et al. 2001). In a retrospective study of 75 lumbar disc herniation patients, 8 of whom re-herniated after primary microdiscectomy, the authors found that the mean body mass index (BMI) of patients with recurrent herniation (33.6 ± 5.1) was significantly higher than those without recurrence (26.9 ± 3.9) (Meredith et al. 2010). In a prospective study of 108 lumbar disc herniation patients undergoing first-time discectomy and followed for up to 2 years, the authors observed that the mean annular defect area was significantly greater in recurrent herniation patients compared with no-recurrence patients (46 ± 20 vs. 32 ± 14 mm^2) (McGirt et al. 2009b). Mean annular defect was also significantly larger in patients with symptomatic early reherniation (within 4 months after surgery) compared to later herniation (57 vs. 39 mm^2) (McGirt et al. 2009b). Clinically silent recurrent disc herniation is common after lumbar discectomy, but treatment is recommended only when correlating radicular symptoms exist (Lebow et al. 2011).

Nucleus Replacement Implants as an Adjunct to Discectomy

Annulus repair following discectomy may be beneficial for retaining the intradiscal material. While patients with tall and healthy discs preoperatively have the most to gain with annular closure (thus reducing the amount of nucleus that needs to be removed), repair of the annulus is not able to restore the biomechanical characteristics

of the disc, and further annular tear adjacent to the repair is possible due to persistent fragmented nuclear material present in the disc cavity. A prospective, multicenter, randomized control trial of 750 patients treated for herniated lumbar discs and randomly assigned in a 2:1 ratio to discectomy with annular closure and discectomy without annular closure found no significant difference in the clinical outcomes (including the recurrent herniation rates) between the two surgical cohorts at 2-year follow-up mark (Bailey et al. 2013).

Discectomy remains one of the rare surgical procedures where the tissues lost to herniation and removed during the surgery are not replaced with any prosthesis. Nucleus replacement implants can be used as void-fillers during a standard discectomy procedure to (1) restore the structural and mechanical integrity of the disc; (2) restore load sharing and synergistic interaction between the implant, remnant NP, AF, and the EP; (3) minimize loss in disc height and accelerated degeneration of the AF; and (4) minimize recurrent disc herniation by acting as an annular-closure-plug.

Furthermore, there has been a growing interest in the development of alternative minimally invasive technologies for the treatment of degenerative disc disease in otherwise healthy patients who suffer from unremitting pain due to damaged and bulging intervertebral discs, and are not responsive to nonoperative care. These patients are candidates for spinal fusion but retain a workable disc height and undamaged facet joints. These patients would benefit from an option which would provide lower risks than spinal fusion and similar improvement in quality of life. The loss of disc function can be mitigated by replacement of the NP with a biologically inert material with a goal of maintaining the disc height and function.

Other Potential Uses of Nucleus Replacement Implants

Pedicle screw-based posterior dynamic stabilizers (PDS) are nonfusion spinal implants that aim to restore normal load sharing and kinematics in a degenerate spinal motion segment (Chamoli et al. 2014). Because these implants are posteriorly placed, the center of rotation of the motion segment is shifted posteriorly upon implantation compared with that of an intact spine; and therefore anterior load sharing cannot be satisfactorily achieved using a PDS implant alone. The cyclic nature of the pedicle screw loading and the micromotions at the bone-screw interface likely increase screw loosening and pullout rates and is one of the major reasons for the implant failure. Replacing the core of the degenerated disc with an NR implant and using PDS as an augmenting device may have the potential to overcome this problem.

An NR implant may be used in hybrid constructs for prophylactic dynamic stabilization of segments adjacent to the fused levels, which could reduce hypermobility and impede the accelerated degeneration of the adjacent segments. The NR implants are advantageous over commonly used TDR implants in hybrid constructs, as they are less invasive, salvage disc structures, and more closely mimic the kinematic signature of an intact motion segment.

Conclusions

Degenerative changes and/or repetitive abnormal loading in the lumbar spine could lead to structural failures of the intervertebral disc and herniation of the nucleus pulposus, all of which may manifest as chronic back and/or leg pain. Although lumbar discectomy is a clinically beneficial procedure for appropriately selected disc herniation patients, revision discectomy rates range from 2% to 18% within the first decade of the primary discectomy, especially in patients younger than 65 years. Nucleus replacement (NR) implants present a promising option to address some of the challenges surrounding standard lumbar discectomy. These implants could be used as void-fillers during a standard discectomy procedure to: restore and preserve the biomechanical integrity of the disc, impede progressive disc degeneration and loss in disc height, and minimize the incidence of recurrent herniation. Nonetheless, long-term follow-up results for the present NR implants reveal high

rates for endplate remodeling and implant subsidence. A detailed multiscale understanding of the mechanisms of disc herniation and reherniation, closure of the annular defect, and the ability to tailor geometry and material properties for individual patients are needed to develop the next generation of NR implants.

Contents

Abstract

Degenerative spinal conditions may lead to abnormal motion and biomechanical instability of diseased spinal segments, resulting in pain, deformity, and neural element compromise. Various spinal fusion techniques have been developed over the years to address spinal segment instability. Degenerative conditions of the lumbar spine can be addressed through different approaches in terms of fusion. These include posterolateral fusion, posterior lumbar interbody fusion, and transforaminal interbody fusion, which are performed with the patient lying prone. Anteriorly, degenerative lumbar

spine conditions can be addressed with anterior lumbar interbody fusion, direct lateral (transpsoas) lumbar interbody fusion, or oblique lumbar interbody fusion (using an anterior to psoas approach). The cervical spine with degenerative changes can be treated with fusion anteriorly, using anterior cervical discectomy and fusion, or posteriorly, with posterior cervical decompression and fusion. The success or failure of the fusion procedure is determined on the absence or presence of pseudarthrosis based on clinical findings supplemented by diagnostic evidence of bridging bone. Imaging modalities most commonly used for evaluation of fusion include radiographs, magnetic resonance imaging, and computed tomography, with CT as the gold standard for assessment. Recent studies support CT as the imaging modality of choice, with some studies presenting different techniques that may aid in the evaluation of fusion status. In the hope of attaining higher outcomes for fusion along with decrease in morbidity associated with graft harvest, several bone graft substitutes and extenders have been developed. Several studies have been produced supporting their use. None have provided clear-cut evidence or recommendations that would help determine any advantage of one bone graft substitute/extender over the other.

Introduction

Degenerative spinal conditions can lead to abnormal motion and biomechanical instability of affected spinal segments, which can result in pain, deformity, neural element compromise, or deterioration. The degenerative cascade is believed to have a complex multifactorial etiology. The process itself may be secondary to aging, genetic factors, metabolic disorders, low-grade infection, neurogenic inflammation, autoimmune response, toxic, or mechanical factors (Hadjipavlou et al. 2008). In order to address spinal segment instability, numerous surgical fusion techniques have been developed over the years.

Several fusion techniques have been described in literature. For the cervical spine, surgeons utilize either anterior cervical discectomy and fusion or posterior cervical decompression and fusion. The most commonly performed fusions are on the lumbar spine. Degenerative conditions of the lumbar spine may be addressed with different techniques such as posterolateral fusion, posterior lumbar interbody fusion, transforaminal interbody fusion, and anterior lumbar interbody fusion. Recently introduced is the so-called lateral interbody fusion [direct lateral interbody fusion (DLIF)/extreme lateral interbody fusion (XLIF™)], which employs a transpsoas muscle approach, and its variation, the oblique lateral interbody fusion (OLIF), a technique that uses the plane anterior to the psoas muscle for its approach. All these procedures do come at a cost, as patients who undergo these operations run the risk of developing complications related to surgery. Fusion strategies have been improved upon with the use of minimally invasive techniques, with goals of limiting blood loss, soft tissue injury, operative time, immobilization, incidence of wound infections, and hospital stay in properly selected patients (Mummaneni et al. 2013; Bach et al. 2014).

Since the inception of various fusion techniques, several studies have been produced that focus on the evaluation and analysis of their clinical and radiologic outcomes. The development of new bone graft substitutes has also prompted investigators to closely examine these products to better understand the possible benefits that they can offer to patients undergoing fusion surgery. With this in mind, the objective of this chapter is to present a comprehensive review and discussion of spinal fusions in human studies.

Clinical Presentation of Pseudarthrosis

Fusion is said to occur once the bone graft within or around a spinal motion segment is deemed absent of any pseudarthrosis or

non-union. Pseudarthrosis refers to the failure of spinal fusion diagnosed more than a year after surgery. Patients with pseudarthrosis may or may not present with any symptoms. If symptomatic, they may complain of axial or radicular pain and be diagnosed with "refractory back syndrome." These may also be associated with claudication or myelopathy as well. Clinical findings are not reliable in the diagnosis of pseudarthrosis. Confirmation is achieved preferably through surgical exploration, but this can be assessed noninvasively through a number of imaging modalities. These imaging modalities include X-rays, computed tomography (CT), magnetic resonance imaging (MRI), bone scan, ultrasound, and radiostereometric analysis.

Imaging Techniques

Routine orthogonal radiographs are requested upon follow-up to determine the progression of arthrodesis, which can be observed as increasing opacification and bridging trabecular bone at the bone graft margins. Static orthogonal radiographs may be inadequate for some surgeons due to its inability to identify motion at the spinal fusion segment. Although controversial, lateral flexion-extension radiographs have been used to rule out motion at the spinal fusion segment, hardware failure, and issues with sagittal alignment (Raizman et al. 2009; Gruskay et al. 2014b). Further assessment can be done by making use of different methods such as measuring the Cobb angle and also by making use of Simmons method and Hutter methods (Hutter 1983; Simmons 1985). Although widely used by both spine surgeons and radiologists, these have problems in terms of concordance with findings on CT images (Figs. 1 and 2).

Computed tomography can be very helpful in instances where there is no evidence of progression of fusion on radiographs. Fusion is present once note of bony trabeculation is found across the fusion level with absence of radiolucency at the graft-vertebral body interface. The downside with using CT scans is its decreased sensitivity to fusion due to metallic artifacts secondary to instrumentation implanted within the spine. The incidence of metallic artifacts has lessened with

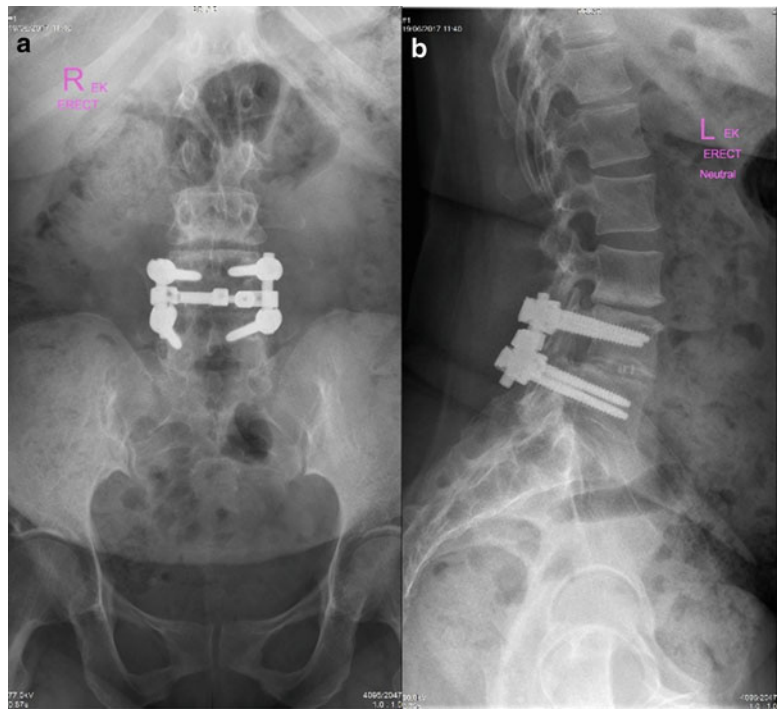

Fig. 1 Standard AP (**a**) and lateral (**b**) X-ray views of the lumbar spine. Posterior decompression and TLIF were performed at L4–5. Note presence of bridging bone at said level

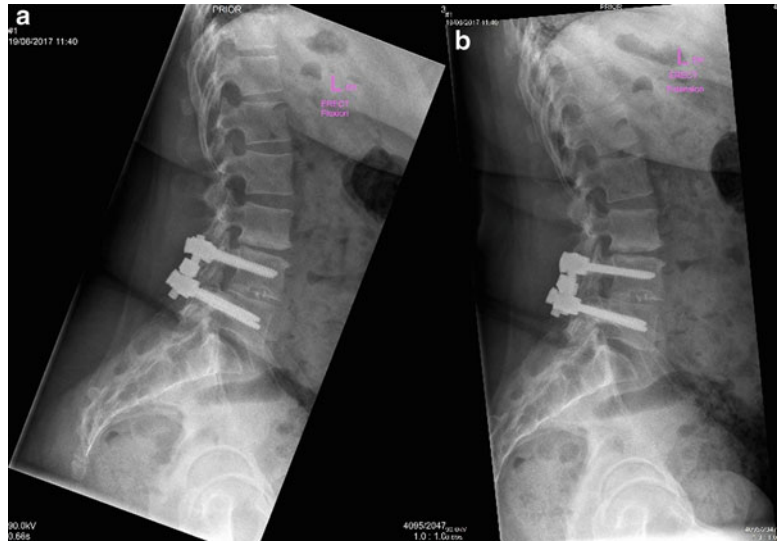

Fig. 2 Flexion (**a**) and extension (**b**) views performed to rule out motion at fused segment

the advent of titanium implants. Despite this disadvantage, computed tomography has been deemed as the gold standard imaging modality for assessing the presence of fusion (Raizman et al. 2009; Gruskay et al. 2014b) (Fig. 3).

Other imaging modalities available for assessing spinal fusion include magnetic resonance imaging, bone scintigraphy, ultrasound, and radiostereometric analysis. MRI is not routinely used for spinal fusion evaluation due to its susceptibility to artifact formation from metallic implants, and its clinical utility, while promising, is not yet established (Kitchen et al. 2018). It is more useful in identifying stenosis and presence of adjacent segment degeneration. Bone scintigraphy is able to ascertain the level of metabolic activity of the spine. Increased uptake is noted in areas of heightened biologic activity and blood supply which may suggest non-union. This is of limited use due to its low sensitivity (50%) and specificity (58%) when compared to surgical exploration. Ultrasound was found to be able to ascertain the presence of fusion if there was note of hyperechoic and shadowing interface across vertebral segments. On the other hand, the presence of scattered and nonbridging echogenic foci indicates possible pseudarthrosis. This imaging modality was found to be more suitable for patients who have undergone posterior instrumentation which may produce artifacts in CT or MRI scans. Radiostereometric analysis allows for three-dimensional imaging of spinal motion in vivo. The use of this imaging modality has been limited to research purposes, despite its high accuracy, and requires bony insertion of tantalum beads (Raizman et al. 2009; Gruskay et al. 2014b).

Multitudes of studies have been performed to evaluate fusion in different regions of the spine. Evaluation of success for a particular technique relies on a combination of clinical and radiologic outcomes. The difficulty lies on properly assessing the quality of evidence and strength of recommendations presented by these studies (Guyatt et al. 2009) (Table 1).

Fusion of the Cervical Spine

Anterior Cervical Discectomy and Fusion (ACDF)

Cervical disk degeneration may present as axial neck pain associated with radiculopathy or myelopathy. Anterior cervical discectomy and fusion is the accepted standard treatment for symptomatic cervical disk degeneration. After removal of the pathologic disc, fusion is carried out via standalone cages inserted into the intervertebral disk space or supplemented by an anterior plate. The cage allows for bridging union of vertebral bodies

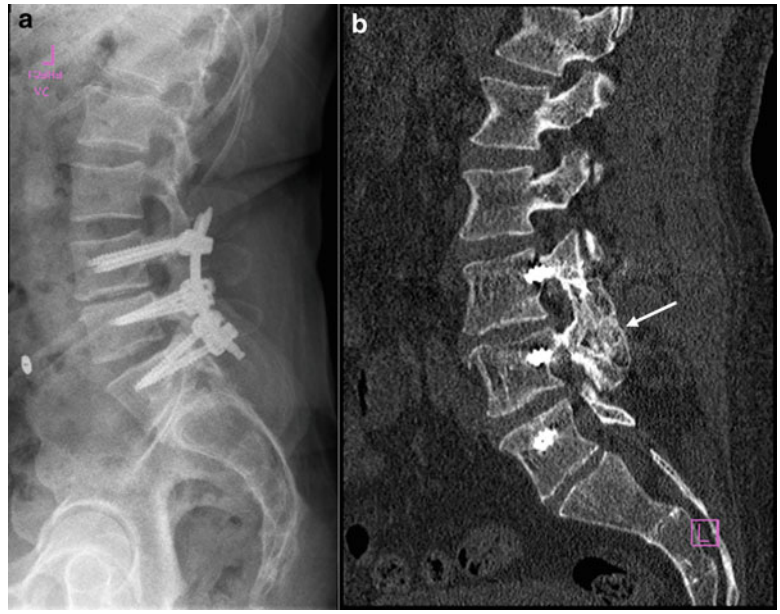

Fig. 3 Lateral radiograph (**a**) of instrumented posterolateral fusion performed from L3 to L5. Sagittal cut of CT scan (**b**) shows abundant fusion mass (arrow) over posterolateral gutter adjoining the levels from L3 to L4. Bridging bone was absent in between L4 and L5

Table 1 Imaging modalities for evaluation of fusion

Imaging modality	Advantages	Disadvantages	Utility
Radiographs	Picks up opacification and bridging bone along graft margins Low cost Easy to perform Dynamic radiographs can be used to assess for translational or angular motion of fusion segment	Occasionally miss presence of bridging bone or bony trabeculations Low radiation exposure	++
Computed tomography	Greater ability to determine presence or absence of bridging bone or bony trabeculations between fusion segments Identification of hardware failure/loosening	Higher radiation exposure compared to radiographs Dynamic CT not common practice Artifact formation from metallic implants may prevent visualization of bone bridges	++++
Magnetic resonance imaging	More useful in identifying stenosis and adjacent segment degeneration	Prone to artifact formation from metallic implants Static imaging modality	+
Bone scintigraphy	Increased uptake due to heightened biologic activity may be secondary to non-union	Low sensitivity (50%) and specificity (58%)	−
Ultrasound	Alternative imaging modality that identifies pseudarthrosis which may present as areas of nonbridging echogenic foci between vertebral segments No radiation	Limited to patients with posterior instrumentation	+
Radiostereometric analysis	Capable of three-dimensional imaging of spinal motion in vivo High accuracy	Limited presently to research purposes Requires tantalum bead insertion around prosthesis	++

to take place once fusion has set in. The addition of a plate is believed to allow for higher fusion rates, decreased pseudarthrosis, decreased graft dislodgement, resistance to segmental kyphosis, and less need for external immobilization.

Several imaging modalities can be used for the assessment of fusion at the cervical level. Besides assessing the quality of fusion present, specific measurements are utilized depending on the specific type of imaging modality used. These measurements are most often taken from dynamic radiographs through the use of lateral flexion and extension views.

The assessment of fusion status through dynamic radiographs is dependent on currently accepted criteria. For example, the US FDA previously defined successful fusion as less than 3 mm of translational motion and less than 5° of angular motion in the lumbar spine. These criteria are also applied in the assessment of successful fusion in the cervical spine (USSDHHS et al. 2000). Traditionally, motion was assessed by measuring the Cobb angle. This has been difficult to evaluate as there is very minimal motion detected with this method. An alternative to the Cobb angle method is the interspinous method (Cannada et al. 2003). In general, there is also low interobserver agreement as well with regard to the assessment of cervical spine fusion on dynamic films (Taylor et al. 2007) (Fig. 4).

A retrospective chart review of 383 patients treated ACDF with a total of 1155 postoperative visits was performed from 2002 to 2007 to determine the utility of radiographs in postoperative monitoring of fusion status. These patients were classified according to normal versus abnormal history and physical examination presentations and also by normal and abnormal radiographs. Patients with normal history and physical examination findings were rarely found to be managed/not left alone [5/879 (0.57%)]. There were 276 visits with abnormal history and physical examination findings. Abnormal radiographic findings were found in 34 out of the 276 visits (12.3%). Revision surgery was advised in 44% of these visits with abnormal radiographic findings (15/34). This study concluded that postoperative radiographs had limited utility in patients with normal history and physical examination findings independent of normal or abnormal radiographic results (Grimm et al. 2013).

A prospective clinical study attempted to evaluate the reliability of detecting pseudarthrosis after anterior cervical fusion using radiography, CT, and MRI as compared to surgical exploration. The investigators found that assessment of fusion status via CT is most closely related with findings upon surgical exploration when compared to the other imaging modalities. This was assessed by evaluating the agreement between findings on surgical exploration and the different imaging modalities and through paired interobserver reliability. Mean Kappa statistics for agreement between intraoperative and radiographic findings were 0.67 (plain radiographs), 0.81 (CT), and 0.48 (MRI), while mean Kappa statistics for paired interobserver reliability were 0.46 (plain

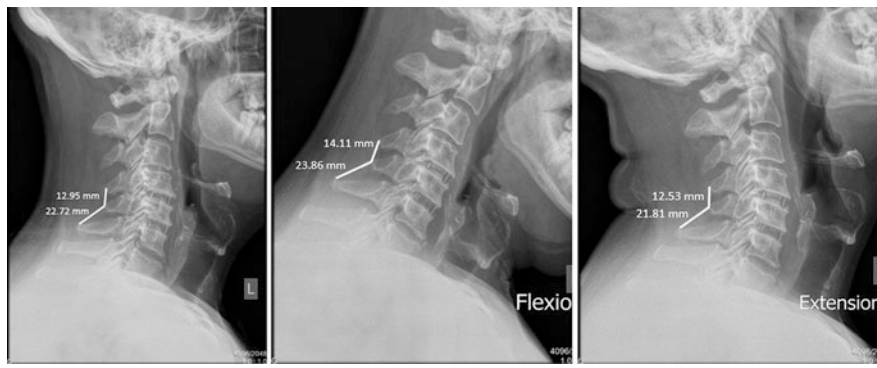

Fig. 4 Lateral X-ray views of the cervical spine showing method of measuring interspinous process distance

radiographs), 0.82 (CT), and 0.32 (MRI) (Buchowski et al. 2008).

On the other hand, Park et al. (2015) found that CT scans may overestimate the rate of fusion after ACDF. They performed a radiographic analysis of patients who had undergone ACDF. This study attempted to compare the fusion rates with CT scans and dynamic radiographs at 3, 6, and 12 months postoperatively. Their results show that the fusion rates post ACDF assessed via radiographs and CT scans were 26% versus 79%, 41% versus 79%, and 65% versus 91% at 3, 6, and 12 months, respectively. This study concluded that overestimation of fusion rates was present upon assessment with CT scans. This is due to the static nature of the fusion levels being assessed. Radiographs, when compared to CT scans, are assessed taking into account dynamic and static factors for fusion.

Ouchida et al. (2015) performed a study comparing the ability of functional computed tomography in determining fusion status versus functional radiography in patients post ACDF. This study was able to determine that functional CT scanning was superior in detecting non-union when compared to functional radiography. Radiographs showed fusion rates of 83.9% and 91.1% at 6 months and 12 months postoperatively, respectively. On the other hand, CT scans revealed considerably lower fusion rates at 6 months (55.3%) and 12 months (78.6%). Patients found to have incomplete union were shown to develop more neck pain postoperatively.

Ghiselli et al. (2011) attempted to determine the gold standard for assessing pseudarthrosis of the cervical spine. This study investigated the ability of CT imaging versus quantitative motion analysis with dynamic radiography to examine for presence of fusion. Findings from imaging were then compared to those found in the patients intraoperatively. The amount of angular motion on radiographs thought to correlate with pseudarthrosis was at more than 4°. The study found this parameter provided for high specificity with a positive predictive value of 100% but was coupled with a low sensitivity as shown by a negative predictive value of 52%. Fusion on CT was defined as presence of bridging bone. CT scans were shown to have a positive predictive value of 100% and a negative predictive value of 73%. This was comparable to the negative predictive value with the use of quantitative motion analysis on dynamic radiographs once the accepted angular motion was changed to a value of greater than one degree (73%). The researchers were then able to determine that by making use of both CT scans and the modified angular motion (1°) on radiographs produces a positive predictive value of 100% and negative predictive value of 85%, thus improving the specificity in detecting for presence of pseudarthrosis in the cervical spine.

Posterior Cervical Decompression and Fusion (PCDF)

Posterior cervical decompression and fusion can be performed through varying techniques. Decompression in itself can be done via different methods. These include laminectomies and laminoplasties, often done in patients with cervical spondylotic myelopathy, which allow for extensive decompression of the cervical canal with potential for postoperative instability of the motion segments. Foraminotomies limit the extent of destabilization and are strictly indicated in patients with stenosis at the foraminal level only. Fusion can be achieved via multiple techniques supplemented with instrumentation through the use of screw fixation. The instrumentation can either be performed with application of lateral mass screws or pedicle screws (Fig. 5).

Lee et al. (2017) analyzed the fusion and graft resorption rates in 56 patients who underwent posterior cervical fusion with pedicle screw instrumentation 1 year postoperatively under CT imaging and dynamic radiography. The patients who participated in this study were classified into three groups according to the type of graft used for posterolateral fusion (autograft, allograft, or mixture of both). Mean resorption rates were as follows: 56.2% (autograft), 75.9% (mixture), and 91.5% (allograft). Despite the resorption rates mentioned, the overall fusion rate was 98.2%.

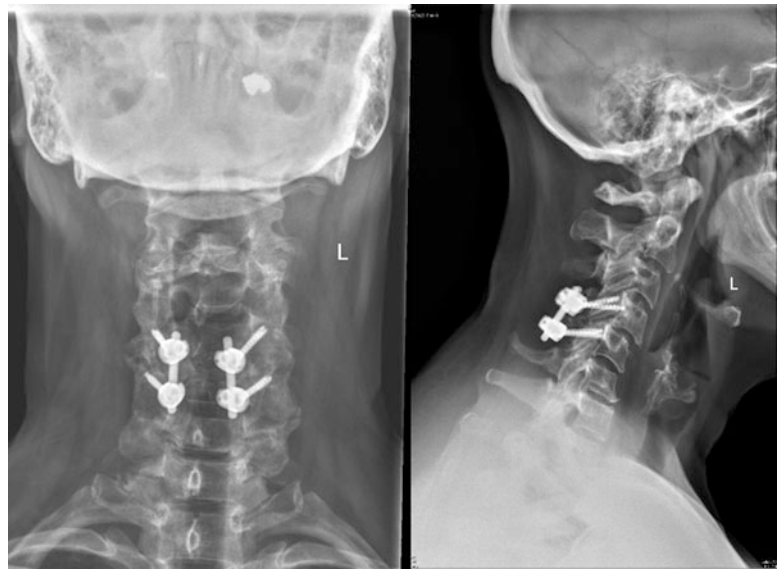

Fig. 5 Posterior cervical decompression and fusion at C4–5 with lateral mass screws

A retrospective case series by Dorward et al. reported on the fusion rates and complications associated with the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) in patients treated with posterior cervical fusion. A majority of patients included in the study were operated on to revise previous surgeries (84.2%). Several patients were also found to have preexisting cervical pseudarthrosis (42.1%). Successful fusion was noted in 89.5% of patients. Radiographic evidence of non-union was found in the remaining 10.5%. Pseudarthrosis occurred in patients with fusions that spanned either occipitocervical or cervicothoracic junctions. Complications were noted in 14 patients (24.6%), with superficial wound infection, pain from fusion levels, and pseudarthrosis being among the most common (Dorward et al. 2016).

Fusion of the Lumbar Spine

Degenerative conditions of the lumbar spine may present as back pain with radiculopathy or other forms of neurologic deficits in patients. These warrant fusion of spinal motion segments with or without decompression of the pathologic intervertebral disk. Techniques utilized for the fusion of the lumbar spine will depend on the type of approach. Several techniques available for the posterior approach include posterolateral fusion, posterior lumbar interbody fusion, and transforaminal interbody fusion, which are then supplemented by posterior pedicle screw instrumentation. Another method for achieving arthrodesis of the spine is by performing anterior lumbar interbody fusion. This technique utilizes a retroperitoneal approach to access the lumbar spine. Recently developed variations of this technique include the direct lateral interbody fusion and oblique lateral interbody fusion. The former gains access to the intervertebral disk via transpsoas technique, while the latter approaches the disk space through a corridor just anterior to the psoas muscle.

Posterior Lumbar Decompression and Fusion

Fogel et al. (2008) determined the accuracy of fusion assessment of posterior lumbar interbody fusions with the use of plain radiographs and computed tomography in comparison to findings on surgical exploration. Successful fusion was found in 168 out of 172 (97%) motion segments fused upon surgical exploration. Interbody fusion had a success rate of 87% (X-ray) and 77% (CT),

while posterolateral fusion was 75% (X-ray) and 68% (CT). They were able to determine that plain radiographs and CT imaging were both accurate in the assessment of fusion status when compared to findings on surgical exploration of the lumbar interbody and posterolateral fusion levels. The investigators also found that CT is unlikely to provide any additional significant information if there is strong evidence of fusion or pseudarthrosis on plain radiographs (Fig. 6).

Carreon et al. (2007b) performed a blinded cross-sectional study on plain radiographs and fine-cut CT scans to evaluate intra- and interobserver reliability and agreement for assessing single-level instrumented posterolateral fusions. Plain radiographs with anteroposterior and lateral flexion-extension views and fine-cut CT scans with sagittal and coronal reconstructions were performed 1 year postoperatively. Fine-cut CT scans were found to have greater interobserver and intraobserver agreement as compared to plain radiographs. Agreement on fusion status between plain radiographs and CT scans ranged from 46% to 59% only. Another study by Carreon et al. (2007a) showed that radiographic findings of facet fusion and posterolateral fusion on fine-cut CT scans yielded 96% fusion rate on surgical exploration. The kappa statistic for interobserver reliability for evaluating facet fusions was moderate (0.42) and for posterolateral fusions was found to be substantial (0.62). The probability of solid fusion on surgical exploration was higher when bilateral posterolateral gutter fusion was present (89%) compared to bilateral facet fusion on CT scan (74%). The study found several poor predictors for non-union upon surgical exploration, which include absence of fusion of unilateral or bilateral facets or through one posterolateral gutter.

The utility of magnetic resonance imaging (MRI) for the evaluation of fusion status post PLIF has been explored in the past. A prospective study investigated the use of MRI in the assessment of PLIF using carbon fiber reinforced polymer cages. The most reliable radiographic finding is the presence of bridging bone within the carbon cage on the coronal planes based on MRI. Kroner et al. concluded that MRI is a reliable imaging

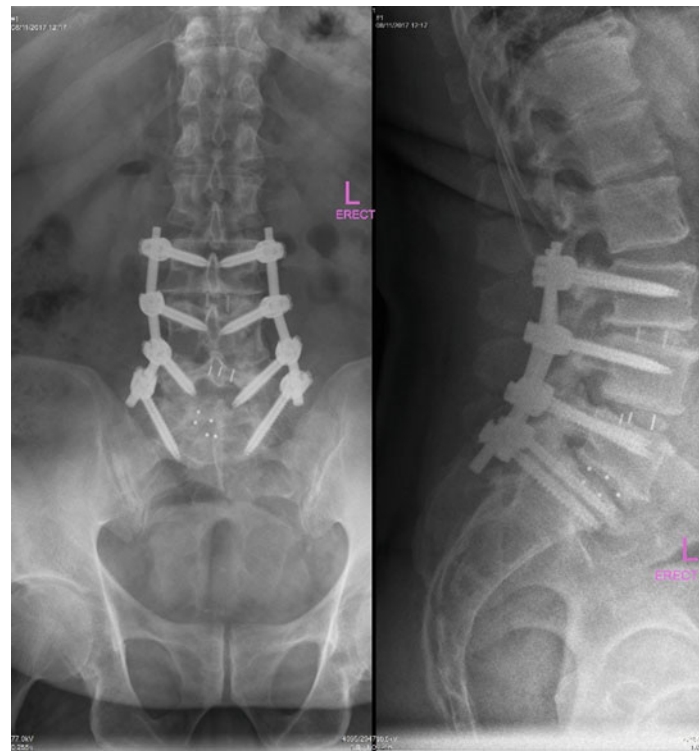

Fig. 6 Multilevel TLIF spanning L3 to S1

method for detecting pseudarthrosis after a period of 2 years post fusion (Kröner et al. 2006).

Nakashima et al. (2011) compared the ability of dynamic radiographs and CT scans with the lumbar spine in flexion and in extension to identify the quality of arthrodesis or fusion in patients who had undergone PLIF. There were 81 patients with a total of 97 fused levels included in the study and were followed for more than 12 months after PLIF. Dynamic radiographs revealed fusion in 90.7% of all operative levels at 10.7 months postoperatively. Patients were then further evaluated, revealing 87.6% fusion on flexion CT and 69.1% fusion on extension CT. Pseudarthrosis detection on extension CT was found to be significantly higher compared to dynamic radiography and flexion CT.

Anterior Lumbar Interbody Fusion (ALIF)

Carreon et al. (2008) once again evaluated the reliability and accuracy of CT imaging versus surgical exploration in determining fusion status, this time around on patients who had undergone anterior lumbar interbody fusion with metallic cages implanted. The study aimed to establish the interobserver reliability with regard to the presence or absence of bridging bone, as well as the anterior and posterior sentinel signs on CT and actual findings of fusion or pseudarthrosis upon surgical exploration of the lumbar spine. On average, 67% of the cases were correctly classified as fused (93% sensitivity, 46% specificity). Interobserver reliability was found to be fair (kappa 0.25). The investigators were able to conclude that their CT scans had a high false-positive rate of determining fusion (Fig. 7).

Fig. 7 ALIF performed at L5-S1. Bridging bone well appreciated at fused segment

Lateral Lumbar Interbody Fusion [Direct Lateral LIF (Transpsoas) and Oblique LIF (Anterior to Psoas)]

Clinical and radiologic evaluation of fusion rates with the use of lumbar interbody fusion via direct lateral/transpsoas approach (XLIF) along with varying types of graft material (autograft, calcium triphosphate, and Attrax) was performed by Berjano et al. (2015). Patients who had undergone the procedure from 2009 to 2013 were assessed through clinical evaluation and CT scans with a minimum of 1-year follow-up. CT scans were evaluated with complete fusion defined as presence of bridging bone within the interbody space. Pseudarthrosis was defined as complete absence of graft material within the cage or where there was presence of radiolucency. Complete fusion was found in 68 out of 78 operated interbody levels (87.1%). Stable but incomplete fusion was noted in eight levels (10%), while pseudarthrosis was identified in only two operated levels (2.6%). Comparison of fusion rate by graft material used revealed successful arthrodesis with autograft in 75% in patients, Attrax in 83%, and calcium trisphosphate having the highest fusion rate of 89% (Figs. 8 and 9).

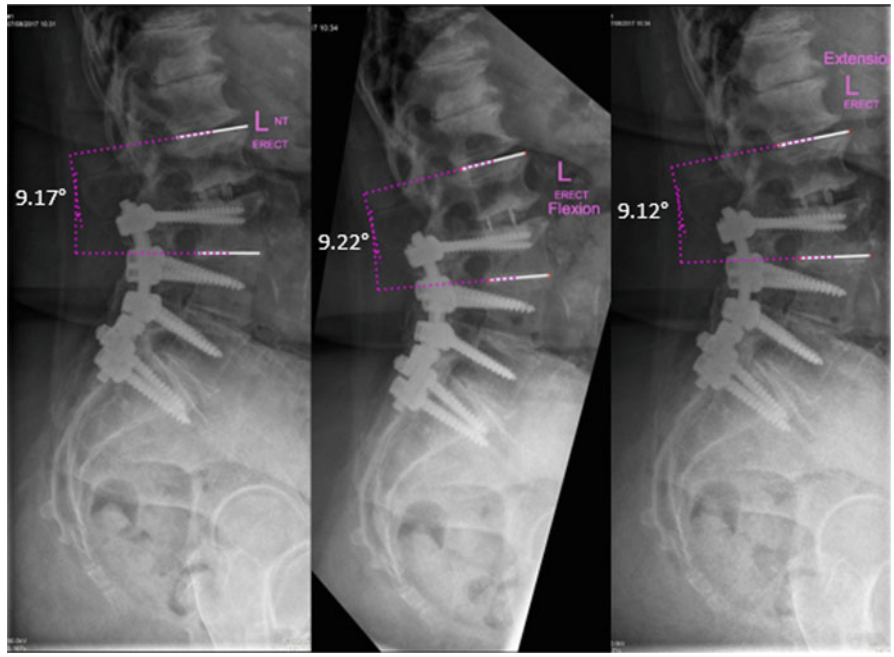

Fig. 8 Lateral views of the lumbar spine post XLIF for adjacent segment degeneration at L2–3. Cobb method was utilized to assess for motion at fusion segment

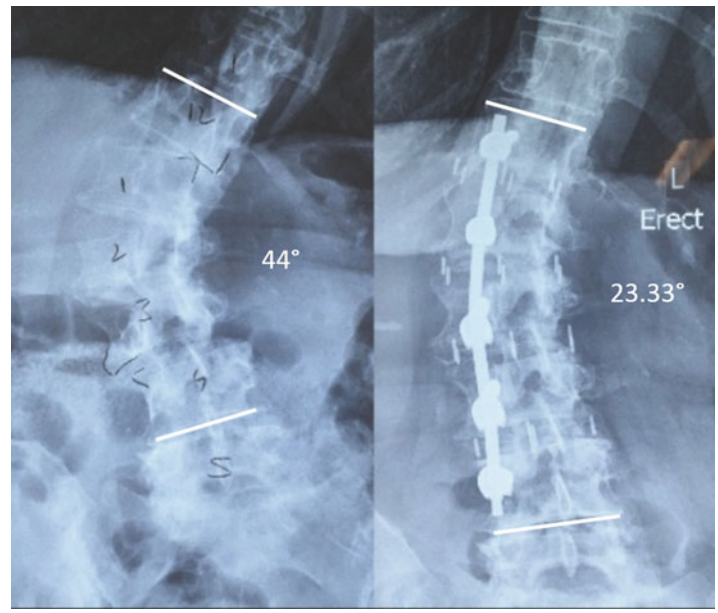

Fig. 9 Degenerative lumbar scoliosis treated with XLIF from T12 to L4. Preoperative curve was at 44°. Correction of 23.33° was achieved after XLIF

Factors to Consider for Further Imaging Evaluation in Pseudarthrosis

Plain radiographs are routinely requested for initial postoperative evaluation of postoperative spinal fusion. These have been found to be inadequate in detecting pseudarthrosis. A retrospective review by Klineberg et al. (2016) evaluated the reliability of anterior fusion grading systems and the ability of health-related quality of life (HRQOL) outcomes to predict pseudarthrosis. Its results showed that the grading system used to evaluate for the presence of fusion missed many pseudarthroses that were confirmed surgically and with fine-cut CT. Low Scoliosis Research Society (SRS) and Oswestry Disability Index (ODI) scores compared to preoperative baseline were found in patients with apparent pseudarthrosis. Patients with poor HRQOL scores indicate the need for further advanced investigations in order to address the possibility of pseudarthrosis (Klineberg et al. 2016).

In light of clinical findings and despite the presence of additional imaging investigations to validate any suspicions of non-union after fusion, there is still great difficulty in reliable confirmation of pseudarthrosis. Besides the prerequisite identification of de novo bridging bone and absence of translational and angular motion spanning the fusion segment, one must also take into account the resorption of the bone grafts, substitutes, and extenders as well. Once pseudarthrosis is confirmed, revision surgery may then be performed in appropriate cases. Autografts or allografts are used again, with possible augmentation through bone graft substitutes or extenders, if these were not used during the index surgery, to increase the possible chances of successful rate of fusion.

Evaluation of Bone Graft Materials for Fusion

With all the techniques available for fusion of the spine, the question of which bone graft material should be used is still up for debate. Autogenous iliac crest bone graft provided similar effectiveness in terms of fusion rate, pain scores, and functional outcomes when compared to local autogenous bone graft and allograft. The use of iliac crest bone graft in spinal fusion is still considered the gold standard due to its osteogenic, osteoconductive, and osteoinductive properties, despite the possible complications associated with harvesting. These included postoperative donor site pain, hematoma, infection, pelvic fracture, and nerve palsy. One study found that use of autogenous iliac crest bone graft in spinal fusions was associated with increase postoperative blood transfusion, extended operative time, and increased length of stay in hospital (Gruskay et al. 2014a; Tuchman et al. 2016). Bone graft substitutes and extenders have thus been developed, which not only address the possible problems that arise with bone graft harvesting but also increase the potential for solid arthrodesis of the spine (Kaiser et al. 2014). Despite the increased number of bone graft substitutes at hand, evidence to support their superiority over autogenous bone graft and allografts is low and hard to come by. Herein lies the difficulty in selecting the most appropriate bone graft material or substitute to aid in achieving successful arthrodesis of the spine (Buser et al. 2016).

Bone allografts can be differentiated into fresh-frozen and freeze-dried products. Both are said to be incorporated slower and to a lesser degree compared to autografts. In terms of fusion rates, autografts are still superior versus allografts alone or in combination with autografts. Fresh-frozen allografts are also found to be stronger, more immunogenic, and more completely incorporated as opposed to freeze-dried allografts. This has also been found to work well when used in anterior lumbar fusion for reconstruction procedures with resulting good fusion rates (Ehrler and Vaccaro 2000). Strong recommendations have also been made with regard to the use of allografts in ACDF, ALIF, and posterolateral lumbar fusion. At present, there is still need for more investigations on its use in TLIF (Gibson et al. 2002; Thalgott et al. 2009; Miller and Block 2011; Buser et al. 2016).

Demineralized bone matrix (DBM) functions as both an extender and augmenter of bone graft material. Its advantages include safety in terms of having no risk of disease transmission and its respectable storage and shelf life. This bone graft

material is not without its disadvantages. Studies have shown varying efficacy and poor predictability, with variable degrees of osteoconductive potential with unknown effect on bone formation due to the different carrier types. The manufacturing process is also unregulated, thus leading to fluctuating amounts of bone morphogenetic proteins found in the different DBM products available in the market (Rihn et al. 2010; Aghdasi et al. 2013; Tavakol et al. 2013). Thalgott et al. (2001) investigated the efficacy of coralline hydroxyapatite with or without DBM as an extender of autogenous bone graft in patients who had undergone instrumented posterolateral fusion. There was an overall fusion rate of 92.5% for this study, but a lower fusion rate was found in patients that had DBM added into the autogenous bone graft (89.3%).

Bone morphogenetic proteins (BMPs) are known for their powerful osteoinductive potential evidenced by their ability to produce ectopic bone, promote spinal fusion, and induce fracture healing. rhBMP-2 and BMP-7 have been found to be safe for use in certain conditions for spine surgery, particularly in ALIF and in revision PLIF (Burkus et al. 2002; Vaccaro et al. 2005). The said products have been involved in off-label use as well, such as in ACDF, TLIF, and PLF. However, judicious use and awareness of their side effects and different dosage effects in different anatomic locations are critical. Concern has risen with regard to the safety and effectiveness of the off label of BMPs. In a systemic and review and meta-analysis by Fu et al. on the effectiveness and harms of rhBMP-2 on spinal fusion, it was found that rhBMP-2 had no clinical advantage over iliac crest bone graft but were not associated with the morbidity of harvesting and difficulties with autograft volume. Several complications have also been found to occur in respect to the type and region of the spine where the fusion was performed. Retrograde ejaculation and other urogenital problems were found to be associated with the use of rhBMP-2 in ALIF although it has been proposed to be approach related, where other authors have found a 0.7% rate with retroperitoneal approaches (Scott-Young 2014). There was an increased risk of wound complications and dysphagia when this particular BMP was used for ACDF which were likely dose related. Although event rates were found to be low, this isolated study also found an increased risk of developing cancer in association with the use of rhBMP-2. These are contrary to the findings of Simmonds et al., who found increased fusion rates with the use of rhBMP-2 and inconclusive evidence with regard to the increased incidence of cancer (Fu et al. 2013; Simmonds et al. 2013). Currently, there does not appear to be any cause-effect relationship between rhBMP2 and cancer.

Ceramics act as bone graft extenders designed with optimized porosity and pore size to allow for bony ingrowth. The advantages attributed with this type of bone graft material are its availability, cost effectiveness, and no risk of disease transmission. The varying resorption rate across the different types (calcium sulfate, beta-tricalcium phosphate, and hydroxyapatite) of ceramics presents as a limiting factor, particularly calcium sulfate, in spine surgery (Rihn et al. 2010). The material is best used to augment the fusion mass and is not recommended as a stand-alone substitute for actual bone graft material. A prospective study found that hydroxyapatite-bioactive glass ceramic used as a stand-alone bone graft substitute had a high incidence of resorption with poor consolidation noted in 95% (21/22) of patients who had undergone instrumented posterolateral fusion (Acharya et al. 2008). Other studies that claim good results with the use of calcium phosphate ceramics were found to have the ceramic mixed with local autograft harvested from the site of decompression (Fujibayashi et al. 2001; Dai and Jiang 2008). Tricalcium phosphate has been found to provide excellent results in ACDF and posterolateral lumbar fusion. The use of beta-tricalcium phosphate (94%) for ACDF yielded fusion rates comparable to those of hydroxyapatite (90%) after 2 years of follow-up. Early fusion rates at 6 months (46%) and 1 year (69%) post ACDF were higher with beta-tricalcium phosphate versus hydroxyapatite (24% at 6 months and 49% at 1 year). Beta-tricalcium phosphate was found viable in patients treated with instrumented posterolateral fusion. Radiographs taken at 24 and 36 months post fusion showed good fusion status with no signs of motion on flexion or extension (Dai and Jiang 2008; Sugawara et al. 2011) (Table 2).

Table 2 Known spinal fusion evaluation methods for various regions and approaches

Fusion region	Approach		Method(s) of fusion assessment	Comments
Cervical	Anterior (ACDF)		X-rays Flexion-extension views Cobb angle Simmons Uses reference points >2° extension is pseudarthrosis Hutter Overlap of images Cannada et al. 2003 Measure interspinous process distance doi: 10.1097/00007632-200301010-00012 Findings on CT have higher correlation with findings on surgical exploration when compared to x-ray and MRI (Buchowski et al. 2008) doi: 10.1097/BRS.0b013e318171927c Combination of CT and dynamic radiographs improved specificity in determining pseudarthrosis (Ghiselli et al. 2011) Modified angular motion (>1°) on radiographs doi: 10.1097/BRS.0b013e3181d7a81a Functional (flexion and extension) CT was found superior over functional (dynamic) radiography in determining non-union (Ouchida et al. 2015) doi: 10.1007/s00586-014-3722-z	Postoperative x-rays of limited value for determining fusion in patients with normal history and physical findings (Grimm et al. 2013) doi: 10.1016/j.spinee.2013.01.018 CT images may tend to lead to overestimation of the presence of fusion due to their static nature (Park et al. 2015) doi: 10.1097/BSD.0b013e31829a37ac
	Posterior (PCDF)		X-rays Flexion-extension views Cobb angle Simmons Hutter CT	High resorption rates noted for allografts and auto/allograft mixture compared to autograft alone (Lee et al. 2017) Despite resorption rates, average fusion rate across different types of grafts was 98.2% Doi: 10.1016/j.wneu.2016.12.027 Non-union in 10.5% of patients after posterior cervical fusion with rhBMP2 use (Dorward et al. 2016) Most common in occipitocervical or cervicothoracic junctions doi: 10.1097/BSD.0b013e318286fa7e

Effects of Reimbursement and Regulation on the Delivery of Spinal Device Innovation and Technology: An Industry Perspective

63

Emma Young

Contents

Abstract

Since the 1990s regulation has been relatively unchanged in the world's second largest medical technology sector, the European Union. However, recent medical device-related incidents involving breast implants and hip replacements have prompted urgent regulatory and compliance reforms. Against the background of increasing global healthcare costs and an aging population, medical devices including spinal devices are about to undergo one of the industry's most transformational regulatory changes. What does this mean for current and potential innovators of new medical device technologies and their beneficiaries? What will future reimbursement and regulatory frameworks look like, and what will be their impact on medical device technology investment? Navigating the complex requirements of innovative medical device development such as increasing regulatory burden and a multitude of differing payer uncertainties can often be the hurdle to sustained device innovation for many companies.

Introduction

Healthcare systems are organized, financed, and regulated in different ways around the world, but most would agree that universal access to innovative technology and quality healthcare at an affordable cost to both the individual and society is an elementary need. Almost all OECD (Textbox 1) countries have universal health coverage for a core set of services (OECD 2015). Statistics on healthcare expenditure and financing are often used to evaluate how a country's healthcare system responds to the challenge of universal access to quality healthcare.

Textbox 1 What is an OECD Country?

The Organisation for Economic Co-operation and Development (OECD) is an intergovernmental economic organization with 36 member countries, founded in 1961 to stimulate economic progress, stability, and world trade (OECD 2018). It is a forum of countries describing themselves as committed to democracy and the market economy, providing a platform to compare policy experiences, seeking answers to common problems, identify good practices, and coordinate domestic and international policies of its members. Most OECD members are high-income economies and are regarded as developed countries.

Source: Based on information from OECD (2018).

Healthcare expenditure is defined as expenditure on health goods and services, including investment in equipment and facilities. As defined by the Australian Institute of Health and Welfare (2017), this definition closely follows the definition that the OECD System of Health Accounts framework provides. It excludes expenditure that is incurred outside the health sector, personal activities, and where health is not the primary expected benefit.

At the macrolevel, health expenditure in Australia is considered within the context of changes in the economy and population growth. The focus is on total health expenditure. Total health expenditure in 2015–2016 in Australia was reported at $170.4 billion–$6.0 billion higher in real terms than 2014–2015 and $63.2 billion higher than in 2005–2006 (AIHW 2017). Health's share of Australian gross domestic product (GDP) has continued to rise, from 8.68% in 2005–2006 to 10.3% (Table 1) in 2015–2016 (AIHW 2017). The share of the economy (or GDP) represented by health continues to steadily grow as reflected in Table 1. Non-government sources (individuals, private health insurance funds, and other non-government sources) contributed an estimated 32.7% toward total health spending in 2015–2016 (AIHW 2017).

The European Union (EU) healthcare spend, as a percentage of GDP, aligns itself closely with the Australian experience. The European Union (EU) reports total health expenditure in 2014, in terms of GDP, ranging as high as 10.9–11.4% in countries such as Germany, the Netherlands, France, the UK, and Switzerland (Table 2) (Eurostat 2017).

In the USA, the National Center for Health Statistics (2017) recorded the total US national health expenditure in 2015 to be US$3.2 trillion, 17.8% of the national GDP. In 2017, it was reported that health expenditure rose to 18.3% of national GDP.

Health systems across the globe are required to rapidly develop and respond to a multitude of factors such as new medical technologies, new health services, and greater access to them, changing health policies and organizational structures and more complex financing mechanisms. Access to healthcare and greater patient choice are increasingly scrutinized against the background of financial sustainability. New medical technologies are improving diagnoses and treatments, but they are also increasing health spending. Medical technology is often viewed as a primary contributor to increased healthcare expenditure. The prospect that spending pressures will escalate raises questions around the benefits and costs of technology advances and the processes for evaluating them. Life expectancy continues to increase steadily in OECD countries, rising on average by

Table 1 Total Australian health expenditure and GDP, current prices, and annual health to GDP ratios of 2005–2006 to 2015–2016

Year	Total health expenditure ($million)	GDP ($million)	Ratio of health expenditure to GDP (%)
2005–2006	86,685	998,458	8.68
2006–2007	94,938	1,087,440	8.73
2007–2008	103,563	1,178,809	8.79
2008–2009	114,401	1,259,280	9.08
2009–2010	121,710	1,297,508	9.38
2010–2011	131,612	1,410,442	9.33
2011–2012	141,957	1,491,741	9.52
2012–2013	146,953	1,527,529	9.62
2013–2014	154,671	1,589,940	9.73
2014–2015	161,617	1,617,016	9.99
2015–2016	170,386	1,654,928	10.3

Data source: AIHW (2017)

3–4 months each year. In 2013, OECD (2015) life expectancy at birth reached 80.5 years, an increase of over 10 years since 1970. This rise in average life expectancy continues to increase the need for treatment of illness and chronic diseases. Interestingly and despite the highest OECD health spend, the US Center for Disease Control and Prevention (2017) recently reported that the 2016 US life expectancy at birth was 78.6 years for the population as a whole – 0.1 year less than it was in 2015. This recent statistic from the largest healthcare economy in the world has sharpened the focus on the relationship between healthcare spend and its effect on overall health improvement.

The Australian Productivity Commission's work on the Economic Implications of an Ageing Australia (Productivity Commission 2005) found that most of the growth in health expenditure over the last 20 years was due to factors such as a greater demand for health services, in combination with the adoption of new technologies. Modelling estimates prepared as part of this report confirm that technology has played an important role in driving total real healthcare expenditure growth. It is reasonable to expect that technologies such as medical devices will continue to play a key role in influencing healthcare expenditure.

As knowledge increases there is a constant uptake of improved, innovative, and inventive medical technology, such as medical devices. However, the rapid advances in device technology continue to drive medical costs upward. It has become increasingly difficult to balance the dual responsibilities of controlling healthcare expenditure while simultaneously enhancing the welfare of its beneficiaries, particularly when it comes to coverage decisions for costly new medical devices. Patient demographics are shifting toward a greater emphasis on notions of well-being and increased activity levels, including an expected standard of health and technology delivery that will enable an aging population to lead more active lives for longer. To be concise, patients expect a better quality of life for longer. Rapid developments in new technologies and their increasing complexity will place demands on regulatory requirements to adapt, as patients increase their awareness of newly developed technologies through sources such as the media and the Internet. At any one time, there are thousands of new technologies undergoing development, most of which will fail to progress to end commercial availability. As a result it is often difficult to identify effective technological advances, let alone the implications for health expenditure.

The influence of a new medical technology on health expenditure will depend on factors such as but not limited to:

- Whether the medical advance will increase or decrease the cost of a particular procedure or treatment
- How the number of procedures undertaken will change as a result of the new medical device

Table 2 2014 EU healthcare expenditure total, per inhabitant and as a percentage of GDP

EU Member	Total health expenditure (EUR million)	EUR per inhabitant	Ratio of health expenditure to GDP (%)
Belgium	41,711	3722	10.4
Bulgaria	3640	504	8.5

- Whether the advance will change the place of treatment, for example, an inpatient to an outpatient basis

Moreover, it is inappropriate to consider only the potential expenditure effects of technology advances in isolation of their expected efficacy and clinical benefits. Spinal pathology and related back pain are among the most prevalent contributors to health expenditure in the world. Within the Australian adult population, the results of a "cost-of-illness" study (Walker et al. 2003) of low back pain (LBP) estimated the direct cost of LBP in 2001 to be AU$1.02 billion, with indirect costs at AU$8.15 billion producing a total cost of AU$9.17 billion. LBP in Australian adults represents an exponential health problem with significant economic burden.

Care for individuals with a spinal pathology, related symptoms, and operative care have long been associated with rising healthcare costs and productivity losses, costing the world's largest

Table 3 EU medical device classification

Class 1	Low risk Non-sterile. Self-certified. Registered within each member state they are sold within
Class 1 (measuring/ sterile)	Low-medium risk Provided sterile and/or have a measuring function.
Class IIa	Medium risk Special controls. NB assessment. Used to diagnose and monitor. Limited invasiveness
Class IIb	Medium risk Full QMS and targeted review of design or technical files by NB. Surgically invasive/implantable
Class III	High risk Similar to IIB + full design review by NB Implants support or sustain human life. Present a potential, high risk of illness/injury

healthcare market, the USA, US$86 billion in 2005 (Bisschop and Tulder 2016). Bisschop and Tulder (2016) state that spinal pathology and related back and neck symptoms are among the most common health problems and are ranked number one with respect to years lived with disability. The global burden is so great that it has compelling and urgent ramifications for health policy, planning, and research in all jurisdictions.

Growth of the global spinal device market is estimated to reach US$17.27 billion by 2021 as reported in a 2017 market research study (Markets and Markets 2017). A number of contributing factors include the rising incidence and prevalence of spinal disorders, development of technologically advanced medical devices, and the global rise in an aging population. The challenge for the payers and regulators in any jurisdiction is to craft a standard for policy, reimbursement, and regulatory provision that both protect patient safety and efficacy while preserving some incentive to spur authentic device research and innovation. Reimbursement policies and supporting frameworks for innovative medical devices differ significantly from the regulatory requirements. With this in mind, what are the effects of reimbursement and regulation frameworks on the delivery of spinal device innovation?

The Regulatory Effect

Medical devices cannot be placed on the European market without conforming to the strict safety requirements of European legislation. In the European Union or EU, three directives cover the medical device sector. Collectively known as the Medical Device Directive (MDD), this legal framework regulates the safety and marketing of medical devices in Europe and is largely mirrored throughout the Australian medical device approval process under the authority of the Australian Therapeutic Goods Administration (TGA). Of the three directives, it is the Medical Device Directive (93/42/EEC) that regulates implantable spinal devices such as screws, rods, cages, plates, and total disc replacements.

Medical device regulations around the world begin by assessing the risk of a device and, more specifically, the risk of the intended use of the device. The regulatory requirements or "burden" are proportional to the estimated risk. The lowest risk or "class" of device (Table 3), such as a reusable surgical instrument, is self-certified. These low-risk devices are required to meet general controls and be registered in their respective jurisdiction. The highest class of device, such as hip replacements and heart valves, must undergo stringent premarket assessment by a qualified body before market placement. Within the European Union, all medical devices are placed into one of the four graduated categories, using the classification rules listed in the Directive 93/42/EEC Annex IX.

Under the Therapeutic Goods Act 1989, medical devices must be included in the Australian Register of Therapeutic Goods (ARTG) prior to supply in Australia, unless exempt. The TGA's current regulatory framework is based on the model recommended by the Global Harmonization Task Force (GHTF) (Textbox 2). A conformity assessment is the key mechanism for assuring a medical device is safe and performs as intended. Conformity assessment certification is issued by a conformity assessment body, and the degree of assessment rigor is determined by the risk classification of the device.

Textbox 2 What is the GHTF?

Founded in 1992, the Global Harmonization Task Force or GHTF was created in an effort to respond to the growing need for international harmonization in the regulation of medical devices (*IMDRF* 2018b). *The GHTF was a voluntary group of representatives from regulatory authorities and members of the medical device industry. The representatives from its five founding members (the EU, the USA, Canada, Japan, and Australia) were divided into three geographical areas, Europe, Asia-Pacific, and North America, each of which highly regulates medical devices using their own unique regulatory framework.* GHTF principles are similar to and largely based on the member countries framework in that device classification is risk based and assessed by third-party bodies. There are a number of jurisdictions such as Japan who currently operate their regulatory frameworks on the GHTF principles.

The GHTF organization had been a mainstay among the regulatory harmonization movements, and the initiative was arguably the most successful effort to harmonize medical device standards around the globe. The GHTF was discontinued with its mission taken over by the International Medical Device Regulators Forum (IMDRF) in late 2011, a successor organization comprised of officials from regulatory agencies around the world (*IMDRF* 2018b).

The TGA issues conformity assessment certification under the Australian regulatory framework, while European-notified bodies issue conformity assessment certification under the European regulatory framework. There is great similarity between the Australian and European processes with both frameworks based on the GHTF principles.

Signed in 1998 and effective since 1999, the mutual recognition agreement (MRA) between Australia and the European Community (EC), known as the EU-AU MRA, officially recognizes the competence of conformity assessment bodies located in the EU to assess compliance of certain types of medical devices with Australia's regulatory requirements. Conversely, the MRA recognizes the competence of Australia's Therapeutic Goods Administration (TGA) to assess medical devices for compliance with EU requirements. According to the TGA (2013), this practice recognizes that conformity assessment is an intensive and potentially expensive process and that unnecessary duplication would increase the costs of many medical devices for consumers and create disincentives to supply products in Australia's small medical devices market.

However, changes to the provisions of the EU-AU MRA came into force on the 1 January 2013 to exclude particular medical devices from the scope of the agreement. Medical devices excluded from the MRA include high-risk devices such as active implantable devices (AIMDs) and class III (high risk) medical devices. Exclusion of these medical devices will continue until confidence-building activities have been undertaken by Australia and the European Union. Certain additional medical devices incorporating materials of biological origin are also principally excluded, with no confidence-building phase planned.

Medical devices covered under the terms of the amended MRA that have undergone a conformity assessment procedure by an EU-recognized notified body and are in compliance with Australian medical device regulations are included by the TGA on the Australian Register of Therapeutic Goods (ARTG). In practice, 97% of applications for inclusions in the ARTG are certified medical devices by EU notified bodies (TGA 2013).

Textbox 3 What is a CE Mark?

CE marking is the medical device manufacturer's claim that a product meets the essential requirements of all relevant European Medical Device Directives. The Directives outline the safety and performance

(continued)

requirements for medical devices in the European Union (EU). The CE mark is a legal requirement to place a device on the market in the EU.

Although a device may be granted an EU approval (CE mark) (Textbox 3), for companies whose devices do not qualify under the amended MRA between Australia and the EC, they must apply for a conformity assessment procedure to be conducted by the TGA. Although the TGA's regulations and approval processes are similar to those applicable in the EU, the full TGA registration process can take anywhere from 2 to 18 months to complete, depending on the risk classification of the device, prior conformity assessment sources, and whether the TGA determines that an audit is required.

A key feature of the European medical device legislation is that it defines what is commonly known as the Essential Requirements or the "ERs." Medical devices can only be placed in the European market if they satisfy the Essential Requirements criteria, specified in Annex I of the Medical Device Directive 93/42/EEC. All medical devices must comply with these requirements. Manufacturers are required to verify each device type or model against each of the requirements, determine whether the requirement is applicable, and demonstrate documented evidence of compliance. In this respect, it is reasonable to assert that Annex I is the foundation of the Medical Device Directive (MDD).

The MDD outlines the core elements that companies need to have in place. It sets out and defines the conformity assessment processes required to assess whether a device is in conformity with the directives, and it lays down precise obligations on the part of the device's legal manufacturer (IOM 2010). Competent authorities (CA), notified bodies (NB), and authorized representatives (AR) are all involved in the CE marking process. Competent authorities exist in each member state and designate, control, and monitor the notified bodies, govern clinical trials, and monitor post market vigilance activities. Notified bodies ensure and certify the safety and compliance of devices and their manufacturers in accordance with the relevant criteria.

The legislation itself is underpinned by "standards." European standards or harmonized standards adopted by a recognized European Standards Organization such as CEN or CENLEC allow manufacturers, other economic operators, or conformity assessment bodies to use these designated harmonized standards to demonstrate that products, services, or processes comply with relevant EU legislation. Other commonly utilized standards are written by the International Organization for Standardization (ISO), while others are in the form of "EU guidelines" called MEDDEVs and GHTF guidance documents.

The European and Australian regulatory frameworks are similar to the US system in that they are all constructed on a risk-based classification system (Table 3). These risk-based frameworks are more similar than different. However, despite the similarities there remains enough difference between them that complying with one does not guarantee compliance with the other. It has been long reported that devices cleared by the FDA have been declined by EU notified bodies and vice versa.

Within Australia, the USA, and the European Union, the highest risk devices have development paths that are heavily regulated and expensive to both commercialize and maintain on the market. In the USA, class III or novel devices require a Premarket Approval (PMA) (see ► Chap. 18, "FDA Premarket Review of Orthopedic Spinal Devices"). Sorenson and Drummond (2014) report over the past 10 years approximately 2% of medical devices have undergone the PMA process, and unlike PMA, direct evidence of safety and effectiveness is usually not required for a 510 (k) application with only 10–15% of those applications containing any clinical data. Medium-risk or class II devices in the USA are usually required to undergo the 510(k) review process, which determines principally whether the new device is "substantially equivalent" to previously marketed or "predicate" devices. Class III (high risk) devices or novel technologies deemed to not possess substantial equivalence undergo the more

stringent PMA process. These technologies must demonstrate safety and efficacy through clinical studies.

Similarly in Europe the evidence requirement increases with the risk of the device. The majority of spinal devices is approved through demonstrating safety and performance in relation to the intended purpose. In most cases the evidence submitted for premarket approval of spinal devices is from non-clinical origins, extensive literature reviews to similar products or small clinical trials. This pathway presents opportunity to market approval with the least regulatory burden.

The large disparity in regulatory burden between class II and class III medical devices allows the development of smaller companies and more rapid innovation cycles for the low-medium-class devices. While small companies have completed US PMAs, the majority of high-risk devices are developed by the larger device organizations (IOM 2010).

The two factors that have the biggest impact on regulated device development are review cycle time and the level of evidence required for approval. The influence and impact of a short device review cycle can be illustrated when comparing US PMA products to European class III devices. The Institute of Medicine (2010) explains for the very reason that the US review cycle time for these products is twice as long as the current European cycle; not only are inventive products introduced later to the US markets, but the US markets often forego revised models of product as the innovation and approval cycles outside the USA are generally much swifter to market.

However, sweeping reforms of the rules that govern the regulation of the medical device sector in Europe represents one of the most disruptive changes to affect the industry in recent times. When the European medical device regulation commonly referred to as the MDR replaces the current set of Medical Device Directives (MDD), companies will have 3 years to comply with a broad scope of new rules for almost every kind of product in the medical device spectrum. Under the new regulations, medical device companies will have to provide substantially more clinical evidence to gain market access or even maintain existing products on the market. Companies will need to conduct audits to determine the new rules' impact on maintaining and upgrading device portfolios. Companies can expect a significantly more costly path to compliance in the European Union. The costs associated with compliance may force a number of companies to take strong steps, such as discontinuing existing device lines or considering acquisition proposals (De Busscher et al. 2016).

The result of this transformation anticipates a stronger, more accountable device industry that may look considerably different from todays (De Busscher et al. 2016). The EU MDD has been in effect since the 1990s. Incremental changes to the text have occurred along the way due to new and emerging technologies which have both challenged the framework and identified gaps. However, it was a series of well-known device events (Textbox 4) that emphasized to both policymakers and the industry an urgent need for regulatory reform to ensure patient safety concerns were adequately attended. On the 26 September 2012, the EU announced a package of reforms to provide a more stringent regulatory framework for medical devices to ensure a higher level of protection of human health and safety (TGA 2013).

Textbox 4 Why Regulatory Reform Was Required

2011 The US FDA warned of serious complications associated with the use of urogynecologic surgical repair mesh after nearly 2874 medical device reports (MDRs) in a 3-year period including injury, death, and malfunction[1]. One thousand five hundred three were associated with pelvic organ prolapse (POP) and 1371 for stress urinary incontinence (SUI).[1]

2012 Poly Implant Prothèse (PIP), a French company, was revealed to have knowingly sold breast implants made with industrial grade silicone rather than medical grade. The reported probability of PIP rupture at 10 years is 25–30% versus 2–15%

(continued)

reported in standard silicone implants[2]. It is reported that approximately 300,000 women were affected.[2]

2010 DePuy (Johnson & Johnson) voluntarily recalled the ASR (metal on metal) hip replacement system after an Australian National Joint Replacement Register (NJRR) reported a failure rate of 13% at 5 years for the device – unacceptably higher than the average. Ninety-three thousand people worldwide were implanted with an ASR device[3]. The ASR hip replacement was removed from the Australian market in 2009 after intervention by the Australian TGA.[3]

[3]Source: TGA (2011)

The introduction of the new EU MDR which entered into force on 25 May 2017 marks the start of a transition period for manufacturers selling medical devices into Europe and other jurisdictions that recognize and approve a CE-marked device under the EU regulations. The MDR, which replaces the Medical Device Directive (93/42/EEC), has a transition period of 3 years. The extensive and long-awaited regulation will come into force in May 2020 and more closely reflects the current FDA scrutiny of product safety by placing stricter requirements on subjects such as clinical evaluation, post market clinical follow-up, and increased traceability of devices through the supply chain. The implications of the new EU MDR on the global medical devices sector are enormous. The European medical technology market is significant and important for the industry, estimated to contribute 31% of the global total (Eucomed 2013).

Traditionally, small and medium companies who did not have the revenue to conduct expensive PMAs in the US viewed the European market as an opportunity to innovate and collect valuable clinical performance data. As more detail has emerged about the composition of the EU MDR, it has become apparent that the full impact of the changes will extend beyond the regulatory framework. Among a plethora of new requirements, a CE mark will require pre- and post market clinical studies, data transparency, tightening of vigilance reporting, and the introduction of a unique device identification (UDI) system similar to that recently introduced into the USA. Additionally, a number of medical devices will be reclassified such as spinal total disc replacement which will increase in its defined risk classification from class IIb (medium risk) to class III (high risk).

According to a recent report by Makower et al. (2010), current FDA and EU regulatory frameworks are creating almost impossible barriers to authentic device innovation. Due to their usually limited financial resources, the future regulatory environment will be particularly challenging for start-up companies who have historically played a key role in driving innovation. Compliance with regulatory legislation is generally viewed as a driver of complexity and cost for medical device businesses, whose regulatory people are tasked with ensuring that the companies who employ them are compliant while curtailing the risks and costs associated with it. However, it is becoming increasingly apparent that tackling frameworks such as the future EU MDR goes beyond the remit of even the most resourced regulatory teams (De Busscher et al. 2016).

Providing data on both new and existing medical devices may require revision and the need to conduct new clinical studies. De Busscher et al. (2016) estimate that some devices will need to have their safety and efficacy validated clinically or be at risk of being removed from the global market. The proven technology concept commonly referred to as "grandfathering" of legacy devices is one of the key changes of the new MDR determined by the commission to now require supporting clinical evidence in compliance with the current standards and regulations.

De Busscher et al. (2016) propose that the additional clinical evidence requirements likely to be stipulated by the EU MDR will mean that products in development may take longer to obtain commercialization, which is likely to impact further on revenues and the raising and allocation of capital. Additionally, the notified bodies that regulate and certify manufacturers of medical devices and

technology will undergo significant changes. Under the EU MDR, the notified bodies' requirements and responsibilities will intensify. Many in the industry fear this will lead to further delays in product certification and audit assessments.

These are transformational shifts for medical device companies. Accessing the EU market or gaining CE mark by complying with current and future regulations, restructuring operations, and planning future business pathways will become an increasingly burdensome activity. For at least a decade, Europe has remained a favorable market entrance for many innovative medical devices joining the market. After obtaining a CE mark (EU approval), a manufacturer could further validate their device clinically and thereby build a complete dossier of evidence that would be both required and beneficial to secure future FDA approval. Leading up to and beyond the EU MDR becoming an industry reality in 2020, this familiar path will need to be reviewed with Europe possibly becoming a less attractive first market destination (De Busscher et al. 2016). It is difficult to estimate how the cost of compliance with this future regulatory framework will financially burden a medical device company. In 2013 Eucomed, an industry body, conducted an industry-wide survey on the financial impact of the updated EU MDR (Table 4).

A reflection of increasing burden and its impact is the reported declining numbers of regulatory submissions for new medical devices in the USA over the past several years. The annual Emergo (2017) study examined approximately 15,000 510(k) applications cleared by the FDA between 2012 and 2016, finding not only that numbers of US applicants have steadily declined but also that the overall number of 510(k) applications cleared by the agency hits a 4-year low in 2016. In an era of greater scientific knowledge and more technology advancements than any other time in history, industry experts question what forces are driving genuine medical technology innovation and invention in a negative direction.

Table 4 Forecast MDR compliance costs (Eucomed 2013)

€17.5b (US$18.9 billion) cost to industry if a centralized premarket authorization system is implemented
€7.5b (US$8.1 billion) cost to industry of compliance with a UDI (unique device identification) system, improvements in labelling, and clinical performance data
€17.5 m (US$18.9 million) cost to small-medium-sized enterprises (SMEs) to bring a new class III product to market under a clinical premarket approval system

Device manufacturers continue to argue that the device industry is fundamentally different from other industries such as the pharmaceutical industry taking into consideration that the engineering and quality frameworks required to support development, market approval, and continuous device innovation are increasingly onerous (Reed et al. 2008). In general, devices tend to have faster commercial cycle times and tend to be characterized by incremental improvements to existing technologies. This difference is increasingly identified by major bodies such as the FDA, evidenced by The FDA Modernization Act defining the "least burdensome approach" (CDRH 2002). The least burdensome concept is defined as a successful means of addressing a premarket issue that involves the smallest investment of time, effort, and resources (e.g., money) on the part of the submitter and FDA, to help ensure scientific integrity while affording a high degree of public health protection and expediting the availability of new device technologies (CDRH 2002).

However, an issue continues to arise when that incremental evolution of technology occurs and the suitability between that technology and existing regulatory pathways does not exist. The prospect of piloting through the increasing requirements of product development and regulatory approvals to then confront a multitude of differing payer uncertainties is often a hurdle to sustained device innovation for many companies.

The Reimbursement Effect

Achieving approval by a regulatory body in any jurisdiction does not imply that a product will be reimbursed by payers or private insurers. Whereas

regulatory approval focuses on safety and efficacy, the payers tend to strongly consider the cost savings and cost-effectiveness in determining whether to cover a new technology. Suitable costings for reimbursement must be obtained while ensuring reimbursement rates are appropriate and balanced accordingly with the cost and benefits of new technologies and expected yet increasing standards of care.

For example, in Australia a new technology pending the classification may gain regulatory approval with the Therapeutic Goods Administration (TGA) without delay. However, in order to commercialize the innovation in the Australian private health system, the device must gain payer reimbursement through approval by the Minister for Health via the government-administered Prostheses List (PL). The Prostheses List Advisory Committee or PLAC's primary role is to make recommendations and provide advice to the Minister for Health. The PLAC advises on the listing of medical devices and their reimbursement benefits. Using evidence provided by the manufacturer, the PLAC makes recommendations on the most clinically efficacious and cost-effective devices. This ensures that privately insured Australians have access to a range of medical devices that are both clinically and cost-effective. Similar to many jurisdictions around the world, approval by the Australian regulatory body (TGA) does not guarantee reimbursement by the government's Prostheses List arrangements. Reimbursement and/or payer coverage can be the factor which decides whether a new medical device will succeed or fail, and the common goal of reimbursement or payer policies around the world is maintaining that balance between cost- and clinical effectiveness of a new technology.

Payment issues are of increasing concern to the healthcare industry. Most who are connected with healthcare acknowledge the rising costs of healthcare and the need to find ways of managing costs more effectively. In fact, some continue to point to technology as a major cause of these increasing costs. The emphasis on cost and the role of technology in costs have placed a large part of the onus on the device industry. It is a prominent inclusion of the company consciousness that innovation is not just creating a better device but includes creating a more cost-effective or financially sustainable alternative to the current offerings (IOM 2001). Of course, it is not that simplistic, and it is challenging for a medical device company to fulfil the criteria for novelty and superiority with cost-effectiveness while also fulfilling the required regulatory principles of clinical safety and efficacy.

Cost is guaranteed to be in the innovation and invention equation, but where do the benefits to patient outcomes place in that equation? In the current global device environment, providers are increasingly pressured to use cost-saving technology as opposed to cost-effective technology. Manufacturers are forced to consolidate, to fashion technologies into commodities, and often to compete on the basis of price alone (IOM 2001). The Institute of Medicine (2001) assert too often pricing contracts and rationing, which are often employed in a number of cost frameworks, fail to balance with the patient benefit and effectiveness side of the equation. There is a multitude of different parties that have an effect on payments for technologies such as multiple insurers and/or government structures who all vary in their approval frameworks for that payment.

Definitive reimbursement is an essential part of the overall concept, design, development, and marketing of the medical device life cycle. For many decades, new innovations have been developed and launched into a market in which prospective payment systems and unanticipated changes have forced key stakeholders to operate in an increasingly efficient and lean manner. The key message is that new innovations must fit within a diminishing yet dynamic operating margin imposed by cost-constrained third parties.

Within the Australian framework, manufacturers of innovative device technology must have an associated procedural code included on the Australian Medicare Benefits Schedule (MBS) for commercial release within the private health system. This is the list of procedures, tests, and consultations for which the Australian Medicare System will subsidize. The MBS is fundamental to the Australian health system and is a prerequisite for private payer device reimbursement.

Devices cannot be included on the Australian Prostheses List (PL) if a related MBS item number does not exist. This requirement can be challenging for the suppliers of authentic innovative or inventive technologies if solid clinical efficacy has not been established. In any market an understanding of these key relationships is essential. Innovative technology that offers substantial clinical and economic improvements may struggle to obtain reimbursement if payer frameworks are not well understood.

Early stage reimbursement strategies are vital for the acceptance and success of an innovative or inventive device. It is absolutely critical for a device company, large or small, to obtain coverage and attract investors. In venture capital there are two important aspects for consideration: feasibility and market acceptance (IOM 2001). The Institute of Medicine (2001) maintains the regulatory and healthcare payment environment which introduces additional levels of risk and uncertainty. In those cases where uncertainty of reimbursement for a particular device under development exists, securing funding for that innovative or inventive technology becomes problematic. While US firms have the dominant position in critical markets, the global industry argues that a large number of innovative devices and clinical breakthroughs are often the product of the smaller businesses. According to the Institute of Medicine (2001), 72% of medical device companies employ fewer than 50 people. Eucomed (2013) reported small-medium-sized companies accounted for 95% of the 25,000 companies in the European medical device industry, while in the USA Stirling and Shehata (2016) report that 80% of the 6500 companies in the medical device sector are small (less than 50 employees).

Smaller companies are nimble and responsive, with a tremendous tolerance for uncertainty and are therefore well suited to be the source of innovation for medical devices. It is the smaller companies that drive a substantial portion of true industry innovation, yet the Institute of Medicine (2001) states that historically out of approximately 6 ideas, only one device will make it to commercial success. An organic advantage by any company is attained by leveraging their knowledge or IP. The Institute of Medicine (2001) asserts that in a global business environment, the small incubators of technology are particularly challenged with respect to increasing financial pressures.

Many small companies lack the infrastructure required to meet worldwide regulatory and marketing activities. The larger companies have an ability to assist with the delivery of innovative technology created by the smaller entities through exchanges such as acquisition, joint ventures, strategic partnerships, contract research, licensing, and royalty agreements (IOM 2001). Large medical device companies have the ability to bring scale to the challenge of globalization and successful product development. The key factors that determine product investment, demand, and eventual commercial success are whether the device is reimbursable or not and the quantum of that reimbursement.

The success of a medical device requires both strategic and coordinated planning. It must be followed by a timely execution of stakeholder-specific promotion, information, and development plans. The most innovative and/or inventive medical devices may never establish commercial success if there is a failure to constrain costs or convince stakeholders of that new technology's increase in value. This was illustrated by the familiar case of the Charité Artificial Disc Replacement (Textbox 5).

The Charité Artificial Disc was originally developed at the Charité University Hospital in Berlin, Germany, in the mid-1980s by leading spine specialist Professor Karin Büttner-Janz and Professor Kurt Schellnack. In 2003 DePuy Spine acquired the Link Spine Group, Inc. for $US325 million gaining exclusive worldwide rights to its principal product, the SB Charité Artificial Disc (Arida et al. 2006). The Charité was FDA approved in October 2004 as an alternative to spinal fusion surgery. While pre-launch, physician and patient dynamics were strongly in DePuy's favor, it did not suppress the negative response from hospitals and payers alike. With strong payer resistance and little hospital and provider enthusiasm, Charité sales waned. In 2006, DePuy announced plans to release 5- and 10-year data

in the future for the Charité (Johnson and Johnson 2006) in the hope of reviving the prospects of what was a revolutionary advance in the spinal device sector.

Textbox 5 Innovation and Reimbursement: A Case Study

The Charité Artificial Spinal Disc was once viewed as revolutionary surgical technology. In October 2004 Charité was the first total disc replacement (TDR/ADR) on the market to receive US regulatory approval and be commercialised for the anterior replacement of diseased lumbar discs.

At the time of a 2006 report by Arida et al. (2006) "The Charité: Lessons in the Launch of a New Medical Device," Charité's commercial success was in doubt. Charité had failed to convince the third-party payers that its use should be covered and reimbursed. On the 14 August 2007, the Centers for Medicare and Medicaid Services (CMS) determined that lumbar artificial disc replacement was not reasonable and necessary for the Medicare population over 60 years of age. CMS further determined that for those Medicare beneficiaries less than 60 years of age, there was no national coverage determination, leaving coverage decisions to be made on a local basis (CMS 2007). Payers cited a lack of evidence that the Charité was as effective as promoted. Follow-up clinical evaluations of the device and the complexity of the surgical procedure cast further doubts about its safety and effectiveness (Sparks et al. 2011).

According to Sparks et al. (2011), the Charité device did not become a physician preference item, and its adoption was actively opposed by purchasing departments and other administrative decision-makers. Summarizing the reports of Arida et al. (2006) and Sparks et al. (2011), DePuy failed to support Charité's launch and subsequent commercialization in the following critical areas:

1. *A disconnect occurred between Text the devices positioning as an alternative to a modern spinal fusion method where the clinical trial supporting this claim was a non-inferiority claim comparing Charité to the BAK cage, a somewhat controversial procedure that had been largely discontinued due to poor outcomes.*
2. *The Charité was priced around US$11,500, approximately 2.5 times that of the BAK cage and BMP (US$4500 each), without securing new procedural codes at or before launch. At that time the Charité was being sold in Australia and Europe for US$4500–$5000. DePuy did not possess a proactive strategy or economic data to prove this but relied on patients, physicians, and advocacy associations to push for reimbursement.*
3. *DePuy largely ignored the role of worker compensation insurance carriers in influencing other payers by not studying the long-term effects of Charité on return to work and productivity gains. A clinical paper was also released in 2004 as a result of the 2003 landmark study "Total Disc Replacement for Chronic Low Back Pain…," which concluded that there was no definitive clinical evidence that disc replacement surgery was efficacious or resulted in fewer adjacent segment problems. The net effect created scepticism in the surgical community over the true clinical value of arthroplasty.*

Sparks et al. (2011) summarize that DePuy did not fully appreciate that the conventional clinical endpoints used to secure regulatory approvals are not necessarily the outcomes that the payer uses making coverage decisions nor the outcomes hospitals use for purchasing purposes. DePuy did not build the body of evidence necessary to establish comparative safety and effectiveness of Charité with payers and

(continued)

physician groups alike (Sparks et al. 2011). Without coverage and clinician support, hospitals were not able to justify the purchase of the Charité device for both cost and coverage reasons, and this very inventive and innovative device failed commercially.

Conclusions

Society places a premium on the delivery of innovative technologies to ensure optimal healthcare. Patients are educated, informed, and interested in their health treatment choices and the outcomes associated with that choice. However, to deliver high-quality innovative technologies, it takes an increasingly substantial investment of time and cost to meet stringent regulatory and payer requirements.

End reimbursement and regulatory obligations are the factors which decide whether a new medical device will succeed or fail. There is no doubt, despite greater knowledge, innovative devices are under increasing regulatory scrutiny, escalating development costs and declining reimbursement. Authentic innovation and invention in the spinal devices sector have slowed down substantially. The spinal device industry is saturated with creative differences or "me too" products that fall within the least burdensome "predicate," "equivalent," or "grandfathering" application processes.

The upcoming European texts defining what constitutes the regulatory requirements of a new or existing medical device will have a profound impact on the innovation pipeline. The challenge for a medical device company to fulfil the criteria for novelty, superiority, and cost-effectiveness while also fulfilling the increased regulatory principles of safety and efficacy will become increasingly difficult. The ultimate impact of regulation on innovation will be viewed empirically. The balance between innovation-inducing factors and the compliance costs generated may differ on a case-by-case basis. Additionally the amount of time required to satisfy regulatory requirements will be essential to enable future innovations.

The investment required to obtain approval will no doubt change, with a profound emphasis on implantable medical devices and small entrepreneurial businesses. The work required to obtain a CE mark under the new EU MDR will place a heavier emphasis on solid clinical dossiers, premarket, and post market, both for new products and iterations of existing products. The assessment process inevitably will take longer than it does today.

This constitutes a concern for device companies who invest huge resources to release a device to market and clinicians who strive to deliver superior technology to their patients. Even after successful clinical data is obtained, the ultimate financial result of investment may be questionable, since payments for products and services through reimbursement mechanisms are not guaranteed.

Accompanying the ratification of the EU MDR is an expectation that a number of intended positive outcomes will transpire. With prodigious access to information, the clinician and the patient are well informed of negative medical device reports such as the incidences presented in Textbox 4. The increased regulatory requirements of the MDR may restore patient and clinician confidence in the medical device industry, ensuring trust in both the quality and the safety of the product. Compliance with these new regulations is predicted to be onerous, costly, and distracting; however all involved with the delivery of healthcare should be reminded of the ultimate goal – better patient safety and quality of product. Investment in transparent clinical processes, better traceability, and the ability to better contain adverse events involving medical devices can only be a positive step toward industry endurance.

The challenge for all stakeholders in the global device market is to craft a standard for policy, reimbursement, and regulatory provision that protect both patient safety and efficacy while carefully preserving incentive to induce the delivery of innovative and inventive technologies.

Abstract

The anterior lumbar approach for spinal pathology is a powerful method to achieve reconstruction. It enables wide discectomy, restores disc and neuroforaminal height, optimizes sagittal alignment, and affords large cross-sectional area of endplates for spinal implants while avoiding neural retraction and posterior muscular damage. It is arguably underutilized given the need for a considerable volume of training and need for comfort with abdominal anatomy and vascular handling that is required in its safe application. The preparation of a patient and surgical setup as well as common techniques for anterior lumbar surgery are described in this chapter. Knowledge of assessment techniques and handling of vascular structures in their normal, anomalous, and pathological states is critical for safe and efficient performance of the procedure. Equally, recognition of vascular problems and measures to deal with them enables spinal surgeons to safely expand their indications for this technique which is aided through a multidisciplinary approach and collaboration with a vascular surgery service.

Keywords

Anterior lumbar interbody fusion · Total disc replacement · Hybrid · Retroperitoneal · Transperitoneal · Vascular anatomy · Atherosclerosis · Vascular injury · Vascular repair · Ureteric injury · Combined vascular and spinal reconstruction

Introduction

The anterior approach offers a number of advantages over the other interbody access techniques currently being utilized. The exposure from L1 to S1 vertebral bodies is possible from the direct anterior transperitoneal approach, the midline rectus splitting approach, the para-rectal splitting retroperitoneal approach, and the oblique and lateral approaches. This provides the surgeon access to the disc and vertebral bodies for multiple indications. The decision about which approach is applicable is dependent on many variables that will be discussed in the review. As such, the anterior approaches that are available provide considerable versatility to treat a variety of pathologies with proven therapeutic success.

Spine surgeons around the world are utilizing the anterior approach to treat pathologies in the anterior column. The incidence of anterior procedures has increased substantially since the publication of multiple Food and Drug Administration class I randomized clinical trials on the results of total disc replacement (TDR) and anterior lumbar interbody fusion (ALIF) that recognized that patient-related outcome measures were improved dramatically and show no signs of decay (Gao et al. 2011). This advance in fusion techniques and the maturation of the therapeutic utility of total disc replacement has led to the increased need for the anterior exposure of the lumbar spine. Most spine surgeons perform their own approaches to the cervical spine but few perform their own approach to

the lumbar spine, instead utilizing "access surgeons." There are two main reasons: The first is the fear of the complications, particularly vascular injury, and the second is the variable and low quality of training provided in the orthopedic and neurosurgical training programs with respect to anterior access, techniques, and utility.

Anterior access requires the surgeon to be familiar with intra-abdominal, retroperitoneal, and vascular anatomy and its variances. Thorough preoperative review of the vascular anatomy is essential, as is the ability to provide a safe mobilization or dissection of the vasculature and ability to repair vascular injury should it arise.

One author has been performing their own access to the spine since 1996 with over 5000 approaches, the majority via the midline rectus splitting retroperitoneal approach (Holt et al. 2003). The indications and pathologies that he has treated have expanded over time such that in complex cases, he utilizes the knowledge and skills of a senior vascular surgeon who has had over 35 years' experience in vascular surgery. The involvement of a vascular surgeon in spinal surgery for the inexperienced surgeon contributes to the efficient and immediate repair of vascular injuries. Hamdan et al. (2008) stated that while exposure to the lumbar spine can be readily accomplished via a retroperitoneal approach, minor vascular injuries during exposure, mostly venous, are not uncommon. Most are easily repaired but occur more frequently when L4-5 is part of the exposure and less commonly when L5-S1 alone is exposed. Major injuries occur in less than 2% of patients.

As the surgeon's volume performance threshold increases (Regan et al. 2006), there is a natural expansion of indications to treat complex deformity, tumor, infection, revision anterior procedures at index, and adjacent levels ranging from patients with pristine vessels through to patients with combined multilevel degenerative disc disease and complex vascular pathologies (calcific atherosclerosis and aortoiliac disease). The vascular surgeon can provide expertise with endovascular techniques such as angioplasty and stenting and open techniques such as repair, endarterectomy, and bypass.

Indications

Anterior reconstructions provide biomechanical support by stabilizing the anterior column. This stabilization can now be performed by static and/or dynamic technologies (Scott-Young et al. 2018a). The common indication for anterior reconstructions is for degenerative conditions that have been recalcitrant to conservative therapeutic modalities (Fritzell et al. 2001). These include discogenic pain secondary to degenerative disc disease (DDD) and internal disc disruption (IDD) (Sehgal 2000). Other degenerative conditions include degenerative spondylolisthesis, isthmic and dysplastic spondylolisthesis, DDD with large herniated discs with verified radiculopathy, post discectomy recurrence and instability, iatrogenic instabilities following posterior decompressive procedures, degenerative de novo scoliosis, and anterior reconstruction for pseudoarthrosis following failed posterolateral, transforaminal, and lateral fusions.

Rare and "red flag" conditions that are commonly treated include vertebrectomy for tumor, trauma, and infection. The treatment of flat back syndromes, deformity, and congenital abnormalities to restore sagittal and coronal balance are often best treated with anterior reconstructions whether it be at single or multiple levels (Kim et al. 2017). The spino-pelvic revolution (Labelle et al. 2005) has enlightened the spine community on its relevance and importance. The sagittal plane can be considered as an open chain of interconnected segments from head to pelvis. The shape and orientation of each segment are closely related and influence the adjacent segment biomechanics (Roussouly et al. 2011). Hence, the enormous influence that consideration of sagittal balance is having on spinal surgery (Labelle et al. 2005).

Benefits

There are many benefits in having anterior surgery skills as part of a surgeon's armamentarium. The approach allows access and treatment of disc pathologies, vertebral pathologies, and multiple levels. It is a powerful tool because it enables a

complete or near-complete excision of the disc and therefore access to the anterior cauda equina. This thorough discectomy allows for removal of herniated discs, extruded disc material, and sometimes sequestered fragments and minimizes any residual pain generators at the posterior disc-annular complex. Complete vertebral body removal for trauma, deformity, tumor, and infection is also possible. This can then be followed by reconstruction where the cage, allograft, or autograft is placed under compression. The endplate provides a large and strong cross-sectional area for supporting the reconstruction that is not afforded by the other approaches.

The anterior approach historically has been performed throughout the twentieth century and was originally used to treat Pott's disease (Ito et al. 1934). Originally, it involved a large transperitoneal approach to access the spine and would require longer recovery times. Modern anterior approaches recognize the importance of minimizing collateral damage (Fraser 1982) and as such more minimally invasive (Ito et al. 1934) or minimally destructive approaches (Ruey-Mo et al. 2008) have been developed. These incisions are limited to between 5 and 8 centimeters, generally subumbilical and utilize the retroperitoneal space to gain access to the anterior spine (Watkins and Watkins 2015). This allows a direct view into the disc space, thus facilitating proper and complete discectomy and annular release. The anterior approach is the optimal approach to allow correct positioning of the device in the midline. The goal is to maximize the size of the device in the medial lateral and anterior posterior plane. This generally minimizes eccentricity and subsidence while maximizing bone integration interface to the implant or the graft. It also allows direct visualization of the posterior annulus and posterior longitudinal ligament and one can release these tissues and thus decrease the incidence of "fish mouthing." While correct release, balancing, and positioning are important for ALIF interbody devices, it is especially important for disc arthroplasty where point loading and abnormal force transmission can result from incorrect sizing and placement.

It provides the surgeon and patient opportunities for a dynamic or static stabilization reconstruction for most symptomatic disc pathologies. DDD has been shown to cause significant morbidity and after identification of the symptomatic disc(s) they can be reconstructed with anterior lumbar interbody fusion (ALIF) or total disc replacement (TDR) (see Fig. 1). The approach can be performed via a muscle splitting incision (rectus interval) and avoids the muscular collateral damage that is associated with the other approaches. There is no devascularization or denervation of the erector spinae muscles that results from posterior approaches or damage to the psoas muscle that results from the direct lateral approach. This allows for significant reductions in patients' back and leg pain which, in turn, improves patients' function and quality of life. There are generally a shorter hospital stay, less morbidity, and faster recovery. Pradhan et al. (2002) compared ALIF and posterior fusion and found there were less blood loss and reduced transfusion rate, operative time, and hospital stay for patients with anterior fusion procedures.

The access to the anterior structures facilitates complete disc clearance and, with that, the ability to correct deformity and decompress the neuroforamen through disc height restoration. Other benefits include direct or indirect decompression of the neural elements centrally, laterally, and in the neuroforaminal region. In addition, powerful restoration of sagittal balance can be achieved anteriorly.

From a mechanical perspective, addressing the anterior column is a sound strategy in that it transmits a relatively high proportion of force and body weight and has reduced risk of subsidence from the large surface contact afforded in graft placement (see Fig. 2). When used as a stand-alone strategy, there are the additional benefits to the patient of avoidance of posterior soft tissue envelope violation or of neural retraction.

It cannot be emphasized enough that the majority of pathologies occur from diseases in the anterior column. Therefore, it is imperative that every certified spinal surgeon be able to use this access to effectively treat the patient's pathologies. By preserving the posterior and lateral paravertebral muscle and avoidance of facet joint dissection or violation as well as by restoration of disc height

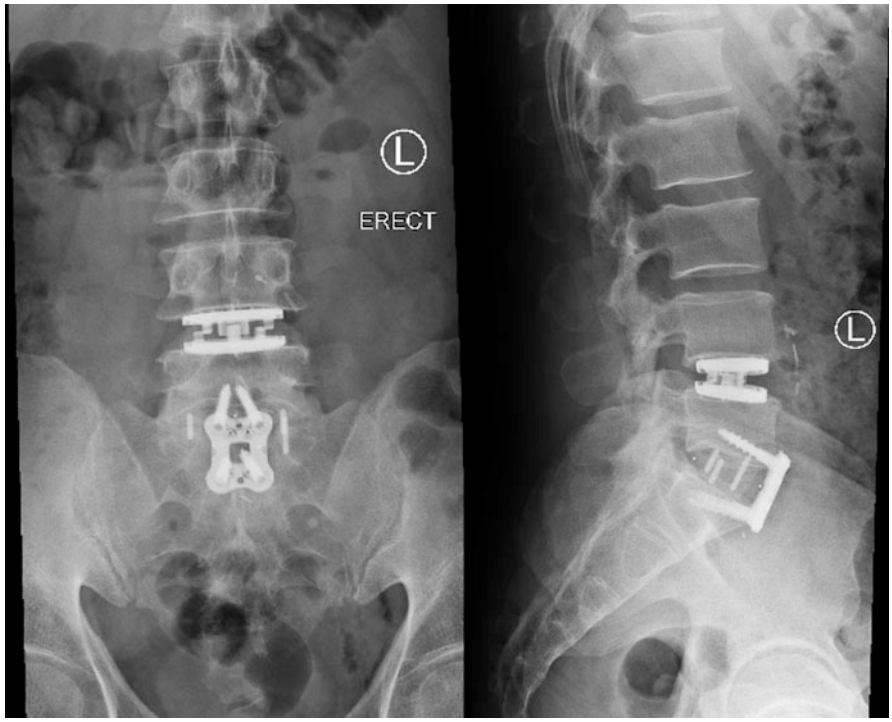

Fig. 1 The anterior approach allows efficient performance of either ALIF, TDR, or a combination of both (hybrid) procedure. Above is an example of a lumbar hybrid procedure with a constrained TDR at L4-5 and an ALIF construct at L5-S1

and lordosis, the incidence of later adjacent segment disease is also reduced. Posterior and lateral procedures do not regularly or predictably restore the disc height and lordosis. Thus, the patient is fused in a kyphotic position and their dynamic stabilizers (erector spinae) that pull them into extension are damaged.

The modern anterior approach has matured and is justified as an alternative for decompressing neural elements, alleviating instability, relieving intractable mechanical back and leg pain, and restoring functionality to the patient or addressing "failed back syndrome."

Contraindications

Contraindications can be classified as absolute and relative. Every patient should undergo a thorough medical and surgical assessment to assess any surgical and/or medical risks in the operative and perioperative period. The history and examination, focusing on cardiac and pulmonary risks, and determination of the patient's functional capacity are essential. The administration of an anesthetic and a surgical procedure is associated with a complex stress response that may present problems in the postoperative period. Assessment of the patient's overall health status is required. This incorporates referrals to specialists to investigate and treat any relevant conditions prior to surgery.

The history should include past and current medical and surgical history, current medications, allergies to drugs, and use of recreational drugs and tobacco use. Height and weight, particularly girth, is important to assess and treat prior to anterior surgery. Patients with a body mass index (BMI) greater than 25 are considered overweight, those greater than 30 are considered obese, and a BMI greater than 35 is considered morbidly obese. Patients who are obese can provide access difficulty and have higher risks and complication rates. These include hernias, wound infection and dehiscence,

Fig. 2 Example of limitations of laterally placed interbody cages not only from limited endplate visualization and disc space balancing but through limited surface area. Failure of the construct is demonstrated here through multiple endplate/vertebral body failures in a susceptible patient

longer operative times, longer hospital stays, higher incidence of deep venous thrombosis (DVT), and possibly less successful outcomes secondary to these issues. Puvanesarajah et al. (2017) reviewed the obese and morbidly obese patients undergoing spine fusion and found that they are at significant risk of major medical complications, wound infections, and 30-day readmissions. Both groups had a longer length of stay and hospital costs. The obese have to be counselled about these risks and be active participants in weight reduction programmes.

Pregnancy, infection, severe osteoporosis, metabolic bone disease, chronic steroid use, multiple prior abdominal surgeries, implant or metal allergies, and severe psychological disorders, to name a few, are probable absolute contraindications to anterior reconstructions. Relative contraindications include any issue that may impede access or mobilization of the vessels. Therefore, conditions such as obesity, intra-abdominal scarring, retroperitoneal scarring, calcific atherosclerosis, abdominal aortic aneurysm, and prior vascular surgery need to be reviewed with respect to risk-benefit analysis. Complex vascular pathologies can be managed but require a multidisciplinary medical and surgical assessment prior to performing these complex surgeries.

Biomechanical Rationale

The basic mechanics of interbody cage fixation have been well investigated (Panjabi 1988). The strength and stability of a construct are important concepts to understand when reconstructing the anterior spine. The strength relates to the absence of structural failure of either the implant or endplate bone. The stability relates to the lack of motion between adjacent vertebrae, which is important to facilitate bone ingrowth and eventual fusion (Jost et al. 1998).

Gerber et al. (2006) found in a comparative cadaver biomechanical study that an anterior screw-plate and pedicle screws-rod constructs both substantially reduced range of motion and increased stiffness compared to stand-alone interbody cages. There was no significant difference in the amount by which the supplementary fixation devices limited flexion, extension, axial rotation, or anteroposterior shear; pedicle screws-rods better restricted lateral bending. This stability can be enhanced by insertion of ALIF cages with larger anterior/posterior dimensions and broader widths. This has the added benefit of less eccentricity and subsidence. The bone density probably plays an important role in reducing subsidence, as does the location of the cage on the endplate. Steffen et al. (1998) recommended more peripheral ring apophyseal contact was best from a biomechanical and biological perspective.

Cunningham et al. (2002) found that in the treatment of spinal deformities, structural interbody support probably is the best method to minimize longitudinal rod and screw-bone interface strain.

Moreover, anterior load-bearing structural grafts and interbody devices have been shown to increase construct stiffness, decrease the incidence of posterior implant failure, permit the use of smaller diameter longitudinal rods, and enhance the rate of successful spinal arthrodesis. The study reinforces the principles of load sharing between the anterior and posterior spinal columns and affirms the biomechanical dominance of anterior column support in circumferential spinal arthrodesis.

Watkins et al. (2014) compared anterior, transforaminal, and lateral interbody fusion techniques to determine which is most effective for restoring lordosis, increasing disc height, and reducing spondylolisthesis. They found improvement of the lordosis was significant for both the anterior and lateral groups, but not the transforaminal group. Intergroup analysis showed the anterior group had significantly improved lordosis compared to both the other groups. The anterior and lateral groups had significantly increased disk height compared to the transforaminal group. Hsieh et al. (2007) similarly found that ALIF is superior to TLIF in its capacity to restore foraminal height, local disc angle, and lumbar lordosis.

Preoperative Assessment and Preparation

Preoperative assessment and preparation of a patient for anterior spinal reconstruction should reliably and accurately identify those patients in whom operative intervention is indicated and any features in their presentation that need to be addressed or considered to make surgical intervention safe and feasible. We shall focus mainly upon the indication of treating DDD as it is by far the most common disorder.

Diagnosis

A diagnosis of symptomatic degenerative disc disease with or without radiculopathy (the most common indication for operative intervention) is usually made with history and clinical examination. A classical history of axial pain that worsens through the day and with prolonged sitting, bending, standing, or lifting that is relieved with recumbence is suggestive of IDD (Lee et al. 2016). There may be associated leg symptoms that suggest radiculopathy from a nerve root involvement due to disc herniation or multifactorial loss of neuroforaminal height (Lee et al. 2016). The clinical picture is then supported by investigations that may include typical imaging findings (degenerative bony changes on radiographs and disc degeneration with or without Modic (Modic et al. 1988) changes observed on MRI), MR spectroscopy, nerve conduction studies/electromyography, and provocative discography.

Preoperative Evaluation

Findings on the history and clinical examination that should be sought in anticipation of any contraindications to surgery or difficulty in the perioperative period include the patient's height and weight (obesity), any smoking or systemic illness that could affect healing or bone quality (e.g., osteoporosis, poorly controlled diabetes, steroid use), any coagulopathy/anticoagulants or prothrombotic tendencies, and any previous intra-abdominal surgery or conditions. Osteoporosis can be difficult to reliably quantify but a focused history and examination with investigations such as DEXA scan or fine-slice CT assessing the architecture and Hounsfield units can be suggestive of a patient that may require delay in spinal reconstruction until bone quality is sufficiently improved with medical treatment.

Screening clinically for any peripheral vascular disease (i.e., pulses), poor nutrition with sarcopenia, or any systemic illnesses (e.g., features of rheumatoid arthritis, vasculitis, or connective tissue diseases such as Ehlers-Danlos and Marfan's syndrome) is imperative. A physician to screen and optimize high-risk patients and provide a perioperative management plan is particularly useful in this regard.

Surgical Planning

In our practice, plain erect radiographs of the entire spine have been largely superseded by the use of low-dose radiation EOS™ scanning. This enables determination of all relevant sagittal, coronal, and

rotational parameters that need to be considered when planning a reconstructive strategy. A quick assessment of the pelvic parameters (pelvic incidence, pelvic tilt, sacral slope), the type of lordosis (I-IV) (Roussouly et al. 2005), and the positioning of C7 plumb line can be done to assist in planning a reconstruction strategy. EOS™ also allows for rapid calculation of the current L5-S1 disc segmental lordosis by subtracting the L1-S1 lordosis from the L1-L5 lordosis.

Restoration of the sagittal balance is the best way to obtain a good result no matter the technique (dynamic, static) or the pathological situation. The only morphological parameter that is constant throughout life is the pelvic incidence (PI). How much the present position of the spino-pelvic complex is in its anatomical position and how much is in its pathologic or functional adaption is difficult to assess (Barrey et al. 2011). When treating patients with a low-grade PI (type I or II) no unnecessary lordosis is required for reconstruction. In patients with higher PI (type 3 or 4) more lordotic augmentation should be considered. Essentially, every spinal reconstruction requires preoperative classification (Roussouly et al. 2005). Patients with hyperlordotic lumbosacral junctions and a high PI can cause difficulty in accessing the disc space given the trajectory and position in relation to the pubic symphysis (see Fig. 3). Flexion and extension films may be useful in revealing the extent of dynamic sagittal instability in the case of spondylolisthesis.

Computed tomography (CT) scans are obtained in the case of any abnormal bony morphology or defects and can help assess the bone quality (relevant to the feasibility of a stand-alone strategy and/or need for augmentation) and status of the facet joints when considering arthroplasty versus arthrodesis for a particular motion segment. For segments that appear close to ankylosed, gas in the disc space indicates movement that can aid in decision-making regarding which levels to include in the reconstruction. CT angiogram has become the standard of care for any multilevel or complex reconstruction to better define the vascular anatomy preoperatively so that any variations or difficulty can be anticipated. This will be further discussed in special vascular cases.

MRI reveals the status of the intervertebral space (quantifies amount of collapse and Modic changes) and surrounding neural structures but

Fig. 3 Example of potential difficulty in anterior access to a L5-S1 disc in a case of dysplastic spondylolisthesis due to obliquity and relation of the disc space to the superior pubic symphysis

also the quality of the posterior elements and paraspinal muscles. This is relevant in deciding the need for retrieval of disc fragments in the canal from anteriorly or for a posterior decompression in addition to an anterior reconstruction in the case of tight multifactorial stenosis. MRI in the axial plane also reveals the presence of a fat plane behind vascular structures or, alternatively, any adhesions to an inflammatory disc.

Provocative discography gives information regarding the contribution of discs to the patient's symptomatology and should generally be performed by an independent third party assessor to exclude or include a questionable motion segment level in a reconstructive strategy (i.e., that particular level is responsible for minor or no symptoms).

Patient Optimization

Infection or bony failure in these cases with complex prostheses would be a disaster and prevention through host optimization is mandatory. Patients need to maximize fitness with maintenance of excellent nutrition including sparse amounts of sugar and simple carbohydrates but adequate protein and vitamin intake (especially vitamin C and complex B). Having optimized "protoplasm" will also favor efficient bony and soft tissue healing. In many cases dietary weight loss is mandatory not only for facilitating exposure but minimizing soft tissue and wound complications. Equally, a frail patient with sarcopenia may benefit from an appropriate strengthening and gentle aerobic program to combat osteopenia as well as higher caloric and protein intake.

Procedure

Pre-incision Setup: Equipment and Personnel

- A large well-illuminated theater and operative headlights are recommended given difficulties in adequate deep abdominal visualization that are associated with standard lights.
- We recommend the use of a Jackson Pro Table Mizuho OSI™ with capability for anterior and posterior approaches (see Fig. 4). Side brackets are placed to enable mount of the abdominal retractor system of choice. The bed is placed in a Trendelenburg position so that gravity allows the intra-abdominal contents to migrate cephalad and pillows are placed under the patient's knees to relax psoas and minimize popliteal compression syndrome.
- A large abdominal retractor is mandatory. We use a modified Thompson retraction system with multiple radiolucent blade variations whose design facilitates attachment and securing at different depths and angles. Alternatives are Omni-Tract™ and Bookwalter systems. A pin insertion (e.g., AUS) or related system for keeping the vessels positioned away from the working corridor is required (see Fig. 5a, b).

Sutures and Needle Holders for Vascular Repair

- 5/0 prolene sutures are on hand to close any cuts or tears as they occur. Smaller than this, the needles are impractical for the control and maneuver in this area of tissue.
- Make sure your vascular needle holders are strong and the teeth and ratchet not worn. In the setting of a large hemorrhage to discover faulty equipment is unsatisfactory.

Vascular Clips and Vascular/Urological Disposables

- Hemoclips also can be used after appropriate clearance of areolar tissue but the surgeon should be aware that they can be displaced by any traction required to mobilize large vessels (see Fig. 6a, b). These are best used prophylactically after isolating and skeletonizing the vessel. They can also be used as an immediate response to small vessel injury with suture as a later step. There are also some well-suited angled clamps which will control the vein edge until a suture is placed and we have these available on all the spinal trays (see Fig. 6).

Fig. 4 Examples of Jackson-type table head down in picture above (**a**) and trays of retractors and instrumentation required in pictures below (**b**–**c**)

- Vascular stents, balloons, and equipment for vascular repair or reconstruction should be available and may be deployed prophylactically, depending on the complexity of the case.
- Ureteric stenting equipment for performance by a urologist is in place for revision cases.

Personnel

- A well-trained and organized theater team is conducive to optimal results. This includes cooperative theater staff, instrument nurses, operating theater technicians, spinal and vascular trained anesthetists, prosthetic device representatives, and office and hospital surgical planners who ensure that a full range of required equipment is available and that the team is well prepared for any unexpected events.
- A Cell Saver™ autologous reinfusion provider is present for all cases.
- An assistant or surgeon skilled at patient positioning, control, and respect for vascular structures and assistance with preparation of interbody grafts facilitates theater safety and efficiency.
- Recovery nurses adept at neurological and vascular observations eases detection of

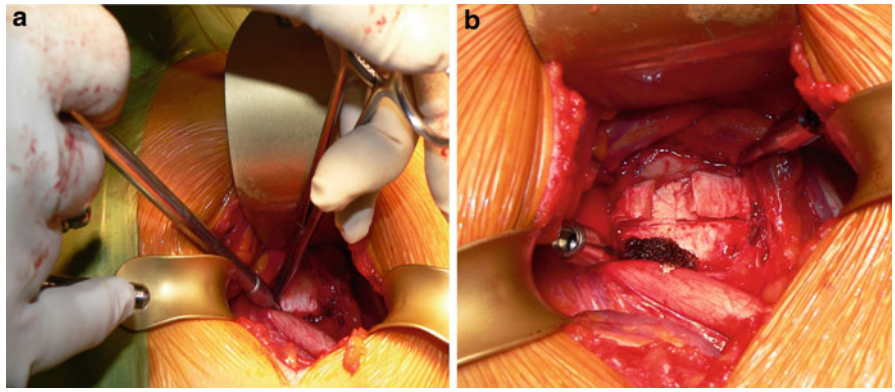

Fig. 5 Exposure of a disc space achieved with use of removable vertebral body pins, in this case AUS pins inserted by mallet and a threaded T-handle, to achieve continued retraction adjacent to a disc space. Insertion under visualization and protection from a peanut retractor (**a**) and sustained retraction for disc access (**b**)

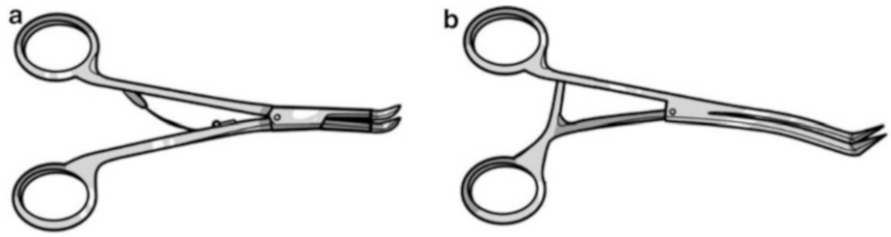

Fig. 6 (**a**) Example of hemoclip applier and (**b**) angled clamp for hemorrhage control

any unexpected immediate postoperative events.

- High dependency or intensive care ward care is recommended for complex procedures or procedures in high-risk patients.
- An inventory and equipment tray layout that not only allows anterior reconstruction but also allows for posterior procedures and vascular repair is mandatory.

Preoperative Setup: Preparation of the Patient in the Perioperative Setting

Skin Care and Preparation

- Preoperative skin care by the patient is the starting point for a successful approach by using appropriate washing and antibacterial soap in the time leading up to the operative dates. Hair should be clipped but not shaved to prevent integument compromise and, in theater, once upon the operating table the patient's skin should be scrubbed and dried. We use Betadine™ antiseptic liquid with the hand sponge from the scrub bay. Then alcoholic Betadine™ solution is used covering the whole area likely required for access including the inguinal areas. The rationale is that rarely one may require access to the vessels for stenting purposes. The skin must then dry before draping and a final cover of the wound is completed with iodine-impregnated adhesive plastic drapes (Parvizi et al. 2017).

Prophylactic Antibiotics

- Usually 2 grams of Kefzol (or an equivalent first-generation cephalosporin) is given on call of the patient to theater and coordinated so that it is in effect at the time of incision. Vancomycin or teicoplanin are considered for high-risk patients.

Anticoagulation

- The strategy is both mechanical and pharmaceutical. Enoxaparin 40 mg subcutaneously is given the evening before the procedure as a

routine. Other anticoagulants are stopped as is reasonably safe in conjunction with the advice of a physician. Positioning of pillows under the knees reduces popliteal obstruction syndrome. The addition of intraoperative calf compression pumps is continued till the next day. TEDS stockings are also worn in the perioperative period until the two-week follow-up.

Elimination

- An indwelling catheter is placed to decompress the bladder, enabling more efficient access, but also enabling monitoring of fluid output and patient comfort while having limited mobility. For retroperitoneal approaches the addition of bowel preparations is not routine, but is recommended to reduce fecal loading for transperitoneal approaches.

Autologous Reinfusion

- Cell Savers™ are set up to be used for all spinal and major vascular procedures so that there is a capability to infuse the patient's own blood in the event of unexpectedly large loss.

Patient Anesthesia and Monitoring

- An array of monitoring of general anesthesia and hemodynamic status including arterial lines is typically instituted.
- For complex deformities, intraoperative neurological monitoring is employed if osteotomies or manipulations are planned posteriorly at the same anesthetic.
- Some surgeons like to utilize an additional Doppler oxygen saturation probe on the left toe to monitor any ischemia caused by arterial retraction.

Intraoperative: Approach for Anterior Reconstruction

Approaches with a Focus on Vascular Access

Once the decision to proceed to surgery is made then the access method to be employed, whether left or right retroperitoneal (LR or RR) or transperitoneal access (TP), needs to be carefully considered. This is really a choice relating to minimizing trauma, safety in mobilizing vessels, and achieving satisfactory exposure to enable completion of the intended reconstruction. Deciding on which approach to utilize in the revision or previous abdominal approach setting has further challenges and presents a unique situation to consider. Generally, an approach to L5-S1 should be a right retroperitoneal. It should be via a rectus midline split and be kept low relative to the disc trajectory. This facilitates future left-sided approaches for adjacent segment disease should it arise. Approaches to L4-5 can be performed via a LR, RR, and TP. Generally, we would recommend a LR. The tip is to not dissect up or down as to minimize vessel or tissue trauma at adjacent levels. Approaches to L3-4, L4-5, and L5-S1 are via a LR if there are no vascular issues and if there is, then a TP approach is appropriate. Any 4 or 5 level approaches are via a TP approach. In every anterior case one should plan for a revision at the index or adjacent level in the preoperative workup. Therefore the approach needs to be atraumatic, direct, and possibly revisable.

A preoperative angiogram is only required if there is vascular pathology or variants in the anatomy that may present issues. Most vascular anatomical patterns and variants are obvious on CT scans and MRI. Always look for the presence of a fat plane under the vessels that will likely need to be mobilized, particularly the venous structures on the axial T2 images (see Fig. 7).

Retroperitoneal Approach

Nonvascular Anatomy

The primary nonvascular area of concern for the team is the genitourinary tract. On the left side, the ureter courses with its blood supply and the gonadal vessels until the ureter tracks medially over the iliac vessels at approximately the level of the common iliac artery bifurcation. More superiorly, the left kidney and its surrounding perirenal fat and fascia are encountered. Care must be taken when mobilizing the ureter to avoid devascularizing it with excessive

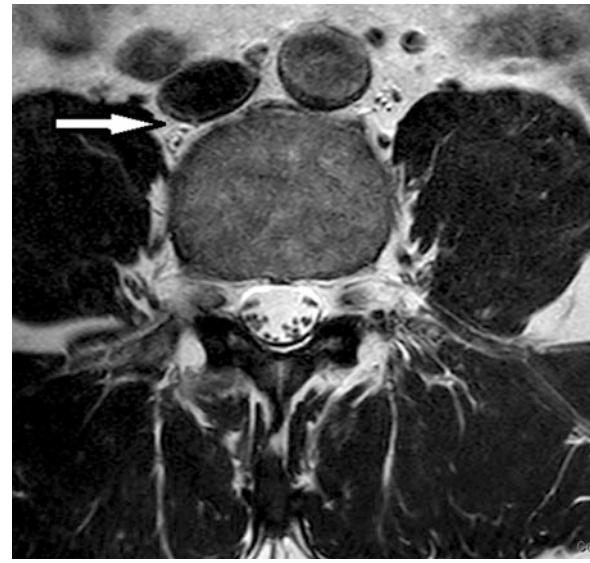

Fig. 7 Adequate fat plane visualized behind the great vessels (white arrow) prior to bifurcation as visualized at the inferior L4 vertebral body

dissection; this can be accomplished by maintaining the ureter with the peritoneum, to which it is adherent. Furthermore, knowledge of the peritoneal folds and space, basic colonic anatomy, and knowledge of the sympathetic nervous anatomy and how they relate to mobilizing the gastric sac en masse are mandatory (see Fig. 8). Details of vascular anatomy and anomalies are further discussed below.

Selection Philosophy

In general, where there is standard anatomy, non-atheromatous arteries, no major venous anomalies, and no previous retroperitoneal surgery, then the retroperitoneal approach is advantageous, with minimal gastrointestinal disturbance and satisfactory access to L5-S1, L4-L5, and L3-L4 levels.

The vast majority of routine cases require an approach to reconstruct three levels or less. The more major cases we have been involved with that required up to four and five levels of disc reconstruction with some cases needing 50 degrees of correction of lordosis are the exception rather than the norm, and we would typically favor a transperitoneal approach in this setting.

The usual approach for the most common problems at L5-S1, L4-5, and occasionally L3-4 is through an infraumbilical midline incision progressing extraperitoneal in the preperitoneum, behind the rectus, and progressing around and then back medially in front of psoas, in the retroperitoneum. This approach is typically limited more proximally by the renal vessels which appear at the L2 vertebral body. The usual approach involves the inferior mesenteric vessels being displaced forward and translated to the opposite side of the approach with the bowel sac. We start the dissection bluntly external to the peritoneum and progress laterally separating the peritoneum below the lower border of the rectus sheath. With experience division of the posterior rectus sheath is rare. The main action initially is using your left index and middle finger to gently peel away the peritoneal sac away from iliacus and then over the psoas muscles. In a single level L5-S1 approach we favor a right retroperitoneal approach as it preserves the option of a left-sided approach for any anticipated future proximal level disease surgery; conversely, in the case of pathology of two or more levels we favor a left retroperitoneal approach. Lift and shift the sac together with the ureter with your hand to the opposite side of the approach away from the iliac blood vessels and eventually the major arteries. The peritoneum is gently dissected bluntly off the vessels so they can be clearly visualized. The hypogastric plexus will move away with the peritoneum. Retraction using the table mounted retractors is then modified to display the vascular

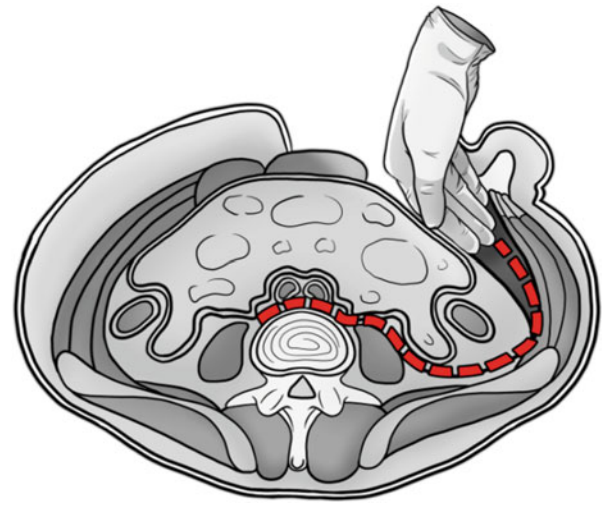

Fig. 8 Schematic of the path of the hand and dissectors around the retroperitoneum in the LR approach to the L4-5 disc. By exploiting the space and mobilizing the peritoneal sac with its contents and the ureter, safe exposure of the vessels and, ultimately, the disc can be achieved

structures and the underlying disc level that is going to be operated on.

Once the peritoneum and the hypogastric plexus have been reflected, one will encounter areolar tissue over the disc space and the anterior spinal artery and venous vessels. Tease with a peanut on a Roberts artery the areolar tissue just to the right of the sacral vessels to the lower right. Insert an AUS-style pin inferior to L5-S1 disc at its lateral margin aiming slightly toward the midline. Next insert a pin superior to the disc on its lateral margin of L5-S1 again aiming slightly toward the midline. These measures keep the right-sided vessels safely away from the surgical area. Ligate the midline sacral vessels and then get under the fat plane and gently mobilize the left common iliac vein up and to the left. Next insert the pin on the superior left of L5-S1. One can also insert another retractor pin on the lower left if needed. We favor the use of AUS™ pins to retract the vessels rather than handheld retractors. Care is needed at this level to avoid injury to the sacral venous plexus which can cause significant bleeding.

The approach to L4-5 is more complicated as the bifurcation of the aorta and the veins varies considerably and is usually closely associated. How the dissection is planned particularly depends on the venous anatomy as this is more compressible and at risk of avulsion and with careful wider dissection these can be mobilized well out of the way. In revision surgery, the fragile vein walls are liable to tears and penetration more easily as dissection is developed through the surrounding adhesive scar tissue.

In the younger patients below 55 years of age with minimal known risk factors, the vessel anatomy and positioning related to the planned operative discs and spinal levels can be deduced from the MRI studies. Often the plan of approach to L4-5 is defined as the dissection above L5-S1 progresses. It is necessary then to understand the options for exposure so that alterations to the exposure can be made – "on the hop" – as the need arises. According to Chiriano and colleagues (Parvizi et al. 2017), in a series of 405 anterior spine procedures, exposure of L4-L5 was able to be accomplished above the left CIA in 44% of cases, between the left CIA and CIV in 45% of cases, and below the left CIV in 11% of cases. An approach between the bifurcations is facilitated by a high location either at the L3 vertebral body or L3-L4 disc space, situations which occur in less than half of patients.

For the older patients it is not only the venous anatomy that is significant but there is increased risk in dealing with aging arteries affected by peripheral vascular disease. The surgeon needs to assess the possibility of problems associated with atheromatous vessels with unstable plaques, ulcers, lumps of medial calcification, displacement and tortuosity, stenosis, occlusion, or aneurysm disease; all of these may be encountered in the access to the operative level(s). The surgeons planning the operation

have to assess potential risks of arterial vessel damage, the likelihood of the type of damage, what measures to have in place to resolve problems at the time of surgery, and what to monitor postoperatively and for how long. Many vascular injuries are only detected very late because of limited understanding of the spinal surgeon, and a multidisciplinary approach to planning and assessment has a role here in reducing injury. For example, there are case reports of a major arterial occlusion such as the common iliac being overlooked for 2 weeks or an occlusion of the left common iliac vein for 2 years with the young patient presenting with severe stasis changes in the affected leg. Sachinder et al. (2011) reported on a series of 560 anterior spine exposures: five patients had arterial injuries; four were diagnosed more than 24 h after the operation with one on postoperative day 13.

The risks of manipulation of a calcified artery include fracture of plaque and dissection which can rapidly progress to vessel occlusion with limb- or life-threatening effects. With such dense calcification, safe compression and flexion of the vessel is not possible. It also should be recognized that aneurysms may be unstable and present the risk of rupture or they may be large and stiff enough to prevent access. On occasions the aortae and iliacs were occluded at the time of presentation. Patients presented with severe symptoms related to the disc degeneration and had proven radiculopathy in conjunction with their pain from vascular claudication. Before proceeding with anterior spinal surgery these patients need vascular surgical assessment.

Left-Sided Retroperitoneal Approach to L4-5 and L5-S1

A standard rectus splitting left-sided retroperitoneal approach to L4-5 and L5-S1 would be the most common and is explained here in detail. Other variants on this approach to access other levels described later use the same principles and techniques detailed below in other subsections.

It is best to palpate the abdomen once the patient is asleep on the table and be aware where the disc spaces are relative to the umbilicus and ASIS so that an appropriately placed incision is performed. The sacral promontory can often be felt by simple palpation. If there are any issues in regard to obesity or inability to palpate, then use of the image intensifier to verify the level and to optimize the trajectory of the incision and the approach to the disc is warranted. The usual incision is midline below the umbilicus. It is recommended that a larger incision be used for the obese who are sometimes brought in for surgery prior to any loss of abdominal girth that we can improve the access rather than encountering limited visualization and increased force of retraction through smaller wounds. With increasing fatty abdominal protuberance the wound may have to be extended to above the umbilicus which is typically unnecessary in patients with a BMI < 30. Given that we aim to improve the safety of the approach for patients, referral to dieticians and physiotherapists for weight loss advice is routinely performed. In some cases, where obesity is refractory over long periods to simple weight loss measures, patients are referred for weight loss surgery as a preliminary step to formal spine reconstruction.

MSY prefers to stand on the right side of the patient. The skin is incised and a diathermy is then used to dissect through the subcutaneous tissues to the rectus fascia trying to maintain full-thickness flaps to the level of the fascia (see Fig. 9a). A one centimeter incision in the rectus fascia is performed; then it is undermined with the left index finger developing the plane between the fascia and rectus muscle. The fascia is then incised with the diathermy distally and proximally extending beyond the skin incision so that you are funneling out rather than funneling in. The interval between the recti is usually identifiable with a fat plane that allows entry into the preperitoneum and by careful dissection, you can enter the preperitoneum on the left- or right-hand side depending on your approach (see Fig. 9b, c).

Next, a Langenbeck retractor is placed under the left rectus and one can see the inferior epigastric vessels travelling up to pass between the posterior border of the rectus and the superior surface arcuate ligament or posterior rectus sheath (see Fig. 9d). It is important not to disrupt these vessels, so use your right index finger to lift them gently off the preperitoneum and take the

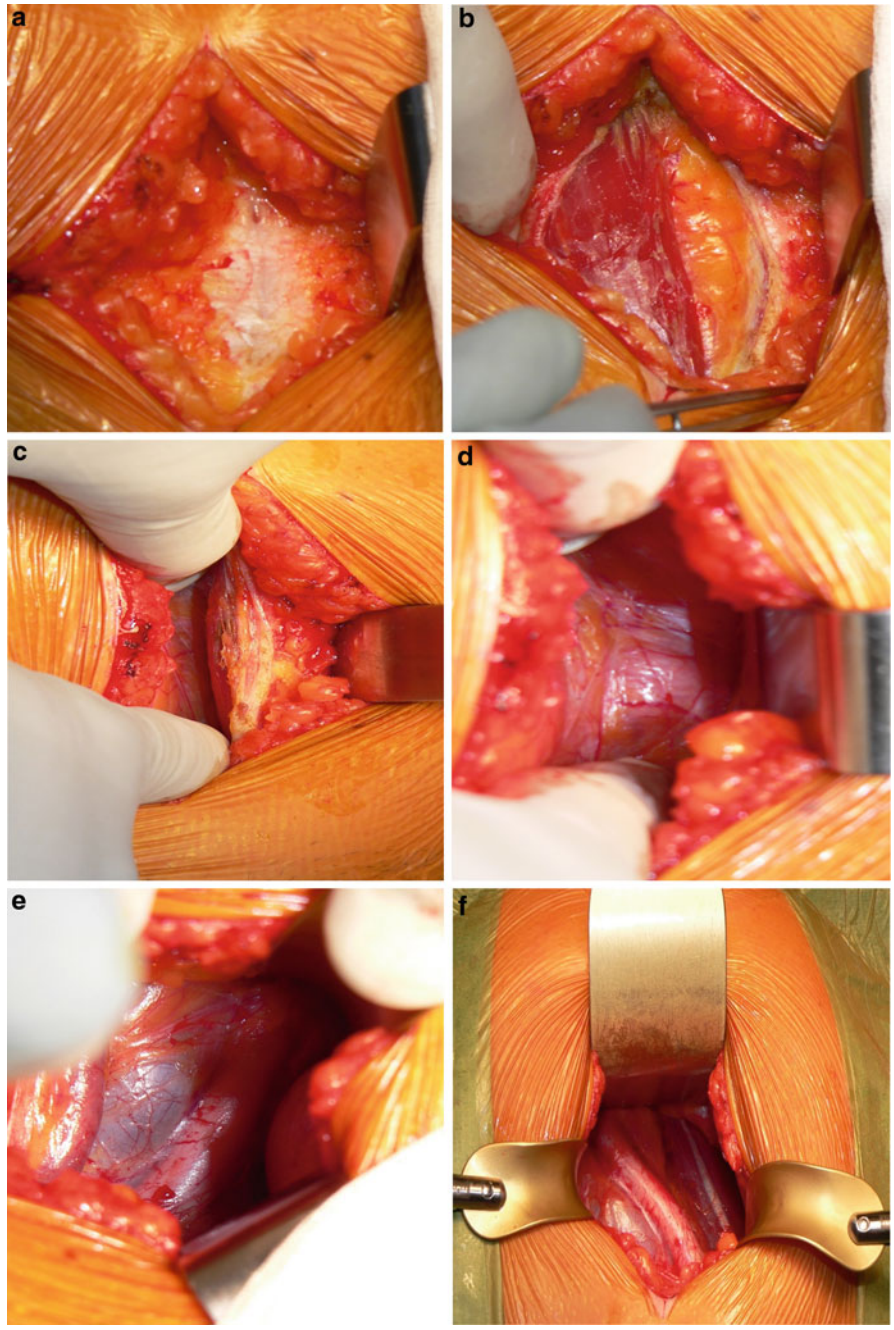

Fig. 9 (**a**) Development of full-thickness skin flaps to rectus sheath; (**b**) following incision of linea alba and posterior fascial incision, preperitoneal fat is revealed; (**c**) the window is expanded with use of fingers; (**d**) identification of superficial vascular leash (inferior epigastric vessels) for protection; (**d**) left Iliac vessels revealed after maneuver to mobilize peritoneum and peritoneal sac; (**e**) exposure of vessels overlying L4-5 following placement of malleable externally mounted retractors and mobilization of peritoneal sac/ureter

peritoneum down with your left index finger. Then, work below the inferior arcuate ligament or the posterior rectus sheath, often palpated as a "soft spot," and move toward the iliac crest. There is usually a small fat pad here that one can peel off the lateral and posterior wall essentially heading

toward the anterior superior iliac spine. Take care not to begin the dissection too deep and distal to the anterior superior iliac spine lest the iliac veins are placed at risk of an avulsion injury.

Slim, fit people can have little adipose tissue between the fascial planes, and the trick is to just persevere with use of the index and ring finger, carefully blunt dissecting the peritoneum off the wall. Once in the iliac fossa you can then peel the peritoneum off quite easily over the iliacus followed by the psoas muscle. Once the peritoneum is retracted to the medial border of the psoas, then place your right hand in the gap and then just peel the peritoneum further off the back wall on the psoas and gently roll the peritoneum off the posterior rectus sheath. This will prevent peritoneal tears. Perform this step gently and just roll your cupped or closed hand in the plane and you will feel it gently separate. The next step is to peel the peritoneum off the vessels. Usually, start down on the lumbar sacral junction. Take the peritoneum, the ureter, and the hypogastric plexus from the left side to the right. Once on the sacral promontory move your left index finger down over the promontory and spread your left middle finger right and ventrally. This maneuver helps lift the hypogastric plexus to the right and to safety. Following this, keep your left hand in the wound and then sweep with your right hand, taking the peritoneum off the vessels up at L4-5 and higher if needed. By taking the peritoneum off the vessels it allows you to assess the vascular anatomy (see Fig. 9e, f). The real benefit is that if there is a vessel injury, access above and below allows you to control the breach and repair it safely. Anterior surgery is much easier when you can visualize the vessels and manipulate them appropriately.

Leaving the peritoneum attached to the vessels is hazardous. In this setting, you cannot adequately see the anatomy and it makes a tear difficult to control; thus, working hard on making sure you can get the peritoneum reflected to give clear access is critical. When reflection of the peritoneum and its contents is performed in the manner detailed previously, the superior and inferior hypogastric plexus is reflected safely. As a consequence, the incidence of retrograde ejaculation reduces and any sympathetic side effects also reduce. There are sympathetics in the plexus and there are also sympathetics that run on the medial psoas gutters and it is important to make sure, when you do use dissection, that you avoid these areas.

Study and be aware of the vascular anatomy from the preoperative MRIs, CTs, or angiograms. Place them on radiographic lightbox in your theater and refer to them before and after reflecting the peritoneum and visualizing the vascular anatomy. This mentality and preparedness will reduce vascular injuries. The aorta, lying to the left and anterior to the vena cava, and the vena cava, lying to the right and posterior of the aorta, bifurcate at L4-5 and the venous structures normally duplicate the arterial system. This is the level where most vascular injuries occur. One can take the vessels left to right in most cases. If the bifurcation is above the L4-5 level and the common vein runs at or above the disc level, one can mobilize the vein up and to the left. At the L4-5 level, the common iliac vein usually runs under and inferior to the left common iliac artery. The trick is to obtain blunt dissect initially with Metzenbaum scissors and then with a peanut dissector and just gently tease and strip the tissue off the lateral aspect of the artery at the level of the disc to expose the disc (see Fig. 10a, b). There may be one or two iliac perforators that come off the common iliac vein that come under the artery and these just need to be clipped and ligated.

If performing an approach at L4-5 and the anatomy dictates a right to left exposure, gently tease the tissue off the artery and have a look for the iliolumbar vein. Some routinely ligate it but I do not think you must do this unless it presents a problem. So, in less than 15% of my cases I will ligate the iliolumbar vein. If you do ligate the iliolumbar vein, tie off first at the origin then reinforce it with clips. Move proximally over the disc and tease the tissues up as this helps release the vessels to mobilize them to the right and down.

If there is any vascular vessel calcification or slightly abnormal vasculature where you need to get better visualization, then you can skeletonize the common iliac artery and put a sling around it and take it over to the left. This gives complete exposure to the common iliac vein and allows mobilization down to the right. The vein has to be mobilized enough to be below the level of the

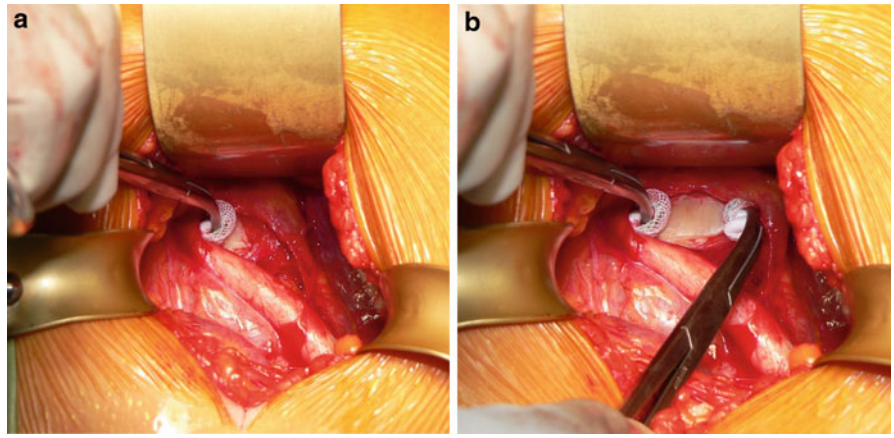

Fig. 10 (**a**) Mobilization and traction provided by periosteal plane dissection with a peanut retractor held with the left hand, (**b**) teasing of areolar tissue across the disc space by a peanut dissector held with the right hand while the left hand maintains traction

disc so that a retractor pin can be placed for retraction and access far enough to the right to allow correct positioning of the prosthesis to be obtained (see Figs. 11 and 12). Next move to the superior right side and insert the retractor pin. Then make your incision in your annulus, reflect the annulus, and insert stay sutures in the annulus to protect the adjacent areas. Normally we just use a 1 or a 2 Vicryl™ (see Fig. 12b).

Then perform a macro-discectomy (see Fig. 12b). This is best done with long pituitaries, Kerrison rongeurs, controlled movements within the intervertebral space with a long sharp Cobb, curettes, and rotational distractors as well as interbody distractors. After the bulk of the anterior disc has been removed by the pituitaries, the Cobb is used to remove the cartilaginous endplate with small, careful, controlled movements. Do not make any lateral movements or rotations as lateral movements will result in the Cobb skiving and sometimes lacerating the adjacent vascular structures and uncontrolled movements can result in penetration into the spinal canal or divots in the endplate which can compromise implantation. One needs to have the appropriate Cobb and the appropriate technique.

The cartilaginous endplate is then removed and the disc space after that is distracted so that we can pare down the posterior annular structures. From there one will usually go to the paddle distractor to increase the disc height and therefore gain access to the posterior annulus and the posterior longitudinal ligament. When one distracts, it is important to balance the lateral annuli to make sure that there is maximum exposure to the endplate and that there is parallel distraction and no evidence of any "fish mouthing."

Initially use a Charité central distractor, then insert a David distractor, and use the Cobb to get the annulus either partly off the posterior endplate superiorly and inferiorly. If it needs to be resected, then Kerrison rongeurs are utilized. After the annulus is released one can perform an internal intradiscal electrothermal therapy with bipolar diathermy, ablating the course of the sinuvertebral nerve around the posterior annulus.

From there, one should reuse the distractor paddle including a T handle paddle to ensure maximal disc height restoration and appropriate posterior release (see Fig. 13a, b). It is important to do this probably three times and to go back and check the disc space and make sure it is cleared and balanced front to back, side to side, and that you have addressed any disc herniations or releases required. If there is a disc herniation, extruded fragment, or a sequestered fragment, they can be retrieved after careful preparation of the disc space and rongeurs. Once you are back at the posterior annulus,

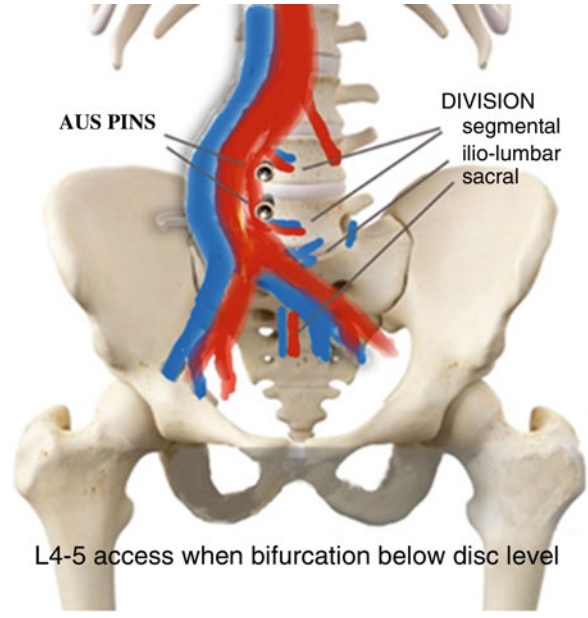

Fig. 11 With vessels held by a peanut retractor and under direct vision, AUS pins are inserted sequentially on a T handle to achieve a working corridor for disc preparation and device implantation

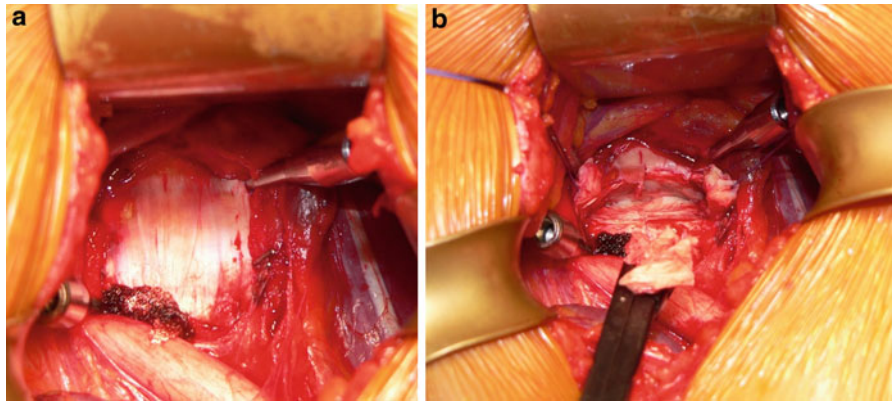

Fig. 12 (**a**) Pin retractor placement to maintain safe exposure of the disc. (**b**) Following an H-shaped annular incision, flaps are mobilized and retracted with stay sutures and a macro-discectomy can then be safely completed with careful use of a Cobb retractor and pituitary rongeurs

insert the David distractor in and rotate the panels out to the left hand side. This gives you clear access into the distracted disc space. From there you can use long Kerrison rongeurs to create a rent in the annulus. If there is a herniation, the rent will already be there. You can then follow that rent and retrieve the herniation. It is essentially just like doing and anterior cervical discectomy except that you have got much more room and you easily evacuate nuclear and annular material.

Once you have got the disc prepared, you can then make a decision about whether the device preoperatively planned for implantation is still appropriate. Whether it be a static or a motion preserving device, the important issue is to achieve maximal cross-sectional area from medial to lateral and anterior to posterior endplate as possible as this aids in supporting the chosen implant (see Fig. 14a, b). This will prevent eccentricity, reduce subsidence, and maximize the graft-bone interface opportunities. Should the endplate

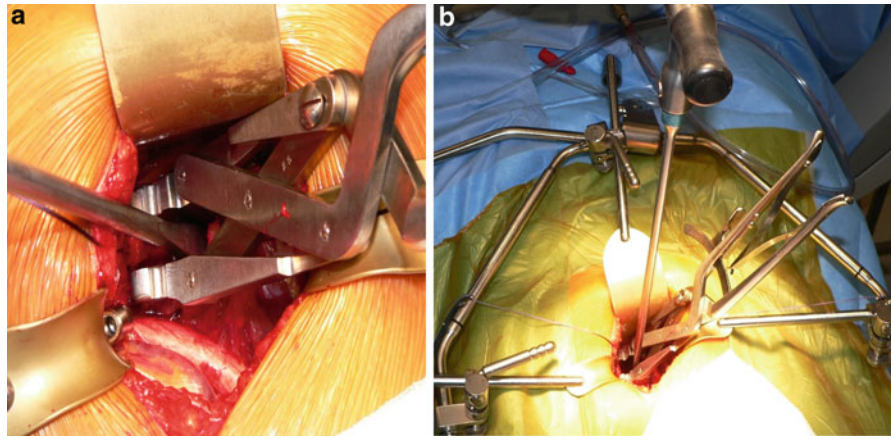

Fig. 13 (**a**) A David distractor is inserted followed by a paddle-style distractor panel to achieve disc distraction for periannular release and full access for discectomy and implantation. (**b**) Example of rotation of a distractor into the disc space splinted by the David retractor to achieve safe distraction while minimizing the risk of endplate breach

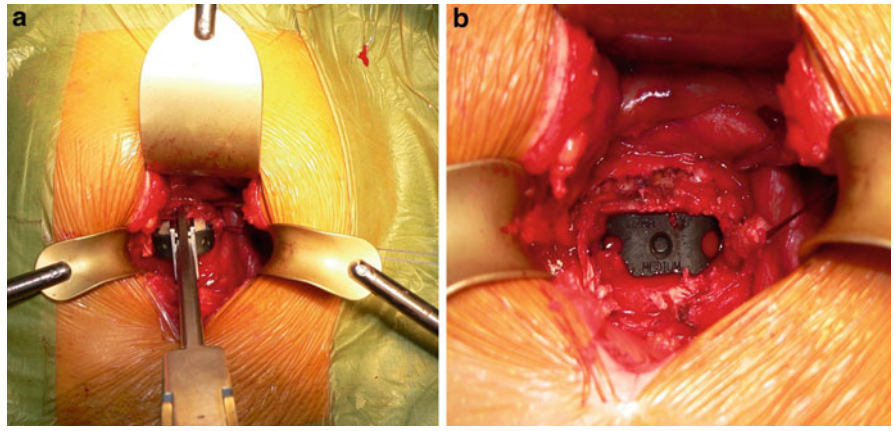

Fig. 14 (**a**) Implantation of an interbody cage loaded with graft. (**b**) Implantation and recession of interbody device prior to annular closure

or vertebral bony cancellous quality be found to be poor (often sensed via limited bony resistance with insertion of AUS pins), then vertebral augmentation should be strongly considered after implantation. This is achieved via insertion of vertebral cement into a Jamshidi needle under fluoroscopy control.

Following implantation, we harvest a fat graft and place it over the implant and then repair the annular flaps and then remove the retracting pins. Should poor quality or sparse fat be available, then use a square of Gelfoam™. The rationale for this is to close the dead space for hemorrhage and reduce the theoretical nidus for adhesions. I think that adhesion barriers should be used generally in young people, who may later require revision or treatment for adjacent segment disease. There is a preference to use Surgiflo™ with thrombin judiciously into the pin holes so that there is no hematoma, which will increase fibrosis in the postoperative period.

Next, carefully release the retractors and massage the peritoneum to the contralateral side of the approach, allowing it to fall back into its natural

position. One should generally perform this repositioning because if this is not performed, the ureter can end up in a more central position and develop a kink in its course. On the rare occasion this can result in a hydroureter above the stricture leading possibly to a hydronephrosis.

Once the peritoneum is back in position, verify the position of the implants radiographically. At this point, reconfirm hemostasis is achieved and secure the fascia with a double loop nylon, making sure the sutures pick up the fascia and not the muscle, aiming for normal tension. Close with an absorbable monofilament in the subcutaneous and subcuticular layers.

Tips on Revision Retroperitoneal Surgery

Revision surgery can be very complicated if the approach is attempted through a previous ipsilateral retroperitoneal approach. There are other options available and these include right retroperitoneal and transperitoneal (preferred). If a revision retroperitoneal approach is performed, then a ureteric stent needs to be inserted preoperatively. In revision, anterior surgery it is expected that the approach to the spine will be complicated by adhesions. Peritoneal tears are common and this may predispose to bowel injuries, ileus, and bowel obstructions in the postoperative period. At the index disc and often at adjacent discs there will be adhesions and fibrosis. This can result in distortion and tethering of vascular structures. Both of these situations greatly increase the risk of injury. As stated above our experience has found transperitoneal approach to be safer and provide a greater chance of success. On some occasions, it is not possible to access the revision level safely. This commonly occurs at the L4-L5 level where the vascular anatomy is often challenging. The vessels may be completely immobile and one must be prepared to spend time performing meticulous dissection. Sometimes the decision to abort has to be made. Consider subperiosteal dissection of the tissues which may provide surprising access on some occasions. In regards to minimizing vascular difficulties during index revision procedures, one should reconstruct over the disc replacement with fats graft or anti-adhesion barriers. This will maximize access to the level and help minimize vascular complications during revision index surgery. A team approach is required in regard to anterior revision cases and will be discussed in a later section.

Transperitoneal Approach

This approach shares the same steps to the retroperitoneal approach to the point of encountering the peritoneum and a generous incision is generally required (see Fig. 15). At this juncture, the

Fig. 15 Midline incision utilized for a L2-S1 transperitoneal approach in a patient with previous abdominal surgeries. Recall that safety and visualization, not the length of the scar, should be the first consideration

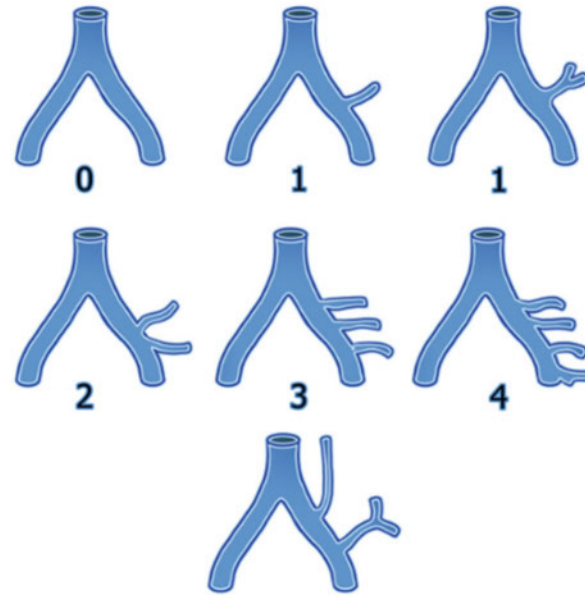

Fig. 16 Variances in the venous anatomy around the left common iliac vein. Notice increasing number of tributaries and sub-tributaries possible here as well as, in the bottom picture, the potential for the presence of an ascending iliolumbar vein

peritoneum is divided. Using the Thompson retractor, the descending colon and the sigmoid are packed into the left paracolic gutter. The transverse colon is lifted with a wide retractor and with displacement of the small bowel to the right, the duodenal-jejunal junction is defined. The major trunk vessels of the aorta and IVC are our main interest when approaching transperitoneally. Dissection nearby through the posterior peritoneum over the right aspect of the aorta allows progressive exposure of the aorto-caval space from the renal vein down aiming to remain to the right of the inferior mesenteric vein.

In the complex cases often requiring 4 level reconstruction or in revision surgery we have found it best to approach the superior aspect initially, defining the space between the aorta and vena cava dividing the segmental vessels and noting that there is often a large vein at the L3 level. In some cases, this is a retro-aortic renal vein. We progress inferiorly to the overlap of the right iliac artery over the left vein. Depending on the position of L4-L5 it may be approached by dissecting the right iliac artery free and mobilizing it and the aorta to the left and the IVC and the left vein to the right and inferiorly. Care with the superior aspect of the left iliac vein will allow control of the iliolumbar vein or neighboring branches to prevent tearing and problems with blood loss. While much attention is focused upon care for the vessel variations (see Fig. 16) and parasympathetics, attention should also be given to the nearby anterior neural structures such as the lumbosacral plexus and obturator nerve.

A lower disc may be better approached beneath the left iliac artery, displacing the vein inferiorly and to the right. In this case, it is sensible to control the vein branches along the superior border early. If the bifurcation of the main trunks is high, L4-L5 may be approached from below, similar to the L5-S1 approach with definition and ligation or clipping control of the middle sacral vessels. The aorta and the left iliac artery can also be displaced to the right, but this requires mobilization of the Iliac artery to limit the displacement forces while it is pinned. The IVC bifurcation is usually above the L5-S1 disc but may occur at the inferior edge of the disc. Adaptation of the standard approach will be required.

A vascular surgeon is required only when there are complex problems such as requirements for 3- to 4-disc level-based reconstructions and/or where there are definite arterial risks and venous anomalies or there is revision surgery.

In all of these cases a transperitoneal access is going to be safer by allowing easier treatment of complications if they occur and better controlled outcomes.

In the space between the aorta and IVC, segmental veins and arteries have to be defined, individually controlled and divided to enable freeing of enough length to allow adequate access of the disk space without tearing the major vessels. In this area, the surgeon should be aware of developmental anomalies and variations such as a 10% risk of a retro-aortic left renal vein, a horseshoe kidney, and left IVC variations (discussed below). Also one must consider abdominal aortic aneurysm and dense calcification of the arteries. These can all be recognized from the preoperative MRI or CT angiography scan and, conversely, can be a major problem if not anticipated at the time of surgery.

Tips on Approaching Operative Levels Below the Bifurcation

We choose to divide the peritoneum centrally over the sacral promontory to obtain access to L5-S1 and L4-L5 if the bifurcation is high enough. This area is usually clear of major structures and the areolar tissue can be progressively elevated until the anterior aspect of the left iliac vein is displayed. The medial edge is then clearly defined. Achieving this may take some time with slowly teasing away fibrous and vascular bands or may require diathermy and/or limited areas of sharp dissection. Once a satisfactory length of the vein edge can be visualized, attention is turned to elevating the vein and freeing it from the posterior surface. In general, it is attached to the anterior spinal ligament and surrounding fibrous tissue. Great care is required here and a combination of teasing the tissue with two pairs of forceps again with or without diathermy and sharp dissection with scissors, working to go deep into the ligament or periosteum, is used to achieve the separation. This is particularly important if this is revision surgery. The median sacral vessels can readily be isolated and controlled by dissection with the peanut dissector of any surrounding areolar tissue to allow clipping and diathermy.

Tips on Approaching Operative Levels Above the Bifurcation

Above the bifurcation the approach we usually use is between the aorta and IVC but a left lateral approach along the aorta can also be used. At the bifurcation level, the aorta can be displaced to the right with the veins. This latter area requires careful definition down the lateral edge of the vein behind the left iliac artery and requires progressive division of the iliolumbar vein, either with clips or ties, and the often multiple accompanying veins in this region, to enable de-tethering and mobilization.

As mentioned earlier, the L4-L5 level access depends on the position of the aortic bifurcation and, often, the easiest approach is between the left common iliac vein and the artery above. If the aorta is of normal size or small and of normal compliance, it is possible to dissect along the left side and retract it to the right. With this approach, care is necessary with the iliolumbar veins, which are best safely controlled early before they are avulsed from the iliac vessels. When dividing the veins attention to the local autonomic nerves is also required.

Revision and Previous Abdominal Surgery

As previously discussed, an approach to the spine in the revision setting will be complicated by adhesions close to the affected disc site affecting ability to access safe planes. The first decision again, with revision, is whether to proceed retroperitoneally or via a direct transperitoneal approach. The majority of the time for revision surgery we consider the direct transperitoneal approach to be safest with the best exposure, especially if access to more superior levels is required. When carefully performed with meticulous technique, blood loss with recent procedures has been of the order of 100 mls, even in a case where we had visualized large pressurized veins on the other side of the peritoneum (e.g., a patient with portal vein hypertension).

The retroperitoneal approach, if being made for the second time, involves tethering and scarring of the retroperitoneal space. The dissection

can be difficult and the ureter is at risk in this tissue. It is our policy to have an urologist place a removable stent as a precaution as this allows easier recognition of the ureter and greatly reduces risk of damage to it. It needs to be recognized that direct trauma is not the only way that tissue damage can occur, with ischemia from repeated dissections being associated with damage to the ureter and the femoral nerve in this region. A resultant leak or neuropathy may result.

If using retroperitoneal dissection for revision, prosthetic replacement, or fusion, our approach has been to develop the dissection plane more superiorly. With access to L4-L5, the most difficult, we commence definition and mobilization of the aorta on its left side, then progress down to the bifurcation, and continue laterally to the left common iliac artery. We have found that the common iliac vein is attached posteriorly and it becomes exposed as the artery is displaced medially. This is likely to be the riskiest part of the operation. To get adequate access the vein has to be freed along 3–4 cm of its length so that it can be displaced medially and a little inferiorly.

Before the vessels can be freed up it is important to mobilize the ureter away from them. This is assisted by having a ureteric stent placed at the commencement of the operation which we do for initial recognition in the revision to the retroperitoneum setting. As the dissection progresses it allows easier definition between the ureter and the adhesions that need to be divided.

Once the lateral edge of the vein is visualized sharp dissection is used with scissors directed posterolaterally allowing the periosteum to be divided which protects the vein. This is continued progressively until the vein is adequately freed inferiorly.

In women it is also very important to understand their gynecological history. Past surgery laterally, e.g., around the tubes and ovaries or involving the lymphatics, can increase the problem. This is pertinent as a case has been reported to us where the iliac vein was totally avulsed as distraction was applied due to dense tethering in the pelvis. Obviously, this can occur no matter which direction of approach is used. Reports of direct iliac vein trauma probably only account for a limited number of cases that have occurred.

With all the endovascular options a skilled vascular surgeon can bring to the table, we have the ability to control hemorrhage with balloons or stent grafts if a major rent in the vessel occurs. We use this with either direction of approach and have the endovascular equipment in the theater. As the potential risks include a threat to life we have considered it useful to place a left iliac vein guidewire "0.035" at case commencement using duplex ultrasound via the common femoral vein when our team has considered the risks are significant. At the end of the case the wire is removed with less risk than a standard venepuncture.

If a prosthetic disc needs to be removed, it is important that the disc type be reviewed and information be sought on disassembly techniques and recommendations from the manufacturer. With the space opened at least partially, the metal plates can be freed with the careful use of a small osteotome between disk and vertebral body and prosthetic extraction facilitated by rotation of the plates. Sometimes a partially or complete vertebrectomy is required to explant the device. Careful assessment for and removal of any collections of metallosis or polyethylene debris should occur before proceeding with standard reconstruction.

We have found the vessels are adequately protected by a Gore-Tex™ prosthetic film allowing the dissection to proceed deep to the film when it has been implanted at the initial procedure.

Ability to Transfer Between Retro- and Transperitoneal Approaches

The decision to use one type of access does not rule out use of the alternative. It is straight forward to transfer from extraperitoneal dissection if problems arise and the upper extent of the approach is not reached. The peritoneum is opened and the bowel moved to expose the interval between the IVC and the aorta. This interval can be widened to expose the upper discs for repair.

Even if surgery has been planned based on a transperitoneal approach it can be switched to retroperitoneal should problems occur. This may require adjustment of what can be achieved.

Vascular Pathology, Injuries, and How to Manage Them

Venous Pathology and Handling Techniques

The iliac veins are at most risk in the pristine abdomen no matter whether the approach to the anterior lumbar spine is made retroperitoneally or transperitoneally. The first decision is whether to proceed retroperitoneally or via a direct transperitoneal approach.

In general, the approach is simplest from the retroperitoneal aspect. There is minimal gastrointestinal manipulation, a limited incision for the patient, and the approach to L5-S1, and L4-L5 is straightforward and L3-L4 often manageable.

The veins should be identified along their edges with progressive mobilization and elevation. The risk of damage and hemorrhage is mainly from unidentified branches. It is easy to get into this problem if the retraction is continuously maintained as the branches empty and remain emptied and thus can be divided without recognition until, with reduction of tension, the depth of the wound tends to allow the severed vein to rapidly fill with blood and into the wound.

The vascular problems are twofold: either hemorrhage from cuts, tears, or avulsions or obstruction with or without thrombus. The latter can occur as the result of trauma or from repairs after the iliac has been clipped/sewn to control hemorrhage or compressed by the operative area behind the right common iliac artery.

The frequent "injury" is really a part of the dissection in the majority that can be prevented by adopting a dissection technique of stretch and relax given that these are viscoelastic structures. Branch veins can be distracted and torn from the common iliacs and vena cava and it is often the smaller veins that are mainly responsible as under distraction they are difficult to visualize when distracted but if pulled or torn can result in a sizable hole in the main vessel with the potential of copious bleeding. Allowing tissue relaxation can give these vessels a chance to fill and, once defined, be isolated and appropriately controlled. This problem is just part of the surgical approach and must be mastered to, firstly, limit injury by the technique of dissection and, secondly, to have the capacity to repair the vessel tear without significant further damage, i.e., enlarging hole or causing the result of critical stenosis or occlusion.

Usually it is the common iliac vein that is bleeding. A calm approach is required to not let this get out of hand. The bleeding needs to be controlled well enough to allow the placement of hemoclips or sutures for control without compromising the vessel lumen. If the lumen is compromised, the problem can be converted to an occlusion rather than a hemorrhage. The left common iliac can be tightly stenosed or occluded by taking large bites to control bleeding. At the time of surgery, secondary to this, all the pelvic veins will become congested as they develop an alternative pathway and feed into the right and on the ipsilateral side the iliolumbar region, this may well make further dissection more difficult and hazardous as all these small vessels will be increasingly pressurized and bleeding will be more likely to occur and more difficult to control. Postoperatively, the risk of extensive DVT is significant and adequate anticoagulation must be given. The patient should also be informed that they are likely to have a congested and swollen leg(s) and have the potential of a lifetime pressure/stasis problem.

Clusters of veins anterior to the sacrum if torn can be very difficult to control. When all else fails, osseous stapling of a mass of Surgicel™ or Gelfoam™ and Surgiflo™ or thrombin-based injectable onto the site to tamponade and coagulate the plexus can resolve a life-threatening situation (see Fig. 17).

If the solution appears very difficult, an endovascular option may be helpful. Recovery of the situation can be achieved by placing a guidewire through the common iliac vein and can allow it to be followed with a balloon to apply tamponade at the site until a formal repair can be carried out (see Fig. 18). The wire needs to be followed by imaging as it is common for the wire to travel up the iliolumbar branches.

If the bleeding is from a difficult or inaccessible site, e.g., posteriorly near the bifurcation, a covered stent may offer a means to solve the

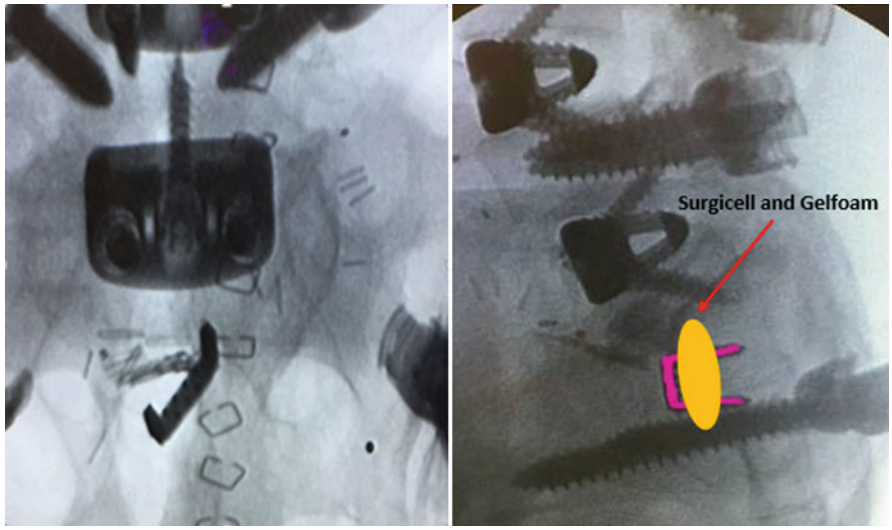

Fig. 17 Use of a Richards staple (usually found in a knee reconstruction instrument tray) for osseous purchase to secure a Gelfoam and Surgicel composite for tamponade in a case of difficult to control sacral venous bleeding

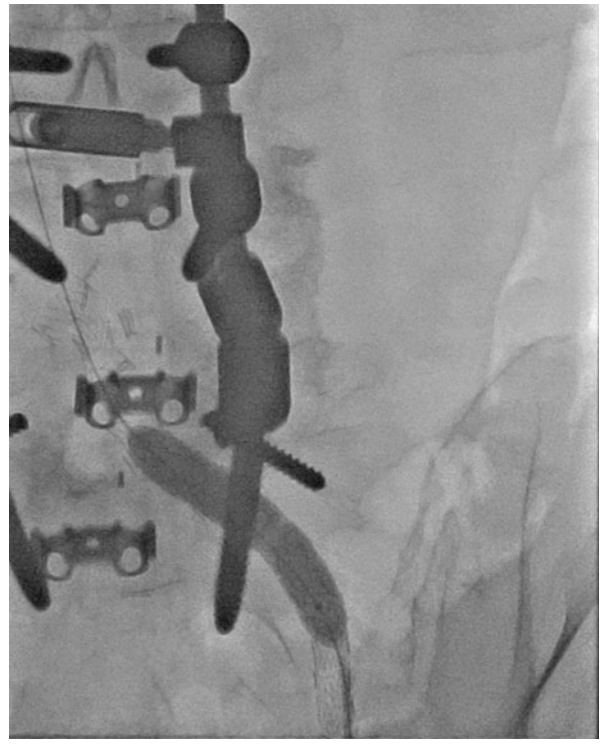

Fig. 18 Vascular balloon employed for hemorrhage control

problem. These can also be used to recanalize an occlusion.

There are no *covered* stent grafts made especially for the major veins and the iliacs often require 14–18 mm stents to fit suitably. The internal method to seal venous injuries would require a type usually used for arterial aneurysm repair. If the prosthesis does not grip inside the iliac vein, it

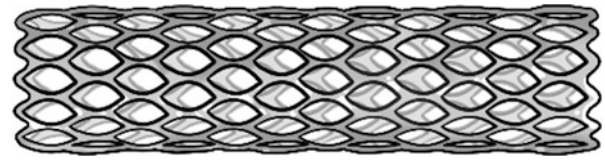

Fig. 19 Expandable stent graft

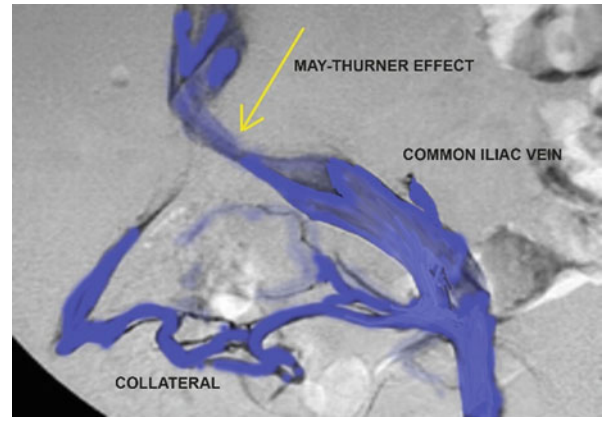

Fig. 20 May-Thurner effect of left common iliac vein compression by left common iliac artery

can end up being discovered as an embolus to the heart. These stent grafts need to be ordered as they are not usually "off the shelf." For a high-volume anterior spinal service it would be sensible to have a choice of stent grafts of different sizes to be suitable for any problems that may arise (e.g., grafts of 12, 14, 16, and 18 mm diameter and 5 cm long) on the shelf. This would generally enable suitable implants for any emergency. With experience, however, the chance of requiring this assistance with an initial approach should be very rare, but it would be useful in the more demanding setting of revision surgery.

The covered stents usually available for the larger sizes 12–14 mm are balloon expandable "Be" stent grafts or by "Atrium V12™." These covered nitinol self-expanding stent grafts maximize their size out at 10 mm but there are larger grafts usually used for iliac artery coverage in aneurysm repair that can be ordered (see Fig. 19).

Vascular surgeons have used these in situations where patients have been referred with a major vessel tear and with a repair attempted but complicated by a tight stenosis which have gone on to occlude, with ensuing serious results of massive limb swelling and stasis change. Thrombolysis with associated stenting has normalized the situation. For the case of simple stenosis (which is not all that uncommon) usually from right common iliac artery compression of the left iliac vein with swelling or a plate filling the space from behind, I prefer a bare sinus-Obliquus stent that conforms well at the IVC bifurcation.

The occlusive venous risk again is most common in the left common iliac vein. There is an anatomical variation associated with lumen compromise and flow restriction named as May-Thurner effect (see Fig. 20) which can be recognized in up to 25% of the population, particularly females.

Control and Repair of a Venous Hole

1. First, bleeding should be controlled by direct pressure on the area preferably by fingers or sponge sticks or, if necessary, placement of DeBakey vascular clamps. Help should be requested early if, upon assessment, the injury will likely require more than simple vascular repair techniques and, additionally, multiple skilled pairs of hands help the situation.
2. Then the vein should be mobilized and skeletonized above and below the site to allow the hole to be situated and visualized on the vein edge; then a series of small hemoclips can be

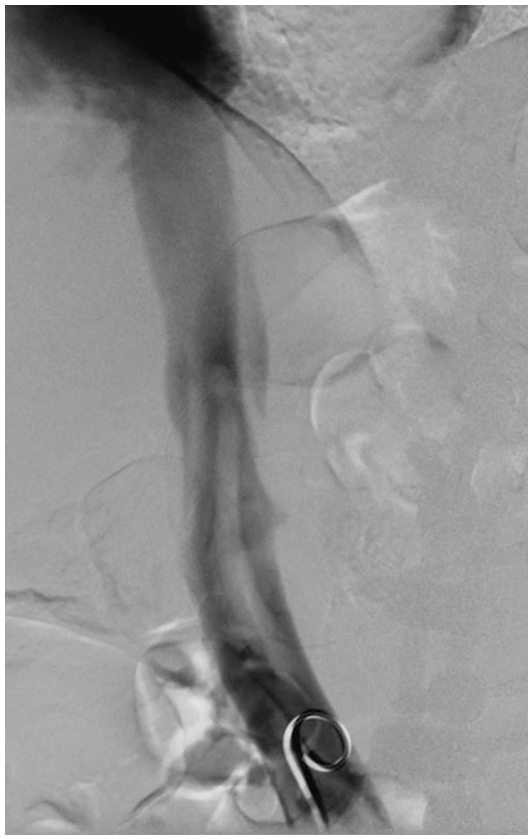

Fig. 21 IVC thrombus originating below the left renal vein after Floseal had been injected into a dural vein to control heavy bleeding during a posterior approach. Angiography at 6 months showed no residual

applied to the area to give satisfactory stable control. If necessary further stabilization can be achieved by using a 5/0 Prolene™ continuous suture to oversew the site without taking excessively large bites and tied with at least 7–8 throws.

3. Use of a sandwich repair can be a useful adjunct to close small venous pinholes without propagating further tearing. This employs a small Teflon or Dacron pledget skewered with the needle and thread twice and then slid down onto the holes for extra buttress and tamponade effect.
4. If extreme difficulty is encountered, then an endovascular wire, followed by a 10 cm angioplasty balloon, should be employed to allow control of iliac bleeding. A covered stent graft could be deployed in such instances if blood loss persists and there is a threat to the patient.
5. If the IVC is the problem, a side clamp or two small angled clamps can be applied until the site can be adequately secured.
6. The most important message is not to panic; a calm, well-considered approach is mandatory to achieve the best results.

Control of Venous Oozing

First-line management for nonspecific oozing is with judicious use of topical hemostatic agents (such as thrombin-based products) combined with an adjuvant volume filler such as Surgicel or Gelfoam. This is useful for controlling oozing from smaller veins, from vertebral body perforators, and from extradural veins. Generally, the topical hemostatic should be applied when there is no easily identifiable large bleeding source amenable to clipping, ligature, or diathermy and should then be assisted in its action by placement of the adjuvant volume filler, pressure agents (e.g., Surgicel gauze) with or without additional pressure from a packed surgical gauze. Adequate time should be given for this combination to take effect and repeating this sequence is often necessary until hemostasis is achieved. When used carefully, it will not upset the function of the cell saver. Spongostan™ can be used; however, it should not be sucked into the cell saver.

Excessive use of hemostatic agents is not without risks given its potential to be absorbed into local venous plexus, with the potential for forming and propagating clots. The vascular surgeon has been asked to treat a patient who developed a large floating clot in the IVC extending from the renal level up to the atrium (see Fig. 21). The clot developed after Floseal™ was injected into the lumen of a heavily bleeding epidural vein. He elected to manage the patient with full-dose low molecular weight heparin at a dose of 1 mg/kg twice daily, which in his experience is the most effective medication for large thrombus. It is possible that small emboli develop as the clot breaks up but no major functional problem developed and follow-up at 3 and 6 months angiography showed no residual thrombus. Furthermore, Floseal™ has been reported to have an association

with inflammatory intraperitoneal adhesions. Fibrillar™ should be used with caution in conjunction with cell saver as thrombosis and emboli have been reported.

Another uncommon technique useful in extremis, particularly in the context of sacral plexus oozing, is for direct tamponade across a wide surface area by placement of an anterior sacral Gelfoam secured to a Richards staple and then impacted into the bleeding anterior sacrum.

Arterial Pathology

Although the veins are at most risk in the pristine abdomen, the arteries are also at risk no matter whether the approach to the anterior lumbar spine is made retroperitoneal or transperitoneal and, particularly, in the elderly patient. The most significantly affected arteries are the iliac arteries and the aorta. The two most common arterial problems are either related to hemorrhage from cuts, tears, and avulsions or related to obstruction. Neither problem is common in high-volume anterior lumbar practice where protocols anticipate significant pathology.

Bleeding events that we have encountered more often relate to the retraction forces required to displace the arteries. If the local segmental vessels or the mid sacral vessels are not appropriately located and ligated/clipped and divided prophylactically, an avulsion injury is possible and will require fine suturing to control.

The tension affecting the vessels can, on occasion, result in a split at the aortic bifurcation as the iliac arteries inferior to this are distracted. This is not able to be satisfactorily repaired until the tension is released, so it is best to pack and pressurize the spot and get on and do the spinal repair and come back and resolve this problem once the spinal repair is complete.

In a similar fashion, we have seen splits and tears develop in the iliac arteries at the site of pins or local retraction. Again, careful suturing is necessary especially in these smaller vessels where technical mistakes in the repair are likely to result in stenosis or occlusion. This is not an area to be controlled with hemoclips; attempts at control with hemoclips have often required endovascular rescue for dissection and marked stenosis.

To check suspected postoperative problems a 3D CT angiogram is required and has to be assessed in multiple rotations. Careful assessment of the study is required as "normal" reports from radiology providers have been on occasion incorrect and proven to be high-grade postoperative stenosis (see Fig. 22).

The first decision in the presence of significant arterial disease is whether to proceed retroperitoneally or via a direct transperitoneal approach.

In general, the approach is simplest from the retroperitoneal aspect. As previously stated, there is minimal gastrointestinal involvement, a limited incision for the patient and the approach to L5,S1, and L4,5 is straightforward, and L3,4 can often be managed. This approach is associated with higher risk if using the ipsilateral side for revision surgery, discussed in detail in our earlier section of venous pathology. We, therefore, opt for a transperitoneal approach or, in some cases, a contralateral left retroperitoneal access (if a right-sided retroperitoneal was the previous access) in these cases. Getting to L3-L4 and above is managed by developing the space between the aorta and the IVC and, when there is extensive calcium plaques above, significant stress is built up in the process of retraction (see Fig. 23). We try and use areas relatively devoid of calcium for the main sites of displacement.

The risk of arterial thrombosis is related to arterial trauma, usually precipitated by dissection. This can occur in minimally diseased vessels but is much more likely when there is a significant degree of atherosclerosis with thick unstable areas of plaque. This is particularly so if there are areas of solid calcification (see Fig. 23). The degree of calcification will influence the risk and it is sensible to involve a vascular surgeon for the approach if the calcification is significant. We use CT 3D angiography with maximum intensity projection to provide the best assessment of the calcium effect.

Atheroma can remain undisclosed until the artery is compressed or retracted and, as such, preoperative identification provides additional

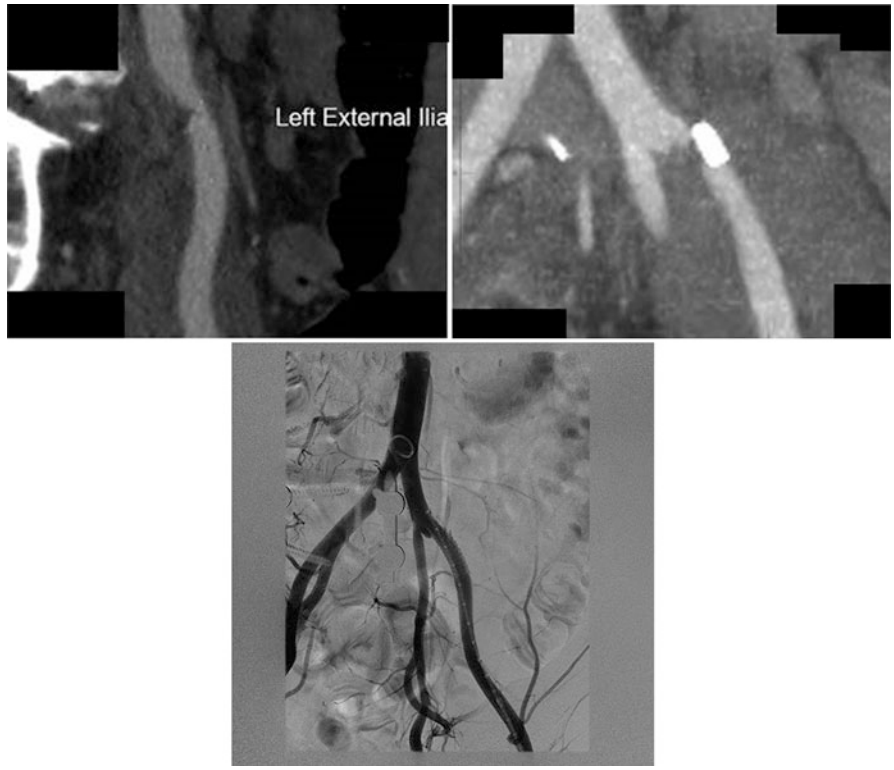

Fig. 22 Sutured tear assessed as satisfactory by radiology postoperatively but likely not assessed adequately in 3D. The problem was resolved with endovascular stent

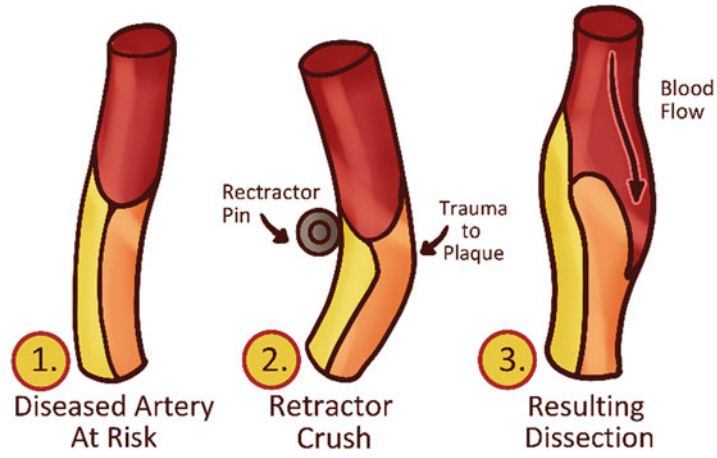

Fig. 23 Different models of injury from arterial handling

safety. While younger patients are at little risk of abdominal atheromatous disease, patients who are aged above 50 years and those who are smokers and diabetics and have other peripheral vascular disease risk factors such as hypertension or hyperlipidemia have an increasingly significant risk of involvement of the iliac artery and aorta. This includes solid plaques, ulcers, and unstable material. With extreme degrees of calcific atheroma now showing in the population, it is prudent to order a preoperative angiogram in any one aged over 50 or with multiple risk factors, particularly if multilevel

surgery is required. If an inadvertent intraoperative thrombosis is diagnosed intraoperatively, it can be treated on table with thrombectomy and stenting (see Figs. 24, 25, and 26).

In some patients, this may require the decision not to proceed with an anterior approach but rather consider alternatives such as lateral or posterior approaches, accepting their relative limitations.

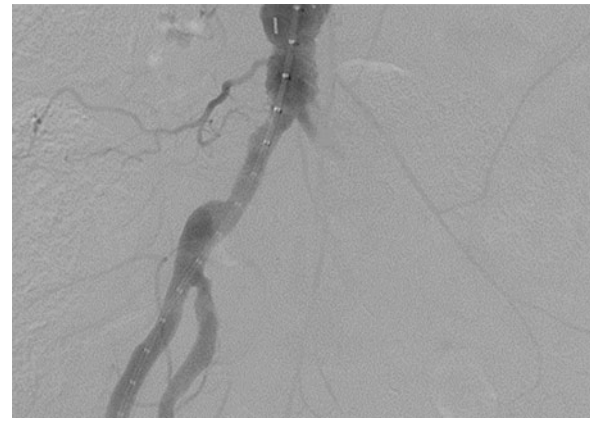

Fig. 24 Occluded iliac artery after retraction

Fig. 25 Kissing stents to resolve occlusion

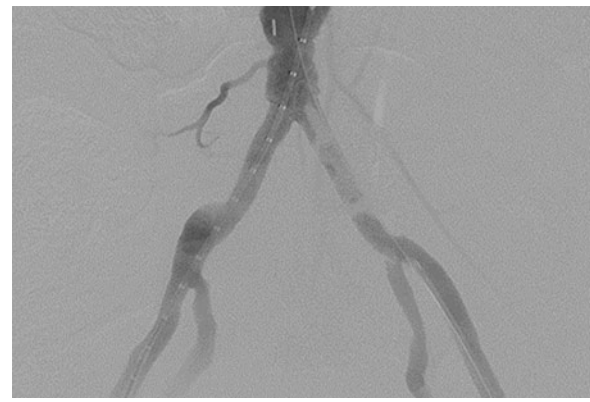

Fig. 26 Restored lumen and flow

The full extent of their limitations and disadvantages are not discussed in detail here but include the inability to fully correct alignment and lordosis, higher risk of neurological injury, higher risk of inadequate disc clearance, and risk of displacement of the prosthesis laterally, posteriorly, or anteriorly. Recognition of such difficult situations may benefit from referral to a high-volume center of excellence for anterior, transperitoneal reconstruction. As discussed below, we have used combined synchronous spinal and vascular surgery to do open vascular and anterior column reconstruction in selected patients. Not only does this provide the opportunity to treat high-risk vascular lesions but also facilitates optimal spinal reconstruction, fusion, replacement, or hybrid procedures from an anterior approach, and we have subsequently published our experience and outcomes with this technique (Scott-Young et al. 2018b).

Another way to deal with lesser disease is to presume a significant risk of dissection and prepare the patient for an endovascular procedure to accompany the main spinal operation as required. When concerned by the vascular appearance perioperatively, a guidewire can be placed via the common femoral artery and placed to the diaphragm on the side considered to be at highest risk. This is usually on the left but depends on the planned approach and the atheroma distribution in the individual patient.

Occlusion occurring by dissection happens at the site of arterial compression and distortion (see Fig. 23). It is possible to check whether there is a high-risk atheroma by carefully palpating the artery before applying the high-grade force needed to manipulate the vessels away from the target intervertebral space.

In addition to dissection and progression to local occlusion, embolization of loose cholesterol or thrombus can occur. This will usually manifest as distal limb ischemia seen as pallor and coolness but often with patchy cyanosis. The emboli can be multiple, small, and fragmented and pulses may be normal at the ankle. There is often little that can be done with this material after the event but surgical intervention, either endovascular or open, may be required to prevent further progression which may be associated with progressive patient decline, possibly culminating with death if enough tissue is compromised.

The frequency of encountering this problem in the increasing number of senior patients with spinal disease has forced us to look at prevention rather than wait until confronted by a white leg with no femoral pulse and severe pain in the postoperative period. When operating on patients with arterial lesions it is critical to have balloons, stents, and stent grafts available to address any complication as soon as it is recognized (see Figs. 24, 25, and 26). This offers much better outcomes than the reported series, where serious limb arterial ischemia from dissection and occlusion has gone undiscovered for days after the index operation. Despite meticulous surgery and preoperative assessment, total unexpected occlusion of a main vessel can occur during surgery in some patients who have minimal vascular disease.

If a previously unrecognized vascular lesion is appreciated intraoperatively, it is advisable to assess further with an on-table angiogram under image intensifier. In this case, an arterial puncture is carried out using duplex ultrasound to minimize risk. A wire and diagnostic catheter can be placed in the aorta to allow general assessment with bilateral obliques as single plane studies may give an inaccurate impression. If the disease is severe, it is sensible to leave the 4F access sheath after the catheter has been withdrawn to allow a further angiogram after the formal spinal surgery has been completed. If the wire is left in situ, it also can serve as a railroad for the deployment of angioplasty balloons and stents if required to resolve dissection and occlusion at a later time. Removal of the wire at completion is a simple matter if intervention has not been required. If a sheath has been required, the site is managed in the usual way. Local pressure for a 4F sheath is used for diagnostics. If a larger sheath has been utilized for intervention, e.g., 6F or 7F, a StarClose™ device is used. Early in our experience with the very calcified vessels we decided to use guidewire placement routinely before opening the abdomen giving a railroad to fix dissection should it occur. With experience we have found we can manage these complex vessels with

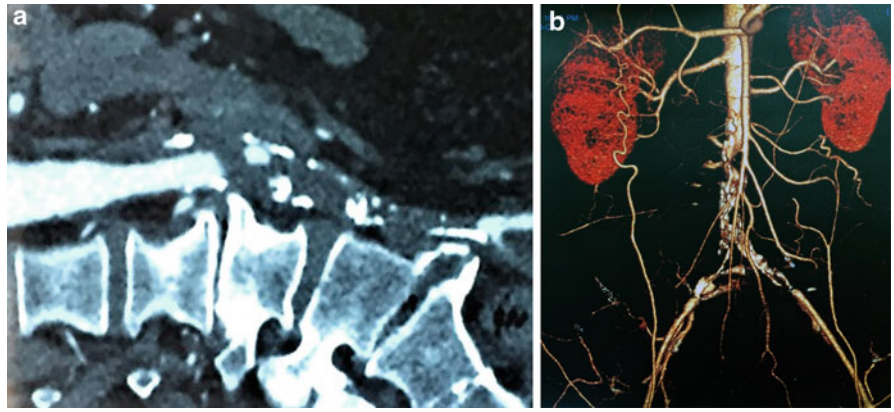

Fig. 27 CT Angiogram examples of an occluded aorta and iliac arteries in sagittal CT and 3D reconstruction modes

limited risk so the use of a pre-emptive wire has been discontinued and we treat if a problem is identified with blood flow obstruction.

Patients with substantial problems of aortic or iliac aneurysms at critical levels or functional occlusion require treatment as a priority above the spinal problem so this needs to be resolved (Fig. 27a, b). From our experience, the anterior approach is significantly superior to other methods we have undertaken, where possible, to proceed with combined synchronous surgical treatment of both problems at the same operation as detailed below (Scott-Young et al. 2018b).

The Rationale for Synchronous Treatment of Concurrent Spinal and Vascular Lesions with the Anterior Approach

When patients with combined pathology were identified, we as spinal and vascular surgeons faced problems from different aspects prior to developing a combined synchronous strategy. For example, the patient might initially present predominantly as a vascular problem with background symptoms related to spinal disease or as a primarily spinal problem with significant vascular disease. In the common case of claudication symptoms, it could be unclear whether it was mainly as a result of spinal pathology, vascular ischemia, or both processes.

Some of these patients had critical vascular problems and should we have had to make a decision for an individual operation, it would have been the vascular surgery which would have "overridden" the spine procedure in importance, in an era where endovascular treatment of AAA was increasingly common. Generally, because of the requirement for a reconstruction with either a complicated stent for the large aortic aneurysms or iliac stenosis or a full aortoiliac or aortofemoral bypass, there would have been great difficulty and significantly increased hazard in attempting an anterior spinal operation subsequently, due to the presence of the reconstruction and significant adhesions. This would leave the patient with residual symptoms from untreated spine pathology.

The other situation was that some patients, with major spinal problems indicating treatment in their own right, were found to also have moderate severity vascular pathology that warranted treatment for prevention of a critical event and the vascular treatment in a staged fashion would make future anterior spinal surgery unsafe. This subgroup of patients were challenging either because of moderate aneurysmal change (4 cm or greater) or extensive atheroma. In these situations, there is an extreme risk of dissection, occlusion, and emboli even in the primary anterior spinal approach setting.

As such, we have developed a multidisciplinary planning and review approach and

this is necessary to inform all options for treatment to the patient, including our offering of an ability to control or repair the vascular disease along with lumbar spine reconstruction under the same anesthetic (Scott-Young et al. 2018b). Considering the need for major spinal reconstruction in someone also affected by moderate to severe vascular disease, we routinely explain the risks of a combined procedure, but that it is feasible to have the benefits of anterior spinal reconstruction if we were to resolve the vascular problem. Open anterior surgery was the best method for the spinal reconstruction notwithstanding the presence of a surgical vascular lesion and, given that vascular reconstruction was possible and indicated using the same exposure, this could potentiate treatment of the vascular lesions as well as excellent access for the spinal reconstruction. This approach also meant less trauma than if the surgeries were carried out independently of each other. We considered that overall there would be less physiological stress to the patient and less overall risk (i.e., from approach-related vessel injuries and adhesions) to the patient if we managed the problems in this way and also it would allow for repair in a group who would otherwise be excluded from the best option for reconstruction of their spine. It should be emphasized, however, that this approach is only undertaken after significant planning and discussion for suitable selected patients with combined disease.

In patients who we have assessed as moderate risk we prepare them for possible intervention at the time of surgery. This may require preparation for an open endarterectomy/thrombectomy (Figs. 28 and 29) if an occlusion occurs after the vessels are forcibly displaced or an angioplasty and stent in some of the higher-risk patients. The vascular surgeon has opted to place a guidewire at the commencement of the

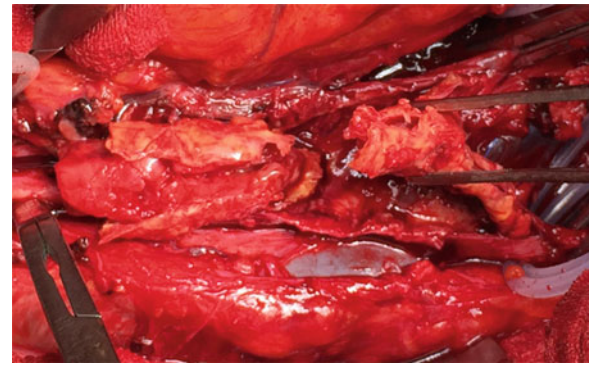

Fig. 28 Endarterectomy

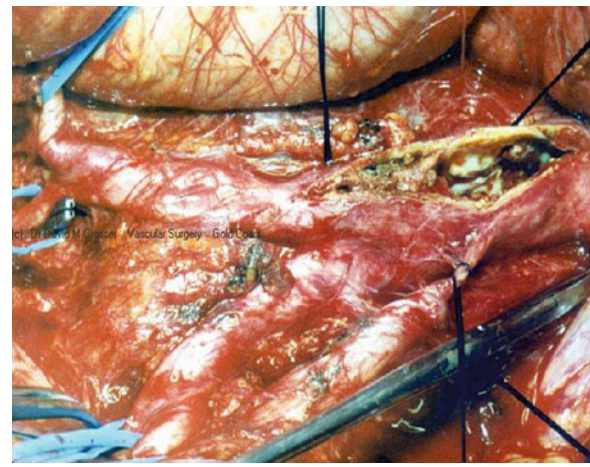

Fig. 29 Aortic iliac atheroma undergoing endarterectomy and thrombectomy

procedure so that we have immediate direct access into the artery.

As the patients required open access to the spine the decision on whether to use open repair for the aneurysms rather than endovascular depended on the fact that this was not more risky than endovascular procedures and, particularly, that in this younger group of patients, open reconstruction would be expected to give a long-lasting and durable result (in my own experience over 30 years) without the continued concern of "endoleak." "Endoleak" can occur in about 10% of endovascular AAA repairs and can present years after the intervention. Some of the vascular lesions we are presented with are extensive and circumferential or of the morphology that would make endovascular treatment difficult (see Figs. 30 and 31). The open approach would also be expected to reduce repeated exposure to CT irradiation and future risk. The same logic applies to management of the extensively diseased occluded aortas with iliac blockages also, where even with covered stent grafts, occlusive complications have been found to occur up to 10–15% with extended follow-up. The longevity with respect to the AAA reconstruction, if the patient survives 30 days postoperatively, is returned to normal.

Lesser vascular conditions require cover for the potential problems likely to occur at the time of surgery. We do this by having a vascular surgeon involved with the planning and risk stratification of selected cases and a plan for resolution if required. Be it an endovascular balloon and stenting of a stenosis or an occlusion associated with a dissection from ruptured plaque or an open endarterectomy or arterial thrombectomy, a vascular surgeon should be available for these contingencies. We are also

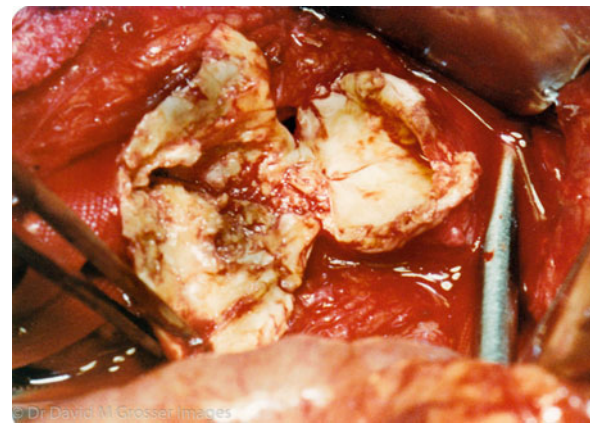

Fig. 30 Extensive circumferential atheroma

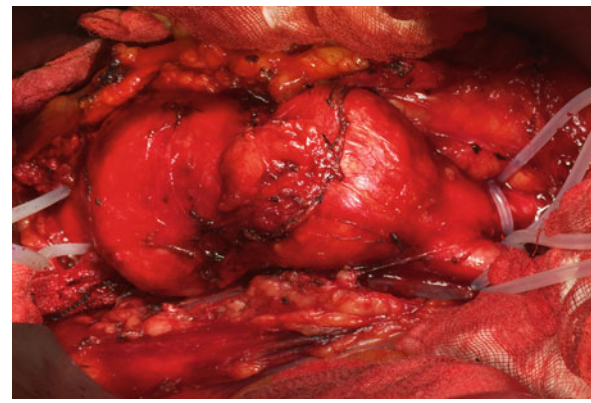

Fig. 31 Large saccular AAA prepared for reconstruction

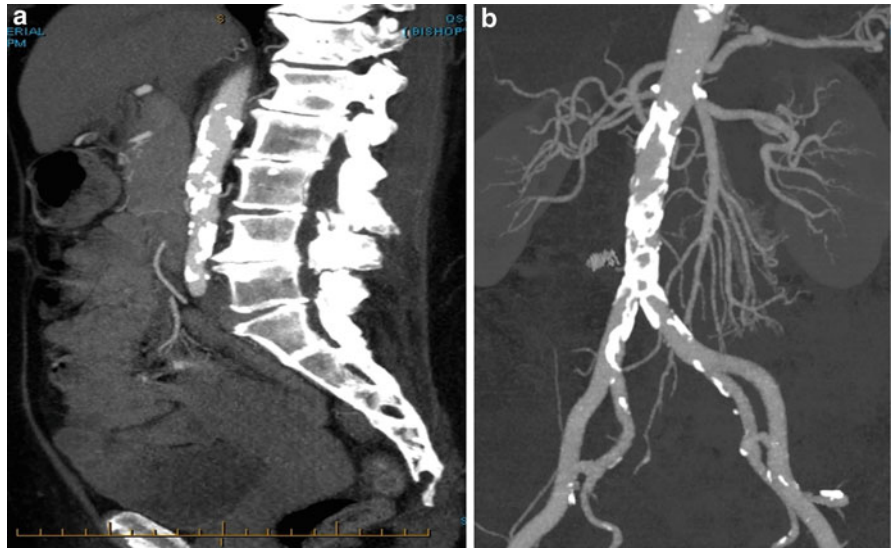

Fig. 32 The patient in this case was carefully approached for a major spine reconstruction but despite the care taken the plaque fractured and two iliacs occluded. This was corrected immediately by bilateral iliac endarterectomy and had no appreciable effect on recovery

prepared to perform an aorto-bi-Iliac or aorto-bi-femoral bypass with Dacron Gelsoft™ graft should a major problem occur (Figs. 32, 33, and 34).

As stated previously, when we are very concerned preoperatively, the vascular surgeon will place an endovascular wire or sheath via the femoral artery up to the diaphragm so that we have

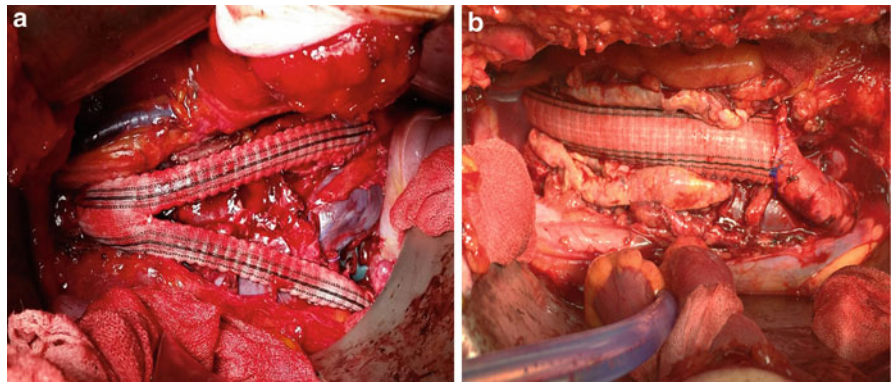

Fig. 34 Examples of aortoiliac treated openly via transperitoneal approach (**a**–**b**) combined with spinal reconstruction

Fig. 35 Left IVC/ duplication – if it is a duplication, it can be divided if the common iliac bridges to the IVC on the right. If it is the sole or main system, it will need to be protected in the same manner as a normal IVC

a direct line for repair. It is just as important for venous control when approaching around the bifurcation at the IVC in redo surgery as there is a significant risk of tears, damage, or compression, which could result in massive bleeding or thrombosis. We have managed these with covered stent grafts when it was not possible to resolve the problem intraoperatively.

Vascular and Renal Anomalies and Variations

Duplication or left inferior vena cava with or without left iliac connection and retro-aortic vein are well described:

- If an angiogram has not been carried out, you might be surprised by a dual IVC, with the left side arising in the same area as the iliolumbar, or by a retro-aortic renal vein.
- Duplication or left IVC (see Fig. 35) can cause problems if not recognized and a standard retroperitoneal approach is used. The bifurcation is such that the best approach to L4-L5 is to the left of the aorta and superior to the left iliac artery. Before ligating this vessel make sure that the right IVC exists or you may create a problem equivalent to an acute vena caval obstruction (Fig. 36).
- A retro-aortic renal vein can cross under the aorta in the L2 or even L2/3 region (Fig. 37a, b) making sideward traction hazardous if not

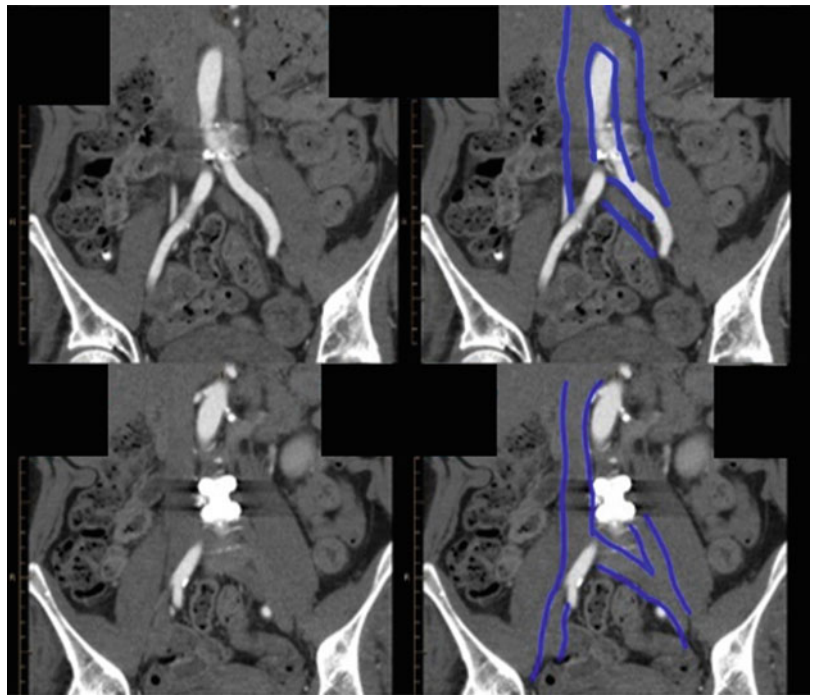

Fig. 36 Duplex IVC with a good left iliac vein; in this case the right IVC can be divided as long as adequate flow in left IVC. Not anticipated as problematic as discs requiring access are at L5-S1 and L3-L4

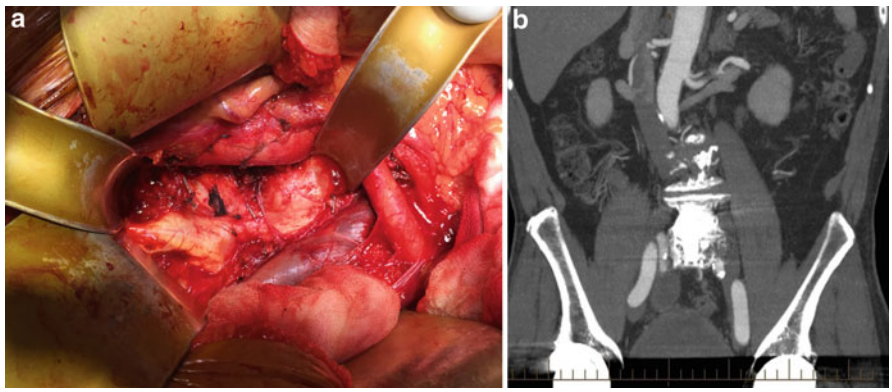

Fig. 37 Clinical (**a**) and coronal CT (**b**) images of a retro-aortic renal vein

recognized and anticipated. Consideration of whether to abandon planned treatment of a higher lumbar level needs to be given if it cannot be safely mobilized.

May-Thurner Effect: Severe Stenosis at Upper Common Iliac Vein Beneath Right Artery

Also known as iliocaval compression syndrome, the left common iliac artery compresses the left iliac vein against the L5 vertebral body. If this affected upper segment of the common iliac is traumatized requiring sutures or transverse clips, further compromise of the vein can occur. External pressure behind the vein after surgery that places plate and screws added to the anterior face of the spine can also limit the vein lumen by additional pressure. This can be resolved with stenting (Figs. 38 and 39).

Occlusion can also occur in this area secondary to emboli from the leg being trapped by the May–Thurner effect. The effect at revision

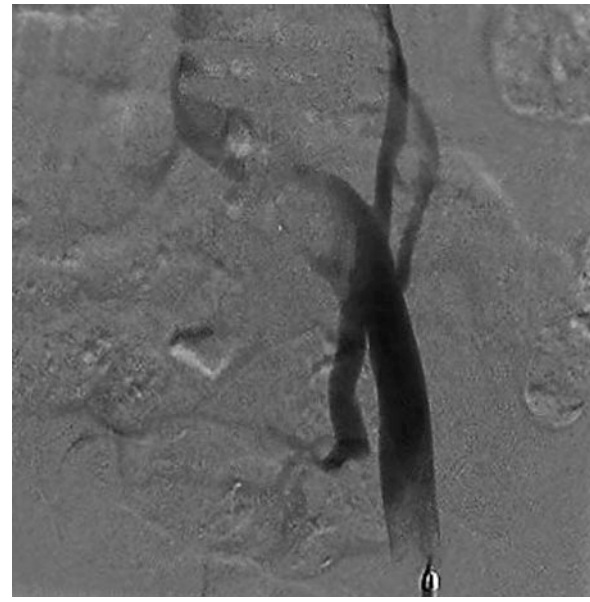

Fig. 38 Post-op external compression of iliac vein

Fig. 39 Normal appearance of left iliac vein after stenting

surgery is a pelvis widely congested by large collateral veins that have developed to divert the venous flow (Figs. 40 and 41). This will make the area between the iliacs much more difficult to dissect and quite hazardous with coils of highly pressurized fragile vessels.

Untreated, the outcome can be chronic stenosis with distal congestion, a swollen leg clinically and the development of large pelvic collaterals (Figs. 41 and 42). A complete occlusion may result with the prospect of permanent stasis effects (Fig. 43).

If recognized, it would be sensible to consider recanalizing and stenting the main iliac venous system prior to any planned anterior spinal surgery as this would resolve the pressure problems and reduce the vascular compromise risk (Fig. 44a, b). The diagnosis might require a 3D CT venous angiogram to adequately assess the venous problem (Figs. 40 and 41).

Fig. 40 3D venous angiogram demonstrates massive pelvic collateral shunts after left iliac thrombosis

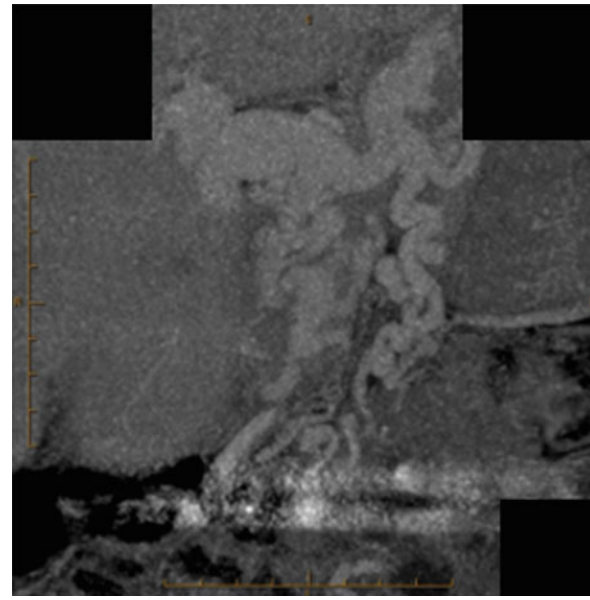

Fig. 41 Massive pelvic venous collaterals demonstrated on CT angiogram

Portal Vein Occlusion with Hypertrophy and Portal Hypertension

Other pathologies that cause significant intra-abdominal venous congestion include cirrhosis and portal vein occlusion and rare problems such as large portal vein aneurysms. These can substantially increase the hazard of the transperitoneal approach. If portal venous hypertension is recognized preoperatively it may be more appropriate to re-approach retroperitoneally in the revision setting.

Renal Anomalies: Low Lying or Horseshoe Kidneys

As well as the study of vessels on preoperative imaging, care should be taken to ensure that there are no renal anomalies that could make access dangerous or difficult. Examples of these are horseshoe kidneys that can obscure anterior access to the great vessels and low lying kidneys which often have associated anomalous vessels and pedicles that could be injured in the course of a standard retroperitoneal approach

Fig. 42 Example of occluded iliac veins presenting with major leg swelling and stasis from iliac DVT 2 years after anterior spine surgery. The patient had been told nothing could be done to assist. Following treatment, the patient now has a patent vein system and normal functional leg

(see Fig. 44a, b). Preoperative consultation with a renal physician and determination of the differential function of each kidney is wise. In this case, a transperitoneal may be preferred to ensure that the renal pedicles do not undergo torsion as a result of the approach.

Postoperative Care

A team approach involving hospital medical staff and well-trained spinal nursing staff is important for prompt review of events related to anesthetic complications, hemodynamic instability, vascular events or neurological insult. Aggressive rehabilitation and specialty physiotherapy need to be involved preoperatively as well as postoperatively to guide and motivate the patients through appropriate perioperative conditioning, mobilization, and in-bed exercises to achieve optimal outcomes and restore functional motion. Judicious postoperative analgesic use is important to be run in conjunction with anesthesia, having regard from the often complex preoperative analgesia regimes these patients present with.

Ward care anticipating problems with anterior surgery is critical. Having an algorithm to manage ileus that commonly results with transperitoneal approach is helpful with regard to diet and fluid balance. For uncomplicated retroperitoneal surgery, a light diet is resumed the day following surgery. Close monitoring of the wound, patient pain control, and appropriate correction of any abnormalities in the patient's laboratory profile help to avoid complications. We aim to remove all drains and tubing (e.g., Painpump™, surgical drains) as soon as possible and complete only a short course of prophylactic intravenous antibiotics. An incentive spirometer is routinely provided as the pain from abdominal surgery can lead to splinting and atelectasis.

Regarding DVT prevention, we utilize low molecular weight heparin, mechanical calf measures and encourage high patient movement as an inpatient with outpatient aspirin and exercise prescribed until follow-up. 100 mg aspirin is prescribed as an outpatient until the first postoperative review.

We then monitor the patient routinely from a spinal point of view for follow-up then with close follow-up with a vascular surgeon for high-risk vascular patients. This includes not only radiological assessment to verify the efficacy of the correction performed but also clinical (outcome scores) and neurological (EMG) follow-up.

Conclusion

Anterior surgery for reconstruction of spine and related disorders is a vital approach to have in a surgeon's armamentarium. A variety of disorders such as degenerative, deformity, trauma, infection, and tumor can be best treated with the anterior exposure of the spine. The approach requires experience to achieve proficiency on the volume-performance curve and, in general, it is wise to have a close working relationship with a vascular surgeon.

Challenges and Lessons from Commercializing Products

Approved Products in the USA: AxiaLIF 65

Franziska Anna Schmidt, Raj Nangunoori, Taylor Wong, Sertac Kirnaz, and Roger Härtl

Contents

Abstract

Axial lumbar interbody fusion (AxiaLIF) was a device used to treat instability and disc degeneration in L4-L5 and L5-S1. Through a para-coccygeal incision and presacral approach, muscular and ligamentous dissection could be avoided. The discectomy and instrumentation was performed through via trans-sacral rod. AxiaLIF was approved in 2004 through a 510 (k) clearance from a predicate device which was an anterior thoracolumbar plate for trauma and deemed a class 2 device with a moderate risk to the patient. While early studies had encouraging results in terms of fusion rates and improvement in clinical outcome measures, most also had a conflict of interest. As the technology was rapidly adopted, the first reports of complications which were visceral injuries emerged casting doubt onto its effectiveness. Only a handful of studies focused on the long-term fusion rate, restoration of lordosis, and indirect decompression. In retrospect, it is apparent that the 510 (k) clearance and classification of the device was incorrect because the predicate was not substantially equivalent to the existing device. The experience with AxiaLIF provides a cautionary tale about new technology – that it should be safe, clinically effective, and have long-term data prior to rapid adoption.

The Parabolic Phenomenon of a Surgical Technique

Innovation is an essential part of advancing patient care (Riskin et al. 2006; Scott 2001). All innovations at some point in time are new; the challenge is to differentiate what is safe from unsafe. The parabolic phenomenon of technological advancement was characterized by Scott et al. and starts with widespread enthusiasm and media coverage on the basis of early case studies. This provides confidence and leads to the rapid adoption of new technology as the next standard of care. As negative reports emerge, the initial enthusiasm disappears as the new device is used in gradually limited circumstances and ultimately, falls into disuse. According to this phenomenon, as complications emerge, surgeons must react quickly to warrant patient safety (Hamilton et al. 2012). In conclusion, the challenge is to introduce new devices and technologies in a way that would flatten this parabolic phenomenon and identify unsafe devices early on with no or minimal exposure to patients.

AxiaLIF as an Example for the Rise and Fall of an Approved Product in the USA

Axial lumbar interbody fusion (AxiaLIF) (Fig. 1) was FDA-approved in 2004 through a 510 (k) clearance (Rapp et al. 2011). The predicate was the K-Centrum Anterior Spinal Fixation System, which was an anterior thoracolumbar plate and screw system for trauma and degenerative spinal disease and deemed substantially equivalent.

In contrast to the predicate system, however, AxiaLIF was a novel para-coccygeal approach to the L5-S1 disc space for interbody fusion through a paracoccygeal incision. The purported advantages over traditional surgery included avoidance of neural retraction and access to the disc space for interbody fusion without muscular and ligamentous dissection. This device was FDA approved for the treatment of degenerative disc disease and spondylolisthesis at levels L4-L5 and L5-S1 (Marotta et al. 2006). Importantly, this approach was seen by early adopters as an attractive option for fusion surgery in patients who had contraindications for traditional ALIF surgery at L4-5 and L5-S1. In addition, AxiaLIF was the first true minimally invasive option (MIS) for the L4-5 and L5-S1 levels as MIS approaches gained popularity with techniques such as lateral lumbar interbody fusion (LLIF). The advent of LLIF was in parallel with MIS approaches to spinal deformity correction; however, direct lateral access to L5-S1 had not yet been described. As a result, the presacral approach from AxiaLIF was an attractive alternative (Anand et al. 2008, 2010, 2014a, b; Boachie-Adjei et al. 2013). In retrospect, it is clear that the AxiaLIF had little in common with its predicate – a thoracolumbar anterior plate system. As described in Scott's parabolic model (Hamilton et al. 2012), the first studies were favorable – but most of them were retrospectively designed and included technical publications and retrospective case series touting the safety and efficacy of the approach (Fig. 2). The case series were promising because of the surgical corridor which obviated the need for an access surgeon, lack of critical structures in the presacral space, decreased operative time, and blood loss (Marotta et al. 2006; Aryan et al. 2008). This initial enthusiasm, driven by the results of several case studies, the presumed advantages, and the possibility for an MIS approach for fusion at the caudal lumbar levels in patients whom traditional approaches were contraindicated led to adoption of the technique by many surgeons. In 2010, the first case report describing a complication was published on a patient who suffered from a rectal injury during an AxiaLIF procedure at L5-S1, which led to an ileostomy (Botolin et al. 2010). In 2011, surgeons witnessed cases of failed multisegment AxiaLIF instrumentation. Revision strategies for AxiaLIF were, therefore, developed and were performed via anterior and posterior approaches (Hofstetter et al. 2011). In the same year, a group of surgeons published their experience after a 34-month follow-up with 68 patients who underwent AxiaLIF

surgery. The overall complication rate was high at 26.5%, ranging from rectal perforation (2.9%), infection (5.9%) to pseudoarthrosis (8.8%). In contrast to the early case series, the authors had no conflict of interests (Lindley et al. 2011). In 2012 and 2013, numerous studies reported after AxiaLIF diminished disc height compared to the preoperative status as well as a loss of segmental lordosis. In these publications, pseudoarthrosis rates were high and mounting evidence from the spinal deformity literature was suggestive of the importance of lordosis, particularly at L4-5 and L5-S1 for sagittal balance, independent of fusion rates (Marchi et al. 2012; Hofstetter et al. 2013; Anand et al. 2014c). Due to improvement in some pain scale metrics (Oswestry Disability Index, Visual Analog Scale), the use of AxiaLIF continued despite a growing body of evidence demonstrating visceral complications, pseudoarthrosis, loss of lordosis, and technical reports describing revision strategies for failed AxiaLIF. For instance, some publications reported a decrease in back and leg pain with follow-up ranging from 2 to 6 years (Zeilstra et al. 2013; Tobler et al. 2013). Furthermore, a systematic literature review from 2015 demonstrated that AxiaLIF had a fusion rate of 93.15% (Schroeder et al. 2015). Interestingly, despite high fusion rates and improvement in pain scores, the authors of this systematic review concluded that AxiaLIF had a high complication rate (12.9%) and that the published literature on AxiaLIF was dominated by retrospective case series with many having conflicts of interest (Fig. 2). Follow-up of patients from the initial publications demonstrated that in long constructs for adult spinal deformity, AxiaLIF was not a good choice and an Anterior Lumbar Interbody Fusion (ALIF) was substantially better at L5-S1. The reported complication profile, morbidity of the approach, failure to achieve lordosis, and mounting evidence of need for revision surgery ultimately led to the demise of AxiaLIF (Anand et al. 2017, 2018) (Fig. 3).

L5/S1 Surgery Goals:
- Study without presenting data on fusion rates, restoration of lordosis, or indirect decompression.
✓ Study, which is presenting data on fusion rates, restoration of lordosis, or indirect decompression.

Fig. 3 Figure demonstrating whether AxiaLIF study presented data on fusion rates, restoration of lordosis, or indirect decompression

incidence, lumbar lordosis, sacral slope, and pelvic tilt were not primarily examined. In the early years of AxiaLIF, a series of company sponsored meetings were organized and the "Association of Presacral Spine Surgeons" was established with the idea of bringing together surgeons who were interested in this novel presacral approach. One of the authors of this present chapter (RH) remembers

a meeting in 2009 when the presented cases clearly showed adequate fusion but the absence of lordosis and lack of restored disc height at L5/S1. This led to heated discussions among the contestants. Ironically, AxiaLIF emerged as a surgical technique at the same time that the influential work by Glassman et al. established the significance of lumbar lordosis to long-term patient outcomes, which began an era of investigation into global spinal alignment parameters (Glassman et al. 2005). Since 2012, and after several years of thorough follow-up, one of the initial authors of AxiaLIF (NA) utilized national seminars to repeatedly caution against using AxiaLIF at the bottom of long constructs for cases of adult spinal deformity. The limitations with the AxiaLIF technique were published by the same author (NA) in 2014 (Anand et al. 2014c). It is now understood that these global metrics may be substantially more important to patient outcomes than high fusion rates alone.

The rise and fall of an approved product in the USA such as AxiaLIF is a great example demonstrating the necessity for constant follow-ups, reflection, timely reporting, the recognition of a significant complication profile, and the failure to address sagittal alignment parameters, which were beginning to be understood as an increasingly important surgical goal, especially at L4/5 and L5/S1 (Schroeder et al. 2015). The predicate for AxiaLIF was the K-Centrum Anterior Spinal Fixation System, a device that was not equivalent to AxiaLIF in terms of the type of implant or access corridor, but received 510 (k) clearance anyways, demonstrating a loophole in the approval process. In retrospect, AxiaLIF should have been mandated as a class 3 device with an attention to safety, subsidence, indirect decompression, restoration of lordosis, and fusion rate.

Conclusions

The lesson to be learned from this failed product is that rapid adoption is not advisable unless independent groups can verify the data obtained by studies that may have conflicts of interest. For instance, Bisschop et al. described that the market approval process for all new spinal device implants should include at least one randomized controlled trial (Bisschop and van Tulder 2016). If favorable results are reported, this randomized controlled trial should then be repeated by different investigators and compared to the standard surgical device or product. In addition, Bisschop's publication also advocated for multi-institutional follow-up for at least 5 years to track long-term outcomes. In the case of AxiaLIF, one group of surgeons followed the recommendations outlined by Bisschop et al. and found that it was not an optimal device during long-term follow up with their patients, despite promising early results (Anand et al. 2008, 2010, 2013, 2014a, b, c, 2017, 2018).

The experience with AxiaLIF provides a cautionary tale about the enthusiastic adoption of new technology. New technology should be safe, clinically- and cost-effective, improve patient outcomes, and at least match the standard of care. Long-term data characterizing safety and effectiveness, without conflicts of interest, are essential. In addition, it also demonstrates that the goals of surgery may evolve and shift over time. When this occurs, the technology should undergo a thorough evaluation to determine whether it fits in the current clinical framework. In the case of AxiaLIF, our understanding of the importance of global sagittal alignment parameters and indirect decompression had significantly advanced by the time AxiaLIF was being utilized. The failure of AxiaLIF should not hamper innovative surgical techniques – but does provide lessons into the importance of long-term data and the duty of surgeons to ensure patient safety and outcomes (Bisschop and van Tulder 2016; Herndon et al. 2007) (Figs. 2 and 3).

Contents

Abstract

The spine product market in the United States and that of the rest of the world shares many similarities but also has significant differences. The FDA approval process of medical devices in the United States has a more stringent, often inconsistent, and prolonged pathway to final approval than when compared to the CE marking process in Europe. In fact, a large number of spinal implants have not yet been either approved or used as widely in the United States as compared to the rest of the world. There are three main spine product categories, namely lumbar artificial discs, interspinous spacers, and dynamic stabilization systems that can be identified as "new" and not as widely used in US markets. After analyzing why some of the products in these categories failed the FDA approval process, we present other unique spine products widely used in European and other international markets but not so commonly seen in US markets.

Introduction

Spinal pathology is one of the most common health problems patients face in North America. Management of such pathology is associated with increasingly high healthcare costs (Raciborski et al. 2016). While the aging population is an important factor associated with these costs, another contributing factor includes the market approval process of spinal implants. According to a recent study in 2017, the global spinal product market is valued at over $14.4 billion USD and is projected to reach $18 billion USD by 2023 (https://idataresearch.com/product-category/spine/). The United States, with its vast medical resources and large population of spine surgeons, is undoubtedly the largest spinal product market, valued at $7.7 billion USD in 2017. In contrast, the European spinal market's total value is just over one-quarter the size of the US at $2.05 billion USD. Interestingly, China is the fastest growing market and, as of this writing, has surpassed the combined market value of 15 countries in Europe at $2.73 billion USD (https://idataresearch.com/product-category/spine/). The purpose of this chapter is to focus on the spine product market in the United States and highlight the differences with those of the European and international markets.

Given the enormous economic impact of spinal products in the healthcare systems of both the United States and Europe, it is imperative to understand the differing spinal products that are available for use in both continents. Additionally, an appreciation of the subtle differences in the approval processes of medical devices in the United States compared to Europe, and an analysis of why some products failed the US Food and Drug Administration (FDA) approval process, will provide further insight into the underlying differences between the two continents.

For the purposes of this chapter, we will focus on three specific spinal product categories: dynamic stabilization systems, artificial intervertebral discs, and interspinous and interlaminar stabilization/distraction devices. These categories were specifically chosen because of the relatively sparse usage of such devices in the US market when compared to the European and other international markets. Each of these product categories has specific examples of products that are either not widely used in the United States or not even approved at all by the FDA. In order to understand why certain products are not available in the US market whereas the same products have been widely used in Europe for many years, a thorough understanding of medical device regulations is important.

Therefore, we will first describe the FDA approval process of such spinal implants and compare and contrast it with respect to the European medical device regulatory process. We will then specifically discuss three case studies of spine products (the Dynesys® Dynamic Stabilization System, the Barricaid® Annular Closure Device, and the DIAM® Spinal Stabilization System) that failed to meet the rigors of the FDA approval process and shed light on the circumstances that led to their failure. Lastly, we discuss products that are not yet approved by the FDA in the United States but are widely used in the European and other international markets. Although there are a myriad of financial, regulatory, and clinical factors that contribute to the differing spine products in use among the US and European markets, we will attempt to highlight three case studies of spine products currently only approved in the European market: the M6®-L Lumbar Artificial Disc, the Helifix® Interspinous Spacer System, and the LimiFlex™ Spinal Stabilization System.

FDA Approval Process Compared to the European Process

From the standpoint of the FDA, medical devices are categorized into three regulatory classes (Sastry 2014). The medical devices that have the lowest risk of causing harm (i.e., thermometers, tongue depressors) are categorized as Class I medical devices. Devices that have some potential harm (i.e., powered wheel chairs, pregnancy test kits) are categorized as Class II medical devices and typically require premarket notification 510(k). Class III devices present significant risk and most require premarket approval (PMA) (Sastry 2014).

Most spinal products fall under Class II and Class III designation.

When a device manufacturer submits a 510(k) premarket notification, the manufacturer must demonstrate that the device is at minimum as safe and as effective ("substantially equivalent") to another already existing legally marketed device ("predicate device") (Rome et al. 2014). In their submission documents, the device companies must compare their device to the predicate device and demonstrate substantial equivalence. In order to meet the requirements of "substantial equivalence," the device must have the same intended use as the predicate device but not necessarily the same technological characteristics (as long as the device does not raise new questions of safety and effectiveness) (Rome et al. 2014).

The Premarket Approval (PMA) process is usually required for devices that pose a significant risk of illness or injury (i.e., Class III devices) or even devices that were found not substantially equivalent to Class I or Class II predicate devices through the 501(k) process (Lauer et al. 2017). Typically, the PMA process occurs in four steps: limited scientific review, in-depth review, advisory panel review, final deliberations and decisions for previously unapproved devices (Lauer et al. 2017). During the limited scientific review part of the process, the FDA will decide whether or not to file the submission at all; instance in which the FDA will refuse to file a submission are not uncommon. If information is incomplete, unclear, or would not stand up to scientific scrutiny, the FDA may refuse to even go forward with filing. During the in-depth review part of the process, the agency will evaluate the device's safety and effectiveness (French-Mowat and Burnett 2012). Safety and efficacy are typically demonstrated through clinical trials and scientifically validated research. The key difference of the European approval process with that of the US is the focus on "efficacy" (French-Mowat and Burnett 2012; Sorenson and Drummond 2014). As we will see later, the European approval process is predicated on safety but not necessarily "efficacy." The third step is the advisory panel review, which consists of a panel of experts independent of the FDA that hold a public meeting. After conclusion of the meeting, the advisory committee submits a final report to the FDA. In the fourth and final step, the FDA will issue either an "approval order," an "approvable letter," a "not approvable letter," or an order denying approval (French-Mowat and Burnett 2012; Sorenson and Drummond 2014).

Often, in order to gather safety and effectiveness data to support a PMA application or a 501(k) submission, the FDA can grant an investigational device exemption (IDE) to a medical device. An IDE allows the investigational device to be used in a clinical study (Ament et al. 2017). Therefore, some of the products that we will discuss later on in the chapter are currently being used under an investigational device exemption until further data can be obtained.

In contrast to the FDA medical device approval process, the CE Mark is a certification mark that indicates conformity with health, safety, and environmental protection standards for products sold within the European Economic Area (EEA) (Mishra 2017). The key difference between the US and European approval processes lies in a device's "efficacy." In the US approach, the FDA assesses the device's effectiveness as well as its risk of harm; however, the CE mark indicates simply that the medical device satisfies certain high safety, health and environmental protection requirements (Mishra 2017). In short, the FDA approval process ensures that a device both poses no harm to consumers but also does what it claims to do. The US approach is not without its critics, who argue that this dual goal of "safety and efficacy" adds inordinate time and unpredictability to the approval process without in fact establishing the effectiveness of the device (Heneghan and Thompson 2012).

With its unpredictable, inconsistent, prolonged, and often expensive path, the FDA's approval process is widely considered more cumbersome than the CE marking process (Heneghan and Thompson 2012). Typically, there is a 1- to 3-year delay in launching new medical devices into general clinical practice in the US compared to in Europe according to a 2012 report by the Boston Consulting group after analyzing approvals from 2000 through 2011 of devices

that were "the most innovative and potentially risky medical technologies" (those requiring PMA) (Kramer et al. 2012). Nevertheless, while the CE mark may be less arduous to obtain, some argue that it is a less powerful certification (Mishra 2017). Especially after the widely publicized breast implant scandal of the early 2000s, in which a French company sold silicone implants (which had CE mark approval but not approved by the FDA) that were later recalled after it was found they had been fraudulently manufactured with unapproved silicone gel, the FDA approval process is sometimes seen as safer for consumers (Lampert et al. 2012). Interestingly, the FDA approval means that the device is approved for use in many parts of the world, while the CE mark has restrictions, sometimes even within the EU. Importantly, even though a medical device has a CE marking, there is no guarantee that the device will be widely accepted by physicians or reimbursable by the government in each European country (https://www.ecnmag.com/article/2012/02/which-way-go-ce-mark-or-fda-approval).

Case Studies of Failed Spinal Products in the United States

Having established the important differences and similarities of the medical device approval process between the United States and Europe, we now turn our discussion to three specific spinal products that failed the FDA approval process: Dynesys® Dynamic Stabilization System (Zimmer Biomet), Barricaid® Annular Closure Device, and the DIAM® Spinal Stabilization System.

Before a discussion of Dynesys or any other pedicle screw-based dynamic stabilization systems can be had, the principle of dynamic stabilization must be described. Dynamic stabilization, also known as soft stabilization or flexible stabilization, involves insertion of flexible materials rather than the traditional rigid ones to allow some movement along the instrumented area of the spine (Tyagi et al. 2018). Essentially, dynamic stabilization devices place the posterior structures under tension and create a focal increase in lordosis. This process may shift load transmission so that certain positions are more tolerable and may limit motion so that painful positions are not experienced (Gomleksiz et al. 2012). As of this writing, no dynamic stabilization devices have received approval from the FDA for use other than as an adjunct to spinal fusion. Once of these dynamic stabilization systems, the Dynesys® Dynamic Stabilization System by Zimmer Spine, was not granted a PMA initially by the FDA for standalone dynamic stabilization and then later was only approved as an adjunct to spinal fusion.

According to the FDA, the Dynesys® Dynamic Stabilization System is intended to "provide immobilization and stabilization of spinal segments as an adjunct to fusion in the treatment of and following acute and chronic instabilities or deformities and failed previous fusion" (https://www.accessdata.fda.gov/cdrh_docs/pdf6/K060638.pdf). The device consists of a titanium alloy pedicle screw and a spacer that consists of surgical polyurethane that holds the vertebrae in a more natural anatomical position; a nylon-like cord runs through the spacers and is pulled taut to limit flexion movements (see Fig. 1) (Dynesys Dynamic Stabilization System 2015).

Initially, Dynesys was granted a 501(k) clearance in March 2004 since it was considered to be "substantially equivalent" to the Silhouette® spinal fixation system. However, the Dynesys system as a standalone device for non-fusion stabilization was later recognized by the FDA as a new type of treatment, and consequently Zimmer Biomet had to apply for a PMA. On the 4th of November 2009, the PMA application for this device was rejected (https://medtech.pharmaintelligence.informa.com/MT028146/Panel-Rejects-Zimmers-Dynesys-Spine-Stabilization-Device).

The Dynesys system was rejected by the FDA despite initially being granted a 501(k) approval. Although the Dynesys system was considered to be substantially equivalent, it should have been regarded as a new dynamic stabilization technique as opposed to a new type of posterior technique (Bisschop and Van Tulder 2016). The Dynesys system thereby received its 510(k) approval long before the first and only randomized control trial was conducted (Bisschop and Van Tulder 2016).

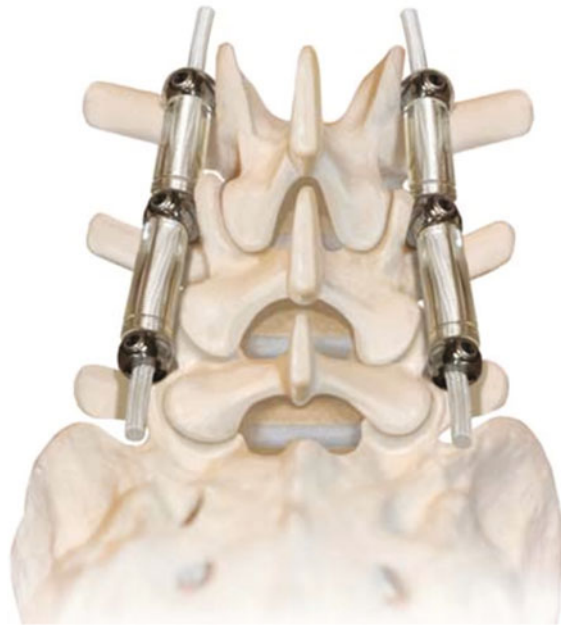

Fig. 1 Dynesys device with titanium pedicle screws, polyurethane spacers and nylon cord the limits flexion (Dynesys Dynamic Stabilization System 2015)

During this time period where there was little published research, the device was in clinical use in Europe since 1999 with over 40,000 patients receiving implants. Consequently, there was not enough evidence in the period between the 510(k) approval and the rejected PMA application to determine whether this device resulted in improved health outcomes compared to standard treatments (Bisschop and Van Tulder 2016). Indeed, short-term clinical results seemed favorable, while long-term complications arose: screw loosening, adjacent segment degeneration, late infection. In a 2010 study of 71 patients undergoing decompression using the Dynesys stabilization system, radiographic evidence of screw loosening occurred in 19.7% of patients (Ko et al. 2010). Of note, the radiographic findings of screw loosening failed to show any associated adverse effect on clinical improvement. The FDA reviewers also pointed to potential bias in the company's study, noting that a majority of patients were treated by researchers with a financial interest in the company. Admittedly, this bias could have been due to chance which would further question the relevance of such a bias claim (Ko et al. 2010).

Another example of a spinal product that failed the FDA's PMA process is the DIAM® Spinal Stabilization System by Medtronic. The device is an "H" shaped silicone and woven polyester device which is sandwiched between two adjacent spinous processes of the lumbar spine (see Fig. 2) (Phillips et al. 2006; DIAM™ 2019).

Once seated in the interspinous space, the device is secured by polyester cables and titanium crimps. This design helps stabilize movement in both flexion and in extension (Phillips et al. 2006). Medtronic described to the FDA that the device was intended to alleviate pain "through the reduction of stresses on the overloaded posterior disc and facet joints," while it "re-tensions the supraspinous ligament and other ligamentous structures" (https://www.fda.gov/downloads/AdvisoryCommittees/CommitteesMeetingMaterials/MedicalDevices/MedicalDevicesAdvisoryCommittee/OrthopaedicandRehabilitationDevicesPanel/UCM486374.pdf). It was first implanted in France in 1997 and has been used for more than 10 years outside the United States (Hrabálek et al. 2009). However, on February 19, 2016, the FDA's orthopedic and rehabilitation devices advisory panel unanimously recommended rejection of Medtronic's DIAM® spinal stabilization implant (https://www.fiercebiotech.com/medical-devices/fda-advisory-panel-votes-against-recommending-approval-medtronic-spine-implant).

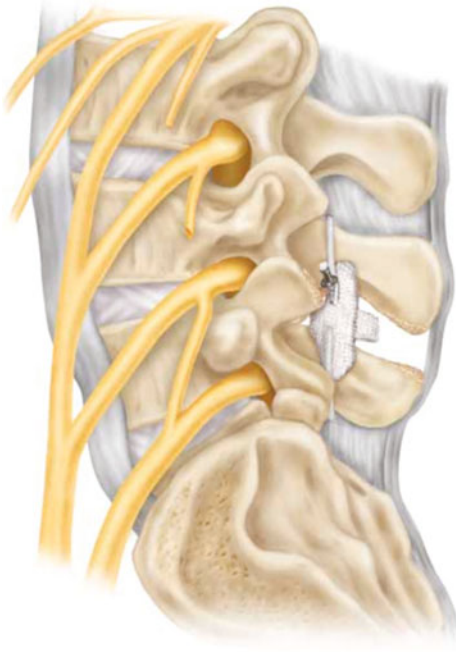

Fig. 2 DIAM® Spinal Stabilization System (DIAM™ 2019)

According to the analysis of the pivotal clinical trial, the FDA expressed significant concerns with the study design. The study population was too heterogenous; there were multiple, potential diagnostic subgroups included in clinical trial. Some of the investigational and nonoperative control subjects were subsequently treated with surgery at adjacent levels, or surgery involving more than one spinal level (https://www.fda.gov/downloads/AdvisoryCommittees/CommitteesMeetingMaterials/MedicalDevices/MedicalDevicesAdvisoryCommittee/OrthopaedicandRehabilitationDevicesPanel/UCM486692.pdf). Furthermore, the screening algorithm was also questioned. It was unclear how a symptomatic level was identified in subjects with multilevel degenerative spinal pathology, whether if subjects had subacute versus chronic degenerative spinal pathology, or if subjects were experiencing primary versus recurrent low back pain. Moreover, some patients randomized to the DIAM® group were allowed to undergo the same nonoperative treatments as the control group. Investigational and nonoperative control patients were also free to pursue non-prescription therapies such as massage and acupuncture. In addition, 60.8% of all of the nonoperative control patients crossed over to receive treatment with the DIAM® investigational device after at least 6 months of treatment lending itself to potential bias on the estimate of the treatment effect (https://www.fda.gov/downloads/AdvisoryCommittees/CommitteesMeetingMaterials/MedicalDevices/MedicalDevicesAdvisoryCommittee/OrthopaedicandRehabilitationDevicesPanel/UCM486692.pdf).

Perhaps the most controversial of the list of concerns that the FDA had were the observed radiographic spinous process erosions and fractures. In the pivotal study, a total of 44.0% (37/84) of subjects were observed to have had an erosion at either the superior or inferior spinous process (or both locations) at 36 months (Crawford et al. 2013). Superior spinous process fractures were observed by the core laboratory in 7.7% (14/181) of the DIAM® subjects at the 12 months timepoint (Crawford et al. 2013). Medtronic representatives pointed to the fact that published literature has documented that plain radiographs may lack sensitivity for the detection and diagnosis of spinous process fractures in subjects with interspinous process spacer devices (https://www.fda.gov/downloads/AdvisoryCommittees/CommitteesMeetingMaterials/MedicalDevices/MedicalDevicesAdvisoryCommittee/OrthopaedicandRehabilitationDevicesPanel/UCM486692.pdf). Despite numerous appeals by Medtronic, the DIAM® Spinal Stabilization System is currently only approved for use as an investigational device until further data can be obtained.

Finally, our discussion of case studies of FDA medical device approval failures will end on the Barricaid® annular closure device. The Barricaid® annular closure device is a permanent implant that is used after a limited lumbar discectomy is performed. The device consists of a polymeric mesh that sits in the posterior intervertebral disc space and is connected to a metallic anchor that is attached to the vertebral body and essentially blocks an opening in the anulus, thereby preventing re-herniation of the nucleus pulposus (see Fig. 3) (Parker et al. 2016; Hahn et al. 2014). The device is particularly effective in patients in whom a limited discectomy is performed with resulting large annular defects and a higher chance of re-herniation. More specifically,

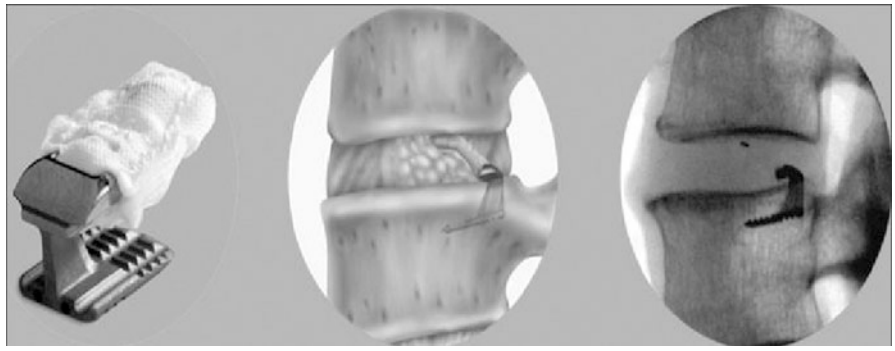

Fig. 3 A metal anchor is inserted parallel to the surface of the endplate and the polymeric mesh forms a barrier that prevents re-herniation of the intervertebral disc (Hahn et al. 2014)

it was indicated in patients with radiculopathy (with or without back pain), a posterior or posterolateral herniation, characterized by radiographic confirmation of neural compression using MRI, and a large annular defect (e.g., between 4 and 6 mm tall and between 6 and 12 mm wide) determined intraoperatively post discectomy, at one level between L4 and S1 (Hahn et al. 2014).

Barricaid's company, Intrinsic Therapeutics, initially submitted an Investigational Device Exemption (IDE) to start a clinical trial in the United States but the IDE was never approved due to safety concerns, so the company performed clinical trials outside of the United States (OUS), including a randomized clinical trial (RCT), to support initiation of a US clinical study (Ledic et al. 2015). FDA and Intrinsic therapeutics never reached consensus on OUS study design, associated protocols, or documents, but the RCT clinical data and nonclinical studies were submitted in a PMA (Ledic et al. 2015). The clinical trial included 554 randomized patients (Klassen et al. 2017). Its purpose was to determine whether a microdiscectomy with a bone-anchored annular closure device resulted in lower re-herniation and reoperation rates and increased overall patient clinical success, when compared to traditional lumbar discectomy without defect closure. The group treated with Barricaid had significantly lower rates of re-herniation (12% vs. 25%, $P < 0.001$), reoperations to address recurrent herniation (5% vs. 13%, $P = 0.001$), and index-level reoperations (9% vs. 16%, $P = 0.01$). However, one main criticism was the high rate of end-plate lesions in the Barricaid group. Eighty-eight percent of the patients receiving Barricaid had endplate changes versus 40% of control patients. The control patient's changes were smaller on average and appeared to stabilize sooner than the Barricaid patient's changes. The Barricaid endplate changes were larger and had a distinctive radiographic feature – according to the FDA's radiologist. Furthermore, some of these endplate changes were lytic in nature and were radiographically distinct from Schmorl's nodes and endplate changes. Furthermore, there were also device integrity issues in the clinical study. The study collected data on 63 implant and instrument retrievals during the study and commercial use and found that the average retrieval was 2.4 ± 1.8 years (Range = 0.1–5.8 years) after implantation (Ledic et al. 2015). The implant was removed primarily due to mesh detachment, migration, new or worsening pain, and/or instability (Ledic et al. 2015). For all these concerns, the FDA panel voted on December 2017 against approval.

Spine Products Approved Outside the United States

After having discussed those products that have failed the FDA approval process, we now turn our attention to those products that are widely used in the European market but not yet approved or widely used in the United States. There are three categories of spinal implants that are currently used widely in the European and other international markets but for a myriad of reasons are not so commonly seen in the US markets: lumbar artificial

Table 1 Lumbar artificial discs

Device name	FDA approval	Manufacturer

Aperius™-PercLID™ System	No	Medtronic
FLEXUS™	No	Globus Medical
Wallis® System	No (only IDE)	Zimmer Spine
In-Space	No	Synthes®

discs, interspinous devices, and dynamic stabilization systems. Although a substantial number of devices in all three categories exist and are currently manufactured, only a couple of these devices are approved for use in the United States. Although not an exhaustive list, Tables 1 and 2 list lumbar artificial discs and interspinous devices that are currently available and are used in different markets throughout the world. For the purposes of this chapter, we will discuss the M6® artificial disc systems by Spinal Kinetics, the Helifix® Interspinous Spacer System by Alphatec® Spine, and the LimiFlex Spinal Stabilization System by Empirical Spine, all of which have been in use in the European markets for many years but not yet approved for use in the United States.

Spinal Kinetics (Sunnyvale, CA) is the manufacturer of the M6 artificial disc systems and has, as of this writing, exceeded 50,000 total implantations of their M6-C Cervical and M6-L Lumbar artificial discs in international markets (https://www.odtmag.com/contents/view_breaking-news/2017-07-25/spinal-kinetics-surpasses-50000-implants-of-its-m6-artificial-disc). M6-C was launched in 2006 and is now approved for use by the FDA in the US markets, while M6-L was launched in 2010 and is currently not FDA approved but used extensively in international markets and has the CE mark (Formica et al. 2017). The M6-L artificial disc has an artificial nucleus pulposus (made from polycarbonate urethane) and an artificial ring of fibrous material (made from polyethylene) and is designed to provide physiologic motion in 6 degrees of freedom (2 degrees in each axial, coronal, sagittal planes). As of this writing, this system is the only artificial disc with 6 degrees of freedom. The inner disc is sandwiched by two titanium outer plates with keels for anchoring the disc into the vertebral body (http://www.spinalkinetics.com/patients/m6-l-artificial-lumbar-disc/). According the manufacturer, the M6-L disc is intended for use for treatment of symptomatic degenerative disc disease (DDD) at one or two adjacent levels between

L3 through S1 and may even have up to maximum 3 mm of spondylolisthesis at the intended level (http://www.spinalkinetics.com/patients/m6-l-artificial-lumbar-disc/). The M6-L disc is currently approved for use in the European Union countries, Australia, New Zealand, Russia, South Africa, Brazil, and United Arab Emirates.

There are a number of artificial lumbar discs that are approved for use in the United States and a wider array of discs that are not yet approved. Although it is by no means an exhaustive list, Table 1 contains a list of the currently used lumbar artificial discs in the United States and international markets (Food and Drug Administration 2012a, b, c).

In addition to lumbar artificial discs, interspinous and interspinous stabilization/distraction devices are also not as widely used in the US market as they are used in international markets. Before we discuss the various interspinous spacer devices used outside the United States, it is worth discussing the rationale behind interspinous distraction. There is no widely accepted term in spine literature, but lumbar interspinous process decompression (IPD) is also known as interspinous distraction, posterior spinal distraction, or interlaminar stabilization. These procedures have been proposed as minimally invasive alternative procedures to laminectomy and fusion (Landi 2014). By distracting the adjacent spinous processes and/or lamina and thereby restricting extension in patients with lumbar spinal stenosis and neurogenic claudication, these interspinous distractor devices can alleviate symptoms that arise from neural compression (Lee et al. 2015). These devices enlarge the neural foramen, decompress the causa equina, and act as spacers between the spinous processes to limit extension of the spinal interspace. Because of the minimally invasive nature of placement of these devices, proponents argue that such techniques lead to shorter hospital stay, preservation of local bone and tissue, reduced risk of cerebrospinal fluid leakage, and is reversible in such a way that it does not limit future treatment options. Some potential complications of these spacer devices are fracturing of spinous processes, incorrect positioning, and mechanical failure of the devices (Lee et al. 2015).

Of the devices that have been commercialized for placement between the spinous process or lamina of a motion segment in the US and international markets, only two such devices are approved for use in the United States: Coflex® Interlaminar Stabilization Device and the Superion® Indirect Decompression System. There is one interspinous spacer device not approved in the United States but widely used in the European markets that we will describe: the Helifix® Interspinous Spacer System. A list of some other interspinous devices can be found in Table 2 (Food and Drug Administration 2012a, b, c).

The Helifix® Interspinous Spacer System is essentially a PEEK (polyetheretherketone) implant that is self-distracting (Pintauro et al. 2017). It has a helical design that essentially can be "screwed in" between the spinous processes of adjacent vertebra. It has a percutaneous delivery mechanism through a posterolateral approach (https://atecspine.com/product-portfolio/thoracolumbar/helifix-interspinous-spacer-system/). After a 2–3 cm incision is made lateral to midline and, under fluoroscopy, a guidewire is inserted to find the interspinous space. Once another instrument, called the ligament splitter, dilates through the interspinous ligament, a dilator trial is positioned between the superior and inferior spinous processes (Gazzeri et al. 2014). Once proper fit is established, the Helifix device is inserted with a rotating movement of the self-distracting helical tip in the interspinous area. This device stretches the ligamentum flavum and the posterior fibers of the annulus fibrosus, thus enlarging the spinal canal (Gazzeri et al. 2014).

Lastly, the LimiFlex™ spinal stabilization system by Empirical Spine received its CE mark in 2009 and has been used to treat more than 2000 patients thus far, primarily in Europe (https://limiflex.com/healthcare-professionals/). The FDA has approved the device for investigational use and a clinical trial has been approved in patients with lumbar spinal stenosis with up to Grade I degenerative spondylolisthesis. The pivotal trial is a multicenter, prospective, concurrently controlled, non-blinded study in which patients will be

randomized to receive either decompression and LimiFlex device implantation or decompression and posterolateral fusion. The LimiFlex device consist of two dynamic titanium rods each with a roller screw and a pre-attached ultrahigh molecular weight (UHMW) polyethylene textile band that straps around adjacent spinous processes. The two titanium rods sit on either side of adjacent spinous processes in a vertical position and the textile band is wrapped around the two spinous processes (LimiFlex Surgical Technique Manual: https://limiflex.com/wp-content/uploads/LB-10108.001.A-LimiFlex-STM_english-for-mail.pdf). By turning the screwing mechanisms on the roller screw part of the titanium rods, increased tension is created on the textile band that increases the angle of lordosis along two adjacent lumbar spinal levels. The pivotal study started in July 2017 in the United States and is expected to conclude in December 2023 (https://clinicaltrials.gov/ct2/show/NCT03115983).

Conclusion

The spine product market is replete with a wide variety of solutions for all of the different spinal pathologies, chief among them being back and neck symptoms. Although many spine products are concurrently used both in the United States and the wider international markets, there are quite a few spinal implants that have not yet been either approved or used as widely in the United States. There are three main spine product categories, namely lumbar artificial discs, interspinous spacers, and dynamic stabilization systems, which have a substantial selection of products that have been in use in the European market for many years. However, as a result of the FDA medical device approval process and its insistence on both safety and efficacy in evaluating spinal products, many of these devices are either still under investigation or outright rejected. In fact, an evaluation of some of the case studies of the FDA approval process of certain spine products has taught us valuable lessons. Ideally, new spinal devices should improve patient outcomes with increased safety at reasonable societal costs. As we have seen from studying the reasons behind the failure of some of the spine products, the main goal prior to dissemination of spinal implants or devices is to have a rigorous evidence-based evaluation. Only then can a successful product emerge from the FDA approval process that will ultimately both be safe for consumers and decrease healthcare costs in the long term.

At the same time, innovation must also be at the forefront of our minds, and spine surgeons in the United States must rapidly evolve and evaluate certain technologies that are widely used in the rest of the world. As we have seen from the extensive list of interspinous spacers, posterior dynamic stabilization systems, and artificial discs that are in use in the international markets, we must critically evaluate and employ the most effective devices available by conducting high-quality evidence-based studies so that our patients can have more surgical options when it comes to the vast array of spinal pathologies that they experience.

Abstract

The incidence of acute traumatic spinal cord injury (SCI) in the USA is approximately 27–81 cases per million people per year with cervical SCI being the most common site of injury. Despite early surgical decompression, secondary injury and the cascade of effects in the ensuing days and months remain one of the biggest barriers in achieving recovery in these patients. A host of pharmacologic, cellular, immunomodulatory, and rehabilitative interventions have been employed over the past several decades in an attempt to improve functional outcome in this population. Though no single intervention is likely to provide a cure, important information has been gained about the heterogeneity of this population and the myriad physiological processes underlying the acute and chronic phases of injury. Herein, we provide a broad overview of the underlying pathophysiology, discuss various cellular, structural, and pharmacologic therapies tested, and address the challenges and insights gained from completed SCI trials.

SCI Background: Demographics, Economic Burden, and Grading Systems

Introduction

Trauma resulting in spinal cord injury (SCI) is often associated with significant morbidity. More than half of all SCI patients develop complications during both the initial hospital stay and after discharge, with long-term problems including veno-thrombo embolism and pressure ulcers from decreased mobility, as well as a variety of pulmonary and gastrointestinal complications (Eckert and Martin 2017). Despite advances in supportive care for SCI, technologies that can directly facilitate spinal cord recovery have been limited. In this chapter we review the various implants and therapies that have been used to improve functional outcome in the SCI population.

Demographics

The annual incidence of traumatic spinal cord injury (SCI) in the USA is estimated at 54 cases per one million people, translating to approximately 17,700 new cases each year (National Spinal Cord Injury Statistical Center Updated 2018). Motor vehicle accidents are the most common cause of traumatic SCIs (Fig. 1), accounting for 38% of all injuries between 2010 and 2014, followed by falls (31%) and acts of violence (13%). Traumatic SCI occurs predominantly in men (78%) and its prevalence is disproportionately high among non-Hispanic blacks (Fig. 2). Notably, the incidence of SCI from falls has nearly doubled since the 1970s (Chen et al. 2016). The average age at time of injury has also increased, from 29 years in the 1970s to 43 years old in 2018. Most injuries occur at the level of the cervical spinal cord (59%), followed by thoracic (32%) and lumbosacral (9%) spine (Ahuja et al. 2017b).

Economic Burden

SCI afflicts devastating physical, psychosocial, and economical consequences on its patients and their families. After discharge from acute hospitalization, the most common outcome is incomplete quadriplegia (Fig. 3). Approximately one-third of all patients with SCI are re-hospitalized in any given year, most often for infections of the skin and genitourinary system (National Spinal Cord Injury Statistical Center Updated 2018). This and other health ramifications lead to staggering costs, ranging from 2 to nearly five million dollars over the course of a patient's lifetime (Fig. 4). In addition, less than one-fifth of SCI patients are employed at 1 year after injury, adding

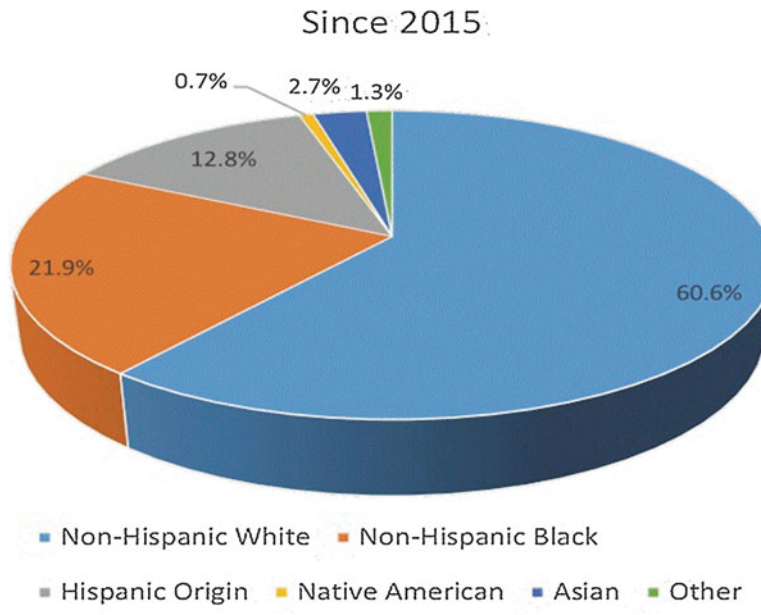

Fig. 1 Most common causes of SCI in the USA from 2015–2018. (National Spinal Cord Injury Statistical Center, Facts and Figures at a Glance. Birmingham, AL: University of Alabama at Birmingham, 2018. Redrawn with permission)

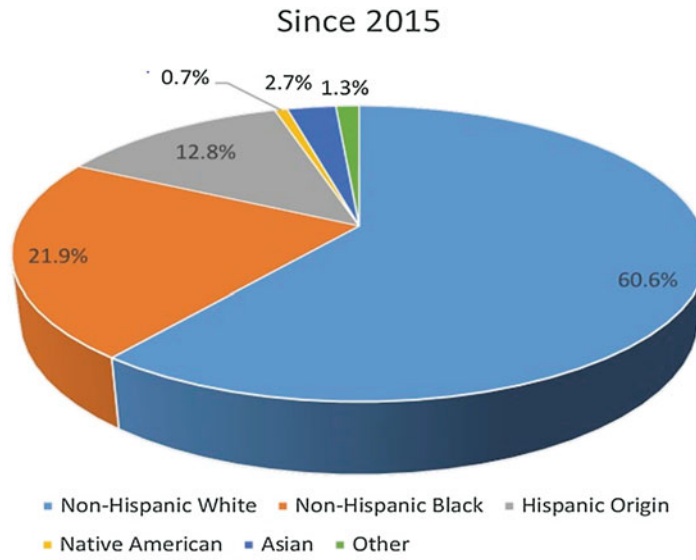

Fig. 2 Distribution of race/ethnicity in SCI cases in the USA from 2015–2018. (National Spinal Cord Injury Statistical Center, Facts and Figures at a Glance. Birmingham, AL: University of Alabama at Birmingham, 2018. Redrawn with permission)

on additional indirect costs from lost wages and benefits. Patients with SCI have persistently higher mortality rates when compared to age-matched controls (Fig. 5), with pneumonia and septicemia as the leading causes for the reduced life expectancy of these patients (Krause et al. 1997). The prognosis of restoring spinal cord function is largely dependent on the severity of injury (as measured by admission American Spinal Injury Association Impairment Scale [ASIA] grade, Frankel grade, or injury completeness) and the level of injury, as these two factors play important roles in the success of rehabilitation and regeneration (Wilson et al. 2012). Given the high morbidity and mortality associated with this population, there is a critical need for the development of new treatments and technologies to restore spinal cord function.

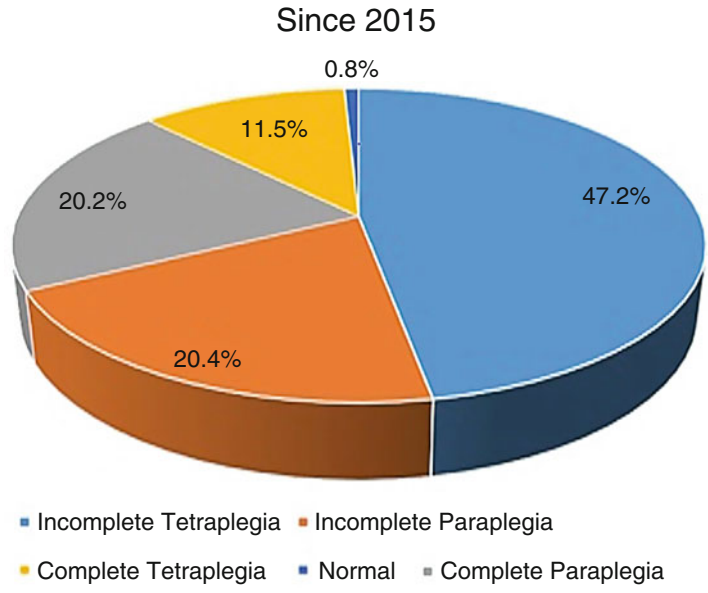

Fig. 3 Distribution of neurological injury in SCI cases in the USA from 2015–2018. (National Spinal Cord Injury Statistical Center, Facts and Figures at a Glance. Birmingham, AL: University of Alabama at Birmingham, 2018. Redrawn with permission)

Severity of Injury	Average Yearly Expenses (in 2017 dollars)		Estimated Lifetime Costs by Age at Injury (discounted at 2%)	
	First Year	Each Subsequent Year	25 years old	50 years old
High Tetraplegia (C1–C4) AIS ABC	$1,102,403	$191,436	$4,891,398	$2,688,229
Low Tetraplegia (C5–C8) AIS ABC	$796,583	$117,437	$3,573,960	$2,198,305
Paraplegia AIS ABC	$537,271	$71,172	$2,391,872	$1,569,714
Motor Functional at Any Level AIS D	$359,783	$43,700	$1,634,139	$1,153,420

Grading Systems in SCI

To accurately characterize the level and extent of cord injury, five main grading systems have been developed and used (Tator 2006). In 1967, the Frankel system was the first to be developed and included five grades of severity. Although it was easy to use and understand, the Frankel system could not quantify recovery and definitions of each grade were imprecise. The Sunnybrook system was developed in 1982, which expanded the repertoire of severity grading and neurologic changes, allowing for increased precision in the clinical evaluation and quantification of recovery in a SCI patient. One major drawback of the Sunnybrook system is its lack of numerical scores

of motor and sensory function. In 1982, the American Spinal Injury Association published the International Standards for Neurological Classification of Spinal Injury (NASCIS), a grading and classification system that would evolve into the current American Spinal Injury Association (ASIA) Impairment Scale (Roberts et al. 2017). Figures 6 and 7 depict the NASCIS scoring worksheet and ASIA Impairment Scale, respectively. Since then, the ASIA system has been refined many times, improving its precision and reproducibility in defining spinal cord injury and allowing for better understanding of the scale's therapeutic implications. The major advantages of the ASIA system include a more accurate definition of a complete SCI and improved methodology for determining motor and sensory scores. One of its major disadvantages is the ceiling effect of Grades C and D, in which patients seldom improve sufficiently to change to the next grade. Of note, the most recent classification system has been the Benzel system, but this system cannot be used in the acute phase of injury, rendering it inappropriate for use in clinical studies.

SCI Pathophysiology: Primary Versus Secondary Injury

Primary Versus Secondary Injury

Primary Injury

An understanding of the mechanisms underlying SCI is essential to develop new strategies for restoring spinal cord function. Traumatic SCI can be pathophysiologically divided into primary and secondary injuries and can be temporally divided into acute (<48 h), subacute (48 h to 14 days), intermediate (14 days to 6 months), and chronic (>6 months) stages (Ahuja et al. 2017b). The primary injury (i.e., the direct traumatic event) causes the immediate mechanical disruption and dislocation of the vertebral column, leading to compression or transection of the spinal cord. On the cellular level, this produces foci of glial and neuronal necrosis, alarmin release, disruption of the microvasculature, and breakdown of the blood–brain barrier (BBB) (Tran et al. 2018). These events together then directly trigger a prolonged secondary injury

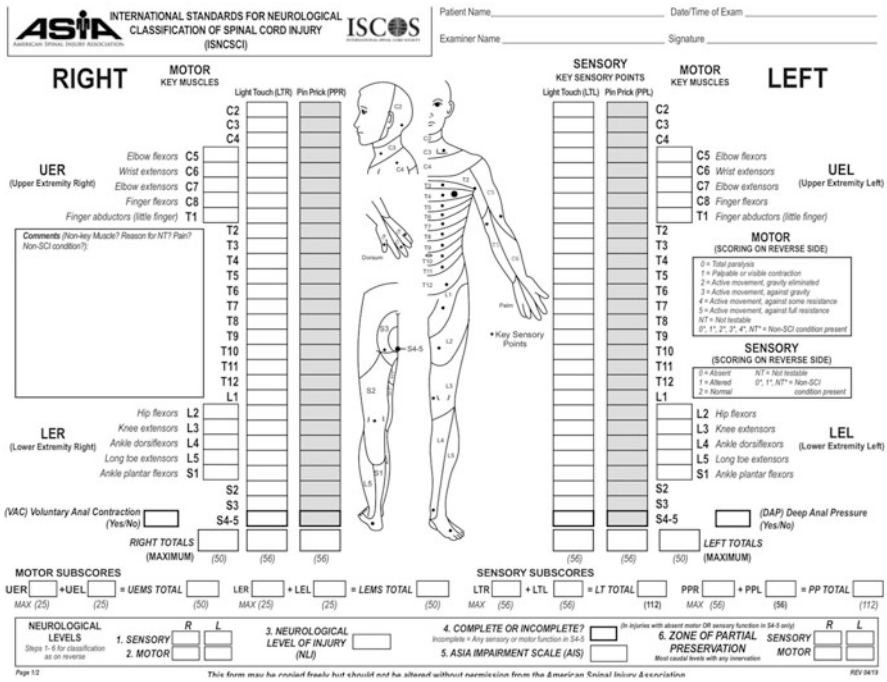

Fig. 6 International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) and ASIA Impairment Scale (AIS) scoresheet

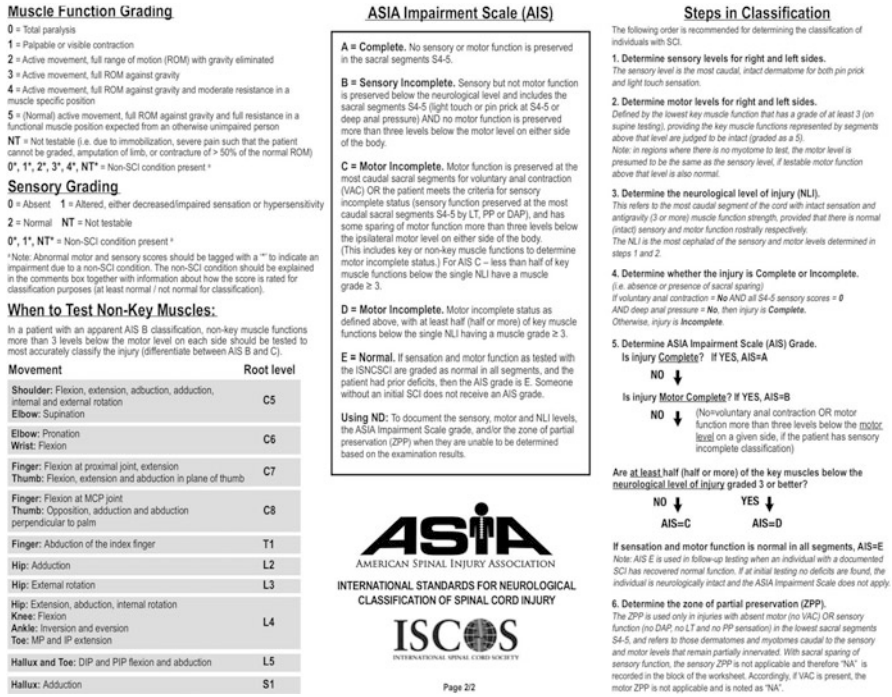

Muscle Function Grading

0 = Total paralysis
1 = Palpable or visible contraction
2 = Active movement, full range of motion (ROM) with gravity eliminated
3 = Active movement, full ROM against gravity
4 = Active movement, full ROM against gravity and moderate resistance in a muscle specific position
5 = (Normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person
NT = Not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)
0*, 1*, 2*, 3*, 4*, NT* = Non-SCI condition present *

Sensory Grading

0 = Absent 1 = Altered, either decreased/impaired sensation or hypersensitivity
2 = Normal NT = Not testable
0*, 1*, NT* = Non-SCI condition present *

Note: Abnormal motor and sensory scores should be tagged with a "" to indicate an impairment due to a non-SCI condition. The non-SCI condition should be explained in the comments box together with information about how the score is rated for classification purposes (at least normal / not normal for classification).

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, adbuction, adduction, internal and external rotation **Elbow:** Supination	C5
Elbow: Pronation **Wrist:** Flexion	C6
Finger: Flexion at proximal joint, extension **Thumb:** Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2

Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments S4-5 by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI).
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
*If voluntary anal contraction = **No** AND all S4-5 sensory scores = **0** AND deep anal pressure = **No**, then injury is **Complete**.*
*Otherwise, injury is **Incomplete**.*

5. Determine ASIA Impairment Scale (AIS) Grade.
Is injury Complete? If YES, AIS=A
NO ↓
Is injury Motor Complete? If YES, AIS=B
NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)
Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO ↓ AIS=C
YES ↓ AIS=D
If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact and the ASIA Impairment Scale does not apply.

6. Determine the zone of partial preservation (ZPP).
The ZPP is used only in injuries with absent motor (no VAC) OR sensory function (no DAP, no LT and no PP sensation) in the lowest sacral segments S4-5, and refers to those dermatomes and myotomes caudal to the sensory and motor levels that remain partially innervated. With sacral sparing of sensory function, the sensory ZPP is not applicable and therefore "NA" is recorded in the block of the worksheet. Accordingly, if VAC is present, the motor ZPP is not applicable and is noted as "NA".

International Standards for Neurological Classification of SCI (ISNCSCI) Worksheet, Updated April 2019. © 2019 American Spinal Injury Association. Reprinted with permission)

cascade, which may viciously cycle for weeks until the glial scar is formed.

Surgical stabilization and decompression is the essential cornerstone of acute treatment for patients during the primary injury. Overall, the goal of surgery is to realign the spinal column and reestablish spinal stability as to relieve compression on the spinal cord. Typically surgery involves open reduction, decompression, and instrumented fusion to bring the spinal column back into anatomical position. By correcting the mechanical disruption, surgery aims to reverse or avert any further primary injury and prevent secondary injury. Although clinical class I randomized evidence supporting the efficacy of early surgical decompression is still needed, several prospective, nonrandomized studies have supported the safety and efficacy of early surgical intervention in traumatic SCI. The prospective, multicenter, cohort-controlled Surgical Timing in Acute Spinal Cord Injury Study (STASCIS; N = 313) compared patients with cervical SCI receiving either early (<24 h) or late (>24 h) decompression. They noted an increased odds of 2 grade improvement in the American Spinal Injury Association (ASIA) Impairment Scale with early decompression (within 24 h) as compared to late decompression (>24 h) (Fehlings et al. 2012). Another study showed that very early decompression (within 8 h) was associated with better motor recovery and improved ASIA grade at 1 year post-injury (Ahuja et al. 2017b). Additionally, several studies have shown an association between early decompressive surgery and greater motor scale recovery, reduced length of stay, lower complication rates, and shorter length of hospital stay.

Secondary Injury

The hallmark of secondary injury is cord damage beyond the initial site of injury. In the simple sense, cell death begets additional cell death in

the secondary cascade. On the cellular level, disruption of the cord microvasculature leads to cell permeability, pro-apoptotic signaling, and ischemic injury, all of which potentiates additional cell death (Ahuja et al. 2017b). Incompetence of the BBB permits the unchecked entry of peripheral immune cells, toxic metabolic products, and other inflammatory substances into the central nervous system (CNS), called forth by alarmin release from necrotic cells. The ongoing necrosis of neurons and glial cells activates additional microglial cells, escalating the inflammatory response around the site of injury. This produces an overwhelming inflammatory response that inflicts damage to nearby cells by driving up oxidative stress, lipid peroxidation, and protein aggregation. Homeostatic imbalance, including the dysregulation of sodium and calcium channels and the overrelease of glutamate from dying cells, induces excitotoxic cell death, causing the release of additional glutamate and alarmin. As injured blood vessels lose their capability for autoregulation, the ensuing ischemia can persist for days to weeks after injury, extending further damage. All of these factors contribute to a harsh post-injury microenvironment that cyclically propagates and magnifies the original injury. In addition, disruption of the BBB in conjunction with the inflammatory response causes cord swelling, leading to further mechanical compression of the spinal cord.

Challenges for Recovery: Cervical Versus Thoracic SCI, Incomplete Versus Complete

Current strategies for neuroprotection and rehabilitation have focused primarily on preserving injured tissue and reducing the secondary injury. These approaches look to curb the inflammatory response and promote neural repair and regeneration after the primary insult. Without interventions to address the primary injury, inherent challenges in restoring SCI function vary depending on the level and completeness of cord injury.

Cervical Versus Thoracic SCI

Restoration of SCI function depends on the level of neurologic injury. A neurologic level of injury is defined as the most caudal spinal cord segment with intact sensation and Grade 3 or greater motor function (Roberts et al. 2017). For dermatomes not covered by muscles (C1-C4, T2-L1, and S1-S4-S5), the sensory level is used to delineate the level of injury.

Cervical SCI

For patients with cervical SCI, C6, and C7 are known to be the critical levels for achieving independence in most daily activities (Welch et al. 1986). The presence or absence of functional triceps is a critical determinant for functional independence in self-care tasks. A strong triceps permits stabilization of the elbow in extension, so that the shoulder depressors can act through the elbow in lifting the body weight, achieving independence in changing from lying to sitting position and in transferring to and from a wheelchair. Though patients with C6 injuries lack an intrinsic grasp, operating a motorized wheelchair is possible at this level through taking advantage of elbow flexion and shoulder abduction and flexion. Sparing of C7 allows for finger extension and flexion, affording even more independence with operating a wheelchair. Almost all cervical SCI patients will still need assistance with lower extremity dressing, bowel and bladder care, and driving. True functional ambulation is nearly impossible without truncal stability provided by thoracic musculature, though neuromodulation efforts have resulted in some success (discussed later in this chapter).

Compared to thoracic SCI, cervical SCI involves a mixture of damage to both central and peripheral nervous systems. Therefore, cervical SCI training approaches and chances of success is dependent on not only the injury of the spinal tracts but also on the damage of the motor neurons and roots, which can cause up to 70% of the paresis seen in C5 to C7 lesions (Dietz and Fouad 2014). The complexity and variability of cervical lesions makes the restoration of cervical cord function much more challenging. Patients with cervical

injuries are also at a higher risk for lifelong ventilator dependency compared to patients with thoracic injuries, restricting rehabilitation capacity and long-term independence (Winslow and Rozovsky 2003). Cardiovascular dysfunction leading to orthostatic hypotension is also more prevalent in cervical injuries (West et al. 2012).

Thoracic SCI

With the assistance of leg braces and pelvic band, the ability to hold an erect position and stand upright is usually reached around T6. At these levels, truncal stability is achieved from innervation supplied to the long muscles of the back, upper intercostals, and transversus thoracis. To be able to ambulate, there must be sufficient pelvic control and at least grade 3/5 strength in both hip flexors and one knee extensor (Branco et al. 2007). Though there is no set level for ambulation, most authors agree that lesions at or below T10 allow for ambulation due to innervation of the thoracic musculature and secondary hip flexors, including the external and internal obliques and latissimus dorsi.

Complete Versus Incomplete SCI

A complete SCI is defined as the absence of all motor and sensory functions in the sacral segments S4–S5. An incomplete injury is defined as the partial preservation of sensory or motor function in the lowest sacral segments (anal sensation, including deep anal pressure and voluntary external anal sphincter contraction). Incomplete SCI can then be further divided into sensory and motor incomplete subcategories. The presence of deep anal sensation may be the only indicator of an incomplete SCI. The determination of a complete or incomplete SCI requires resolution of spinal shock. Spinal shock is characterized by an initial depolarization of axonal tissue immediately after injury and is a physiologic response to trauma. Spinal shock involves a transient period of flaccid paralysis during which the patient is areflexic. Notably, this includes the absence of the bulbocavernosus reflex, a spinal-mediated reflex involving S2–S4. After return of this reflex, the patient can be assessed accurately for completeness of cord injury.

Complete SCI

The zone of partial preservation is used only with complete injuries. The zone of partial preservation documents dermatomes and myotomes caudal to the neurologic level of injury that remain partially innervated and is recorded for motor and sensation for the right and left sides. Presence of a zone of partial preservation is associated with improved neurologic recovery (Wilson et al. 2012). Otherwise, prognosis for neurologic recovery in a patient with a motor/sensory complete lesion (ASIA Impairment Scale A) is grim. Complete quadriplegics are unable to ambulate and only 5% of complete paraplegics will have sufficient motor recovery to permit ambulation (Branco et al. 2007). Waters et al. (1992) and Waters et al. (1993) found that of complete lesions assessed 1 month after injury, 90% of those causing complete quadriplegia and 96% of those causing complete paraplegia remained complete. Schönherr et al. (1999) found that approximately 1 month after injury, 100% of those causing complete quadriplegia and 96% of those causing complete paraplegia remained complete. The most recent data from the National Spinal Cord Injury Statistical Center (NSCISC) report a much higher rate of conversion from complete to incomplete status in quadriplegics, with 30% overall conversion and 15% to motor incomplete (Marino et al. 2011).

Incomplete SCI

As the amount of spared spinal cord tissue determines the effectiveness of rehabilitation training, the presence of an incomplete injury, as compared to a complete injury, is consistently associated with improved neurological recovery. This is because the success of facilitating meaningful plasticity during training depends on the presence of certain physiological prerequisites. In order to produce a locomotor electromyography (EMG) pattern in patients with SCI, afferent input from load receptors is needed (Dietz 2009). For example, no meaningful leg muscle activation occurs in individuals with complete SCI during supported stepping if there is no loading of the sole of the foot. This makes obtaining significant muscle activation in patients with complete SCI much more challenging than in patients with incomplete SCI. An additional factor that may also contribute

to the smaller EMG amplitudes in patients with complete paraplegia is a loss of descending noradrenergic input to spinal locomotor centers (Dietz 2012).

Concepts: Functional Regeneration, Neuroprotection, Immunomodulation

Many promising strategies are being explored in an attempt to regain function after spinal cord injuries, with a strong focus on regeneration. In the literature, several comprehensive reviews have been conducted on the status of translational advances in spinal cord injury (Badhiwala et al. 2018; Venkatesh et al. 2019; Ahuja et al. 2017b). While there are a number of promising strategies for treating SCI, there are currently no effective and reliable treatments that have achieved regeneration in SCI. Two major principles in the field of regeneration have focused on neuroregeneration and neuroprotection. Neuroregenerative techniques have predominantly focused on stem cell lines that can restore lost neurons. For neuroprotection, research has focused on factors that both promote regeneration and limit inhibitory factors. Different stem cell lines have the potential to regenerate neural circuits, provide trophic support, modulate the inflammatory response, and remyelinate damaged axons. To support both endogenous and implanted stem cells, there has also been a strong focus on neurotrophic factors that promote neuron growth and reagents that block inhibitory factors such as the formation of scar tissue. These immunotherapies serve as an adjunct to promote spinal cord regeneration through increasing cell survival and engraftment (Ahuja et al. 2017a; Tsuji et al. 2019).

A parallel strategy focuses on biomaterials that can mimic the physiological extracellular matrix and provide support and structure to regenerating neural structures. Biomaterials can be used to make scaffolds that provide guidance for existing damaged neurons and allow implanted cells to propagate and differentiate. Another goal of scaffolds has been to minimize secondary injury after SCI through inhibiting apoptosis and necrosis, limiting the formation of glial scar and serve as a vehicle for the delivery of immunomodulators and cell therapies (Liu et al. 2019).

A separate strategy for restoring SCI function is through neuromodulation with electrical interfaces. Neuromodulation is currently successfully in use for many neurological disorders, including deep brain stimulation for Parkinson's disease and epidural stimulation for pain. In the setting of SCI neurostimulation has already been used to help with respiratory pacing, bladder control, and restoring volitional movements through peripheral stimulation. New research suggests that spinal cord stimulation may also promote regeneration. Neuromodulation can also be adapted to restore motor and sensory function by creating an interface that connects the central nervous system with peripheral extremities. Through brain–machine interfaces, a tetraplegic patient has been able to perform reach and grasp movements. As technological advances continue, the field of neuromodulation will continue to increase in potential (James et al. 2018).

While there have been significant steps toward restoring function in SCI patients, to date there is no widespread and effective therapy available for regeneration or technology that restores function. In the following sections of this chapter, we review the current advances made, as well as challenges encountered in the different focuses of ongoing research. As the field continues to advance, an effective therapy will likely emerge from a combination of the various strategies already in development.

Results from Acute SCI Interventions: Stem Cells, Pharmacologics, Hemodynamic Strategies, CSF Drainage, Bio-Scaffolds, and Neuromodulation

Stem Cell Therapies

A wide variety of stem cell types have been explored with the goals of neuroprotection and neuroregeneration. Extensive research has shown promise in restoring function in SCI animal models (Hong et al. 2018). Cell therapies have been proposed to provide functional benefits

in SCI through several proposed mechanisms: neuroprotection, immunomodulation, axon sprouting and/or regeneration, neuronal relay formation, and myelin regeneration (Assinck et al. 2017). Stem cells for transplantation originally were developed from embryonic stem cells (ESCs), however given ethical and supply issues, induced pluripotent stem cells (iPSCs) have gained traction as favorable alternative. iPSCs have been successfully induced into specific neurons and glial cells, providing a more feasible source of cells to study. Studies have found success in integrating these stem cells into host circuitry in animal models. Neuronal stem cells (NSC) have been shown to enhance neurotrophic signaling, promote remodeling of neural circuitry, improve remyelination, and modify the extracellular matrix.

Supportive cell types are just as important as neurons themselves. Oligodendrocyte precursor cells (OPCs), mesenchymal stem cells (MSCs), olfactory ensheathing cells (OECs), and Schwann cells have thought to promote neuroprotection through several mechanisms. OPCs can secrete neurotrophic factors and remyelinate denuded axons. MSCs aim to regenerate damaged connective tissue and modulate inflammation. OECs have also been shown to induce regeneration and endogenous remyelination. Schwann cells are robust structural scaffolds in the peripheral nervous system that have been shown to modify astrogliosis in a way that facilitates remyelination and regeneration (Ahuja et al. 2017a; Badhiwala et al. 2018).

Cell therapy effectiveness will depend highly on the specific cell type, route of administration (IV, intrathecal and intraparenchymal), and timing. Ongoing trials explore and optimize each of these variables, with many different types of stem cells. The injection of MSCs, OPCs (AST-OPC-1), and autologous Schwann cells have all been been explored safely in phase I trials in SCI patients (Anderson et al. 2017; Priest et al. 2015; Jin et al. 2019). Despite successful preliminary trials, multiple late-stage trials have hit significant challenges, both scientific and financial. The Geron Corporation had launched a clinical trial of embryonic stem cells for SCI in 2010, citing "capital scarcity and uncertain economic conditions"(Lukovic et al. 2014). Another clinical trial by Stem Cells Inc. (Newark, CA) showed positive safety profiles in human fetal–derived NSC transplants into cervical and thoracic spinal cord injury sites. Further trials however did not show a significant response with clinically derived stem cell lines and studies have been terminated (Anderson et al. 2017). Despite failed trials, there continues to be a strong effort in clinical studies of cell therapies. The first human trial using iPSC has recently been approved to start (Tsuji et al. 2019).

Other than specific stem cells, other cells including macrophages and whole bone marrow have been thought to have potential to improve the microenvironment for neurological recovery. The bone marrow cells include hematopoietic stem cells, macrophages, lymphocytes, and marrow stromal cells. The bone marrow cells may secrete important cytokines as well as other essential factors for the survival and differentiation of neuronal cells.

While cell therapy is promising, there are also significant risks as with any new technology. A case of OEC implantation in the site of a chronic T10–11 complete SCI was found 8 years after implantation to have developed into an intramedullary spinal cord mass requiring resection (Dlouhy et al. 2014). This report raised concerns about the safety surrounding implantation of stem cells and highlights the importance of long-term monitoring. While the majority of stem cell trials have not reported significant adverse events, the follow-up time period for these trials has been limited to a few years. These reports should not deter the advancement of stem cell research but provide scientists with more information on how to safely proceed.

Pharmacologics

Steroids

Methylprednisolone sodium succinate (MPSS) was used in early spinal cord injury trials for its immunomodulatory and anti-inflammatory roles, both reducing neutrophil and macrophage

migration while also playing an important role in reduction of membrane peroxidation. The (National Acute Spinal Cord Injury Study) NASCIS I was a double-blind, randomized controlled trial performed comparing low-dose and high-dose administration in acute SCI. Results showed no difference between groups and the trial was stopped early. The NASCIS II trial was conducted with higher dose MPSS and compared with naloxone and placebo. Analysis was stratified based on timing of administration (<8 versus >8 hrs) and adjusted for the severity of injury (Bracken et al. 1990). Results demonstrated improvement in motor and sensory function in those patients who received MP within 8 hrs and no significant differences in either treatment arm greater than 8 hrs from injury. Wound infections and GI bleeding was observed with greater frequency in the MP group. Lastly, the NASCIS III trial was designed to compare 24 h MPSS infusion to a 48-h MPSS infusion. These two dosing schedules were compared with a 48-h infusion of a third drug, tirilazad mesylate, an inhibitor of lipid peroxidation. Results suggested that patients who received MPSS infusion as a 48-h infusion had improved motor function at 6 weeks and 6 months. Preplanned subanalysis demonstrated those who received MPSS between 3 and 8 h post-injury were more likely to improve at 6 months, though with increased risk of severe sepsis and pneumonia (Bracken et al. 1997). As a result, published guidelines offer a Level I recommendation against the use of MPSS in acute SCI, though the debate continues and recommendations are to continue evaluation in future higher-quality studies (Donavan and Kirschblum 2018).

Hemodynamic Intervention

Prevention of secondary ischemia and spinal cord hypoperfusion is paramount in the management of acute SCI. Cervical and upper thoracic SCI carry a risk of spinal shock due to variable interruption of the sympathetic outflow from cell bodies residing in the thoracic spinal cord. As such, strict hemodynamic monitoring and blood pressure (BP) parameters have been advised, though the recommendations have been controversial. Loss of supraspinal sympathetic regulation permits hypotension, bradycardia, and arrythmias. Post-mortem histological analysis of SCI patients with severe cardiovascular dysfunction shows more severe white matter and axonal degeneration in those patients who have severe cardiovascular dysfunction after SCI (Furlan and Fehlings 2008). Maintenance of mean arterial pressure (MAP) 85–90 mm Hg for the first week after acute SCI currently carries a Level III recommendation, according to published guidelines (Walters et al. 2013). While there is no universal agreement as to the vasopressor of choice, some studies have indicated that norepinephrine may be preferable to dopamine (Altaf et al. 2017).

CSF Drainage

Similar to the principles of TBI management, swelling and edema after SCI can have deleterious effects on local tissue perfusion. Surgical decompression, followed by efforts to prevent hypotension, hypoxia, and other secondary insults, is paramount in the management of acute SCI. Prevention of spinal cord ischemia can be accomplished by increasing perfusion and/or reducing intrathecal pressure by way of CSF drainage. This has been well described in vascular surgery where it is routinely employed after thoracoabdominal aortic aneurysm repair. A prospective randomized trial of 22 patients (ASIA A-C, inclusive of C3-T11 injury levels) was performed to evaluate the effect of 72 h of CSF drainage on peak intrathecal pressure (ITP) and correlated with neurological recovery after acute SCI (Kwon et al. 2009a). Though the study was not powered to detect differences in neurological outcome, there were no significant associated adverse effects reported in the study arm and spinal cord perfusion pressure was consistently higher during the duration of the study. An ongoing multicenter Phase IIb randomized controlled trial (NCT02495545) comparing the efficacy of CSF drainage and MAP elevation to MAP elevation alone is currently enrolling patients through the December 2019.

Growth Factors

Several important growth factors, have been identified and gained attention as neurotrophic agents in the central nervous system. Conversely,

inhibitory factors that inhibit neuronal growth have also been explored to understand the barriers to regeneration. All of these are being explored for their potential to be medications in treating SCI. By optimizing the microenvironment, these medications have the potential to enhance the regeneration of both endogenous cells and implanted stem cells.

Hepatocyte growth factor (HGF) is a c-Met receptor ligand that has been shown exert regenerative effects, including angiogenesis, after tissue injury in many epithelial organs. Studies in rodent models have shown that HGF in the central nervous system promotes angiogenic activity, prevents disruption of the blood–brain barrier, and promotes the survival of neurons after cerebral ischemia. Preclinical SCI studies investigating the use of intrathecal HGF in nonhuman primate models found improved ventral motor neuron survival and better motor outcomes, with significant improvements in upper limb recovery (Badhiwala et al. 2018; Kitamura et al. 2011). While most pharmacologics have been investigated through IV administration, a handful has been used intrathecally during the time of initial injury. In one human trial, HGF has administered as intrathecal injection at the time of injury and repeated weekly. Study results are still pending (Warita et al. 2019).

Granulocyte colony stimulating factor (G-CSF) is a small glycoprotein that has shown potential for enhancing cell survival and modulating inflammatory cytokine pathways. It is expressed on microglia and promostes expression of neurotrophic factors while inhibiting pro-inflammatory markers. G-CSF has been shown in mouse models to enhance neurogenesis and reduce apoptosis, with associated improvements in hind limb function (Koda et al. 2007). A randomized controlled trial in Iran showed that subcutaneous administration of G-CSF showed subtle but significant improvements in motor and sensory function compared to a placebo group in a population of incomplete subacute SCI (Derakhshanrad et al. 2018). Another group in Korea has experimented with G-CSF and isolated bone marrow cells injected during surgery at the site of contusion in six patients within 7 days of SCI. While the patients showed some neurologic recovery, the study mainly demonstrated the safety of the procedure (Park et al. 2005). Further multicenter trials will be needed to reinforce these findings.

Fibroblast growth factor (FGF) protects against excitotoxic cell death and reduces free radical generation (Badhiwala et al. 2018). FGF has been shown in several animal models to promote regeneration of spinal tracts (Cheng et al. 1996). This was first translated to human studies in 2004 when surgeons applied sural nerve grafts and fibrin glue infused with a closely related FGF: acidic FGF (aFGF) in a SCI patient, with improvement from wheelchair bound to ambulating with a walker (Cheng et al. 2004). Two further trials of aFGF administered during laminectomy without the nerve grafting have been done with additional doses of aFGF/fibrin through lumbar puncture at 3 and 6 months post-surgery. No significant adverse events were reported and ASIA motor and sensory scores showed significant improvement 24 months after treatment (Wu et al. 2008, 2011). The studies however did not have control arms, and further large-scale randomized controlled trials are currently enrolling.

Rho Signaling

The Rho signaling pathway regulates axon growth and is upregulated after SCI. Activation of the GTPase Rho A leads changes in the actin cytoskeleton and collapse of regenerating axons, neurite retraction, and increasing apoptosis (Nori et al. 2017). Medications that inhibit the Rho pathway have the potential to relieve the inhibition on axonal growth. C3 transferase is a toxin produced by clostridium botulinum and can block the Rho pathway. VX-210 aka Cethrin is a C3 transferase that has been used in clinical trials dosed in a fibrin sealant and administered during planned decompression/stabilization surgery after SCI (Fehlings et al. 2018, 2011). However an interim analysis of phase IIb/III trial suggested futility, and studies have been halted.

Neurite growth inhibitor A (NOGO-A) is a myelin-associated protein that functions through NOGO receptors and forms co-receptor complexes with the TNF receptor family proteins to activate the GTPase Rho A. This activates the Rho

pathway as discussed above and leads to inhibition of axon growth. A NOGO-A inhibitor (ATI355) has gone through a phase I clinical trial in 52 patients with SCI with acute SCI injury (4–60 days post-injury). The medication was administered via continuous intrathecal infusion over 24 h to 28 days. The published results confirmed safety and tolerability after 1-year follow-up with minimal adverse events, and no major adverse events attributable to ATI355. Future efficacy trials are still pending (Schwab and Strittmatter 2014; Kucher et al. 2018).

Excitotoxicity

Once the spinal cord is injured, the damaged cells release excess glutamate and leads to excitotoxic damage. Numerous medications have been explored in treating SCI with the targeted effect of limiting inflammation and excitotoxicity. Riluzole is a benzothiazole anti-epileptic that can reduce excitotoxicity though sodium blockade and reduction of presynaptic release of glutamate. This medication is already approved for neurodegenerative disorders including amyotrophic lateral sclerosis, and has been shown to reduce neurodegeneration and effects of traumatic injury by modulating excitotoxicity. The Riluzole in Spinal Cord Injury Study (RISCIS) trial has shown safety of oral administration of Riluzole in acute SCI. Phase II/III trials are now pending (Siddiqui et al. 2015).

Minocycline, a tetracycline antibiotic, also has been found to have anti-inflammatory, anti-oxidant, and anti-apoptotic properties. It has been shown to minimize N-methyl-D-aspartate (NMDA)-induced excitoxicity. Its effects may stem from its ability to modulate inflammatory effects of microglia (Shultz and Zhong 2017). Given its clinical availability and established safety as an antibiotic, it has been an attractive drug for clinical trials and is currently pending Phase III trials.

Gacyclidine is a noncompetitive NMDA recept antagonist that has targeted effects of reducing inflammation and excitotoxicity. Animal models showed possible attenuation of spinal cord damage. Early-stage SCI trials in humans have been completed but efficacy has yet to be shown (Donavan and Kirschblum 2018). Similarly, Magnesium also antagonizes NMDA receptors and has been explored for its potential to reduce inflammation and excitotoxicity. It has been used together with scaffolds, discussed in a later section, to treat SCI. To date, none of the medications have shown a clear benefit in the treatment of SCI.

Previously Explored Pharmacologics

A number of trials have shown negative results without further research. Thyroid releasing hormone (TRH) has been shown to antagonize many aspects of secondary injury. It was studied in a small clinical trial in 1995 in acute SCI with negative results (Lehrer 1996). Opioid antagonism has also been explored given the potential neurotoxic effects of endogenous opioids in SCI. The NASCIS II trial included a trial arm of naloxone which showed negative results. Gangliosides are glycolipids abundant in nervous tissue. In vitro experiments have shown potential benefit of gangliosides in enhancing axonal growth, and an experimental ganglioside GM-1 (monosialoate-trahexosylganglioside), also known as Sygen, had shown promise in animal models of SCI. Its efficacy however was not shown in a large RCT, and no future studies have been planned.

Bio-Scaffolds

Another strategy to facilitate regeneration focuses on providing support and guidance for damaged neurons through scaffolds that can both facilitate growth and inhibit antagonizing factors and the formation of glial scars. Many different natural materials have been used, including collagen, chitosan, alginate, and fibrin. Natural materials have advantages including biocompatibility, biodegradability, and low toxicity. Synthetic materials have also been developed, including various polymeric biomaterials, with the advantage of more controllable biodegradability and physicochemical and mechanical properties. Polyethylene glycol (PEG) is one synthetic biocompatible polymer that has shown potential to stimulate angiogenesis, reduce glial scar formation, and promote axonal regeneration through its ability to act as a

fusogen and stabilize compromised neuronal membranes. In animal models of SCI, PEG has been shown to improve hind limb function.

The potential of biological scaffolds can be augmented by seeding with pharmacologics, immunomodulators, and stem cell lines, providing an environment that provides both neuroprotection and positive growth factors. The addition of magnesium to PEG has been used in rat models of SCI and shown to provide tissue protection and improved locomotor recovery (Kwon et al. 2009b). While promising results have been demonstrated in animal models, the evidence in humans is limited (Liu et al. 2019). Few biological scaffolds have been translated from the research lab to clinical trials. Complications ranging from seroma formation to meningitis have been reported in human subjects (Liu et al. 2019).

The neuro-spinal scaffold (InVivo Therapeutics Corp, Cambridge, Massachusetts) is a porous polymer scaffold composed of poly(lactic-co-glycolic acid) covalently conjugated to poly-L-lysine that has been one of the few scaffolds to be used in humans. A preliminary study of one patient who sustained a spinal cord contusion at T11–T12 had the neuro-spinal scaffold placed during surgical decompression and fusion for the acute injury (Theodore et al. 2016). The patient preoperatively had a T11 AIS grade A complete injury, and 12 months postoperatively was noted to be L1 AIS grade C. Preliminary results from a larger study of 16 patients (INSPIRE study) showed that 7 (44%) reached the primary endpoint of ASIA Impairment Scale conversion at 6 months. While one patient was lost to follow-up, the remaining six patients who converted retained their improvements at the 12-month mark. Further large-scale studies as part of INSPIRE 2.0 are currently undergoing (Anon n.d.).

Neuromodulation

An alternative approach to SCI focuses on the development of electrical stimulation to augment or modify neuronal function. As technological advances in materials science and computing are made, the possibility of neuromodulation to restore spinal cord function becomes closer to reality. Stimulation can be applied direction to the muscle, peripheral nervous system, or even central nervous system to drive motor output (Fig. 8). Technologies have been explored in brain stimulation, brain–machine interfaces, spinal cord stimulation, and peripheral stimulation.

Peripheral Stimulation

Functional electrical stimulation (FES) involves the application of electrical stimulus to generate muscle contractions. By targeting specific muscles of interest, FES can induce controlled movements in the limbs and body. FES has successfully been used to improve ambulation in patients with incomplete SCI through generating contractions in the limbs (Badhiwala et al. 2018). While originally envisioned as a permanently worn device, FES may also be used as a clinical intervention with a limited number of training session. One case report describes how FES training allowed a patient to regain meaningful movement in his upper extremities (Popovic et al. 2016). Through the help of stimulation patients can potentially gain muscle strengthening as well as neuroplastic changes and cortical reorganization. This concept will be compared with conventional occupational therapy in an ongoing phase III multicenter trial.

Brain Stimulation

Brain stimulation has also been explored as an option to help SCI and explores the possibility of increasing the activity of residual pathways. Transcranial direct current stimulation (tDCS) and transcranial magnetic stimulation (TMS) are two noninvasive techniques that have been explored in combination with motor training to augment existing neurological pathways. As noninvasive procedures, both tDCS and TMS are considered safe and low risk, and have been researched extensively in the treatment of neuropathic pain in SCI with mixed results (Fregni et al. 2006; Wrigley et al. 2013; Gao et al. 2017). Several small studies have used multiple sessions of tDCS in small groups of patients in the chronic phase of SCI with some improvement in upper and lower extremity function (Gunduz et al.

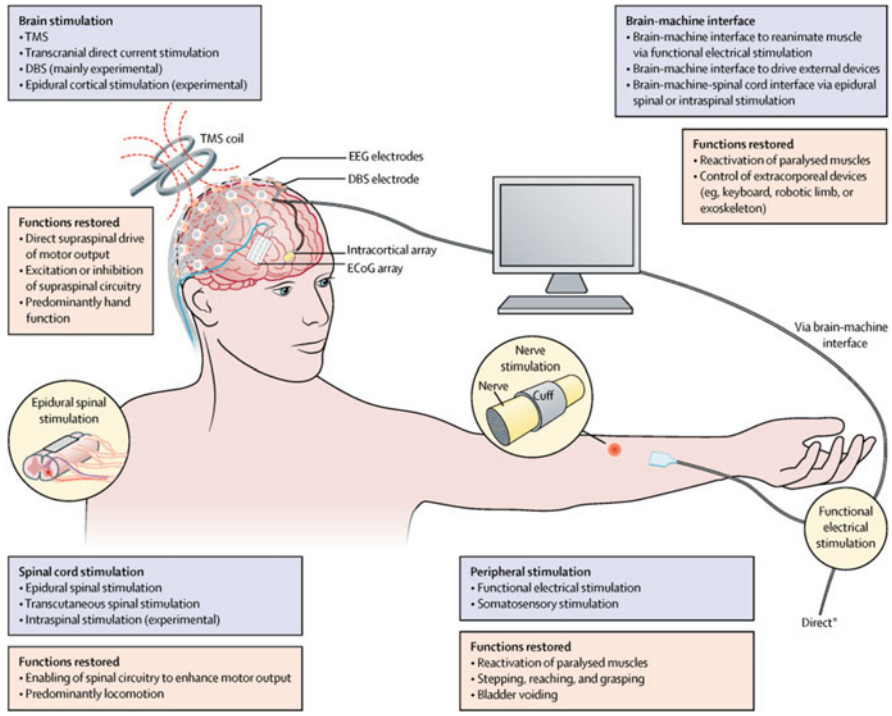

Fig. 8 Neuromodulation targets in SCI. https://ars.els-cdn.com/content/image/1-s2.0-S1474442218302874-gr1.jpg (Copyright requested through RightsLink). (Reprinted from Lancet Neurology Volume 17, Issue 10, Nicholas D James, Stephen B McMahon, Edelle C Field-Fote, Elizabeth J Bradbury, "Neuromodulation in the restoration of function after spinal cord injury," Pages 905–917, 2018, with permission from Elsevier)

2017). This therapy may be synergistic in conjunction with current rehabilitation therapies. tDCS in combination with direct motor cortex stimulation with epidurally implanted electrodes has also been shown to promote axonal sprouting and improve motor control in animal models. (Zareen et al. 2017)

Spinal Cord Stimulation

Epidural spinal cord stimulation has been implanted above the dorsal surface of the spinal cord extensively for chronic pain with a good safety record. This has allowed several initial SCI case studies to be completed where epidural stimulation of the lumbosacral spinal cord augmented recovery in chronic, motor-complete paraplegic SCI patients (Rejc et al. 2017; Grahn et al. 2017). In lumbosacral epidural electrical stimulation, a 16-electrode array is implanted over spinal segments L1–S1. Recovery of voluntary movement with epidural stimulation was observed in motor-complete patients 2 years post-injury (Angeli et al. 2014). There are two proposed mechanisms for this late recovery. First, there is activation of previously "silent" anatomical connections from epidural stimulation. These few remaining descending connections have been present since the time of injury but were insufficient to activate motor pools until epidural stimulation enhanced central excitatory drive by altering spinal cord circuitry. Stimulation may facilitate excitation of propriospinal interneurons, which support propagation of voluntary command to the lumbosacral spinal cord. Second, the continued improvement of voluntary movement with repetitive epidural stimulation and training suggests plasticity with the recruitment of novel neuronal pathways and synapses with time. These results suggest the ability of the spinal networks to learn with task-specific training and improve motor pool recruitment to promote force generation and accuracy.

Epidural stimulators have also been explored in chronic cervical injury and results suggest improvement in grip strength (Lu et al. 2016). In cervical epidural stimulation, two 16-contact percutaneous epidural leads are placed spanning C4–T1. Immediate improvements in maximal hand strength and control were seen in chronic, motor-complete tetraplegic SCI patients within one testing session and incremental, sustained improvements were observed after repeated stimulation. These results suggest that epidural stimulation facilitates the recruitment of viable, but previously nonparticipating, cervical interneuronal networks projecting to motor pools, similar to is observed with epidural stimulation to the lumbosacral spinal cord.

A number of clinical trials have also been investigating transcutaneous spinal cord stimulation (tcSCS) with a similar conceptual goal. tcSCS is less accurate but is noninvasive and inexpensive. However clinical trials of both direct SCS and aSCS are small, and larger clinical trials will need to be done to confirm initial findings.

Brain Machine Interfaces

Brain machine interfaces (BMI), also referred to as brain computer interface (BCI), have been a popular and exciting research topic. The technique allows the recording and decoding of brain activity and translates the information to generate functional output. This concept has shown promise in individual case studies (Bouton et al. 2016; Ajiboye et al. 2017). Recording devices range from noninvasive scalp surface EEG electrodes to invasive subdural or epidural implanted electrocorticography electrode arrays (ECoG) and intraparenchymal microelectrode arrays. The invasive devices have predominantly been implanted on the cortical surface gyri, often in the motor cortex. Neural activity is captured from these devices and decoded by a computer with the goal of interpreting movement plans. Noninvasive devices have a lower signal quality, while invasive recording devices are much more sensitive. The decoded signals are translated into commands that can be used to control an external device, such as prosthetic robotic limb or a cursor on a computer screen (Lee et al. 2013). One of the first implantations of BMI in humans was done by the BrainGate group at Brown University, where a small array implanted in the motor cortex allowed continuous control of a computer cursor in patients with severe SCI (Hochberg et al. 2006; Kim et al. 2008). Application of this technology goes beyond rehabilitation for SCI or stroke patients. Both the Department of Defense and commercial companies have funded efforts to master the ability to decode brain signal with the goal of human enhancement.

There are several barriers that will need to be addressed prior to widespread clinical applications of BMI. The technology currently requires a large amount of highly advanced and specialized technology, which has high costs that would make such a therapy inaccessible and unaffordable. Current participants are still required to be connected to a computer interface, which would not translate well to daily function. Implanted electrode arrays also are prone to gliosis and physical damage, resulting in loss of recordings. As the technology advances to become more portable, affordable, and durable, it will continue to expand in potential uses.

Challenges: Translational Studies, Timing of Intervention, Ethical and Economic Considerations, and Considerations in Clinical Trial Design

Consistency of Results

As with any research, the translation of research from the bench to patient care carries significant challenges. Animal models vary greatly from humans in body size, anatomy, and their response to severe SCI. While we try to control the variability in experimental models, patients carry significant heterogeneity in their individual characteristics and the type of SCI endured. This highlights the importance for early experiments to show a clear and significant benefit before moving on to higher-level trials, and likewise early-phase clinical trials will need to show the same to justify the cost of recruiting a larger population that is likely more heterogeneous.

Risks

While stem cells have been extensively studied in the laboratory, our experience with their use in humans is relatively limited, and we may not know the full range of potential side effects and complications associated with this therapy. As previously discussed, the use of olfactory nasal ensheathing cells for spinal transplantation led to the unwanted growth of a multicystic mass (Dlouhy et al. 2014). Conversely, immunotherapies that block the innate immune responses may prevent scar formation, but may also block protective processes and adversely affect spontaneous recovery (Putatunda et al. 2018). Government regulatory policies may help ensure the safety of translational research, but can also introduce further challenges by blocking potentially effective variations, such as adjustments in dose amount or number.

Timing

As the field of spinal cord injury moves into translational research, challenges surrounding clinical studies arise. One of the most important challenges is determination of timing of therapeutic intervention, which affects both recruitment strategy and potential treatment effects. A window of opportunity may exist for SCI patients in which a response to treatment is only possible for a limited time period after acute injury. This would limit studies to focus on patients in the acute or subacute phase of injury.

Studies that focus on acute injury face issues with accessing individuals within a few hours of presentation, requiring a developed infrastructure in trauma centers. In the acute setting, treatment effects are also more likely to be confounded by spontaneous neurologic recovery or other injuries and complications. The patients that are most likely to benefit from experimental treatments are sometimes also the most likely to spontaneously improve, which makes treatment effects very difficult to detect. While chronic SCI studies may be easier to recruit, patients showing high potential for recovery may not want to take on the risk an experimental approach carries. The burden of extensive follow-up and testing can also lead to difficulty in following the progress of studied patients (Blight et al. 2019; Blesch and Tuszynski 2009).

With respect to completed trials examining the effects of timing of surgical decompression, initial results from surgical trials (Vaccaro et al. 1997) showed no difference in ASIA motor score or grade in patients undergoing early (<72 hrs) versus late (>5 days) surgical decompression and 1-year average follow-up. All of these patients received high-dose methylprednisolone. The question of optimal surgical timing remained unanswered and gave rise to the Surgical Treatment of Acute Spinal Cord Injury Study (STASCIS) trial, which was intended to compare the efficacy of early (<24 hrs) versus late (>24 hrs) surgical decompression on 6-month outcomes in cervical SCI patients (Fehlings et al. 2012). All patients were aggressively medically managed with MAP goals >85 and 60% of enrolled patients received methylprednisolone as determined by each study team. Multivariate regression analysis, when controlled for methylprednisolone and type of injury (complete versus incomplete), demonstrated patients undergoing early surgical decompression were 2.8 times more likely to improve at least two grades in AIS (ASIA Impairment Scale) grade at 6 months. Several prospective cohort studies since have shown a benefit of early decompression. Subsequent retrospective studies have also shown significant improvement in 1-year SCIM (Spinal Cord Independence Measure) scores, AIS grade improvement, and AIS grade conversion in patients undergoing ultra-early decompression (<8–12 hr) after traumatic cervical SCI (Grassner et al. 2016; Burke et al. 2018).

Ethical Challenges

While a cure for SCI would transform the lives of affected patients, it is paramount to ensure that the research to achieve this goal is done ethically. The use of stem cells derived from embryos sparked intense ethical debate, with concern of whether

embryos should be considered "persons." As a result of this concern governments worldwide have strictly regulated the use of embryonic stem cells in research. The advent of induced pluripotent stem cells (iPSCs) through genetic reprogramming of somatic cells provided a useful alternative to embryonic stem cells and has significantly minimized this ethical controversy. There are also ethical concerns surrounding animal models of SCI, as lesions of the spinal cord significantly impact the quality of life of an animal. Animal use protocols should ensure the well-being of any animals experimented on.

Once a promising therapy is demonstrated in an animal model, a difficult question is when this should be translated into human trials. Experimental interventions of the spinal cord carry significant risk, as their effects in animals do not always perform the same in humans. Given that recovery in the early stages of injury is difficult to predict, it is a concern that a new therapy could inhibit or negatively affect spontaneous recovery. It is important for researchers and governing research and ethics review boards to carefully ensure the scientific validity, favorable risk–benefit ratio, and respect for human rights. Additionally studies should be designed to maximize safety while ensuring the best care for the patient. An additional ethical challenge arises in patient selection. Patients that have the most severe injury need the most help; they are also the least likely to recover. Ultimately, the high costs of human trials limit the number of participants with strict inclusion criteria that maximize the potential to detect a possible therapeutic benefit (Rosenfeld et al. 2008).

Costs

It is predicted that by 2025, global spending on clinical trials will reach $68.9 billion a year (May 2019). The estimated costs for preclinical studies alone can costs hundreds of millions of dollars (Trounson and McDonald 2015). Stem cell lines can cost thousands of dollars to produce. While rodent models of SCI are widely available and accessible, they do not reflect humans in an anatomical and physiological way. Larger animal models, such as primates, greatly increase in costs as well as regulation. These costs are nominal compared to human clinical trials, and costs continue to increase for late-stage trials as the number of patients required increases and the study becomes more complex. The high financial burden makes careful planning and patient selection imperative to achieve the highest likelihood of identifying effective therapies.

Challenges and Considerations in Designing of Clinical Trials

Various surgical and therapeutic trials have been conducted over the last several decades with the goal of improving functional outcomes for the spinal cord–injured population. Some have been randomized controlled trials (RCT) while others have primarily been cohort studies. Extensive reviews of the trials in SCI can be found in the literature (Tator 2006; Hawryluk et al. 2008; Donavan and Kirschblum 2018). In order to conduct effective and efficient future trials, it is imperative to review the important lessons learned from previous experiences.

One must appreciate the unique challenges in studying this population as well as the areas of possible conflict that can impact results and affect the success of measured outcomes. As outlined eloquently in his review of human SCI trials, Dr. Tator addresses the important shortcomings in SCI research and trial design (Tator 2006). Spinal cord injury itself is a heterogenous disease process. Not only are cervical and thoracic SCI populations quite different in their injury pattern and propensity to regain function, but complete and incomplete populations are also crucially different. Incomplete SCI patients have more capacity to recover than those with complete injury but the myriad pathophysiological mechanisms at place are difficult to control for in any given trial. As alluded to earlier, the complete SCI population is more homogeneous and therefore may be a better population to study, despite the fact that potential for recovery is less than the former. Though it makes good sense to design trials

based upon level of injury, thoracic ASIA grade A patients comprise less than 15% of the SCI population, for example, making trial accrual challenging. There are also limitations to our currently used ASIA grading system. For example, a ceiling effect exists for Grades C and D, making it difficult for patients to move out of one category to the next level of improvement. Spontaneous recovery presents a unique but omnipresent phenomenon. It was estimated by Burns et al. that approximately 60% of ASIA grade B through D patients move to a higher grade. Since these grades account for over 50% of patients with SCI, they must be included in trials. However, efficacy of a given intervention may be difficult to distinguish from the natural history in these patient populations. Further, combined upper and lower ASIA motor scores can be similar yet indicate vastly different cervical and thoracic SCI populations with varying degrees of injury and prognosis for recovery. As such, there has been an effort to stratify patients at trial entry into different levels and severities to more accurately quantify recovery. Lastly, and as is certainly the case for surgical trials, difficulty with blinding and timing of intervention provide unique challenges. It is of critical importance that examiners be blinded to treatment groups to minimize bias. This may require mandatory bandaging of surgical and "sham" sites or cooperation on the part of the patient to conceal their treatment group. Optimal timing of intervention has not been well established, though it has been hypothesized that neuroprotection be initiated early while subacute to chronic injury may be optimal for trials aimed at assessing regenerative capacity. These are only a few of the important points to consider when designing or evaluating results in SCI trials.

Currently no one effective therapy exists for restoring function in SCI. This emphasizes the need for continued research and translational studies. Despite the many challenges that exist in the research pathway, many translational human studies are underway. Both successes and failures will aid in our understanding of SCI and pave the road toward developing promising therapies. Throughout the process, it is equally important to ensure that ethical standards are adhered to. Through guidelines and careful review of each step, ethical challenges can be minimized to ensure the safety of all patients.

Contents

Abstract

A biologic product is derived from a biological system and may include osteogenic, osteoinductive, and/or osteoconductive properties that are required for efficient bone regeneration. Current biologics include autologous or allogenic bone products, growth factors, and bone graft substitutes. Each of these therapeutic approaches presents unique advantages and challenges that require further development. Due to known, inherent challenges of current biologics, a single approach may not be sufficient to address complex issues presented in patients with significant issues in the spine, especially those at high risk for nonunion. While a combinatory approach is certainly

interesting, a new therapeutic modality that combines different aspects of bone repair and regeneration may be needed. Stem cell and gene-based approaches have been investigated to address unmet clinical needs, which may include systemic issues and/or suboptimal microenvironment at the site of implantation. Intricate interactions and molecular cross-talks between osteogenic, osteoinductive, and osteoconductive biologics that are required for successful bone fusion are still under investigation.

Introduction

Two or more vertebrae may be fused to stabilize the spine for a variety of clinical conditions such as degenerative disc disease, vertebral fracture, scoliosis, and other conditions that cause instability of the spine. The height of an intervertebral disc may be up to 16 mm (Zhou et al. 2000) and represents the distance between two adjacent vertebrae that needs to be filled with new patient bone for a successful interbody fusion. In the absence of a true, effective osteogenic element in the treatment modality, this distance may present a significant challenge for the right type of cells on either side to migrate out from their native environment and bridge the bony gap, especially in patients with risk factors such as diabetes, aging, and smoking. As an example, a significant difference was observed in nonunion rates between nonsmokers and smokers (14.2% vs. 26.5%) (Glassman et al. 2000). Thus, a proper understanding of various therapeutic modalities, size and type of bony gap (or defect), and microenvironment, where bone regeneration must take place, is critical for a successful fusion.

A biologic medical product (or biologic) refers to a therapeutic modality that is derived from a biological system (e.g., animals, humans) and used to address a clinical condition. For bone fusion, it includes any biological elements that have osteogenic, osteoinductive, and/or osteoconductive properties, which participate in regeneration of bone in a clinical setting. An intricate interaction or molecular cross-talk between these properties may be necessary for efficient bone regeneration. The osteogenic component may include stem and progenitor cells (e.g., mesenchymal stem cells [MSC]), bone marrow-derived products (bone marrow aspirate), and autograft/allograft. It is typically referred to viable cells that can directly contribute to repair and regeneration of bone at the affected site. Exogenous (transplanted) or endogenous (native) cells that can proliferate and differentiate into mature bone cells may be considered osteogenic. An osteoinductive factor participates in differentiation of bone precursors toward the terminal lineage. It can modulate local microenvironment to promote tissue healing post-injury. Osteoinductive factors include bone morphogenetic proteins (BMPs), fibroblast growth factor-2 (FGF-2), and platelet-derived growth factor (PDGF) (Khorsand et al. 2017; Kim et al. 2015). An osteoconductive element provides a scaffold that can support the function of osteogenic cells and osteoinductive factors structurally to regenerate, fill, and bridge bony void or defect with new bone. It may be derived from a biological system or produced synthetically. In this chapter, current clinical uses of each of these components that participate in bone repair and regeneration and their inherent challenges are discussed.

Autologous Bone

Currently, technologies addressing the need to repair bone defect or void are extensive, but none currently offer the benefit of a personalized approach that is safe, relatively noninvasive, and anatomically defined for autologous bone formation. As described above, an ideal bone product would be osteoconductive, osteoinductive, and osteogenic. Autologous bone (autograft) meets the above criteria and is considered the “gold

standard" for bone repair and regeneration. Local autologous bone is often inadequate. Therefore, it is important to consider many factors such as potential morbidity due to the harvesting procedure, tissue condition at the harvest site, mechanical and structural implication of graft harvesting, and patient condition among others. Autologous bone is traditionally harvested from the iliac crest but can also be collected from other sites such as the rib, vertebral body, and fibula. The iliac crest has been considered the "gold standard" source since the amount of bone available for harvesting is relatively large compared to the other sites. A wide variety of harvesting techniques are available depending on the type of bone subject to harvesting and the approach used, including trapdoor (bone flap), window (removal of segmental bone), splitting (fissure in the iliac crest), and trephine extraction ("minimally invasive") techniques. Overall, there has not been consensus as to which technique results in a better clinical outcome, especially the risk of complication and morbidity associated with the harvest procedure of choice. While the use of autologous bone graft has shown exceptional efficacy, regardless of the type of harvesting methods or sites used, with a fusion rate greater than 94% (Sawin et al. 1998), donor site morbidity still presents a significant problem. Pain at the donor site was reported in 16% of patients who reported a worse pain at the donor site (iliac crest) than the primary surgical site in addition to difficulty walking (15.1%), employment (5.2%), recreation (12.9%), household chores (7.6%), sexual activity (7.6%), and irritation from clothing (5.9%) at 1 year follow-up (Kim et al. 2009). Similar findings were observed in other studies with a longer follow-up period (Sasso et al. 2005; Schwartz et al. 2009). Although there have been efforts to reduce donor site morbidity including restricting the area for harvesting and use of a suction drain (Kurz et al. 1989), the clinical outcome of using autologous bone is still less than optimal due to donor site morbidity, increased blood loss and frequent need for blood transfusion, prolonged operative time, risk of nerve damage, and a revision in many cases (Mulconrey et al. 2008).

Allogeneic Bone

Allogeneic bone (allograft) is considered an alternative source of graft material and eliminates the donor-site complications associated with autologous bone harvest procedures (Ehrler and Vaccaro 2000). It is harvested from cadaveric and living donors and is typically stored in a bone tissue bank. Fresh-frozen allografts, freeze-dried allografts, and demineralized bone matrix are the most commonly used forms of allogenic bone, and each preparation method brings certain advantages and disadvantages to a bone grafting procedure (An et al. 1995). Across all methods of preparation, allograft is more immunogenic and displays a decreased rate of graft integration in comparison to autograft (Ehrler and Vaccaro 2000). Fresh-frozen allografts are treated with antibiotics after harvesting and must be frozen below −70 °C to preserve the quality and viability of the graft material (Laitinen et al. 2006). The composition and structure of fresh-frozen allograft is most similar to those properties of autologous bone. Fresh-frozen grafts retain the most structural integrity of any processed allograft, which provides an optimal matrix for osteogenesis at the graft site. This preparation method also preserves a significant amount of endogenous BMPs known to be osteoinductive. However, the presence of cellular debris activates a host immune response and leads to increased risk of graft-site inflammation, delayed bone regeneration, and higher failure rate (An et al. 1995; Laitinen et al. 2006). Freeze-dried allografts are prepared similarly to fresh-frozen grafts with the addition of a dehydration process. Dehydration renders the graft material shelf-stable at room temperature and thus more readily stored for future use (Ehrler and Vaccaro 2000). Freeze-dried allografts carry a decreased risk of infection and immunogenicity at the graft site. This allograft type contains no live cells and fewer viable growth factors, but the mineralized portion may still provide a significant osteoinductive effect (Mellonig 1995). A potential drawback of freeze-dried allograft is decreased mechanical stability and structural strength, rendering the graft more brittle and prone to fracture (Cornu et al. 2000).

Demineralized bone matrix (DBM) is more extensively processed than fresh-frozen and freeze-dried allografts. Acid treatments are used to remove the inorganic, mineralized components of bone leaving behind the organic collagen matrix composed of type I collagen, non-collagenous proteins, and various growth factors (Lee et al. 2005). DBM is sold in numerous commercial formulations and is subject to a great deal of variability in processing techniques. Differences in acid solutions, temperature, particle size, terminal sterilization, and demineralization time result in lot-to-lot variability, yielding inconsistencies in BMP content and osteoinductive potential (Lee et al. 2005; Wang et al. 2007). DBM does not provide structural support as the mechanical properties of bone are significantly diminished secondary to the demineralization process (Pacaccio and Stern 2005). Generally, DBM is indicated for use as a bone graft extender and is not thought to be sufficient as a stand-alone bone graft substitute for reconstructive orthopedic procedures. Allograft materials made of minimally or highly processed allogenic bone are relatively abundant in supply and are effective in regenerating bone. Overall, the structural integrity and osteoinductivity of fresh-frozen allograft is preferred over freeze-dried allograft and DBM products, despite the risk of immunogenic complications.

Growth Factors

BMP-2

Bioactive agents including growth factors with osteoinductive functions are administered for spinal fusion as a means to promote endogenous bone formation and healing. BMPs are a family of osteoinductive growth factors with important roles in development and are known to stimulate osteoblastic differentiation of stem cells. BMP-2, or recombinant BMP-2 (rhBMP-2) produced in vitro by mammalian or bacteria cells, is the most widely studied and has been approved by the FDA for anterior lumbar interbody fusion (ALIF) in 2002 (US Food and Drug Administration 2019a). rhBMP-2 is typically administered with a carrier such as demineralized bone matrix or biodegradable collagen sponges at doses in the range of 3.5–20 mg (Duarte et al. 2017). A commercially available product for ALIF, Infuse™ Bone Graft (Medtronic), contains rhBMP-2 with an absorbable collagen sponge carrier inserted in a titanium cage to provide mechanical support. Early clinical studies demonstrated the Infuse™ product to be superior to iliac crest bone graft with 94% versus 88.7% fusion, respectively (Burkus et al. 2002a, b). Radiographs and computed tomographic (CT) scans provided evidence of rhBMP-2 driven osteoinduction in the interbody cages within 6 months of surgery and new bone formation in the surrounding disc space by 24 months post-surgery in all patients (Burkus et al. 2003). Follow-up studies compared cortical allograft dowels with or without rhBMP-2 for single level ALIF. All patients receiving the allograft with rhBMP-2 showed radiographic evidence of fusion by 12 months which remained stable through 24 months ($n = 79$, 100% fusion) compared with controls ($n = 52$, 89% and 81.5% fusion at 12 and 24 months, respectively) (Burkus et al. 2005, 2006). In addition to improving bone formation, the use of Infuse™ is simple with reduced operation times, length of hospital stay, and volume of blood loss compared to bone graft therapy (Burkus et al. 2002a). FDA has granted additional approvals for Infuse™ in polyetheretherketone supports for ALIF and oblique lateral interbody fusion (OLIF, US FDA 2019b).

The use of rhBMP-2 with the Infuse™ product was widely adopted for ALIF (on-label) as well as many off-label applications. In 2010, off-label use of rhBMP-2 was reported to be as high 85% including primary cervical, primary thoracolumbar, posterior lumbar, transforaminal lumbar, and posterolateral spinal fusions (Ong et al. 2010). When used as directed for ALIF, industry-sponsored clinical study publications reported efficacy rates superior to allogenic or autologous bone with adverse events rarely observed. Follow-up publications and review of FDA data summaries focused attention on a number of complications and adverse events including implant displacement, subsidence, osteoclast-mediated bone

resorption, ectopic bone formation, inflammation, life-threatening cervical swelling, urogenital complications, and possible increased risk of tumor formation (Carragee et al. 2011a; Savage et al. 2015; Faundez et al. 2016).

In addition to osteoinductive properties, rhBMP-2 enhances osteoclast activity which has been linked with subsidence or abnormal bone resorption. Localized areas of bone remodeling were noted at 12 months post-surgery by CT scan in 18% of patients receiving cortical allograft dowels with rhBMP-2 (Burkus et al. 2006). These regions resolved by 24 months in follow-up CT scans. Patients treated with rhBMP-2 within the disc space during transforaminal lumbar interbody fusion were observed with 69% vertebral bone resorption and 74% graft subsidence (McClellan et al. 2006). Radiologic analysis of interbody fusions in the cervical or lumbar spine performed with a polyetheretherketone cage and rhBMP-2 demonstrated endplate resorption in all cervical and most lumbar fusions with concomitant cage migration and disc space subsidence (Vaidya et al. 2008). Ectopic bone formation beyond the implant site has also been reported and is thought to be a consequence of leakage of rhBMP-2 from the collagen sponge due to pressure during the placement procedure or the use of irrigation or suction near the graft site (James et al. 2016). Leakage occurring in the epidural space may result in nerve root compression and is noted more frequently in transforaminal lumber interbody fusion (Rihn et al. 2009).

Use of rhBMP-2 in cervical fusions has resulted in severe, life-threatening swelling in the head and neck leading to dyspnea and dysphagia (Shields et al. 2006). Procedure-related swelling around the cervical spine contributes to constriction of airways and nerves that lie in close anatomical proximity. The life-threatening nature of these complications may require interventions such as intubation, anti-inflammatory medications, tracheotomies, or additional surgeries (Smucker et al. 2006; Fineberg et al. 2013). Seroma formation was also noted when the Infuse bone graft was used for occipitocervical fusion (Shahlaie and Kim 2008) with elevated levels of inflammatory cytokines including IL6, IL8, and TNFα reported in seroma fluid (Robin et al. 2010). The severity of inflammatory complications related to rhBMP-2 use in the cervical region prompted FDA to issue a public health warning regarding the use of this product in the cervical region in 2008 (Crawford et al. 2009). Use of rhBMP-2/Infuse™ products in pediatric spinal fusions is also contraindicated (Epstein 2013). No differences in infection rates were noted in spinal fusions with and without rhBMP-2 in a retrospective study by Williams et al. (2011) suggesting swelling events to be related to hypersensitivity rather than infection.

A number of urogenital complications have been reported including retrograde ejaculation and bladder retention with incidence rates up to 6.3% and 9.7% respectively, although in most studies these events were not statistically greater than observed in control groups (Carragee et al. 2011b). Further studies of 10-year outcomes following rhBMP-2/Infuse™ for ALIF suggest these complications may be related to concomitant prostatic disease with specific correlation to rhBMP-2 difficult to establish (Comer et al. 2012). Other studies suggest transperitoneal and laparoscopic approaches increase risk of urogenital adverse events in comparison to a retroperitoneal approach (Burkus et al. 2002a; Than et al. 2011).

BMPs have developmental and regenerative roles in many organ systems and are known to regulate cell growth and differentiation as well as stem and progenitor cell functions. Members of this family of proteins are frequently upregulated in tumors of diverse organ systems and the spine is a common site for tumor metastases leading to concerns that rhBMP-2 use in spinal fusions may increase tumor risk (Carragee et al. 2013). Retrospective analysis by Devine et al. (2012) did not find evidence of increased cancer risk when rhBMP-2 was used as approved. Higher doses of rhBMP-2 (40 mg) were linked to small increases in cancer risk, as was the use of rhBMP-7. In agreement with these findings, retrospective studies of cancer incidence in Medicare patients receiving rhBMP-2 over a 5-year period were not associated with an increase in cancer risk (Kelly et al. 2014; Beachler et al. 2016). Likewise,

an analysis of database studies of rhBMP-2 in spinal fusion was unable to detect a significant increase in local or distant site tumor formation (Cahill et al. 2015).

OP-1 (BMP-7)

Osteogenic protein 1 (OP-1), also known as BMP-7, is another member of the family of BMPs with osteoinductive potential. In spinal fusion, rhBMP-7 is delivered in a collagen putty (Olyppus Biotech). When compared with autograft bone for noninstrumented posterolateral lumbar fusion, the OP-1 implant was similar, but not superior to autograft bone (Johnsson et al. 2002). FDA approval, under an investigational device exemption, was granted in 2004 for OP-1 putty in posterolateral spinal fusion (Vaccaro et al. 2003, 2004). Radiographic and clinical outcomes were at least equivalent to the autograft cohort over the 2-year follow up period, with no adverse events reported (Vaccaro et al. 2005a, b). The OP-1 putty was also assessed as an adjunct to autograft bone for intertransverse process lumbar fusion in a small clinical trial (Vaccaro et al. 2003). Inclusion of OP-1 putty with the autograft bone was not shown to improve spinal fusion, although product safety was demonstrated with no adverse events reported. In a study with 4-year follow up, OP-1 putty was compared with iliac crest autograft and shown to be equivalent in promoting fusion and advantageous from a procedural view due to less blood loss and shorter operative times (Vaccaro et al. 2008a, b). In a randomized, multicenter trial, there were fewer fusions in the OP-1 cohort (54%) than in the iliac crest autograft groups (74%) (Delawi et al. 2016). More recent clinical trials are focused on the use of OP-1 in uninstrumented posterolateral fusions (Olympus Biotech, http://www.clinicaltrials.gov/ct2/show/NCT00679107). The safety profile of OP-1 in terms of adverse events appears to be superior to rhBMP-2; however, this should be interpreted with caution until larger OP-1 trials are completed. In terms of effectiveness, OP-1 has not been shown to be superior to autograft bone and direct comparisons with rhBMP-2 have not been conducted.

NELL1

Other growth factors have shown potential in spinal fusion studies in animals. Neural EGFL like 1 (NELL1) is an osteoblast-specific growth factor which acts in bone maintenance and repair to promote expansion of a progenitor population (James et al. 2017). When delivered in a demineralized bone putty carrier, NELL1 was found to be effective for spinal fusion in rats (Li et al. 2010). In a sheep spinal fusion model, NELL1 delivered in demineralized bone matrix promoted 100% fusion by 3 months with advantages in bone volume and mineral density compared to demineralized bone alone (Siu et al. 2011). Studies by Yuan et al. (2013) compared NELL1 in demineralized bone matrix with the BMP-2/Infuse™ bone graft product in a rat spinal fusion model. Fusion rates were similar in both groups (100%). Histological analysis demonstrated the presence of adipocytes and cyst-like bone formation in the rhBMP-2 graft cohort and increases in bone formation, ossification, and vascularization in the NELL1 group (Yuan et al. 2013).

Growth Factor Combinations

Combinations of growth factors have also been tested in animal spinal fusion studies including angiopoietin 1 (ANG1) and cartilage oligomeric matrix protein (COMP). ANG1 is a secreted factor with important roles in vascular development and angiogenesis. COMP is a BMP-binding protein expressed during endochondral ossification and shown in vitro to enhance BMP-2 activity (Ishida et al. 2013). A recombinant chimeric protein composed of COMP and ANG1 delivered in a collage sponge for lumbar fusion was shown to be effective (89.5% vs. 38.5% in sham-treated controls) in rats (Park et al. 2011). Greater bone volume, mechanical strength, and vascularity were also reported in fusions with the COMP-ANG1 chimeric protein. Endogenous BMPs are soluble factors thought to be present in nanogram concentrations, but supraphysiological doses of 3.5–20 mg are commonly utilized in spinal fusion

applications (Ishida et al. 2013). In an effort to reduce rhBMP-2 dosage and therefore improve product safety, co-administration of COMP and rhBMP-2 was shown to induce equivalent bone formation at lower doses than rhBMP-2 alone in a rat model of spinal fusion (Refaat et al. 2016).

Other growth factors studied in animal models for spinal fusion include AB204 (Activin A/BMP-2 chimera), calcitonin, FGF-2, growth differentiation factor 5, insulin-like growth factor 1, transforming growth factor β, noggin, peptide B2A, and secreted phosphoprotein 24 (Cottrill et al. 2019). In general, these studies suggest that growth factors alone or as an adjunct to bone autografts enhance spinal fusion efficacy. Adverse events associated with rhBMP-2 administration at pharmacological doses raise valid concerns about the safety of growth factor therapies with this family of proteins. Combinatorial approaches or methods to reduce dosage to physiological levels may provide safer, less expensive options. Growth factors such as NELL1, with greater specificity of action, may improve safety and efficacy but clinical trials have not yet been reported.

Stem and Progenitor Cells

An ideal population of cells for bone repair and regeneration must be able to self-renew and proliferate to provide a long-term reservoir of cells available to respond to biological cues. Also, they must be able to differentiate toward mature osteocytes without resulting in fibrosis. In a strict sense, a true stem cell must be able to self-review and differentiate toward multiple lineages clonally at the single-cell level. Progenitor cells have a limited capability to self-renew, proliferate, and differentiate. Stem and progenitor cells that participate in osteogenesis may reside in and near bone or at another location such as adipose tissue. Similar to the hematopoietic system, osteogenic stem and progenitor cells must also be capable of maintaining healthy, long-term homeostasis of the skeletal system. Single human bone marrow-derived high proliferative potential-mesenchymal colony-forming cells (HPP-MCFC) have been investigated for their ability to give rise to another generation of HPP-MCFC and differentiate into multiple lineages clonally (Lee et al. 2013). HPP-MCFC are present at a frequency of about 7% in typical bone marrow mesenchymal cell cultures and show a significant osteogenic activity when induced with osteogenic growth factors. Although controversies still exist, these proliferative and multipotent cell populations derived from different tissue sources are referred to as MSC. MSC have been identified in bone marrow, bone, fat, muscle, and umbilical cord (UC). However, most of studies on MSC are not performed clonally, and it is difficult to conclusively claim their "stem-cell-ness." MSC that have been isolated in culture show expression of different surface markers such as CD29, CD44, CD90, CD49a-f, CD51, CD73 (SH3), CD105 (SH2), CD106, CD166, and Stro-1 and lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR in addition to plastic adherence and potential to differentiate toward multiple lineages (Dominici et al. 2006; Maleki et al. 2014). STRO-3+ mesenchymal precursor cells have shown an ability to partially reconstitute extracellular matrix (ECM) at 6 months following intradiscal administration into degenerate discs in sheep (Ghosh et al. 2012). Other cell types with similar phenotypic and functional properties have been described including adipose-derived stem cells (ASC) (Minteer et al. 2013), MSC isolated from different locations in umbilical cord (Nagamura-Inoue and He 2014), long bone (Toosi et al. 2017), and dental pulp (Kawashima et al. 2017).

Healthy bone is maintained through formation by osteoblasts and resorption by osteoclasts. An intricate balance between osteoblastic and osteoclastic activities determines the health of bone. The lifespan of osteoblasts (~2–100 days) and osteoclasts (~12 days) are relatively short, and these cells must continually be replenished by stem and progenitor cells. For example, bone marrow-derived MSC have been shown to proliferate and differentiate toward the osteogenic lineage, regulated by numerous signaling pathways such as β-catenin-dependent Wnt (D'Alimonte et al. 2013), Hedgehog (Salem et al. 2014), NELL1 (Lee et al. 2017b), and BMP signaling. Osteogenesis involves several steps that includes ECM

production (organic phase) and mineralization by hydroxyapatite (inorganic phase), followed by differentiation of osteoblasts into osteocytes through embedding in bone matrix and subsequent apoptosis. Osteoclasts have also been shown to participate in osteogenesis by inducing expression of Wnt 1 through the release and activation of TGF-β (Ramasamy et al. 2014). Thus, the microenvironment for bone stem and progenitor cells would include several factors as described above. A deficiency in any component of the microenvironment may result in an aberration in osteogenesis, similar to the hematologic aberrations noted with hematopoietic microenvironment changes. Also, self-renewal and differentiation of stem cells that participate in bone regeneration can be affected directly by specific epigenetic changes, leading to aberration in gene expression and metabolic bone disease (Pérez-Campo and Riancho 2015). It is entirely possible that unnatural or adverse microenvironment provided by a bone graft substitute may have a negative impact in bone repair and regeneration, regulated by proliferation and differentiation of stem and progenitor cells. Thus, the stem and progenitor cell microenvironment need to be considered carefully when transplanting these cells for clinical applications.

MSC are very responsive to their microenvironment (Lander et al. 2012). However, a database of approximately 700 clinical trials on MSC registered in ClinicalTrials.gov as a therapeutic agent indicates that the majority of these trials either did not use any carrier by injecting MSC directly into patients or used ceramic-based carriers (unpublished observation). While an increasing number of preclinical studies focus on MSC and their microenvironment, no clinical trials have considered the effects of the microenvironment on stem cell function. The clinical effectiveness and efficacy of MSC remain inconclusive, although these cells are investigated extensively as shown above, and there have not been any MSC-based therapies approved by the US Food and Drug Administration. Another comprehensive review on the use of MSC in close to 500 clinical trials revealed that the beneficial effect of MSC-based treatment could be principally due to their immunomodulation and regenerative potential (Squillaro et al. 2016). However, issues such as MSC heterogeneity, lack of standard isolation methods, donor heterogeneity, immunogenicity, and cryopreservation bring complexity to the interpretation of clinical data. In addition, in most cases, the host microenvironment may not have been ideal for long-term survival and desired function of transplanted cells.

Gene Therapy

Gene therapy is one strategy to optimize the tissue environment for bone healing or regeneration through delivery of genes encoding for osteoinductive or osteogenic factors. Treatment with a therapeutic osteoinductive factor typically requires large doses of recombinant proteins. In contrast, the use of regional gene therapy to modify native or implanted cells to produce the same protein of interest is potentially more physiologically relevant and cost effective (Phillips et al. 2005). Typically, a gene of interest is delivered to cells which then produce and secrete the target protein into the extracellular environment in a sustained pattern mimicking physiological secretion. The transgene may be introduced in vivo via local injection into patient tissue or in conjunction with transplants of stem or progenitor cells with the gene of interest introduced ex vivo. Local in vivo injection methods are comparatively simple and may provide a readily available, off-the-shelf product, although precise control of transgene delivery to cells in vivo remains a major challenge. Advantages of the ex vivo transduction approach include the ability to expand cells in culture to sufficient numbers essential for bone repair and the capability to quantify target protein production. Some of the challenges include the time and labor necessary for cell expansion and transduction, and risk of inflammatory response due to viral proteins (Baltzer and Lieberman 2004).

Many studies have explored the use of BMPs in gene therapy applications for spinal fusion (Barba et al. 2014). Early attempts at direct percutaneous in vivo gene delivery demonstrated that adenoviral

vectors containing BMP-2 promoted bone formation (Musgrave et al. 1999; Alden et al. 1999). Later studies explored various cell types for ex vivo gene modification followed by transplantation at the fusion site. An ideal cell type for this application should be readily harvested, easy to expand in culture, amenable to gene modification, and have inherent osteogenic and osteoinductive properties. MSC, which can be harvested from bone marrow and are known to differentiate toward osteogenic, chondrogenic, and adipogenic lineages, are a logical choice and have been widely studied as a source of autologous cells for this purpose. MSC genetically modified with BMP-2 were implanted by direct injection into thoracic disc spaces (Riew et al. 2003) or lumbar paraspinal muscles (Hasharoni et al. 2005) and resulted in bridging bone formation in pigs and mice, respectively. Biomechanical tests demonstrated BMP-2-modified MSC-mediated spinal fusion and were as effective as bilateral fusion with stainless steel pins in a mouse model (Sheyn et al. 2010). To improve efficacy, BMP-2-modified MSC were implanted on collagen sponges or demineralized bone carrier matrix and shown to promote abundant bone formation and fusion rates superior to administration of BMP-2 alone (Wang et al. 2003). Additional studies in the rat model of lumbar fusion drew similar conclusions (Peterson et al. 2005; Miyazaki et al. 2008a). In follow-up studies, Miyazaki et al. (2008b) found adipose-derived MSC, which are easier to isolate from patients, to be comparable with bone marrow MSC in this model. Adenoviral-mediated BMP-2 modification of fibroblasts prior to injection along the paraspinous musculature induced heterotopic ossification, new bridging bone, and greater than 90% fusion by 4 weeks in both immune-competent and immune-deficient mice ($n > 40$ per group, Olabisi et al. 2011). Other members of the BMP super-family explored in spinal fusion studies include BMP-4 (Zhao et al. 2007), BMP-6 (Laurent et al. 2004), BMP-7 (Hidaka et al. 2003), BMP-9 (Helm et al. 2000; Dumont et al. 2002), and combinations of BMP-2 and -7 (Zhu et al. 2004; Kaito et al. 2013) with most studies reporting high rates of fusion in rodent or rabbit studies. Despite promising preclinical results in small animal models, the translation of BMP-directed adenoviral mediated gene transfer for spinal fusion to human patients faces challenges including the presence of neutralizing antibodies from previous exposures to adenovirus (greater than 80% of adults are seropositive) which limit effectiveness (Kim et al. 2003), systemic toxicity, and regulatory barriers to clinical trial approval (Wang 2011).

Ideal viral vectors for gene delivery in spinal fusion applications should be capable of delivering the desired transgene efficiently to initiate the bone formation required for the fusion process, but also self-limiting to avoid excessive or abnormal bone formation. Non-integrating, adenoviral vectors induce high, yet transient, levels of gene expression and are the vector of choice for most spinal fusion studies as outlined previously. Lentiviral vectors, which may infect nondividing cells and are known to insert within the host cell genome, have also been studied for this application. Rat MSC transduced with a lentiviral-BMP-2 vector were implanted in hind limb muscle pouches and observed to induce robust bone formation (Sugiyama et al. 2005) in a proof-of-principle study. Bone marrow MSC transfected with lenti-BMP-2 were implanted in collagen sponges and shown to induce spinal fusion in rats (Miyazaki et al. 2008b). Direct comparisons of adenoviral or lentiviral BMP-2 ex vivo gene therapy in MSC seeded on collagen sponges for implantation suggest improved bone formation with lentiviral delivery (Miyazaki et al. 2008c) at 8 weeks post implantation. Longer studies will be necessary to assess safety and risks of insertional mutagenesis with lentiviral vector approaches. Nonviral gene transfer approaches including sonoporation, electroporation, and nucleofection are thought to be safer than viral delivery methods, but low transfection efficiency has limited their application in spinal fusion studies (Sheyn et al. 2008; Makino et al. 2018).

Other osteoinductive proteins studied for gene therapy applications in spinal fusion include NELL1, LIM mineralization proteins (LMPs), and SMAD family member 1 (SMAD1). Lu et al. (2007) utilized adenoviral-mediated NELL1 delivery in demineralized bone matrix to show improved bone quality and maturity at 6 weeks post implantation in a

rat spinal fusion model. In comparison to BMP-2 administration, goat MSCs carrying the NELL1 transgene promoted less bone mass but greater trabecular and chondroid bone formation (Aghaloo et al. 2007). LMP1 encodes an osteoinductive intracellular protein which promotes bone growth and skeletal organization. Initial studies of LMP1 for gene therapy in spinal fusion utilized bone marrow cells transfected with LMP1 cDNA with results demonstrating successful fusion (Boden et al. 1998) in rats. Bone marrow or buffy-coat cells transduced with adenoviral LMP1 for 10 min and implanted in demineralized bone or collagen-ceramic composite sponges were shown to induce posterolateral lumbar fusion in rabbits (Viggeswarapu et al. 2001). To improve ease and efficiency of cell isolation, autologous dermal fibroblasts from skin biopsies were transduced with adenoviral-LMP3 and shown to induce ectopic bone formation in muscle (Lattanzi et al. 2008). SMAD1, a downstream target of BMPs, is a key intermediary in expression of genes driving osteoblast differentiation and thus proposed to induce osteogenesis more specifically than BMPs. MSC transduced with SMAD1C and implanted on gelatin sponges were shown to support efficient new bone formation in a rabbit model of lumbar spinal fusion (Douglas et al. 2010).

Despite the promising results of preclinical gene therapy studies for spinal fusion, translation of these results to therapies for human patients has shown little progress. Variables which will need to be optimized to move gene therapy approaches forward include choice of vector, therapeutic gene, delivery method (in vivo or ex vivo), source of cells for ex vivo modification, and implantation or injection strategies. The risks associated with the viral vector-mediated delivery including systemic toxicity, insertional mutagenesis, and genomic instability constitute significant barriers to bringing such therapies into the clinic (Wang 2011). Regulatory approval for gene therapy approaches for spinal fusion, a procedure which may influence quality of life but for which the underlying pathology is typically nonlethal, may be difficult to achieve.

Microenvironment

In a therapeutic situation, it may be critical to consider the effects of the implant site on the fate of transplanted stem and progenitor cells and growth factors. It is entirely possible for a damaged or diseased implant site to have an unintended consequence on incoming cells and growth factors. For example, as described above, growth factors may leak out of the implant site and result in unintended consequences locally and systemically, especially if growth factors are introduced at a dose significantly higher than their physiological levels (as seen with BMP-2). In addition, in a healthy intervertebral disc, numerous factors such as cytokines, growth factors, endogenous cells, enzymes, and mechanical stimuli regulate the balance between the anabolic and catabolic processes. However, decreased proteoglycans and collagen II, increased proteinases and cytokines, and decreased (acidic) pH have been observed in a degenerating intervertebral disc (Huang et al. 2013), caused by aging, disease, trauma, or mechanical stress. These factors may comprise an unfavorable microenvironment and present a significant challenge when stem and progenitor cells are considered as a therapeutic option. Thus, it is imperative that biologics must be delivered within a carrier that can retain therapeutic elements and maintain a healthy microenvironment for tissue repair and regeneration.

A hostile microenvironment at a disc impacts directly on the success of any attempted interbody fusion. Anterior cervical discectomy and fusion (ACDF) is the most common fusion surgery in cervical spine. Interbody fusion is also often utilized in lumbar spine: transforaminal lumbar interbody fusion (TLIF), posterior lumbar interbody fusion (PLIF), direct lateral interbody fusion (DLIF), and anterior lumbar interbody fusion (ALIF). Without successful fusion, the patients may have persistent or new pain and the implants utilized for fusion may fail, possibly leading to another surgery. Posterolateral fusion is very common in lumbar spine, and it may pose even more challenging microenvironment. Successful fusion depends on a solid bony growth spanning the transverse processes with adjacent

ligament and musculature that may interfere with bone regeneration. As discussed previously, restoration of the microenvironment affected by various exogenous and endogenous, adverse physiological influences may be required prior to and/or at the time of stem and progenitor cell transplantation (Lee and Kim 2012).

Autologous bone harvesting and implantation result in transfer of not only stem cells that reside in the harvested bone but also their microenvironment. Undoubtedly, autologous bone harvested from a non-load-bearing site such as the iliac crest consistently results in a positive clinical outcome and is considered the "gold standard" for bone repair. As described above, transplanted bone marrow-derived MSC taken out of their native microenvironment and expanded do not result in clinical outcomes similar to implantation of bone. Thus, implantation of both stem and progenitor cells along with their native microenvironment ("autograft") is unarguably better than cells ("cell transplantation") alone. However, the clinical outcome when using the autograft approach is less than optimal due to donor site morbidity (especially pain), fracture, infection, increased blood loss, prolonged operative time, and risk of nerve damage. In addition, autograft is limited in quantity, and quality is suboptimal depending on the patient. Due to these risks and limitations, bone graft substitutes have been increasingly utilized instead of autograft. Bone graft substitutes are generally not indicated to be used with stem and progenitor cells but known to participate in bone regeneration, potentially reestablishing the microenvironment for bone stem and progenitor cells that are residing at the site of injury or transplanted.

Bone graft substitutes are discussed in ▶ Chap. 11, "Bone Grafts and Bone Graft Substitutes" in this book and broadly categorized into allografts, ceramics, polymers, and biologics. Several factors such as mechanical stress, vascularity, and surface characteristics of graft material have demonstrated to influence the stimuli and microenvironment of cells. These factors seem to have a collective influence on the osteogenic differentiation of stem cells through epigenetic/gene upregulation mechanisms. For example, mechanical stretch induced downregulation of GNAS (stimulatory G-protein alpha subunit) isoforms of mesenchymal cells and upregulation of osteogenic differentiation transcription in in vitro models (Vlaikou et al. 2017). In another study, mechanical stress in osteoblast precursor cells in 3D scaffolds experienced greater signaling through MAP kinase pathway (Appleford et al. 2007). Tissue engineered bone constructs of DBM and nanoscale self-assembling peptides provided with decreased pore size and increased charge field resulted in better enrichment of osteogenic cells (Hou et al. 2014).

Ceramic-based bone graft substitutes include calcium phosphate, calcium sulfate, hydroxyapatite (HA), β-tricalcium phosphate (β-TCP), and bioactive glass. HA scaffolds showed a greater degree of ectopic bone formation than β-TCP when implanted with MSC in rats (Denry and Kuhn 2016), but better attachment and spreading of MSC were observed with β-TCP while expressing G-protein coupled receptor (Barradas et al. 2013). Surface modification of calcium phosphate cement with arginine–glycine–aspartate (RGD) showed a significant improvement in attachment, survival, and proliferation of MSC (Chen et al. 2012), indicating that additional coating may be required to provide an optimal environment for MSC. Similarly, it has been postulated that the initial contact with blood primes the surface and prepares calcium phosphate ceramic scaffolds (CPS) for viable in situ cell seeding (Denry and Kuhn 2016). In addition, CPS show a very slow degradation rate (Bružauskaitė et al. 2016; Winter et al. 1981) and are not radiolucent, thus interfering with the visualization of new bone formation by radiographic evaluation.

Poly-lactic acid (PLLA) (Holderegger et al. 2015), polyglycolic acid (PGA) (Generali et al. 2017), and poly-DL-lactic-co-glycolic acid (PLGA) (Mendes Junior et al. 2017) have been proposed as a synthetic bone graft substitute. All of these synthetic materials show exceptional compatibility with MSC and support osteogenesis. However, PLLA, PGA, and PLGA degrade within 30 days (Generali et al. 2017) and may not be able to bridge a critical size bone defect,

considering natural bone regeneration over several months. Growth factors such as BMP-2 has received a significant attention due to its potent osteogenic properties and safety issues including adverse effects (e.g., life-threatening inflammatory complications), ectopic bone formation, osteoclast activation, and induction of adipogenesis (James et al. 2016). Other growth factors such as fibroblast growth factor-2 and insulin-like growth factor-1 have been shown to induce osteogenesis (Nagayasu-Tanaka et al. 2015; Guntur and Rosen 2013). However, as shown with BMP-2, patient safety must carefully be considered before clinical utilization.

ECM is an essential regulator of stem cell function and a critical component of stem cell microenvironment. ECM is primarily comprised of proteins (e.g., collagen, laminin, fibronectin, elastin) and carbohydrates (polysaccharides). While various proteins in ECM have been investigated for bone regeneration, the clinical utility of the polysaccharide component has not yet been explored fully. Carbohydrate-based, polysaccharide materials have been used to regenerate bone in preclinical settings including cellulose (Park et al. 2015), alginate (Hung et al. 2016), chitosan (Levengood and Zhang 2014), and glycosaminoglycans (Mathews et al. 2014). Carbohydrate-based materials have a long history of use in various medical applications and are nontoxic, biocompatible, soluble, and biodegradable. These properties make carbohydrate-based polymers an excellent scaffold for tissue engineering. A recent study reported that supramolecular sulfated glycopeptide nanostructures with a trisulfated monosaccharide on the surface amplified signaling of BMP-2, resulting in enhanced bone formation (Lee et al. 2017a). Thus, carbohydrate-based polymers may play a key role in developing novel therapeutic approaches and addressing the microenvironment issue in near future as shown in recent studies on stem cells (Batchelder et al. 2015b), tumor heterogeneity (Batchelder et al. 2015a), and cardiac tissue regeneration (Baio et al. 2017).

These therapeutic approaches using bone graft substitutes aim to generate bone by providing an osteoconductive environment for endogenous cells and factors and/or inducing osteogenesis and migration of host cells into the target site, reestablishing the microenvironment conducive to tissue regeneration. Bone regeneration and repair are fairly successful in healthy individuals, but high-risk patient populations have been reported to show nonunion rates as high as 40% for bone fusion (Scott and Hyer 2013). In well-controlled preclinical studies, diabetes showed a significant negative effect on bone regeneration compared to healthy animals under the identical experimental conditions including bone graft substitutes (Camargo et al. 2017). Thus, it is clear that bone graft substitutes alone are not sufficient for bone regeneration in high risk patients.

Conclusions

Contrast to small defects that the body can heal spontaneously, critical bone defects (>25 mm) have a higher probability of nonunion (>50%) and require a therapeutic intervention (Haines et al. 2016). Current biologics available for bony fusion address one or two components of complete bone repair and regeneration: osteogenicity, osteoinductivity, and osteoconductivity. A product or combination product that possesses all of these properties may be needed to close or bridge a critical bone defect in a functionally meaningful manner, especially in patients with high risk factors, in addition to systemic or local environment (microenvironment) that may adversely influence the patient outcome.

Abstract

With increasing numbers of patients requiring spine surgery, there has been an emphasis on technological advances designed to enhance surgical outcomes and improve patient safety. In particular, the number of elective spinal fusion surgeries in the USA continues to increase. Instrumentation of the spine with pedicle screws is frequently used for indications including deformity and instability. With neurovascular structures near the pedicle, accurate screw placement is of paramount importance to ensure good outcomes. Reported complications related to pedicle screw malposition range from 1% to 54% (Molliqaj et al., Neurosurg Focus 42(5): E14, 2017). Currently, there are several techniques described for inserting pedicle screws, including freehand manual insertion based on anatomic landmarks and fluoroscopy, manual insertion with navigation assistance systems, and robotic-assisted methods.

Introduction

With increasing numbers of patients requiring spine surgery, there has been an emphasis on technological advances designed to enhance surgical outcomes and improve patient safety. In particular, the number of elective spinal fusion surgeries in the USA continues to increase. Instrumentation of the spine with pedicle screws is frequently used for indications including deformity and instability. With neurovascular structures near the pedicle, accurate screw placement is of paramount importance to ensure good outcomes. Reported complications related to pedicle screw malposition range from 1% to 54% (Molliqaj et al. 2017). Currently, there are several techniques described for inserting pedicle screws, including freehand manual insertion based on anatomic landmarks and fluoroscopy, manual insertion with navigation assistance systems, and robotic-assisted methods.

The goal of this review is to focus on robotic-assisted surgical platforms used for the insertion of pedicle screws by highlighting their history and reviewing the literature regarding the current state of robotic platforms in spine surgery. In addition to detailing the history of robotics in spine surgery we will discuss terminology and definitions as well as reported benefits and costs associated with their use.

To better understand the basic concepts of robotics, it is important to understand or define the terminology that is used to describe robotics pertaining to surgical platforms. By definition, a robot is a machine capable of automating one, or a series of actions or steps in a procedure (Urakov et al. 2017). According to the Robot Institute of America, a robot is defined as a reprogrammable, multifunctional manipulator designed to move material, parts, tools, or specialized devices through various programmed motions for the performance of a variety of tasks (Jacofsky and Allen 2016). Robots should play an integral role in surgery to be classified as "surgical robots." There are several different ways to categorize robotic platforms, but their actions are classified as being either direct or indirect. Robots act directly when they cut tissue or mill bone into a predetermined and final desired shape, or indirectly by holding cutting jigs or drill guides (Chen et al. 2018). Furthermore, both direct and indirect surgical robotic platforms are further classified as passive, semi-active, and active systems (Jacofsky and Allen 2016).

Passive, Semi-Active, and Active Systems

Passive systems are used to complete a portion of the surgical procedure under direct, continuous control of the operating surgeon. The robotic instrument acts as an extension of the surgeon's hand and is unable to function without an operator engaging the device. Examples of passive systems include the OMNIbotics (OMNI) and the da Vinci surgical robot (Intuitive Surgical) (Chen et al. 2018).

Semi-active systems require surgeon involvement but provide feedback in the form of haptics (tactile, auditory, or visual) that restrict what can be done surgically to prevent the user from operating outside of a predetermined boundary. Semi-active systems can theoretically enhance the surgeon's control of the robotic instruments and increase surgical safety by preventing the surgical instruments from entering a "no-fly zone" as determined by the surgical plan. Current examples of semi-active systems include the Mako robotic arm–assisted surgical platform (Stryker) for total knee arthroplasty and the Navio surgical system (Smith and Nephew) used in unicompartmental knee arthroplasty.

Finally, active systems can perform a task entirely independently through the use of preprogrammed algorithms and predetermined parameters for surgical resection of tissue without direct manipulation by a surgeon or operator. Active systems allow for surgeons to initiate and stop the robot's activity but do not allow for continuous control, or the ability to alter the robot's actions intraoperatively (Chen et al. 2018). Current examples of active systems which are fully autonomous include the ROBODOC Surgical System and TSolution One (Think Surgical) (Chen et al. 2018).

Supervisory-Controlled, Telesurgical, and Shared-Control Systems

Additionally surgical robots have been classified into three main categories of systems, according to Kochanski et al. which are supervisory-controlled systems, telesurgical systems, and shared-control systems (Kochanski et al. 2019).

Supervisory-controlled systems are designed so that the surgeon can plan the robotic portion of the case before beginning the procedure. The surgeon initiates the procedure, then allowing the robot to perform its portion of the case autonomously under the direct supervision of the surgeon, making it an active system. Telesurgical systems, which are passive, offer the surgeon complete control of the robot at all times. Examples of telesurgical systems include the Georgetown robot and the Spine Bull's-Eye robot, both designed for use in spine surgery and the da Vinci surgical robotic system (intuitive surgical) which is widely utilized in various surgical specialties. Lastly are the shared-controlled systems, which allow for the robot and surgeon to share control of surgical instruments concurrently. Notably, most spine surgical robots on the market today such as the Mazor X, Excelcius GPS, and the ROSA spine robot are classified as shared-control systems. These systems require either preoperative or intraoperative CT or fluoroscopic imaging and use proprietary software to plan trajectories for pedicle screw placement. Once the preoperative plan is confirmed, the surgeon manually inserts the pedicle screws using the robotic instruments as a guide.

Image-Based Systems

Currently, most orthopaedic and spine robotic systems require a preoperative plan and computer model on which to base the surgical procedure. Having a preoperative plan to execute is one aspect of orthopaedic and spine robotic systems that differentiates it from other surgical robots, such as the da Vinci. Having a specific reproducible plan, which allows the surgeon to preoperatively or intraoperatively analyze and predict the desired result before any tissue is resected is a significant advantage of these systems (Jacofsky and Allen 2016).

The patient's anatomy must be registered via mapping points on the bone with a navigated tool during the registration process or via intraoperative scan in both system types so that the robot knows where the instruments are in space relative to the patient's anatomy. In image-based systems, this

Fig. 1 Intraoperative CT scan used for imaged-based planning to map the patient's anatomy in the prone position and register instruments used in lumbar fusion

registration is referenced to the preoperative imaging. Currently, preoperative CT or an intraoperative CT scan is used (Fig. 1). Intraoperative CT limits the need for bony registration as the navigation arrays are typically included in the scan. Potential disadvantages of image-based systems include increased cost, patient inconvenience, and increased radiation exposure to the patient during CT (Jacofsky and Allen 2016). Potential advantages include extremely accurate mapping of the patient's anatomy, which increases the precision of implant placement.

History of Robotics in Surgery

Robotic surgical platforms are used in many surgical specialties, including gynecological, urological, thoracic, orthopaedic, and general surgery over the last two decades. According to early reports, the use of the UNIMATION PUMA 200 (Programmable Universal Manipulation Arm, Nokia) during a neurosurgical biopsy performed in 1985 marked the first documented robotic-assisted surgical procedure (Chen et al. 2018). That same system was repurposed and used for the transurethral resection of prostate tissue, which eventually lead to the development of the ProBot, which was designed explicitly for prostate surgery (Jacofsky and Allen 2016). With a growing body of evidence supporting their safe and predictable implementation, the field of robotic surgery began to proliferate. Since then, the integration of robotics in the operating room has steadily increased across a variety of surgical specialties.

Robotic surgery began to gain momentum in the year 2000 when the da Vinci surgical robotic system (intuitive surgical) was approved for use in urologic, gynecologic, and general laparoscopic procedures by the US Food and Drug Administration (Perez-Cruet et al. 2012). The da Vinci is a robotic system that offers surgeons the ability to perform a variety of soft tissue procedures with more minimally invasive technique (Jacofsky and Allen 2016).

The first applications of the da Vinci platform were directed towards soft tissue procedures such as laparoscopic prostatectomies and gynecological surgeries that were readily adopted. In fact, in 2012, 85% of prostatectomies in the USA were performed with robotic assistance (Chen et al. 2018). The da Vinci surgical robot is a telesurgical platform that allows the surgeon to control the docked surgical robot from a remote station that is outside the sterile field yet within the same operating room as the patient. This ability allows the surgeon to visualize the patient and surgical field in an augmented three-dimensional view, provided by endoscopic cameras, which allows

for real-time decisions to be executed with unparalleled precision while minimizing soft tissue trauma typically experienced by the patient. The da Vinci articulating robotic arms serve as extensions of the surgeon's instruments and are under complete control of the operating surgeon at all times.

While the da Vinci robot has not been as widely adopted by spine surgeons for routine surgical techniques, it has been reported to be used for the resection of paraspinal tumors, transoral odontoidectomy, and in laparoscopic-assisted anterior lumbar interbody fusion (D'Souza et al. 2019). For the treatment of spine trauma, the da Vinci robot was recently used in a minimally invasive retroperitoneal approach for the treatment of an L3 fracture with corpectomy and expandable cage implantation with a good clinical outcome (Lippross et al. 2020).

Robotics and Computer-Assisted Navigation

Historically, robotics and image-guided navigation systems used in spine surgery have been considered mutually exclusive technologies. However, both technologies fundamentally rely upon radiographic imaging and stereotaxic principles in order to provide precision and accuracy during spine surgery (Ganz 2011). Stereotaxy refers to the use of instruments that relate anatomical targets within the body with radio frequency markers using a cartesian coordinate system. This can provide the surgeon with haptic feedback when accessing areas of the surgical field that are difficult to appreciate visually (Ganz 2011).

Stereotactic techniques have since been applied to the field of spine surgery and lead to the development of the intraoperative CT with Stealth Station navigation (Medtronic Inc.). The robotic systems described in this chapter involve the automated performance of various portions in the operation. However, image-guided systems have the benefit of providing real-time haptic feedback to the surgeon, who then uses that information to perform those portions of the case manually.

Both image-guided navigation and robotics systems that have historically been used in spine surgery are fundamentally based upon stereotactic principles coupled with pre/intraoperative patient imaging and registration (Fig. 2). Similar to navigation-assisted techniques, robotic systems also rely on radiographic imaging and stereotaxis for trajectory planning and drilling of pedicle screw bone tunnels and screw insertion (Kochanski et al. 2019). Historically robotic systems have lacked the real-time navigation that image-guided systems utilize. However, newer robotic systems such as the Excelsius GPS (Globus Medical), ROSA Spine (Zimmer-Biomet), and Mazor X Stealth (Medtronic) allow for real-time image guidance coupled with the precision and accuracy of an automated robotic arm to ensure a proper trajectory when inserting pedicle screws (Kochanski et al. 2019).

History of Robotics in Spine Surgery

Robotics have been implemented throughout the majority of surgical specialties, and spine surgery is no exception. To date, the use of robots in spine surgery has primarily been limited to using a planning platform to assist with pedicle screw placement which is often used to stabilize the vertebral column in spinal fusion surgery (Urakov et al. 2017). Metallic screws are inserted into each pedicle involved at each vertebral level involved in an operation, and then rods are inserted through the heads of all screws on each side in order to support the vertebral column. Accurate positioning of the pedicle screw is essential given the proximity of the neurovascular structures, including the spinal cord, spinal nerve roots, and major blood vessels. The goal of modern robotics systems in spine surgery is to assist surgeons in consistently placing pedicle screws with accuracy and precision based on advanced imaging and guidance software. Currently, there are only three manufacturers with five robots approved by the FDA indicated for instrumentation of the spine in the USA. These include Mazor's three generations of robots: the SpineAssist, the Renaissance Guidance System, and Mazor X (Mazor

Fig. 2 Spine surgeon inserting pedicle screws under navigation with instruments registered via intraoperative CT scan

Robotics), the ROSA Spine robot (Zimmer Biomet), and the Excelsius GPS (Globus Medical).

Mazor Robotics

Mazor Robotics was founded in 2001 in Israel. The company brought the first commercially available robot for spine surgery to market. Starting with the FDA approval of SpineAssist in 2004, the company's technology continued to evolve with the launch of the Renaissance Guidance System in 2011, and eventually the Mazor X which was released in the USA in 2016. As Mazor is the longest standing company to produce approved spine surgical robots, the majority of the published literature has focused on these systems.

Mazor: SpineAssist

The first robotic-assisted platform to reach the US market, with applications specifically designed for use in spine surgery, arrived in 2001 with SpineAssist (Mazor Robotics). SpineAssist was approved for use in the USA in 2004 and became the first commercially available mechanical guidance system used for the placement of pedicle screws in thoracolumbar surgery (Theodore et al. 2018). SpineAssist, which is the spinal application of its predecessor SmartAssist (Mazor Robotics), is a shared-control semi-active platform that is rigidly attached to the patient's iliac crest or spinous process, unifying the patient and robot. This ensures that patient movement due to positional changes or respirations does not interfere with the position of the robot relative to the patient, thus potentially providing higher accuracy with the placement of pedicle screws. SpineAssist was designed to accurately guide and assist the surgeon in drilling and placing spinal implants such as pedicle screws, however, the actual instrumentation of the patient's spine is performed by the surgeon and not the robot itself.

The SpineAssist System consists of two units: a small hexapod robot that can move with six degrees of freedom and a separate computer workstation with a graphic user interface. Using the workstation, the surgeon plans the trajectory for pedicle screw placement at any time prior to the start of the case (Shoham et al. 2007). During

the operation, the robot's base platform is mounted on the vertebrae using a disposable sterile clamp system. The coordinates of the desired screw insertion trajectory are obtained from preoperative plans made by the surgeon using a reconstructed CT image, which is obtained pre- or intraoperatively. Following a registration process that involves matching two intraoperative fluoroscopic images with the preoperative CT scan, the planned coordinates are then translated to each of the robot's six articulators to create the required motion. The computer system controls the movement of the robot to the desired position where the guide arm is then activated to move into the preplanned trajectory. The surgeon performs the manual drilling and screw insertion via an open or percutaneous technique according to the patient's needs (Shoham et al. 2007).

Mazor: The Renaissance Guidance System

Mazor Robotics' second-generation robot and successor to SpineAssist is the Renaissance Guidance System. The Renaissance is a miniature robotic platform that acts as a mechanical guidance unit that can be mounted directly to the patient via bone-anchored attachments to the spine or pelvis or the operating table (Malham and Wells-Quinn 2019). A three-dimensional marker is attached to the platform before the intraoperative CT scan is performed using an intraoperative CT with the patient prone on the operating table. The images are uploaded into the Renaissance System's interface, and the surgeon uses the information to plan the procedure using the system's software. The patient's anatomy can be reviewed in coronal, axial, and transverse planes to ensure that the proper trajectory is planned before instrumentation. Once the plan is complete, the robot's guidance system is mounted to the platform and automatically sent to the preplanned trajectory where the surgeon can use the system to place K-wires that are then used to guide the insertion of cannulated pedicle screws. The Renaissance Guidance System has been used in approximately 30,000 cases.

Mazor: Mazor X

Newer robotic platforms such as the Mazor Robotics' third-generation spine surgical robot, the Mazor X (Fig. 3), which was released in the USA in 2016, utilize an automated mechanical arm fixed with a drill guide which assists in drilling and pedicle screw insertion, with or without K-wire placement. This feature requires surgeons to introduce instruments using the robotic arm, which provides haptic feedback if tools deviate from a preplanned trajectory. The surgical robot is either mounted to the operating table or the floor and is connected to the patient similarly using bone anchors as with the Mazor Renaissance System (Malham and Wells-Quinn 2019). There is an associated computer station with a user interface that contains the planning software that allows for planning of screw

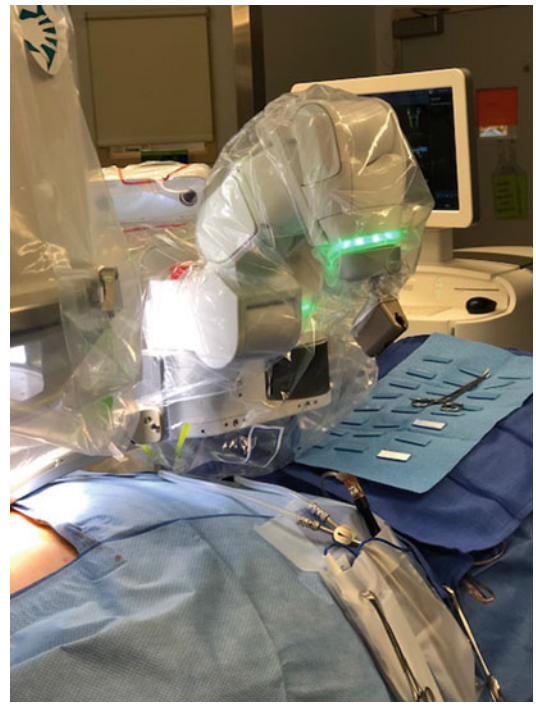

Fig. 3 Mazor X robotic arm used in posterior lumbar instrumented fusion

Fig. 4 Spine surgeons localizing appropriate levels using fluoroscopy for treatment of the lumbar spine with the Mazor X Robotic platform

trajectories based on the patient registration process. The automated robotic arm, which is controlled by the user interface and directed by the surgeon, can move between preplanned screw trajectories at various levels quite rapidly, allowing the surgeon to drill while providing tactile feedback to ensure adequate purchase as instruments enter the bone. Once the setup and registration process are performed, the automatic movements of the robotic arm between various levels allow for rapid and accurate insertion of pedicle screws potentially decreasing total surgical time. The Mazor X system retails at approximately $1000,000 with disposable costs ranging from $1000–$1500 per case according to recent market reports (Fig. 4).

Mazor Robotics' newest addition to their robotics line combines its navigation technology with Robotics to form the Mazor X Stealth robotic-assisted surgical platform. Mazor X Stealth received its FDA approval in2018 and was used in its first cases in early 2019 just after the acquisition of Mazor Robotics by Medtronic (Minneapolis, MN). The Mazor X Stealth allows for the union of the computer navigation software, and the Mazor robotic-assisted surgical platform to improve accuracy and precision of pedicle screw placement in spine surgery. By combining these two technologies, surgeons can use software to formulate their preoperative plan based on a 3D analysis of the patient's anatomy. This allows surgeons to place pedicle screw trajectories accurately with the assistance of the robotic arm and receive navigation feedback in real time to ensure that trajectories match the preoperative plan.

ROSA Robot

The ROSA Robot, which stands for Robotic Stereotactic Assistance, was initially developed in 2007 by MedTech in Montpellier, France (now Zimmer-Biomet), for use in cranial surgery in Europe. The company expanded its applications for the platform and developed ROSA Spine which was cleared for use in the USA by the FDA in early 2016. ROSA Spine combines navigation technology with robotic assistance to aid surgeons in placing pedicle screws according to

preplanned trajectories, and performance of transforaminal lumbar interbody fusions (Chen et al. 2018; Lonjon et al. 2016). With the patient in the prone position on the operating table, the ROSA Robot's floor-mounted platform is brought into position at the side of the table, while the separate navigation camera is placed at the foot of the patient. A referencing marker is rigidly mounted to the patient's iliac crest, which monitors the patient's movements, either respiratory or due to manipulation by the surgeon. Intraoperative fluoroscopic images are obtained using a specific registration pattern held by the robotic arm. The images are then uploaded directly to the user interface where the surgeon can begin using the planning software to plan the ideal trajectory for each screw. Once the trajectories have been planned, the articulating robotic arm can handle marked instruments that are confirmed by the navigation camera to enable accurate placement of instruments according to the preplanned trajectories. This allows for real-time adjustments to be made to account for the patient's respiratory movements, which are continuously monitored by the navigation cameras (Lonjon et al. 2016). The ROSA Spine Robot, which retails for just over $600,000, is the least expensive of the three leading systems with automated robotic arms available in the market.

Excelsius GPS

The Excelsius GPS released by Globus Medical (Audubon, PA) in 2018, received FDA approval for use in spine surgery in 2019. This system uses proprietary software for planning pedicle screw trajectories and an automated robotic arm to guide instruments simultaneously with navigation technology and has proved to be safe and effective as a means for inserting pedicle screws (Galetta et al. 2019). A recent single institution study demonstrated a 99% rate of successful pedicle screw placement out of 562 screws placed using the Excelsius GPS system in minimally invasive lumbar spine surgery using a variety of approaches (Huntsman et al. 2020). One advantage of this system is the ability for robotic-assisted insertion of pedicle screws without the use of K-wires. By using real-time image guidance, the surgeon is able to manipulate a variety of compatible surgical instruments according to the preoperative plan via the robotic–navigation interface. Excelsius GPS is indicated for spinal instrumentation from C1-pelvis and is compatible with most imaging systems using preoperative or intraoperative CT or fluoroscopy. The Excelsius GPS costs approximately $1,200,000, with an average cost of $1000 per procedure in disposables required for its use.

Benefits of Robotic-Assisted Spine Surgery

There have been many benefits reported in the literature attributed to the use of robotic-assisted spine surgery including minimally invasive applications, improved accuracy, reductions in radiation to OR staff, decreased blood loss, faster pedicle screw insertion time, reduction in human error due to tremor or fatigue, and decreasing the learning curve associated with pedicle screw insertion technique among resident and fellow trainees (Li et al. 2020; Siddiqui et al. 2019). Of which, pedicle screw placement accuracy and reduction in radiation exposure to surgeons and operating room staff have been the most widely reported.

Benefits: Improved Accuracy of Robotic-Assisted Pedicle Screw Placement

In many studies, the accuracy of pedicle screws is evaluated using postoperative CT scans, which are used to confirm the trajectory of the screw within the cortical bone of the pedicle. These images are graded based on the Gertzbein-Robbins classification, where the deviation of the screw is measured against the "ideal" trajectory of the screw. According to this classification system, Grade A is an interpedicular screw without a breach of the cortical layer, a Grade B screw breaches the cortex but is deviated <2 mm laterally from the pedicle, and Grade C and D are breaches of <4 and <6 mm,

respectively (Solomiichuk et al. 2017). While theoretically, a more displaced screw may have a higher chance of postoperative complications, the clinical significance of this radiographic definition in the absence of clinical symptoms is not well described (Kochanski et al. 2019). The majority of screws with a minor breach of the pedicle cortex may still maintain excellent biomechanical properties and are unlikely to require revision. Thus, in the absence of clinically apparent neurologic of vascular symptoms or biomechanical instability, a minimally displaced screw is unlikely to cause unwanted complications. However, clinically significant misplacement of pedicle screws can cause fractures, neurologic or vascular impairment, injury to the dura, and biomechanical instability (Solomiichuk et al. 2017).

A multicenter retrospective review evaluating the accuracy of pedicle screw placement using SpineAssist (Mazor Robotics) in the placement of 3271 pedicle screws was performed by DeVito et al. Pedicle screws were placed using the robotic platform and then evaluated and graded using post-op CT. They found 98% of robotic pedicle screws placed to be clinically acceptable when evaluated using fluoroscopic X-rays before leaving the operating room. One hundred and ninety-eight patients underwent postoperative CT analysis, and 98.3% of the screws placed were found to be within 2 mm of the pedicle cortex. Only 1.7% of the screws placed had a pedicle wall breach greater than 2 mm (Kochanski et al. 2019). This study was consistent with previously published literature demonstrating that robotic-assisted techniques are a safe and effective option for the insertion of pedicle screws.

In a retrospective series performed by Molliqaj et al., 439 thoracolumbar pedicle screws were inserted using SpineAssist (Mazor robotics), and 441 screws were inserted using a freehand fluoroscopic-guided technique by experienced spine surgeons. The accuracy of screw placement was determined by neuroradiologists who were blind to the treatment group. Each screw was independently evaluated and graded based on the Gertzbein-Robbins criteria. In the robot-assisted group, 366 (83.4%) of screws placed were found to be perfectly intrapedicular (Gertzbein-Robbins Grade A) vs. 335 (76%) in the freehand group. Additionally, 93.4% of robotic-assisted pedicle screws were classified as nonmisplaced, defined as Gertzbein-Robbins Grades A and B, compared to 88.9% of the screws in the freehand fluoroscopy ($p = 0.005$) (Molliqaj et al. 2017).

The Renaissance system (Mazor Robotics) was evaluated for accuracy and safety for use in lumbar spinal fusion surgery by Kim et al. The study compared robot-assisted posterior lumbar interbody fusion (Robot-PLIF) vs. a conventional freehand open approach (Freehand-PLIF). A total of 37 patients were treated using the robotic-assisted platform, and 41 patients were treated with the conventional freehand approach. Of the pedicle screws inserted using the Robot-PLIF approach, 93.7% were Grade A, with 5.7% Grade B, and 0.6% Grade C breaches, respectively. All breaches occurred in the lateral wall of the pedicle in the Robot-PLIF group. In the Freehand-PLIF group, 91.9%, 7.6%, and 0.6% of pedicle screws placed were classified as Grade A, B, and C breaches, respectively. The Grade C breach was an inferior wall violation resulting in a subsequent nerve root irritation that required revision. Additionally, it was noted that none of the 74 screws in the Robot-PLIF group violated the proximal facet joint, while 13 of the 82 Freehand-PLIF groups violated the proximal facet joint ($P < 0.001$) (Kim et al. 2017).

Hu et al. investigated the accuracy of robotic-assisted pedicle screw placement as well as learning curve associated with spinal instrumentation using the Mazor Renaissance platform. They found that over the course of 150 cases performed by a single surgeon there was an overall increase in the accuracy of pedicle screw placement that was associated with the increasing number of cases performed using the robot. By dividing patients into groups of 30, the investigators analyzed pedicle screw accuracy when placed by the robot, the rate at which pedicle screws had to be converted to manual insertion due to malposition, and the overall rate of malposition of screws placed robotically. They found that when analyzed by intraoperative fluoroscopy and post-op radiographs, there was a greater than 90% success rate in pedicle screw placement after the first 30

cases using the robot (82% in the first group of 30 cases, 91–95% in the following 120 cases). Additionally, the number of screws that had to be converted to manual insertion decreased from 17% in the first 30 cases and 7% in the last 30 cases in the study. Screw malposition using the robot also decreased with increased surgeon experience notably from 1.4% in the initial group and 0% in the last group. The authors concluded that improved accuracy, decreased rates of screw reinsertion, and decreased rates of screw malposition could be achieved after the surgeon completes the initial 30 cases using the robot. These findings were consistent with other published reports, and have been replicated with another surgeon evaluated outside of the study (Hu et al. 2014).

These studies suggest that robotic-assisted techniques can consistently, safely, and accurately be used to insert pedicle screws that are at least as acceptable as the current conventional techniques. Further research is needed to determine if robot-assisted techniques are both statistically and clinically significantly superior than the current standard in terms of safety and accuracy of pedicle screw insertion.

Benefits: Decreased Radiation Exposure

Intraoperative fluoroscopy has been widely used in orthopaedic surgery and is particularly helpful in minimally invasive spine surgery such as percutaneous pedicle screw placement. Radiation safety, including limiting dose and exposure, to patients, surgeons, and staff, is of significant concern and has been receiving increased attention in published literature. There are several ways to standardize and quantify radiation exposure. The Gray (Gy), which is used to express an absorbed dose of radiation, is the actual physical quantity of one joule of radiation energy per kilogram of matter. The sievert (Sv) represents the biological equivalent of an effective dose on tissue and can be used to measure the cumulative dose of radiation absorbed by tissue over time. For healthcare workers, an upper limit of 20 millisieverts (mSv) of radiation exposure per year has been established by the international commission of radiological protection (Hayda et al. 2018).

Radiation exposure among spine surgeons varies considerably and assessing radiation exposure in spine surgery can be challenging due to a lack of standardized reporting. For instance, some studies report radiation exposure in time (seconds) per screw, whereas others report total radiation generated throughout a case using an entirely different scale or measurement (Malham and Wells-Quinn 2019). As such, implementing new technologies such as robotic surgical systems that can potentially decrease the risk of this occupational hazard in spine surgery would likely be beneficial to OR staff.

One of the proposed benefits of robotic-assisted surgical systems is that they can potentially limit radiation exposure to operating room staff. CT imaging can be performed before the day of surgery or using an intraoperative CT scan with the surgical staff outside the operating room. In a study performed by Mendelsohn et al., patients undergoing intraoperative CT-assisted lumbar spine surgery were found to be exposed to 2.77 times more radiation (5.69 mSv) than patients in a fluoroscopic-assisted control group. However, the surgeon and OR staff were exposed to approximately 2.5 times less radiation in the intraoperative CT group when compared to the fluoroscopy group (Hayda et al. 2018). In another study by Costa et al., patients undergoing CT-based navigation-assisted lumbar spine surgery were exposed to a mean of 5.15 mSv of radiation, whereas the surgeon and staff who were outside the operating room at the time of the scan were reported as having no radiation exposure. Both studies confirm that the use intraoperative CT increases radiation exposure to the patient by approximately 7.5 mSv, which is less than that sustained during a routine lumbar CT. Additionally, radiation exposure to the surgeon and staff were reported to be decreased in both studies (Hayda et al. 2018).

A review of literature demonstrated promising results when evaluating radiation exposure measured in seconds of fluoroscopy time comparing robotic-assisted vs. traditional freehand insertion

of pedicle screws. A study performed by Kandlehardt et al. demonstrated an average radiation exposure time of 34 s per screw in the robotic-assisted group vs. 77 s per screw in the fluoroscopic-assisted freehand group (Kochanski et al. 2019). Likewise, Schoenmayr and Kim reported a decrease in radiation exposure by 40% when comparing robotic systems to traditional techniques. Additionally, Roser et al. found an average fluoroscopy time of 31.5 s per screw for using traditional freehand technique vs. 15.98 s per screw in the robotic-assisted cohort in a prospective randomized study evaluating the two groups (Kochanski et al. 2019). These studies demonstrate positive results and support the proposed benefits of reductions in total radiation exposure associated with robotic-assisted spine surgery. However, further research is likely needed to determine the impact of robotics systems on total radiation exposure to both surgeons and patients due to differences in surgeon experience, operative technique, and imaging protocols for robotics systems used between these studies and others like them (Kochanski et al. 2019).

Costs

Introducing robotic-assisted techniques may potentially improve precision and accuracy in the operating room, but the ultimate acceptance of robotic surgery into mainstream surgical practice will be heavily dependent on its cost-effectiveness. According to a 2019 market analysis, the average upfront cost of a spine surgical robot can be anywhere from 600,000–1,300,000 dollars depending on the model and purchasing agreement for a health system. Additionally, there is typically an annual service contract that can cost as much as $100,000 to service and maintain the robot (Ahern et al. 2020). Over time the total costs to operate, service, and maintain each robot accumulate and thus increase the total cost of each surgical procedure in which the robot is used. As such, the added upfront costs, added surgical time, and training of the surgeon, and OR staff must be considered and weighed against the potential benefits of robotic-assisted surgery. According to a review by Ahern et al., these added upfront costs could be offset if robotic-assisted spine surgery can continue to decrease operating room time, hospital length of stay, and rates of revision surgery (Ahern et al. 2020). Although the learning curve for robotic-assisted surgery is steep and volume dependent, once surgeons become familiar with their use, operating room times may decrease leading to more operating room efficiency (Ahern et al. 2020). Additionally, costs may be recouped by capturing a greater portion of patients who desire robotic-assisted procedures.

Limitations

Despite the reported benefits, there is still a lack of published data demonstrating conclusive evidence that suggests that long-term clinical outcomes in spine surgery are significantly improved with robotic-assisted techniques when compared to traditional methods. More extensive studies are needed to investigate further if robotic-assisted techniques in spine surgery are beneficial enough to justify the upfront and maintenance costs associated with their use.

Discussion

The goals of spine surgery are to improve patient functioning and reduce morbidity associated with disease of the spine. Over the last two decades, robotic-assisted technologies for use in spinal instrumentation have evolved rather quickly. The rapid growth and integration of imaging, navigation, and robotics in spinal surgery provide surgeons and health systems with an increasing number of options in spine surgery. Robotic techniques have been shown to be safe and effective in treating instability and deformity caused by degenerative spine disease or trauma as well as in other complex cases where patient anatomy may be distorted such as revision or tumor surgery. It is important to note that over the long term, most industries that have implemented robotic technology have demonstrated increased

production capacity, improved precision, and decreased costs.

There are many reported advantages of robotic-assisted spine surgery including minimally invasive applications, improved accuracy of pedicle screw placement, and decreased radiation exposure to the surgeon, and operating room staff. While the reported advantages and potential benefits of using robotic-assisted techniques are promising, they must be weighed against the increased direct costs associated with purchasing and maintaining the surgical robot, added surgical time, and the ongoing education and training of the surgeon and operating room staff on the robot's use.

While it is not the goal of this review to argue in favor or against the use of robotics in spine surgery, robotics in the operating room are likely here to stay. In spine surgery, technologies such as computer navigation and robotic-assisted techniques continue to evolve in an effort to improve patient outcomes, decrease complications, and increase patient safety. As such, more high-quality studies are needed to investigate improvement outcomes, efficiency, and reductions in total costs of care in order to provide the information that spine surgeons and health systems will need to decide if they will implement robotics into their practice.

Acknowledgments The authors would like to thank Allegheny Health Network's Department of Orthopaedic Spine Surgery, the Allegheny Health Network Neuroscience Institute, Robert Pezzin, and all those who contributed to this review.
