better focus on the important physics that KMC methods are most useful that, in addition to accelerating the simulation, they provide a much clearer picture of the fundamental mechanisms dominating specific processes.

# 9    Applications

Off-lattice KMC methods have been used to study a wide range of system, including metal on metal diffusion (Henkelman and Jónsson 2001), interstitials and vacancy clusters in c-Si (El-Mellouhi et al. 2008; Trochet et al. 2015), methanol decomposition on Cu, (Xu et al. 2009) Fe (Brommer et al. 2014; Restrepo et al. 2016) and Ni (Mahmoud et al. 2018), ion-implanted relaxation in Si (Béland et al. 2013; Béland and Mousseau 2013; Jay et al. 2017), ion- and neutron-irradiated metals (Béland et al. 2015b; Lu et al. 2016) and alloys (Béland et al. 2016; Lu et al. 2016; Osetsky et al. 2016), grain boundary diffusion in Cu (Pedersen et al. 2009), hydrogen diffusion in Al grain boundaries, (Pedersen and Jónsson 2009) a solid-solid phase transformation in Mo (Duncan et al. 2016) defects in amorphous Si (Joly et al. 2013), Li impurities in Si (Trochet and Mousseau 2017) and C impurities in Fe (Restrepo et al. 2016, 2017), and many more.

We review here a few applications that represent some of the strengths and limitations of these methods.

## 9.1    Loop Transformation in FeCr

Off-lattice KMC is a powerful tool to simulate the long-time kinetics of point defects and small defect clusters. However, it is not limited to these relatively simple problems and can be used to capture slow kinetics involving extended defects. A good example of such a problem is the transformation of $1/2\langle 111 \rangle$ prismatic dislocation loops in Fe into $\langle 100 \rangle$ prismatic dislocation loops. $1/2\langle 111 \rangle$ and $\langle 100 \rangle$ loops in bcc Fe and FeCr are common interstitial-type defects observed in neutron- and ion-irradiated samples. The $1/2\langle 111 \rangle$ loops are known to be fast one-dimensional diffusers, which are closely related to void swelling. $\langle 100 \rangle$ loops are largely immobile. The ratio of formation of $1/2\langle 111 \rangle$ to $\langle 100 \rangle$ loops is directly linked to void-swelling rates. However, collision cascades simulations in bulk Fe predict the formation of $1/2\langle 111 \rangle$ loops, but not of $\langle 100 \rangle$ loops. There must be a post-cascade mechanism that permits the transformation of the post-cascade defects into $\langle 100 \rangle$ loops. High-temperature MD simulations – more than $1000\,\mathrm{K}$ – of two $1/2\langle 111 \rangle$ loops intersecting and transforming into a single loop suggested that this reaction solely leads to one large $1/2\langle 111 \rangle$ loop (Terentyev et al. 2008). Using off-lattice KMC in Fe (Xu et al. 2013) and FeCr (Béland et al. 2015a), a novel mechanism for the transformation of two $1/2\langle 111 \rangle$ into a $\langle 100 \rangle$ was discovered, which is illustrated in Fig. 6. At $600\,\mathrm{K}$, the waiting time was $200\,\mathrm{ns}$ in off-lattice KMC – i.e., a $0.73\,\mathrm{eV}$ overall activation barrier. This mechanism was later confirmed by molecular dynamics, as reported in Xu et al. (2013). The simulations in FeCr
**Fig. 6** An illustration of the transformation of two $1/2\langle 111 \rangle$ interstitial clusters into a $\langle 100 \rangle$ loop in FeCr (10 at. % Cr). The red circles indicate the subregion that is changing orientation within the interstitial cluster. Gray spheres are Fe atoms not sitting on bcc lattice sites, orange spheres are Cr atoms not sitting on bcc lattice sites, and yellow atoms are empty bcc lattice sites. The simulation cell contains 16074 atoms. (The figure is adapted from Béland et al. 2015a)

(10 at. % Cr) also indicated that Cr decoration of the interstitial clusters favor the transformation to a large $1/2\langle 111 \rangle$, relative to the situation in pure Fe. This was a good example of a situation where off-lattice KMC was able to predict a mechanism that helped guide further MD simulations.

## 9.2    Phase Transformation in Mo

Figure 7 illustrates both the success and limitations of the off-lattice KMC method for the simulation of a transition between a complex A15 phase to the lower-energy BCC state in bulk Mo (Duncan et al. 2016). In this calculation, the interatomic interactions are described by an embedded atom method potential (Zhou et al. 2001). The formation and dissolution of complex (topologically close-packed) phases are important both for understanding the hardness and fracture of Ni-based superalloys (Sinha 1972). In Fig. 7a the phase transition from A15 to BCC is observed with AKMC to occur at 300 K over time scales of microseconds. The atoms are colored according to a common-neighbor analysis (Faken and Jónsson 1994) to better visualize the interface (gray) between the A15 (red) and BCC (blue) phases.

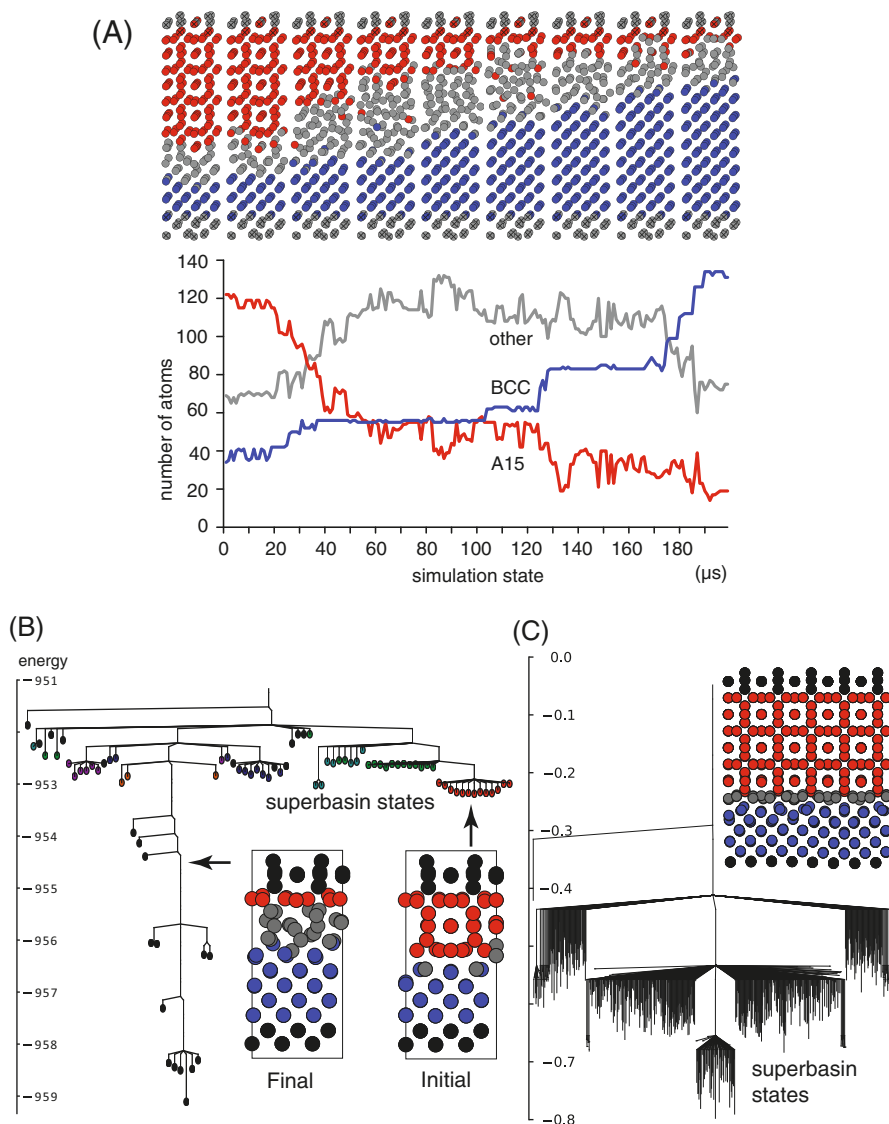
The simulation in Fig. 7a involves only a few hundreds of atoms, and yet we can already see a system-size-related problem caused by the disorder at the phase boundary. Specifically, as shown by the disconnectivity graph in Fig. 7b, there are many states connected to the initial state by low barriers which form a superbasin. All of these states must be enumerated in the AKMC simulation, as well as the rates between them. Only then a MCAMC move can be used to find a higher barrier process leading to interface motion, to the final state indicated. An analysis of the superbasin states shows that most transitions within the superbasin involve groups of atoms switching from A15- to BCC-coordinated. The fundamental problem is that when there are several such independent groups of flickering atoms, the total number of states in the superbasin grows combinatorially with the number of groups. This catastrophic situation is shown clearly in Fig. 7c where the supercell is increased and the total number of states in the superbasin is so large that even a single-layer transition between A15 and BCC cannot be observed with our off-lattice KMC machinery.


**Fig. 7** (**a**) AKMC simulation of a transition from the A15 complex phase in Mo to the lower-energy BCC phase, which occurs on the timescale of microseconds at room temperature. (**b**) A disconnectivity graph showing that disorder at the interface between the phases gives rise to many states connected by low barriers. (**c**) As the system is made larger, the number of states in the superbasins grows combinatorially, making the simulation intractable for simulating even a single-layer transition

## 10      Discussion

Off-lattice KMC approaches have allowed to study the long-time dynamics of systems that were long off-limits, including systems with many defects, alloys, interfaces, grain boundaries, and even fully disordered materials. These methods have also demonstrated that, even for systems that appeared simple, unexpected mechanisms could play a significant role and that even lattice-based methods would benefit from constructing their event catalog using unbiased search methods.

### 10.1     Limits

While open-end saddle point search methods such as ART, ART nouveau, and the dimer methods are powerful, we still lack a fundamental theoretical support for establishing the completeness of the generated event catalog. How many event searches should one launch by atom? When can one be certain that all relevant events are found? From experience, we know that, with ART nouveau, lower-energy barrier are found much more often than very high barriers. For a method such as k-ART, this is certainly positive. Moreover, comparison with MD and other methods, when possible, suggest that it recovers all previously identified mechanisms. Yet, it is not possible to assess, even statistically, what the error is with these methods contrary to what can often be obtained by the MD-based accelerated approaches of Voter and colleagues (see discussion above). Theoretical bounds or limits would certainly help greatly to ensure that these simulations do capture the essential physics.

While off-lattice with or without on-the-fly catalog building KMC approaches can reach time scales inaccessible to MD, these methods remain much heavier than lattice-based atomistic KMC and are typically limited to a tens of thousands of KMC steps, not counting, for course, analytically handled flickers. These methods can therefore only be applied to systems where physically relevant mechanisms are largely dominated by local mechanisms.

For example, vacancy-induced solute diffusion in metal, where one must wait for a vacancy to diffuse near a solute to see the atom jump, is much too expensive for these types of simulations. To overcome these limitations, one could solve directly in the equilibrium distribution of vacancies of the system for the time step between configurations with vacancies near a solute or couple off-lattice KMC with lattice-based KMC so that the vacancy diffusion away from solutes can be solved efficiently while the elastic effects and interactions between solutes and points defects are addressed exactly with off-lattice description. Clearly, other possibilities exist, and work will have to be performed in this field to assess the best way of coupling these scales.

Also, the total number of defects that can be effectively handled by off-lattice KMC is typically limited to a few hundred defects. Increasing the number of defects increases the computational cost in two ways. (1) Events must be assigned to each additional defect. While efficient recycling of events can minimize the

associated computational cost, such recycling is not always an option. For example, in concentrated alloys, the number of local configurations grows combinatorially with the number of elements, which limits the usefulness of recycling events. (2) As the number of defects increases, the total rates increases as well, which reduces the waiting time of each KMC step. More KMC steps – i.e., more computational resources – are necessary to reach the same time scales. While synchronous (Shim and Amar 2005; Martínez et al. 2008) and asynchronous (Shim and Amar 2006) KMC parallelization techniques offer a possible solution to this problem, this is still an unresolved challenge for off-lattice KMC.

Another fundamental limit of on-the-fly KMC is that it probes the potential energy surface. If the problem of interest involves significant entropic contributions to the free energy, exploring the potential energy surface might lead to incorrect predictions. On the other hand, many free energy landscape-based methods suffer from the "curse of dimensionality" (Althorpe et al. 2016); to be effective, these accelerated methods necessitate that a proper – and relatively small – set of reaction coordinates be inputed. In the future, we can imagine on-the-fly KMC being used to find promising reaction coordinates to be used as input for accelerated free energy methods.

## 10.2   Future Developments

Beyond these questions, a number of other developments should be undertaken to improve the efficiency of off-lattice KMC methods.

**Moving beyond master-worker parallelization**  As larger systems with more defects are simulated, the computational overhead of the master-worker parallelization scheme of current off-lattice KMC codes will become a bottleneck. The way forward may be to switch to a decentralized parallelization scheme. While it entails challenges in regard to cataloging, recycling, and load-balancing, such an approach could significantly increase the scalability of off-lattice KMC.

**Recycling basins to handle flickers**  The absorbing Markov chain algorithm described above – i.e. the superbasins – can be define states either as global configurations – cf. Sect. 6 – or local configurations – (Fichthorn and Lin 2013). The latter can provide a significant acceleration over the former as it can decouple the kinetics of non-interacting defects. This local treatment of superbasins is implemented in a number of the current off-lattice codes. A further acceleration would be to reuse superbasins built previously if the configurations are encountered again. This would increase the bookkeeping costs but can largely use the same geometrical and topological classification tools that are currently used to recycle events.

**Extended defects**  Off-lattice KMC can handle certain extended defects. For example, it was used to simulate the propagation of a grain boundary in Mo (Duncan

et al. 2016) and to simulate the transformation of prismatic dislocation loops in bcc Fe and FeCr (Xu et al. 2013; Béland et al. 2015a). However, the kinetics of dislocation lines and their interactions with other extended defects has not been captured yet by off-lattice KMC. This is an important challenge, since MD cannot simulate such kinetics at strain rates consistent with experiments. However, building an event catalog for a dislocation line – which contains thousands of interconnected possible sites where events may be take place – is a daunting task.

## 11    Conclusion

The last years have seen considerable developments with respect to accelerated atomistic methods, with access to ever more powerful computers and the introduction of new algorithms. These tools are giving modelers access to questions that could not even be asked in a recent past, increasing their interest for communities that are more turned to applications rather than methodological developments.

This additional interest will be beneficial to the field as it attracts new researchers with original ideas, knowledge, and skills, which will result in accelerated developments. Yet, as we have shown here, in spite of some limitations and questions, even in the current implementations, off-lattice kinetic Monte Carlo methods can deliver new insights for a wide range of problems dominated by activated diffusion.

The codes are available, and there is no reason today not to try them!

## 12    Code Availability

Various version of ART nouveau are available at http://normandmousseau.com. The kinetic ART package can be obtained freely by writing to MT or NM. The EON code is available at http://henkelmanlab.org/eon/.

**Abstract**

As high-performance computing systems now rely on hardware parallelism for continuous improvements in performance, the timescales accessible to direct molecular dynamics (MD) remain limited by the relatively stagnant performance of a single processor. While spatial decomposition allows extremely large systems to be simulated for short periods of time, alternative methods are needed to extend these simulations to significantly longer timescales. Although parallel means to produce long-timescale trajectories have been known since the late 1990s, several newer methodologies falling under the umbrella of accelerated molecular dynamics (AMD) have recently been developed with parallelism in mind. In this chapter, we review the current state of the art in replica-based AMD and review several additional means of parallel scaling. Following a brief introduction to the serial AMD procedures, the chapter is organized into three general categories of parallel extensions: replication, speculation, and localization.

## 1 Introduction

Although CPU technology has generally kept pace with Moore's law over the past few decades, serial clock-speed performance has stagnated. Therefore, both hardware and software developers have been forced to rely on parallelism to continue improving the performance of both personal devices and leadership-scale machines. Within scientific computing, this has motivated significant efforts in the application and development of parallel algorithms, including many related to molecular dynamics (MD). For direct MD, these algorithms have focused on the most computationally intensive task: the calculation of forces on each atom for every sequential time-integration step. Increasing the simulation timescale has therefore been synonymous with decreasing the wall clock time (WCT) needed to calculate the forces (i.e., the WCT needed for each integration step).

For example, the so-called force-decomposition approaches employ shared memory techniques to speed up the calculation of forces. This approach is typically more scalable for computationally expensive potentials, like those based in quantum mechanics (Niklasson et al. 2016) or neural networks (Smith et al. 2017), where the amount of work is sufficiently large relative to the communication overhead. When the expensive potential can be approximated by a less-accurate (but faster) surrogate potential, the multi-time step parareal approach can be used to further leverage abundant parallel resources (Audouze et al. 2009). A significant speedup (with respect to conventional CPU architectures) can also be obtained using application-specific integrated circuits (ASIC) to optimize chip-level logic pipelines. Although this approach has been used to produce millisecond MD simulations for biomolecular systems (Shaw et al. 2008), the overall performance is still limited by the need for sequential time integration. Further scaling, i.e., across multiple nodes, usually relies on spatial decomposition methods. In fact, spatial decomposition methods have been so successful that modern petascale machines are routinely used to simulate billions

of atoms, or more, for short periods of time (Plimpton 1995; Germann and Kadau 2008; Zepeda-Ruiz et al. 2017).

While these approaches can be used for efficient weak scaling (i.e., efficiency can be maintained if the problem size increases in proportion to the number of cores), communication and synchronization overheads limit the potential for strong scaling (i.e., increasing the number of cores at fixed system size). This is because the true bottleneck of direct MD is the need to perform time-integration steps sequentially, requiring parallel algorithms to synchronize before (or after) each force calculation. As such, efforts to accelerate the force calculations alone are ultimately limited to the same timescales as serial MD (for small system sizes and fast interatomic potentials). Given that serial time integration is typically limited to microsecond timescales, conventionally parallel MD is still prevented from capturing critical long-time phenomena, such as thermally activated processes.

In this chapter, the typical material subjects of interest are solid-state configurations of atoms that are likely to evolve at finite temperature through so-called *rare events*. Here, a rare event corresponds to a state-to-state transition that is likely to occur on a timescale that is, on average, much larger than the time-integration step. States are defined as coarse regions of configuration space that are usually, but not exclusively, basins of attraction on the potential energy surface (PES). Good state definitions are such that a typical MD trajectory spends a long time within a state before moving on to another one. When the evolution of a system is truly dominated by rare events, a direct MD simulation becomes unlikely to pass through more than a small handful of states.

To capture dynamical processes that are driven by rare events, specialized simulation techniques are typically needed to bypass the limitations of sequential time integration. This chapter focuses specifically on the accelerated molecular dynamics (AMD) family of techniques. In a nutshell, the AMD strategy to long-timescale simulations is to leverage the disparity between rapid thermal fluctuations within a state, and activate state-to-state transitions, to controllably accelerate the simulated dynamics. AMD is distinct from adaptive kinetic Monte Carlo (AKMC) (Henkelman and Jónsson 2001), because MD is used to discover every transition in the simulated trajectory, avoiding the need to build a complete rate catalog for every visited state.

Beginning in 1997, three AMD methods were proposed to accelerate the generation of state-to-state trajectories for rare-event systems, namely, hyperdynamics, which relies on a direct manipulation of the underlying PES (Voter 1997), parallel replica dynamics (PRD), which relies on the parallel accumulation of MD time (Voter 1998), and temperature-accelerated dynamics (TAD), which relies on the exponential increase in transition rates as the temperature is increased (Sørensen and Voter 2000). For the sake of a self-contained review, we will briefly reintroduce these *original* AMD methods and refer the reader to the first issue of the *Handbook of Materials Modeling* for a more in-depth discussion of the theoretical details (Uberuaga et al. 2005). In this chapter, our primary goal is to highlight recent and ongoing efforts to improve upon the performance of established techniques, using parallel algorithms.

Of the original AMD methodologies, only PRD is a fundamentally parallel approach. However, recent work has shown that a number of parallel techniques can also be leveraged by the other methods. In this chapter, we will focus our discussion on the most recent advances in this spirit. Generally, these approaches fall into (at least) one of the following three categories: replication, speculation, and localization.

## 2   Serial AMD

Before discussing recent developments, we first review the methodologies that do not require parallel computing resources to achieve a speedup (boost) with respect to direct MD. We present only the fundamental concepts of these methodologies to provide a foundation for the following discussions on replication, speculation, and localization. The reader is referred to the referenced resources for a more comprehensive discussion.

## 2.1   Hyperdynamics

As in all the AMD methods, the goal of hyperdynamics is to use a modified MD-based approach to find an appropriate first-escape path from the current state more quickly than MD would (Voter 1997). Here, "appropriate" means that the relative probability of choosing a particular escape path is the same as it would be in direct MD (i.e., proportional to its rate constant) and that the time at which the escape occurs is drawn from the same distribution.

Hyperdynamics achieves this by executing dynamics on a modified potential surface, $V(X) + V^b(X)$, in which the nonnegative bias potential $V^b(X)$ has been added to the original potential to partially "fill in" the basin. The main requirement on $V^b(X)$ is that it be zero at all dividing surfaces between states. The derivation assumes that transition state theory (TST) holds on both the original and modified potentials; i.e., there are no correlated events such as recrossings or multiple hops, so every crossing of a dividing surface is followed by loss of memory in the new state. In this limit, the transition rate between states is directly expressible as a thermodynamic quantity: the equilibrium flux of trajectories through the dividing surface between states. When this is a good approximation, it can be shown that hyperdynamics will increase all transition rates out of a given states by the same factor, the so-called boost factor, which is defined as:

$$\eta^{hyper} = \langle \exp(+V^b(X(t))/k_B T) \rangle. \tag{1}$$

In other words, the state-to-state dynamics on $V(X)$ and $V(X) + V^b(X)$ are equivalent up to a rescaling of time by $\eta^{hyper}$ to account for the fact that physical time flows $\eta^{hyper}$-times faster on the biased potential as compared to the original one.

The design of an effective, and valid, bias potential is a major project in itself, as it must be zero at all dividing surfaces in spite of having no explicit knowledge of where those surfaces may be. While a number of alternatives are available, Miron and Fichthorn (2003) proposed a particularly effective, geometry-based form, expressed in terms of "bond" lengths, where a bond is defined as any pair of atoms within a threshold distance of each other (typically the threshold would be set a little larger than a nearest-neighbor distance in the native crystal form). The idea behind the bond boost bias is to make $V^b = 0$ for any geometry in which one or more bonds is distorted (either shortened or lengthened) beyond a threshold value (e.g., 30%). For bond $j$, the "equilibrium" bond length $r_j^{eq}$ is the distance between the pair of atoms when the system potential energy has been minimized (i.e., at the basin-bottom configuration $R_{min}$), and the relative distortion of bond $j$ is defined as

$$\varepsilon_i = [r_j - r_j^{eq}]/r_j^{eq}. \tag{2}$$

In the "simple bond boost method" (Perez et al. 2009) (SBB), the bias potential depends only on the distortion $\varepsilon_{max}$ of the most distorted bond in the system,

$$V_{SBB}^b = V_{SBB}^b(\varepsilon_{max}) = \begin{cases} V_{max}^b \left[1 - (\varepsilon_{max}/q)^2\right], & |\varepsilon_{max}| < q \\ 0, & \text{otherwise,} \end{cases} \tag{3}$$

where $q$ is the threshold distortion for complete shutdown of the bias and $V_{max}^b$ is the maximum possible bias energy. (Note that the original bond boost method requires the use of an envelope function to allow multiple bonds to contribute to the total bias potential.)

## 2.2 Temperature-Accelerated Dynamics (TAD)

Temperature-accelerated dynamics efficiently predicts the escape path from a given state by performing basin-constrained MD (BCMD) at an elevated temperature compared to the actual physical system of interest (Sørensen and Voter 2000; Zamora et al. 2016a). In BCMD, high-temperature MD is performed as usual, but whenever a transition is detected, the system is placed back into the original state (effectively constraining the dynamics to a single PES basin). This is repeated until one can assess that the transition that should have occurred first at the original temperature has been observed at the high temperature. To project the observed transition times at high temperature onto a hypothetical low-temperature time line, the method assumes that harmonic transition state theory (HTST) holds (Vineyard 1957). Using this approximation, an observed high-temperature transition along pathway $j$ corresponds to a hypothetical low-temperature transition at time

$$t_j^{Low} = t_j^{High} \exp\left[E_j \left(\frac{1}{k_B T_{Low}} - \frac{1}{k_B T_{High}}\right)\right]. \tag{4}$$

Here, $k_B$ is the Boltzmann constant, $T_{\text{High}}$ is the high temperature used for BCMD, $T_{\text{Low}}$ is the low temperature of interest, and $t_j^{\text{High}}$ is the observed transition time at $T_{\text{High}}$. The value of the energy barrier for pathway $j$, $E_j$, is typically calculated using the nudged elastic band (NEB) method of Henkelman et al. (2000).

Since an elevated temperature tends to favor high-barrier transition pathways, it is important that BCMD be performed until it becomes sufficiently unlikely that a later transition at $T_{\text{High}}$ will correspond to the earliest transition at $T_{\text{Low}}$. In practice, this "stop" time, $t_{\text{Stop}}^{\text{High}}$, is defined in terms of the shortest low-temperature transition time, $t_{\text{Short}}^{\text{Low}}$, an adjustable uncertainty parameter, and an assumed minimum pre-exponential factor.

For the following discussion, we define $t_{\text{Winner}}^{\text{High}}$ as the value of $t_j^{\text{High}}$ corresponding to $t_{\text{Short}}^{\text{Low}}$ when the TAD procedure is completed for the current state. In order to predict a long-time trajectory involving many sequential state-to-state transitions, this procedure is typically repeated after moving the system into the state corresponding to the winning high-temperature transition time, $t_{\text{Winner}}^{\text{High}}$, once $t_{\text{Stop}}^{\text{High}}$ has been reached.

### 2.2.1 Synthetic-Mode TAD

In practice, the performance of any AMD method is limited by the rate of state-to-state transitions in the simulated physical system, i.e., the boost is typically controlled by the fastest processes that change the state of the system. For users and developers of rare-event simulation techniques, this is often referred to as the *low-barrier* problem. When a system is able to visit a large number of distinct states without having to overcome significant energy barriers (relative to $k_B T$), the standard TAD procedure will have very little opportunity to provide a boost. For many realistic systems, local clusters of neighboring states will be connected by energy barriers that are much lower than those separating the cluster from external states. This type of cluster is often referred to as a superbasin of states, because it can be defined as a basin of other PES basins. Since the system can typically move among the internal states of a superbasin at a much faster rate than it can escape into an external state, an MD trajectory is likely to revisit the internal states many times before making its way to another (super) basin.

One significant advantage of TAD is that its theoretical foundation allows a so-called *synthetic mode* to be used whenever superbasins are encountered (Sørensen and Voter 2000). When individual states are revisited many times, synthetic mode provides a means to leverage the total high-temperature BCMD time that has already been accumulated over all previous visits. The basic idea is that $t^{\text{High}}$ need not be reset to zero when the TAD procedure is initiated in a state that has already been explored. Instead, the high-temperature clock can pick up where it left off during the previous visit, as long as every previously observed escape pathway is explicitly represented as a future transition at a predetermined time, and the projected low-temperature time is offset from the previous visit.

The predetermined transition times for a given escape pathway can simply correspond to previously observed high-temperature transitions that were not accepted. However, if the escape path has a known (or approximately known) transition rate, a corresponding escape time can be randomly sampled. If the low-temperature transition rate can be accurately estimated for a given pathway, using either observed statistics or a direct calculation, the pathway can be promoted to *synthetic mode*. Once a pathway is in synthetic mode, all future transition times correspond to synthetic predictions that are determined using a sampling procedure similar to kinetic Monte Carlo (KMC). This means that subsequently observed MD transitions along synthetic pathways no longer need to be projected onto the low-temperature time line.

It is clearly advantageous to allow $t^{High}$ to grow as large as possible within a single state, because the fixed increment in $t^{Low}$ projected by each MD step grows exponentially with $t^{High}$. After a state has been revisited many times, the synthetic-mode procedure can result in the accumulation of enough $t^{High}$ to accept many synthetic transitions at once. After this has happened in every internal state of a superbasin, the performance of synthetic-mode TAD can approach that of KMC, until the system escapes from the superbasin. In practice, the synthetic mode is invaluable for the simulation of realistic material defects. For this reason, the procedure will also play a critical role in the performance of some parallel TAD extensions discussed below.

Now that hyperdynamics and TAD have been briefly introduced, the stage has been set to describe their parallel extensions. But, before doing so, we will first describe the basic procedure behind the remaining original AMD method, PRD, and introduce the broader concept of parallel replication.

## 3 Replication

Although PRD was first introduced in 1998 (Voter 1998), the method has recently experienced a coming of age, both due to the increasing availability of parallel computing resources and to a better mathematical understanding of the underlying theory (Le Bris et al. 2012). Also key to its usefulness is the fact that the general time-wise decomposition approach used by PRD, referred to here as *parallel replication*, can be extended to improve the performance of other methodologies. In the following, we will review the current state of the original PRD approach and present recent PRD+X efforts to combine parallel replication with other AMD approaches. In order to best describe the fundamentals of parallel replication, we will start by reviewing the basics of PRD. For a more comprehensive introduction, the reader is referred to the recent review by Perez et al. (2015).

### 3.1 Parallel Replica Dynamics (PRD)

For PRD, we assume that there are $N_r$ dedicated computing units available, called *replica* processes, that are each capable of carrying out independent MD

simulations. Starting with the system in some initial state, the PRD algorithm follows the steps illustrated in Fig. 1:

1. Let one replica carry out MD until it remains in the same state for a correlation time ($\tau_c$). This is called the decorrelation stage (blue).
2. Broadcast the decorrelated state to the other $N_r - 1$ replicas (orange). These replicas then independently carry out MD until they spend $\tau_c$ in the initial decorrelated state, rejecting transitions whenever they are detected. This is called the dephasing stage (red), because it is used to ensure that each replica is statistically independent.
3. After successfully dephasing/decorrelating, each replica enters the parallel stage (green), where it independently carries out MD, periodically checking whether a transition occurred (note that different replicas can enter the parallel stage at different times).
4. Once a transition is detected, the replica on which the transition occurred triggers a new decorrelation step, initiating a new algorithm cycle. At each cycle, the total simulation time is incremented by the duration of the decorrelation stage, plus the sum of the MD times accumulated on all replicas during the parallel stage (blue + green).

This algorithm has been shown to produce an arbitrarily accurate state-to-state dynamics, simply by adjusting the value of $\tau_c$ (Le Bris et al. 2012). For a physical system with a well-defined global transition rate of $k_g$, the speedup of PRD over direct MD can be written as

$$\eta^{\mathrm{PRD}} = N_r \left( (1 + f_Q)(1 + 2N_r k_g \tau_c) \right)^{-1},$$  (5)

where $f_Q$ is the fractional number of additional force calculations, per MD step, needed to periodically assess whether a transition has occurred. Note that Eq. (5) assumes that serial MD is performed by each replica process.

**Fig. 1** Illustration of the PRD algorithm for a simple energy landscape where the states are defined as local basins of attraction on the PES (black curves). For each idealized geometry, the circle indicates the position of the system on the landscape. The different stages of the algorithm are indicated by colors: decorrelation (blue), broadcast (orange), dephasing (red), and parallel (green)

This analysis suggests that the parallel efficiency of PRD is inversely proportional to $k_g$ and that perfect speedup of $N_r$ can be obtained only in the limit where $k_g \rightarrow 0$. This general rule is not specific to the performance of PRD but also describes the upper bound on the other original AMD methods. That is, while both standard hyperdynamics and TAD can provide a significant boost factor without the need for parallel computing resources, the optimal boost should be comparable to PRD with $N_r \rightarrow \infty$. When combining replication-based parallelism with these other AMD approaches (PRD+X), as we will discuss below, parallelism alone cannot move the performance of these methods beyond the theoretical limits of pure PRD on a sufficiently large number of cores. However, if such a number of cores are not available, a PRD+X combination might allow for the optimal boost to be achieved with more accuracy than X-only, since it will allow for a less aggressive bias potential in hyperdynamics or a lower high temperature in TAD.

To help express the advantages and limitations of replication, as well as the other parallel methodologies to be discussed below, it is useful to directly compare the available performance of PRD with that of spatially parallel MD. Following the analysis of Martínez et al. (2014), Fig. 2 shows a comparison of the available simulation timescale (x-axis) and length scale (y-axis) for both MD and PRD. The plot assumes a 24-hour simulation using a classical interatomic potential, with an escape rate per atom of $k = 10^5$ (s atom)$^{-1}$, a 1 fs MD time step, an execution

**Fig. 2** Comparison of the simulated timescales and length scales accessible to both MD and AMD, given a 24-hour run time on a hypothetical exascale machine. The specific shapes of the MD and PRD *polygons* are based on benchmark simulations and analysis presented in reference (Martínez et al. 2014). The shape of the PRD region assumes a per-atom escape rate of $k = 10^5$ (s atom)$^{-1}$, a 1 fs MD time step, a processor speed of 1 μs per atom per time step, and 12 million processors on the whole machine. The theoretical parallel limit is shown as a dashed black line. The intended direction of improved performance is also shown for speculation and localization

time of 1 μs per atom per time step on a single processor, and 12 million processors on the whole machine. Note that the size-dependent escape rate is here given by $k_g = k N_{at}$, where $N_{at}$ is the number of atoms in the system.

Since PRD must rely on parallelism to access extended timescales, limits on available computing resources will always lead to an upper limit on performance. In Fig. 2, this theoretical limit is depicted by a dashed black line that divides the plot into upper and lower triangles. The x-intercept of this line can be defined by the $k_g \rightarrow 0$ limit of Eq. (5). It is important to recognize that, unlike PRD, neither hyperdynamics nor TAD are strictly prevented from accessing the upper triangle of this performance landscape, because they do not rely on parallelism to achieve their boost. However, at increasingly large computational scales, the actual performance of AMD methods is increasingly more likely to depend on the value of $k_g$ than on the parallel limit.

Figure 2 clearly shows that PRD can provide access to a significant portion of spatiotemporal simulation space that is inaccessible to direct MD at the exascale. However, the plot also illustrates that the global transition rate can prevent PRD from reaching the theoretical parallel limit on a large machine. Breaking this limitation is the motivation behind many of the novel speculation and localization approaches that will be described below.

## 3.2    PRD+X

### 3.2.1    Parallel Replica Hyperdynamics (PRH)

The parallel replica hyperdynamics method (PRH), corresponding to the combination of PRD and hyperdynamics, is almost as old as its two components (Voter and Germann 1998). Given an appropriate hyperdynamics bias potential, combining these two methods is straightforward: PRD is performed as usual, except the dynamics on each replica is performed on the biased potential surface, $V(X) + V^b(X)$, to further accelerate the local transition rate. Since each replica process will experience a boosted transition rate of $k_g \eta_r^H$, where $\eta_r^H$ is the hyperdynamics boost factor obtained on each replica, the new algorithm can be expected to provide a speedup of

$$\eta^{PRH} = N_r \eta_r^H \left( (1 + f_Q)(1 + 2 N_r \eta_r^H k_g \tau_c) \right)^{-1}. \tag{6}$$

This approximate equation demonstrates that the available boost factors of PRD and hyperdynamics do not simply multiply, because the efficiency of PRD will be inhibited by the boosted transition rate experienced by each replica. The maximum possible speedup in PRH therefore tends to that of PRD as the number of processors increases. However, the hybrid technique can be very valuable when resources are limited. For example, in cases where $\eta^{PRD}$ is limited by $N_r$, rather than $k_g$, it is very likely that PRH will outperform PRD-alone.

### 3.2.2   Parallel Replica TAD (ReplicaTAD)

The newest PRD+X combination is the parallel replica TAD method (ReplicaTAD) (Zamora et al. 2018). ReplicaTAD uses one computing unit to carry out the original TAD procedure, including all NEB calculations, and $N_r$ to carry out high-temperature MD using PRD.

In contrast to original PRD however, ReplicaTAD uses replication to reach $t_{\text{Stop}}^{\text{High}}$ as quickly as possible, rather than to decrease the waiting time to observe a single transition (although this is also achieved). Since TAD uses BCMD rather than direct MD, the parallel replication procedure can be performed in a way that is more efficient than the original PRD. For example, individual replicas must dephase only when they locally observe a transition, and, when this occurs, the final state does not have to be broadcasted to every other replica but only to the master.

Like PRH, ReplicaTAD is powerful but unlikely to outperform pure PRD if unlimited parallel resources are available (this does not consider the case where the synthetic mode can be used by ReplicaTAD to escape superbasins). Although BCMD allows for the use of a more efficient replication procedure, the elevated temperature means that the parallel replica efficiency is worse than it would have been at the low temperature of interest. However, the real advantage of ReplicaTAD is that computational resources can be used to improve the accuracy of the TAD procedure. Since the kinetics in most material systems departs from HTST predictions when the temperature becomes too large, TAD is most accurate when $T_{\text{High}}$ approaches $T_{\text{Low}}$. While a low $T_{\text{High}}$ setting is likely to produce a meager boost in serial TAD, adding parallel replication can produce a boost that is equivalent to, if not larger than, the serial TAD boost with an optimal $T_{\text{High}}$ setting.

## 4   Speculation

Speculative execution is a well-established technique used across various applications such as distributed computing and modern CPU logic. For many modern pipe-lined CPU architectures, for example, the use of branch prediction is often required to achieve optimal performance. The basic idea is that, when excess computing resources are available, it may be preferable to perform certain tasks before there is any guarantee that the task is necessary, so long as the early execution of said task has the potential to decrease the overall execution time.

Within the context of AMD, parallel speculation generally refers to the parallel scaling of a parent method by leveraging speculative execution in states that the physical system is expected to visit (or revisit) in the future. Execution becomes speculative in nature when the simulated trajectory has yet to require additional MD in that state to continue. Although it is generally not straightforward to make accurate predictions of future needs, there are at least two situations in AMD where this can be done relatively simply. The first of these cases occurs during any TAD simulation. The second case occurs when the trajectory is trapped in a superbasin. Next, we discuss two recent approaches intended to address these speculative execution opportunities.

## 4.1    Speculation in TAD

The opportunity for efficient speculation within the TAD method arises from the use of BCMD. While transitions are explicitly rejected before the proper low-temperature transition is finally identified, their occurrence can be used to accurately *predict* the next official state along the trajectory (note that we use the term *official state* to describe a state that is included in the final state-to-state trajectory).

### 4.1.1    Speculatively Parallel TAD (SpecTAD)

The speculatively parallel TAD (SpecTAD) method uses speculative execution to scale the serial TAD algorithm across multiple processors (Zamora et al. 2016a). As mentioned above, the nature of BCMD leads to an ideal opportunity for speculative execution. After a transition pathway is first observed at high temperature, an idle processor can be used to immediately begin executing the TAD procedure in the final state if it is possible that the transition will ultimately be accepted. For many real TAD simulations, speculative execution can allow significant parallel scaling, because $t_{\text{Stop}}^{\text{High}}$ can be more than an order of magnitude longer than $t_{\text{Winner}}^{\text{High}}$. Since Eq. (4) is used to update $t_{\text{Short}}^{\text{Low}}$ as soon as the NEB is performed for each high-temperature transition, it is also straightforward to decide which speculative states should be prioritized for exploration on the available CPU resources.

The basic SpecTAD procedure requires relatively simple modifications to the traditional TAD approach. The most significant change is that a new master process is needed to build the long-time trajectory of many sequential state-to-state transitions. This master process does not need to perform any MD or know much about the TAD procedure. Instead, this process simply manages some number of speculation processes that are each responsible for performing a modified TAD procedure in a single assigned state. When a speculation process is not performing TAD, it simply waits for the master process to assign it a new state (in practice, this idle waiting time is what typically limits the parallel scaling of SpecTAD). As illustrated in Fig. 3, the simulation will begin with the master sending the initial state geometry (State A) to a random process (Process 0). Note that the processes in Fig. 3 are labeled in the order that they are first assigned a state but that any idle process could be used to explore each state. When a process is assigned a new state, it executes the TAD procedure with the following modifications:

1. When $t_{\text{Short}}^{\text{Low}}$ is replaced by a new transition at $T_{\text{High}}$, using Eq. (4), a speculation message must be sent to the master process. This message will include the geometry of the neighboring state corresponding to the new $t_{\text{Short}}^{\text{Low}}$.
2. When $t_{\text{Stop}}^{\text{High}}$ is reached, the master process must be alerted that the most recent speculation from this process actually corresponds to the winning transition for the corresponding state visit and that this process is now idle.
**Fig. 3** Schematic illustration of SpecTAD on an idealized 2-D potential energy landscape. Each rectangle corresponds to a distinct speculation process, which executes a modified TAD procedure in a single assigned state. The simulation begins with the master process assigning State A to Process 0, where the red-dashed line circle corresponds to a detected transition, on Process 0, to State B. Once informed of the transition, the master process assigns State B to Process 1, and the same process is repeated when a transition is detected in State B (blue-dashed line circle)

3. Processes must occasionally probe for a kill message from the master. This message indicates that this process is currently exploring a state that is no longer a priority.

Although the schematic illustration in Fig. 3 excludes the killing of speculation processes to reassign work, the intended execution flow is clearly shown: as soon as Process 0 detects a transition that allows it to set (or reset) $t_{\text{Short}}^{\text{Low}}$, the master process will assign the next expected state (State B) to an idle speculation process (Process 1). This same procedure is then repeated in State B, leading to a third speculation process (Process 2) exploring State C. Since $t_{\text{Stop}}^{\text{High}}$ can be orders of magnitude longer than $t_{\text{Winner}}^{\text{High}}$ for each distinct speculation process, all three processes can perform much of their work in parallel.

In contrast to replication-based AMD methods like ReplicaTAD, the parallel efficiency of SpecTAD is clearly dependent on the total number of transitions that occur in the official low-temperature trajectory. Since the only source of parallel speedup is the concurrent execution of TAD in speculative future states, the simulation of a trajectory with N transitions could never use more than N cores efficiently. In practice, this is not a stringent limitation, as long-time simulations often include thousands of transitions or more. Instead, the maximum parallel speedup is more typically limited by the ratio: $\tilde{w}_{\text{Stop}}/\tilde{w}_{\text{Winner}}$, where $\tilde{w}_{\text{Stop}}$ corresponds to the average wall-clock time (WCT) needed to reach the stop time for a given state and $\tilde{w}_{\text{Winner}}$ corresponds to the average WCT needed to find the winning transition. Since each speculation process must discover its winning transition before subsequent states

can be explored, this ratio gives an approximate upper bound on the attainable parallel speedup.

### 4.1.2 Synthetic-Mode SpecTAD

Like the original TAD method, SpecTAD is particularly well-suited for the simulation of physical systems containing superbasins of states. This is because each speculation process can employ synthetic-mode transitions to leverage previously accumulated $t^{\text{High}}$ in revisited states. More importantly, however, is the fact that the application of synthetic transitions can actually improve the overall parallel efficiency of SpecTAD. Although the synthetic-mode procedure is likely to reduce the value of $\tilde{w}_{\text{Stop}}$, the procedure will even more dramatically reduce the value of $\tilde{w}_{\text{Winner}}$. Since the procedure requires that future time stamps be assigned to all escape pathways observed during previous visits, it becomes likely that the winning transition out of a revisited state can be accurately predicted before any additional MD is performed. Therefore, once a SpecTAD simulation becomes stuck within a deep superbasin of known states, it becomes possible for the simulation to use all available resource to escape from the superbasin.

### 4.1.3 Hybrid SpecTAD

Although SpecTAD is certainly a powerful extension of the original TAD method, in general, pure speculation is unlikely to be the most efficient use of parallel resources. For example, when a physical system exhibits anharmonic behavior above some modest temperature, an accurate simulation may require that the value of $T_{\text{High}}$ be set relatively close to $T_{\text{Low}}$. In such cases, ReplicaTAD will often outperform SpecTAD, because the $\tilde{w}_{\text{Stop}}/\tilde{w}_{\text{Winner}}$ ratio becomes too small for pure speculation to scale efficiently. However, in that case, a flexible combination of both speculation and replication can be used to efficiently improve the TAD boost for any $T_{\text{High}} > T_{\text{Low}}$.

The basic idea behind the *hybrid* SpecTAD method (Zamora et al. 2018) is to allow for the combination of both speculation and replication. This is accomplished by modifying the SpecTAD algorithm to utilize $N_r$ local replica processes within each of the $N_s$ speculation processes. Using this scheme, which is schematically illustrated in Fig. 4, each speculation process performs a ReplicaTAD procedure, using $N_r + 1$ computing units. It is useful to note that this hybrid method will improve upon the performance of conventional SpecTAD, even when $N_r = 1$, as NEB calculations and MD can then be executed concurrently.

In practice, the most important advantage of hybrid SpecTAD is that it provides a straightforward way to trade accuracy and resources. It becomes practical to start with an MD-accurate method with $T_{\text{High}} = T_{\text{Low}}$ and then to raise the high temperature until the required timescale can be accurately accessed, using whatever computing resources are available. The application of an elevated temperature also opens up the opportunity to promote repetitive events into synthetic mode – possibly leading to KMC-like performance.

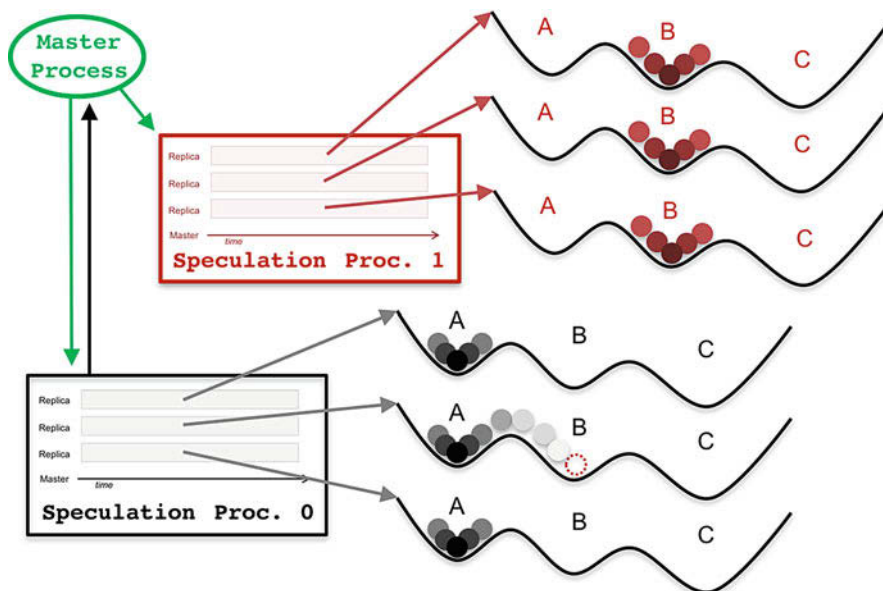
The development of this new hybrid method demonstrates the advantages of combining multiple forms of parallelism. In contrast to MD-accurate methods,


**Fig. 4** Schematic illustration of hybrid SpecTAD on an idealized 2-D potential energy landscape. Each rectangle corresponds to a distinct speculation process, which uses a local master process, and $N_r$ local replica processes, to execute a modified TAD procedure in a single assigned state. Like conventional SpecTAD, a global master process is used to manage the assignments of states to available speculation processes

however, TAD-based algorithms are not limited to the lower triangle presented in Fig. 2. In practice, the boost available from hybrid SpecTAD can be many orders of magnitude larger than the theoretical parallel limit. For example, recent work by Zamora et al. (2016b) has leveraged both synthetic-mode transitions and speculation to achieve boost factors greater than $10^{15}$ over MD, corresponding to years of simulated time. By combining replication and speculation, extreme boost factors like this should become even more accessible, because parallel resources are more efficiently used to accelerate the rate at which internal superbasin states are explored.

## 4.2    Speculation in PRD

The TAD formalism offers a straightforward way to speculate which transitions are likely to occur in the future, as a transition is always observed at high temperature before it is officially accepted as a valid low-temperature transition. This delay opens a window of opportunity to overlap calculations in different states. Such a delay is however not available in PRD, since transitions are accepted as soon as they are observed. Nonetheless, if one can hazard a prediction that some states might be visited, or revisited, in the future, it can be leveraged to improve efficiency of replica methods like PRD.

### 4.2.1 Parallel Trajectory Splicing (ParSplice)

The parallel trajectory splicing (ParSplice) method (Perez et al. 2016) is an extension of PRD, designed to dramatically improve the parallel efficiency when states are likely to be revisited. Like PRD, the ParSplice boost is obtained through replica-based parallelism. However, the worker processes are no longer synchronized in the same states. Indeed, the key idea in ParSplice is to factor the problem of generating a long state-to-state trajectory into independent tasks that can be carried out concurrently, independently, and asynchronously. These tasks are to generate so-called trajectory *segments* such that the system remained for at least $\tau_c$ in a given state prior to the beginning of the segment and at least $\tau_c$ in a given state (potentially different from one where the segment began) prior to the end of the segment. It can be shown using the same formalism developed for PRD (Le Bris et al. 2012) that such segments can be assembled (or spliced) into a proper state-to-state trajectory as long as the new segment begins in the same state where the trajectory currently ends.

The improvement in efficiency over PRD is primarily due to aggressive book-keeping: first, segments that cannot be immediately spliced into the main state-to-state trajectory are stored in a database for future use in case the trajectory revisits their starting state at a later time; second, end points of segments, which are by construction proper starting points for subsequent segments, are stored and reused in order to avoid having to re-dephase in states that have been previously visited. Taken together, this insures that computer cycles invested in MD can potentially be leveraged to create the state-to-state trajectory.

Efficiency is further improved through speculative segment execution. Indeed, as shown in Fig. 5, ParSplice workers are not constrained to run in the same state. Instead, segments can be simultaneously generated in multiple states according to the *expected likelihood* that they will be spliced into the trajectory in the future. Operationally, this likelihood optimization is carried out using simulations of the possible future evolution of the trajectory based on a kinetic model that is constructed on the fly. As with SpecTAD, this procedure is speculative in nature because one cannot certify that the segment that is about to be generated will be indeed spliced into the trajectory. Exploiting this uncertainty however enables a considerable increase in the parallelism available to the algorithm – one can parallelize over the possible futures of the trajectory, in addition to its present state – thereby dramatically increasing scalability in some cases.

ParSplice performs best in the rather common situation where the trajectory is trapped in a superbasin of states (Perez et al. 2018). In this case, the same states will be revisited over and over, which maximizes the probability that completed segments are already available at the current end of the trajectory and that dephased starting points are available to efficiently generate additional segments. Further, the evolution of a trajectory in a superbasin is statistically predictable. This allows for the optimal assignment of additional segments in the different states within the superbasin. It was recently shown that ParSplice can maintain excellent performance as long as the escape out of the superbasin is slow, even when individual intra-basin transitions occur so rapidly that a synchronous PRD approach would be inefficient
**Fig. 5** Illustration of the ParSplice method. Trajectory segments are independently and concurrently generated in multiple states. These segments are then assembled into a long state-to-state trajectory by splicing together segments whose end points match

(Perez et al. 2018). This enables one to leverage massive parallel resources to investigate complex systems where the distribution of transition rates is very wide.

It is useful to recognize that ParSplice is actually a natural combination of both parallel replication and speculation. For this reason, the general resource-management approach can be used to efficiently scale the performance of hyper-dynamics or TAD on parallel resources. In the case of TAD, there is no reason that a master process needs to directly splice the generated segments into a single official trajectory. Instead, the master can separately splice many distinct high-temperature trajectories, corresponding to both current and speculative states, and then use Eq. (4) to project each of these spliced trajectories onto a single (official) low-temperature trajectory. When compared to the existing version of hybrid SpecTAD, the incorporation of a ParSplice-based resource management procedure would effectively produce an adaptive load balancing mechanism to optimally choose the number of replication and speculation processes in use. Given the significant value of efficiency in the world of high-performance computing, this expected outcome is a powerful motivation for further development.

## 5    Localization

While replica and speculation-based parallelism can allow an AMD method to access significantly longer timescales than direct MD, other techniques are often needed to allow the boost to be maintained at larger length scales. Indeed, the boost

of a traditional AMD method often scales poorly with an increase in the system size, because the global transition rate will also proportionally grow. For example, an infinite system will always experience at least one transition occurring at some location at any given time. Since PRD, TAD, and hyperdynamics all rely on a separation of timescales between thermal fluctuations and state-to-state transitions, their performance suffers when these timescales converge. That is, once the average transition time becomes shorter than the correlation time of the system, the original AMD methods no longer provide any advantage over direct MD.

In order to improve the spatial scaling of traditional AMD methods, new approaches have been introduced based on the concept of localization. Although the global transition rate is likely to grow when a physical system increases in size, the transition rate within a given local region is unlikely to change, because a very large majority of transition processes are local in nature, so that while the absolute number of possible transitions increases with system size, their spatial density remains relatively constant.

In the following section, we discuss two novel methodologies that exploit this locality. First, we discuss the synchronous sub-lattice (SL) algorithm, which has been used to improve the performance of the PRD and TAD approaches. Second, we discuss the recently introduced local hyperdynamics method, which can improve the spatial scaling of hyperdynamics without the need for SL decomposition.

## 5.1    Synchronous Sub-lattice Decomposition

The synchronous sub-lattice (SL) algorithm is a two-layer spatial decomposition routine that was originally designed to improve the spatial scaling of KMC simulations (Shim and Amar 2005). Over the past decade, this approach has also been used to improve the performance of both TAD (Shim et al. 2007) and PRD (Martínez et al. 2014). The recursive subdivision procedure, at the heart of SL, results in a set of noninteracting regions that can be advanced concurrently in time. This ultimately allows multiple computing units to work on distinct localized regions of the sample, in parallel.

In contrast to spatially parallel MD, the approach is designed to reduce the frequency of communication between neighboring regions while retaining a sufficient level of accuracy. Figure 6 shows a two-dimensional SL decomposition schematically, where numbers and letters refer to domains and subdomains, respectively. Starting with a system of atoms, the global geometry is first partitioned into domains, which can each be assigned to distinct processors (numbers in Fig. 6). Each domain is then further divided into a set of $2^{Dim}$ sub-domains (letters in Fig. 6), where $Dim$ is the number of spatial dimensions used in the decomposition. Intra-domain labeling is assigned in a cyclic fashion, so that sub-domains sharing the same letter do not interact. The collection of all sub-domains with a matching label (letter) is called a sub-lattice.

**Fig. 6** Illustration of the synchronous sub-lattice algorithm used in SLPRD and parTAD. Note that the image corresponds to a two-dimensional discretization, requiring four sub-domains for each *processor* domain
To advance the global simulation time by $\tau_{adv}$ using the SL procedure, each of the $2^{Dim}$ sub-lattices are chosen sequentially, with the full loop resulting in a sub-lattice cycle. For each loop iteration, a desired modeling algorithm (KMC, PRD, TAD, etc.) is used to advance the simulated time by $\tau_{adv}$ within the corresponding sub-lattice. Since the sub-lattice is composed of noninteracting sub-domains, each of these regions can be advanced concurrently by distinct processors.

Since neighboring sub-domains must be synchronized on a timescale that is coarse relative to MD time integration, a boundary skin must be added to each of the sub-domains when the local time is advanced. This skin must include an inner boundary of moving atoms (the light-gray region surrounding sub-domain $0_D$ in Fig. 6), as well as an outer boundary of fixed atoms (the dark-gray region in Fig. 6). Although the inner-boundary atoms are allowed to move when the local time is advanced, the sub-domain must explicitly reject any transitions outside the inner boundary, unless the center of mass (the center of mass of all atoms involved in the transition) is contained within the sub-domain.

The SL algorithm is designed to address boundary conflicts in which two mutually exclusive events occur at some domain boundary. However, it does not avoid causality errors in which events happening at different times might affect the dynamics of the system. Although an extension of the original algorithm exists in which causality errors are completely avoided (Martínez et al. 2008, 2011), some small bias is still introduced by the spatial decomposition itself. In most cases, this bias is known to be relatively small (Shim and Amar 2005; Martínez et al. 2011).

### 5.1.1   Sub-lattice PRD

The sub-lattice PRD method (SLPRD) corresponds to an SL implementation in which PRD is used to advance the simulated time within each sub-domain (Martínez et al. 2014). In general, the parallel speedup of SLPRD is given by

$$\eta^{\text{SLPRD}} = \frac{\tilde{\eta}_{\text{sd}}^{\text{PRD}} D}{\mathcal{O}(skin)},\tag{7}$$

where $D$ is the number of domains , $\tilde{\eta}_{\text{sd}}^{\text{PRD}}$ is the average PRD speedup achieved in each local sub-domain, and $\mathcal{O}(skin)$ is the additional overhead corresponding to the aforementioned boundary regions. The $\mathcal{O}(skin)$ overhead is a linear function of the extra number of atoms in each sub-domain and can be obtained through MD simulations (Martínez et al. 2014). In the hypothetical scenario that $\mathcal{O}(skin) \rightarrow 1$, SLPRD produces an ideal weak scaling of the average PRD boost achieved in each sub-domain. However, the proportion of boundary atoms, with respect to the *active* atoms, is strongly dependent on the size of each processor domain. For this reason, the most efficient use of computing units often requires large SL domains and spatially parallel force calls within each replica process.

In practice, the SLPRD algorithm becomes most advantageous (relative to original PRD with spatially parallel force calls – also known as ParPRD) when there are both many atoms to simulate and many computing units available. For example, Martínez et al. (2014) have directly compared real simulations with a more-detailed form of Eq. (7) to produce the performance projections in Fig. 7. In this figure, MD, ParPRD, and SLPRD are all assumed to leverage spatially parallel force calls. The results clearly show that the SL algorithm becomes most effective when the computing system is extremely large and that the potential for weak scaling is not strongly dependent on the per-atom transition rate of the system.

Although SL does require the computationally expensive use of boundary atoms, the development and analysis of an SLPRD method is certainly a significant AMD advancement. This work has clearly demonstrated both the advantages and limitations of combining SL with a replication-based method like PRD. This accomplishment has ultimately paved the way for the ongoing development of a new sub-lattice ParSplice (SLParSplice) method. Both the theoretical and measured performance of SLPRD, as presented in Martínez et al. (2014) (and reviewed above), can be taken as a lower bound on the available performance of a quality SLParSplice implementation.

### 5.1.2   Sub-lattice TAD

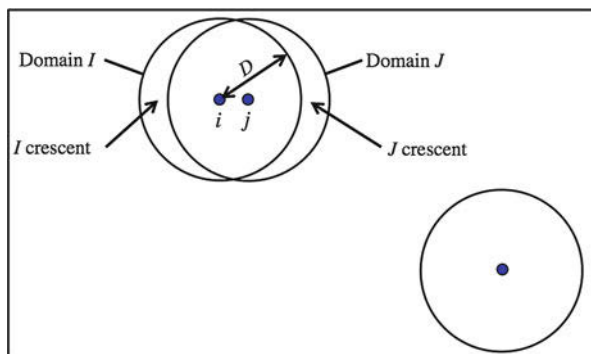
In addition to KMC and PRD, the SL algorithm has also been used within the *parallel* TAD method (parTAD) to dramatically improve the spatial scaling of TAD (Shim et al. 2007). ParTAD is very similar to SLPRD, in the sense that AMD is used to advance the simulation time within each sub-domain of the decomposed sub-lattice geometry. In practice, however, parTAD has an even better chance of achieving improved spatial scaling, because TAD is known to scale especially
**Fig. 7** Speedup vs. the number of total processors in the system with (**a**) 54,784 atoms and $k = 10^5$ (s atom)$^{-1}$ and (**b**) $10^6$ atoms and $k = 10^6$ (s atom)$^{-1}$. SLPRD(A) and SLPRD(S) show analytical and simulated results, respectively. (Figure reproduced with permission from Martínez et al. 2014)

poorly. That is, for a serial simulation of $N_{at}$ atoms, the run time is expected to scale approximately as $N_{at}^{3+1/3+\gamma}$, where $\gamma = T_{Low}/T_{High}$. This behavior can be improved, to $N_{at}^{2-\gamma}$, when *local* NEB calculations are employed (Shim et al. 2013). However, such a localization must be performed with care, since an undersized NEB geometry can lead to a significant error in the calculated saddle-point energy and therefore the transition rate. Instead of localizing these calculations directly, SL can accomplish the same NEB performance while also reducing the effective transition rate within each domain. Overall, the parallel execution of parTAD can lead to a logarithmic scaling of the serial TAD boost with respect to system size.

## 5.2    Local Hyperdynamics

In hyperdynamics, because the bias potential must go to zero whenever the system is near a dividing surface, increasing the system size will necessarily lead to a lower boost factor for a given definition of the bias potential. Thus, for any proper bias potential, the boost will decay to unity in the limit of large system size. Local hyperdynamics (Kim et al. 2013) mitigates this problem by taking advantage of the

**Fig. 8** Schematic illustration of local hyperdynamics system, showing local domains $I$ and $J$ centered on bonds $i$ and $j$ (shown as dots), respectively. Every bond (or atom) in the system has its own domain. Distant domains do not interact with each other. (Figure reproduced with permission from Kim et al. 2013)



intrinsic locality of the transition pathways. In systems where transitions are local, the dynamics in two regions separated by a large distance evolve independently. More precisely, we define a *locality range L*, beyond which the correlation between bond distortions is zero or smaller than some threshold value set by the user. Given this locality assumption, we define a modified hyperdynamics procedure that only requires that the bias force on an atom be zero when there is a *nearby* geometry distortion taking the system near a dividing surface. We briefly describe the method here, while full detail can be found in Kim et al. (2013).

The local hyperdynamics (LHD) procedure is designed to generate an appropriate escape from the current state, in the same spirit as hyperdynamics, but in a way that maintains a constant boost factor as the system size is increased. In principle, LHD can utilize most any form of bias potential, but for this discussion, we will focus on the use of the simple bond boost (SBB) form, a simplified version (Perez et al. 2009) of the bond boost bias (Miron and Fichthorn 2003), as discussed above. For this type of bias, the natural entity of interest is the bond, rather than the atom. We define a domain $J$, centered on bond $j$, which includes all bonds out to a distance $D$ from $j$, as shown in Fig. 8. Every bond in the system has such a domain associated with it, so that, for example, an $N$-atom fcc system would have roughly $6N$ overlapping domains. For each domain $J$, a scaled version of Eq. (3),

$$V_J^b = V_J^b(\mathbf{R}_J) = C_J V_{\text{SBB}}^b(\mathbf{R}_J), \tag{8}$$

is employed to compute the domain bias energy $V_J^b$, using only the coordinates of the atoms that belong to that domain, as denoted by $R_J$. If, in domain $J$, bond $j$ is the most distorted bond, then the gradient of Eq. (8) is employed to determine the force on bond $j$; otherwise, the force on bond $j$ is zero. (Note that the force on a bond corresponds to the equal, but opposite, force on each atom composing the bond.) Each domain has a bias-energy scaling factor $C_J$; these scaling coefficients are adjusted to give the same average boost factor $B_{\text{target}}$ for every domain in the system. This is accomplished using a *boostostat*, which nudges the coefficient up or down at each time step by an amount proportional to $B_{\text{target}} - B_J$, where $B_J$ is

the instantaneous boost on bond $j$. This is a key component of the LHD procedure, ensuring that all bonds in the system advance in time at the same accelerated rate (on average). We choose a boostostat coupling constant that is not too high (which would distort the dynamics and change the escape rates) and not too low (which would not allow the system to settle into the proper behavior quickly enough relative to the time to next escape. (Note that the best value of $B_{target}$ is system dependent.)

An important characteristic of LHD is that because the force on each bond is governed by a local energy definition, the system dynamics overall is not conservative (i.e., the dynamics with the Langevin thermostat turned off will not be conservative). Surprisingly, though, this procedure nonetheless gives impressively accurate rate constants, typically within a few percent of the exact rates, determined by comparing to MD or regular hyperdynamics benchmarks for various systems. We have shown (Kim et al. 2013) that as the domain size $D$ is increased, the LHD dynamics should become increasingly accurate, even when $D$ is still smaller than the system size. This is because the relative contribution from the crescent regions (see Fig. 8), which give rise to the mismatch between the actual force on bond $j$ and the force on bond $j$ expected by bond $i$, decreases with $D$. (When $D$ is large enough that each domain includes the whole system, then LHD trivially reduces to regular hyperdynamics.) We have also shown (Kim et al. 2013) that for a homogeneous system (all bonds equivalent) and the SBB bias, when $D \geq 2L$, the dynamical evolution will be consistent with Langevin dynamics, in spite of the apparent nonconservative nature, and the accelerated escape rates should be correct. We do not yet know how to show, nor is it necessarily true, that the LHD results are correct for an inhomogeneous system (inequivalent bonds), although the accuracy of the results we have obtained is suggestive.

When a transition from the current state occurs, in addition to redefining the SBB bias potential, adjustment of the $C_J$ coefficients is required for all domains affected by the geometry change caused by the transition. The boostostat, with a properly chosen coupling coefficient, takes care of this, ideally on a timescale that is short compared to the time until the next event in this region. Also, one or more new bonds may have formed due to the transition, requiring creation of new domains and new $C_J$ values, which can be initiated with a good starting guess (e.g., the average $C_J$ value for all bonds in the system), after which the boostostat settles them in.

LHD will give constant boost for an arbitrarily large system, provided that no new lower-barrier pathways show up as the system size is increased; an example for a homogeneous system is shown in Fig. 9. In a massively parallel implementation, LHD will give good parallel weak-scaling provided the extra work required when transitions occur is distributed such that it does not grow with the number of transitions in time.

Although SL could also be used to scale the performance of hyperdynamics, the method requires the use of many boundary atoms to accurately perform MD within each distinct sub-lattice domain. In contrast, the local hyperdynamics approach to localization does not require the use of fixed/free boundary atoms and can therefore be expected to be more efficient than a hypothetical SL-based alternative.
**Fig. 9** Boost factor for local hyperdynamics, red (+), and regular hyperdynamics, green (×) for bulk Ag systems of various sizes modeled with an embedded atom method potential (Voter 1988). (Figure reproduced with permission from Kim et al. 2013)

## 6    Discussion

In this chapter, we reviewed a variety of modern techniques for performing long-timescale AMD simulations using parallel computing systems. The approaches broadly fall into three categories: replication (PRH, ParSplice), speculation (SpecTAD, ParSplice), and localization (SLPRD, parTAD, and local hyperdynamics). Clearly, it is possible for an AMD method to fall into more than one of these categories. For example, the most novel feature of ParSplice is that it can leverage speculative execution to outperform PRD when states are often revisited. However, the ParSplice boost itself relies on a generalization of the replication concept. In fact, the performance of ParSplice is very similar to that of PRD when states are not likely to be repeated, because they are both built on the replication foundation.

Like all the AMD methods that came before them, the primary challenge facing modern AMD algorithms is the so-called *low-barrier* problem. As discussed earlier in the chapter, the boosts of the original PRD, ParSplice, TAD, and hyperdynamics methods degrade dramatically as the global transition rate ($k_g$) increases. When high rates stem from large system sizes, localization methods can be leveraged to lower the effective value of $k_g$.

Unfortunately, many systems have large $k_g$ because the dynamics are simply dominated by low-barrier transition pathways. When these low-barriers connect states into superbasins, modified state definitions or advanced techniques such as SpecTAD and ParSplice can still reach very long timescales. In other words, recent techniques can exploit more general separations of timescales than only between vibrations and transitions. Problems however remain: for example, while it might in principle be possible to define suitably metastable states on complex energy landscapes, doing so in practice remains a considerable challenge that will require new mathematical or physical insights or novel machine-learning

approaches. Further, as the computational scale increases, maintaining efficiency becomes increasingly difficult, as one has to identify a large amount of work that can be carried out concurrently. However, the number of processors that can be efficiently leveraged to generate escapes out of a single or a few states is limited. Efficient speculation then becomes critical, and new developments will be required to make this process efficient.

Although challenges exist, the value of AMD is clearly expanding with the availability of parallel computing resources. In light of new mathematical understandings and rapidly improving parallel algorithms, there is good reason to expect the available time and length scales to continue improving. What is especially exciting, however, is that these AMD advances can (and will) be used to dramatically accelerate the simulation of highly accurate MD-based trajectories. Since computationally expensive force calculations often result in clear opportunities for strong scaling, it has just recently become practical to leverage electronic-structure-based approaches within AMD methodologies. Given that some parallel approaches can be tuned to achieve arbitrary accuracy (with respect to the underlying interatomic forces), it is reasonable to expect that massively parallel AMD will lead to significant materials research progress in the coming years.

# 7   Applications and Lessons Learned

In this chapter, we have focused our attention on the theoretical details of several new parallel AMD methodologies for long-timescale simulations. Since all of the highlighted techniques are still under significant development at the time of writing, some have yet to be used to investigate high-profile materials phenomena. A few of these methods, however, have already proven useful for materials applications of clear technological interest. For example, SpecTAD has been used to investigate the effects of di-vacancy and di-interstitial formation on the mobility of point defects in magnesium aluminate spinel ($MgAl_2O_4$), a complex oxide with applications in both nuclear reactors and military body armor (Zamora et al. 2016b). In $MgAl_2O_4$, the formation of point defect clusters often leads to a complex potential energy landscape in which the system will need to move through a series of deep superbasins for net defect migration to occur. Within each of these superbasins, the energy barriers can be at least an order of magnitude smaller than those needed to escape to external states. For this reason, *synthetic-mode* SpecTAD is extremely effective and can be used to reach years of simulated time at experimentally relevant temperatures. In this case, the long-time simulations provided sufficient simulation data to fully characterize the self-diffusivity of various point defect clusters across a range of possible temperatures.

ParSplice has also proven to be a valuable tool for the investigation of material systems that evolve in time through superbasins of states. Recently, for example, ParSplice was used to simulate the long-time relaxation of platinum nanoparticles, which are of significant interest for possible applications in catalysis and medicine (Perez et al. 2018). By tracking the evolution of an initially disordered

Pt nanoparticle, this work demonstrated that ParSplice can be used to simulate significantly longer timescales than either direct MD or PRD. Since the trajectory is likely to visit many of the same states repetitively, the algorithm can efficiently leverage thousands of cores to produce a simulation rate greater than 1.4 microseconds per minute of WCT (at 300K). For the same physical system, the efficiency of the traditional PRD approach is significantly lower, because the lack of speculation and extensive bookkeeping leads to a much higher dephasing overhead. In fact, this application of ParSplice produced so many state-to-state transitions that a dedicated clustering algorithm was needed to post-process the data (Huang et al. 2017). Using a 16 microsecond (70,000-transition) ParSplice trajectory, the Perron Cluster Cluster Analysis (PCCA) was used to detect a series of ~10 critical superbasin clusters connecting a metastable Marks decahedral state with the thermodynamically favored icosahedral state for a 147-atom nanoparticle.

The possibility of generating large quantities of state-descriptive data is an important similarity between the aforementioned applications of SpecTAD and ParSplice. As a by-product of favorable superbasin simulation performance, these methods can generate state-to-state trajectories that are more difficult to interpret than traditional AMD methods. In order to achieve optimal boost factors, less-important trajectory information (like the details of some intermediate and/or repeated states) is sometimes ignored. For example, the $MgAl_2O_4$ SpecTAD application captured billions of rare events, meaning that information about many of the state visits is necessarily excluded from the raw output. In ParSplice, the generation of splice-able segments is specifically designed to allow shallow intermediate states to be ignored. While it is a clear performance advantage over PRD to allow segments to include multiple intermediate transitions, the properties of a segment can make the final ParSplice trajectory more difficult to parse. Overall, a valuable lesson learned through these recent applications is that high-performance simulation methods tend to require high-performance analysis tools. As parallel algorithms continue to improve, the growing volume and complexity of the raw simulation data is likely to become a key concern for the developers and users of these methods.

# 8 Conclusion

In a world with an increasing availability of distributed computing clusters, the value of parallel algorithm development is continuously growing. As high-performance computing vendors prepare for the exascale and beyond, it is becoming clear that hardware parallelism is likely to increase for the foreseeable future. In this chapter, we have reviewed a variety of modern advances in parallel accelerated molecular dynamics (AMD). To provide a reasonable organization of concepts, we began by introducing the serial AMD approaches and then discussed three distinct classes of parallel methods: replication, speculation, and localization. An emphasis was placed on the more recently developed methods, especially those expected to play a

significant role as the high-performance computing world approaches the exascale. Given the wide range of opportunities and challenges for the application and development of parallel AMD on modern computing resources, there is significant motivation for ongoing and future work.

### Abstract

The objective of this review chapter is to present recent results on the mathematical analysis of the accelerated dynamics algorithms introduced by A.F. Voter in collaboration with D. Perez and M. Sorensen. Using the notion of quasi-stationary distribution, one is able to rigorously justify the fact that the exit event from a metastable state for the Langevin or overdamped Langevin dynamics

can be modeled by a kinetic Monte Carlo model. Moreover, under some geometric assumptions, one can prove that this kinetic Monte Carlo model can be parameterized using Eyring-Kramers formulas. These are the building blocks required to analyze the accelerated dynamics algorithms, to understand their efficiency and their accuracy, and to improve and generalize these techniques beyond their original scope.

# 1    Introduction

The objective of this chapter is to review recent works on the mathematical analysis of the *accelerated dynamics techniques* introduced by A.F. Voter and coworkers from the late 1990s up to recently (Voter 1997, 1998; Sørensen and Voter 2000; Perez et al. 2015a). The objective of these methods is to efficiently simulate thermostated molecular dynamics trajectories over very large timescales. The mathematical analysis which has been developed gives the set of assumptions underlying these algorithms and a way to assess their accuracy. This helps to understand their limitations, but also to improve and extend these numerical methods beyond their original scope.

The aim of statistical computational physics and molecular dynamics is to infer from a microscopic model of matter its macroscopic properties. At the microscopic level, the atomic configuration is given by a set of positions of the atoms (or group of atoms), and the basic ingredient is a potential energy function:

$$V : \mathbb{R}^d \to \mathbb{R}. \tag{1}$$

Here $d$ is the number of degrees of freedom (typically three times the number of atoms), and the function $V$ associates to a given atomic configuration its energy. We will not discuss here how to build such a function $V$. Let us simply mention that this is related to the construction of so-called force fields, which requires a lot of chemical intuition to infer the functional form of the force field and good parametrization using either experimental data or ab initio computations to evaluate the electronic structure associated with given positions of the nuclei. Combining optimally these informations in order to improve the predictive abilities of force fields is a very lively research subject, at the interface between physics, chemistry, numerical analysis, and data sciences.

For a given potential $V$, at a fixed temperature $T$, the configurations of the atomic system at thermal equilibrium are distributed according to the Boltzmann-Gibbs measure (a.k.a. the canonical measure):

$$\mu = Z^{-1} \exp(-\beta V(q)) \, dq \tag{2}$$

where $q \in \mathbb{R}^d$ is the positions of the atoms, $\beta^{-1} = k_B T$ ($k_B$ being the Boltzmann constant), and $Z = \int_{\mathbb{R}^d} \exp(-\beta V(q)) \, dq$ is assumed to be finite. Computing averages with respect to $\mu$ gives access to so-called thermodynamic quantities. Examples include heat capacity, free energy difference, stress, etc. The focus of

this work is rather to discuss numerical methods to compute *dynamical quantities*, namely, observables which depend on the trajectories of the molecular system: transition times, transition paths, reaction mechanisms, etc. This requires to define a dynamics. The typical dynamics one should have in mind is the Langevin dynamics:

$$\begin{cases} dq_t = M^{-1} p_t \, dt \\ dp_t = -\nabla V(q_t) \, dt - \gamma M^{-1} p_t \, dt + \sqrt{2\gamma \beta^{-1}} dW_t \end{cases} \tag{3}$$

where $(q_t, p_t) \in \mathbb{R}^{d \times d}$ denotes the positions and momenta of the particles at time $t \geq 0$, $M$ is the mass tensor, $\gamma > 0$ is a friction parameter, and $W_t$ is a standard $d$-dimensional Brownian motion. Under loose assumptions on $V$, this dynamics is ergodic with respect to the phase-space canonical measure $\overline{Z} \exp(-\beta(V(q) + p^T M^{-1} p/2)) \, dq \, dp$, where $\overline{Z} = \int_{\mathbb{R}^d} \exp(-\beta(V(q) + p^T M^{-1} p/2)) \, dq \, dp$. The marginal in $q$ of this measure is the measure $\mu$ defined above (see (2)). In particular, for any test function $\varphi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$,

$$\lim_{t \to \infty} \frac{1}{t} \int_0^t \varphi(q_s) \, ds = \int_{\mathbb{R}^d} \varphi d\mu. \tag{4}$$

In the following, we will also consider the overdamped Langevin dynamics which is obtained from (3) in the limit $\gamma \to \infty$ or $M \to 0$ (see, e.g., Lelièvre et al. 2010, Section 2.2.4):

$$dX_t = -\nabla V(X_t) \, dt + \sqrt{2\beta^{-1}} dW_t \tag{5}$$

where $X_t \in \mathbb{R}^d$ denotes the positions of the particles. More precisely, the over-damped Langevin dynamics is, for example, derived from the Langevin dynamics in the large friction limit and using a rescaling in time: assuming $M = \text{Id}$ for simplicity, in the limit $\gamma \to \infty$, $(q_{\gamma t})_{t \geq 0}$ converges to $(X_t)_{t \geq 0}$. Again, under loose assumptions on $V$, this dynamics is ergodic with respect to the canonical measure $\mu$. The Langevin and overdamped Langevin dynamics are thus thermostated dynamics: they describe the evolution of the system at a given temperature $T$. Simulating these dynamics over large timescales in order to have access to macroscopic properties of the system (both thermodynamic and dynamical quantities) is the objective of molecular dynamics simulations with applications in many scientific areas: biology, chemistry, materials sciences, etc. To obtain accurate results, this requires to simulate stochastic dynamics in large dimension over very large timescales.

The main difficulty when simulating the dynamics (3) or (5) in practice is that they are metastable. This means that the trajectory of the positions $(q_t)_{t \geq 0}$ or $(X_t)_{t \geq 0}$ remains trapped for very long periods of time in some regions of the configurational space called *metastable states*. This is actually expected from a physical viewpoint: these metastable states typically correspond to some macroscopic conformations of the system. In materials sciences, for example, one could think of these metastable states as positions of some defects in a crystal or of some adatoms on a surface.

In biology, these metastable states can be associated, for example, with molecular conformations of a protein. And it is indeed expected that the residence times in these metastable states are much larger than the typical timescale of vibration within the metastable states. In practice, one needs, for example, to use timesteps of the order of $10^{-15}$ s to discretize (3), while the typical phenomena of interest occur over timescales of the order of $10^{-6}$ s up to seconds or even more! The numerical counterpart is twofold: to compute thermodynamic quantities, the convergence of time averages such as (4) is very slow; and to evaluate dynamical quantities of interest, namely, typically transition paths and transition times between metastable states, one needs to sample rare events, namely, the exit from metastable states and the transition to a new metastable state. The objective of the *accelerated dynamics* algorithms is indeed to efficiently sample metastable dynamics in order to have access to some dynamical quantities. Let us make precise that we are here considering numerical methods to sample the whole dynamics from states to states and not, for example, the ensemble of reactive paths between two given metastable states, for which other dedicated methods can be used (splitting techniques (van Erp et al. 2003; Allen et al. 2005; Cérou et al. 2011), transition path sampling methods (Dellago et al. 1999), etc.)

The basic idea of the *accelerated dynamics* algorithms is the following: if the stochastic process $(q_t, p_t)_{t \geq 0}$ or $(X_t)_{t \geq 0}$ remains trapped for a sufficiently long time in a metastable state, it forgets the way it entered this state, and this means that the exit event from this metastable state can be modeled by the exit event of a kinetic Monte Carlo model, namely, a pure jump Markov process. This will be explained in Sect. 2. We will then show in Sect. 3 that, in the small temperature regime, it is possible to parameterize the kinetic Monte Carlo model modeling the exit event using Eyring-Kramers laws, which gives the basis for a rigorous foundation of the harmonic transition state theory. From these properties, it is then possible to devise efficient algorithms to simulate metastable dynamics. This is explained in Sect. 4. The bottom line is that the details of the dynamics within metastable states are not interesting: only the exit events from these states need to be simulated.

## 2    Kinetic Monte Carlo Models and Quasi-stationary Distribution

In this section, we consider a set $S \subset \mathbb{R}^d$, which is assumed to be bounded, regular, and open. This set is intended to be associated with one state of a kinetic Monte Carlo (kMC) model, and we would like to relate the exit event from $S$ using the Langevin (3) or overdamped Langevin (5) dynamics and a kinetic Monte Carlo model. We will first present in Sect. 2.1 how the exit event from a state is modeled in a kinetic Monte Carlo model. We will then introduce in Sect. 2.2 the notion of quasi-stationary distribution (QSD), which is the basic ingredient to connect the simulation of the exit event from a set $S$ for (3) or (5) with a kMC model, as explained in Sect. 2.3. Finally, we will conclude this section with a discussion on the way to estimate the convergence time to the QSD in Sect. 2.4.

## 2.1 Kinetic Monte Carlo Models

Kinetic Monte Carlo models (a.k.a. Markov state models, see Bowman et al. 2014 and Schütte and Sarich 2013) are continuous-time Markov processes with values in a discrete state space, namely, a jump Markov process (see Voter (2007) for a nice introduction to kMC models). They consist of a collection of states that we can assume to be indexed by integers and rates $(k_{i,j})_{i \neq j \in \mathbb{N}}$ which are associated with transitions between these states. For a state $i \in \mathbb{N}$, the states $j$ such that $k_{i,j} \neq 0$ are the neighboring states of $i$ denoted in the following by:

$$\mathcal{N}_i = \{j \in \mathbb{N}, \, k_{i,j} \neq 0\}. \tag{6}$$

One can thus represent such a jump Markov model as a graph: the states are the vertices, and an oriented edge between two vertices $i$ and $j$ indicates that $k_{i,j} \neq 0$.

Starting at time 0 from a state $Y_0 \in \mathbb{N}$, the model consists in iterating the following two steps over $n \in \mathbb{N}$: Given $Y_n$,

- Sample the residence time $T_n$ in $Y_n$ as an exponential random variable with parameter $\sum_{j \in \mathcal{N}_{Y_n}} k_{Y_n, j}$:

$$\forall t \geq 0, \; \mathbb{P}(T_n \geq t | Y_n = i) = \exp\left(-\left[\sum_{j \in \mathcal{N}_i} k_{i,j}\right] t\right). \tag{7}$$

- Sample independently from $T_n$ the next visited state $Y_{n+1}$ starting from $Y_n$ using the following law:

$$\forall j \in \mathcal{N}_i, \; \mathbb{P}(Y_{n+1} = j | Y_n = i) = \frac{k_{i,j}}{\sum_{j' \in \mathcal{N}_i} k_{i,j'}}. \tag{8}$$

The associated continuous-time process $(Z_t)_{t \geq 0}$ with values in $\mathbb{N}$ defined by:

$$\forall n \geq 0, \; \forall t \in \left[\sum_{m=0}^{n-1} T_m, \sum_{m=0}^{n} T_m\right), \quad Z_t = Y_n \tag{9}$$

(with the convention $\sum_{m=0}^{-1} = 0$) is then a (continuous-time) jump Markov process.

The exit event from the state $i$ is thus modeled by the couple of random variables $(T, Y)$ where:

1. $T$ and $Y$ are independent;
2. $T$ is exponentially distributed with parameter $\sum_j k_{i,j}$;
3. $Y$ takes the value $j \in \mathcal{N}_i$ with probability $\frac{k_{i,j}}{\sum_{j' \in \mathcal{N}_i} k_{i,j'}}$.

The question we would like to address in the following is: when can one use such a model to simulate the exit event from a metastable state for the Markov dynamics (3) or (5)? The cornerstone to make this connection is the notion of quasi-stationary distribution, which will be introduced in Sect. 2.2.

The interest of using a kMC model rather than the Markov dynamics (3) or (5) to model the evolution of the system is twofold. From a modeling viewpoint, new insights can be gained by building such coarse-grained models that are easier to handle. From a numerical viewpoint, the hope is to be able to build the jump Markov process from short simulations of the full-atom dynamics from states to states. Then, once the rates have been defined, it is possible to simulate the system over much larger timescales than the time horizons attained by standard molecular dynamics, either by using directly the jump Markov process or as a support to accelerate molecular dynamics (see, e.g., Voter (1997, 1998) and Sørensen and Voter (2000) and Sect. 4). It is also possible to use dedicated algorithms to extract from the graph associated with the jump Markov process the most important features of the dynamics (e.g., quasi-invariant sets and essential timescales using the large deviation theory of Freidlin and Wentzell 1984), see, e.g., Wales (2003) and Cameron (2014).

## 2.2    Quasi-stationary Distribution

In this section, we focus for simplicity on the overdamped Langevin dynamics (5). Generalizations to the Langevin dynamics (3) are expected to be true and are the subject of works under progress (see, e.g., Nier (2018) for a first result in that direction). Let us consider the first exit time from a fixed set $S \subset \mathbb{R}^d$:

$$T_S = \inf\{t \geq 0, \ X_t \notin S\}.$$

The exit event from $S$ is fully characterized by the couple of random variables:

$$(T_S, X_{T_S}).$$

The basic intuition already mentioned in the introduction is that if the process remains for a sufficiently long time in $S$, it should be possible to model the exit event by the exit event of a kMC model. This naturally leads us to consider the quasi-stationary distribution which is the invariant law for the process conditioned to stay in $S$.

**Definition 1.** A probability measure $\nu_S$ with support in $S$ is called a quasi-stationary distribution (QSD) for the Markov process $(X_t)_{t\geq 0}$ if and only if

$$\forall t > 0, \ \forall A \subset S, \nu_S(A) = \frac{\displaystyle\int_S \mathbb{P}(X_t^x \in A, t < T_S^x) \, \nu_S(dx)}{\displaystyle\int_S \mathbb{P}(t < T_S^x) \, \nu_S(dx)}.$$

In other words, $\nu_S$ is a QSD if when $X_0$ is distributed according to $\nu_S$, for all positive $t$, the law of $X_t$ conditionally to the fact that $(X_s)_{0 \leq s \leq t}$ remains in the state $S$ is still $\nu_S$.

The QSD satisfies three properties which will be crucial in the following. We refer, e.g., to Le Bris et al. (2012) for a proof of these results and to Collet et al. (2013) for more general results on QSDs.

**Proposition 1.** *Let $(X_t)_{t \geq 0}$ follow the dynamics (5) with an initial condition $X_0 \in S$. Then, there exists a probability distribution $\nu_S$ with support in $S$ such that*

$$\lim_{t \to \infty} \mathcal{L}(X_t | T_S > t) = \nu_S, \tag{10}$$

*where for a given $t > 0$, $\mathcal{L}(X_t | T_S > t)$ denotes the law of the random variable $X_t$ conditioned to the event $\{T_S > t\}$. The distribution $\nu_S$ is the QSD associated with S.*

A consequence of this proposition is the existence and uniqueness of the QSD. In some sense, the QSD can thus be seen as the longtime limit of the process conditioned to stay in the state $S$.

Let us now give a second property of the QSD.

**Proposition 2.** *Let $L = -\nabla V \cdot \nabla + \beta^{-1} \Delta$ be the infinitesimal generator of $(X_t)_{t \geq 0}$ (satisfying (5)). Let us consider the first eigenvalue and eigenfunction associated with the adjoint operator $L^* = \mathrm{div}\,(\nabla V + \beta^{-1} \nabla)$ with homogeneous Dirichlet boundary condition:*

$$\begin{cases} L^* u_1 = -\lambda_1 u_1 \text{ on } S, \\ \quad u_1 = 0 \text{ on } \partial S. \end{cases} \tag{11}$$

*The QSD $\nu_S$ associated with S satisfies:*

$$d\nu_S = \frac{u_1(x)\,dx}{\displaystyle\int_S u_1(x)\,dx}$$

*where $dx$ denotes the Lebesgue measure on S.*

The QSD thus has a density with respect to the Lebesgue measure, which is nothing but the ground state of the Fokker-Planck operator $L^*$ associated with the dynamics with absorbing boundary conditions. The existence, uniqueness, and positivity of this ground state are a standard consequence of the ellipticity of the operator $L^*$ and the boundedness of the set $S$.

Finally, the last property of the QSD concerns the exit event from $S$, when $X_0$ is distributed according to $\nu_S$.

**Proposition 3.** *Let us assume that $X_0$ is distributed according to the QSD $\nu_S$ in $S$. Then the law of the couple $(T_S, X_{T_S})$ (namely, the first exit time and the first exit point from $S$) is fully characterized by the following properties:*

1. *$T_S$ is independent of $X_{T_S}$.*
2. *$T_S$ is exponentially distributed with parameter $\lambda_1$ (defined in Eq. (11) above).*
3. *The law of $X_{T_S}$ is given by (Here and in the following, the superscript $\nu_S$ in $\mathbb{E}^{\nu_S}$ or $\mathbb{P}^{\nu_S}$ indicates that the stochastic process starts under the QSD: $X_0 \sim \nu_S$.): for any bounded measurable function $\varphi : \partial S \to \mathbb{R}$:*

$$\mathbb{E}^{\nu_S}(\varphi(X_{T_S})) = -\frac{\displaystyle\int_{\partial S} \varphi\, \partial_n u_1\, d\sigma}{\beta\lambda_1 \displaystyle\int_S u_1(x)\, dx} \tag{12}$$

*where $\sigma$ denotes the Lebesgue measure on $\partial S$ induced by the Lebesgue measure in $\mathbb{R}^d$ and the Euclidean scalar product and $\partial_n u_1 = \nabla u_1 \cdot n$ denotes the outward normal derivative of $u_1$ on $\partial S$.*

Proposition 3 explains the interest of the QSD. Indeed, if the process is initially distributed according to the QSD in $S$ (namely, from Proposition 1, if it remained for a sufficiently long time in $S$), then the exit event from the state $S$ can be modeled using a kinetic Monte Carlo model, since the exit time is exponentially distributed and independent of the exit point. This will be explained in more detail in the next section.

*Remark 1 (From overdamped Langevin to Langevin).* As mentioned above, the existence of the QSD and the convergence of the conditioned process toward the QSD for the Langevin process (3) require extra work compared to the over-damped Langevin process (5). For results in that direction, we refer to the recent manuscript (Nier 2018). The main difficulties are twofold: (i) even if $S$ is a bounded set, the associated ensemble in phase space is not bounded (the velocities are indeed not bounded) and (ii) the Langevin dynamics is not reversible and not elliptic (noise only acts on velocities, not on positions). This implies some difficulties when studying the spectral properties of the infinitesimal generator with absorbing boundary conditions on $\partial S$.

## 2.3    Modeling of the Exit Event from a Metastable State

Using Proposition 1, if the process $(X_t)_{t \geq 0}$ remains sufficiently long in the state $S$, the random variable $X_t$ is approximately distributed according to the QSD $\nu_S$. Then, from Proposition 3, the exit event $(T_S, X_{T_S})$ satisfies the basic properties needed to be modeled by the exit event of a kinetic Monte Carlo model: $T_S$ is independent from $X_{T_S}$ and exponentially distributed.

**Fig. 1** The boundary $\partial S$ of the domain $S$ is divided into four subdomains $(\partial S_i)_{1 \le i \le 4}$, which are the common boundaries with the neighboring states $(S_i)_{1 \le i \le 4}$

To be more specific, let us consider the domain $S$, and let us divide its boundary $\partial S$ into subsets $(\partial S_i)_{i=1,\dots,J}$ associated with transitions to neighboring states $(S_i)_{i=1,\dots,J}$ (see Fig. 1 for a schematic representation in the case $J = 4$). The next visited state is thus defined by the random variable $Y_S$ with values in $\{1, \dots, J\}$ defined by:

$$Y_S = i \text{ if and only if } X_{T_S} \in \partial S_i.$$

Let us now introduce the rates: for $i = 1, \dots, J$,

$$k_i = \lambda_1 \mathbb{P}^{\nu_S}(X_{T_S} \in \partial S_i) \tag{13}$$

where from (12)

$$\mathbb{P}^{\nu_S}(X_{T_S} \in \partial S_i) = -\frac{\displaystyle\int_{\partial S_i} \partial_n u_1 \, d\sigma}{\beta \lambda_1 \displaystyle\int_S u_1(x) \, dx}. \tag{14}$$

We recall that $(\lambda_1, u_1)$ has been defined in Proposition 2. Now, from Proposition 3, we obviously have the following properties on the couple of random variables $(T_S, Y_S)$:

1. $T_S$ and $Y_S$ are independent.
2. $T_S$ is exponentially distributed with parameter $\sum_{j=1}^{J} k_j$.
3. $Y_S$ takes the value $i \in \{1, \dots, J\}$ with probability $\frac{k_i}{\sum_{j'=1}^{J} k_{j'}}$.

which are exactly the properties needed to model the exit event using a kMC model (see Sect. 2.1).

**Fig. 2** The points $(z_i)_{i=1,\ldots,5}$ are the five local minima of $V$ on $\partial S$. The point $x_1$ is the global minimum of $V$ on $S$. In a global kMC model, exits through the neighborhood of $z_1$ is associated with a transition to $S_1$, exits through the neighborhoods of $z_3$ and $z_4$ are associated with a transition to $S_3$, etc
Notice that we have here considered a partition of the boundary $\partial S$ dictated by the a priori knowledge of neighboring states, having in mind a global kMC model as defined in Sect. 2.1. If one is only interested in simulating the exit from $S$ (without any a priori knowledge of $\mathbb{R}^d \setminus S$), a natural partition of the boundary is then

$$\partial S = \cup_{i=1}^I B_{z_i}$$

where $(z_i)_{i=1,\ldots,I}$ are the local minima of $V$ on $\partial S$ (see Fig. 2) and for all $i \in \{1, \ldots, I\}$, $B_{z_i}$ is a neighborhood of $z_i$. Indeed, in the small temperature regime, exits through $\partial S$ occur around the local minima of $V$ on $\partial S$ (this will be discussed in Sect. 3.2, see Remark 3). More precisely, for the mathematical analysis in Sect. 3.2, we will define $B_{z_i}$ as the basin of attraction of $z_i$ for the dynamics $\dot{x} = -\nabla_T V(x)$ in the boundary $\partial S$ (where $\nabla_T V$ denotes the tangential gradient of $V$ along the boundary $\partial S$):

$$B_{z_i} = \left\{ x_0 \in \partial S, \ \lim_{t \to \infty} x(t) = z_i, \ \text{where } x(0) = x_0 \text{ and } \dot{x} = -\nabla_T V(x) \right\}. \quad (15)$$

We will then show that exits through $B_{z_i}$ actually only occur through a neighborhood of $z_i$ in the small temperature regime $\beta \to \infty$. Using this partition, one can thus simulate the exit event as explained above through a couple of random variable $(T_S, Y_S)$, where $Y_S = i$ if the exit occurs through the neighborhood $B_{z_i}$ of $z_i$ (where $i \in \{1, \ldots, I\}$). The associated rates are those defined above, replacing the partition $(\partial S_i)_{i=1,\ldots,J}$ by $(B_{z_i})_{i=1,\ldots,I}$:

$$k_i = \lambda_1 \mathbb{P}^{\nu_S}(X_{T_S} \in B_{z_i}) = -\lambda_1 \frac{\displaystyle\int_{B_{z_i}} \partial_n u_1 \, d\sigma}{\beta \lambda_1 \displaystyle\int_S u_1(x) \, dx}. \quad (16)$$

As explained above, this is useful to simulate the exit from the state $S$ much more efficiently than by integrating in time the Langevin (3) or overdamped Langevin (5) dynamics. It can be used as such in a kinetic Monte Carlo model. It is also the basic ingredient of the accelerated dynamics that will be discussed in Sect. 4. These algorithms aim at accelerating the sampling of the metastable trajectories of the Langevin or overdamped Langevin dynamics, by efficiently generating the exit event from a metastable state $S$ when those dynamics get trapped in $S$.

Notice that the results presented here are very general: they hold for both energetic and entropic traps and for any Markov dynamics as soon as a QSD exists (nonreversible Markov dynamics, discrete-time Markov dynamics, etc.).

One practical difficulty to use the results above as such in a kMC dynamics and in some of the accelerated dynamics algorithms is that one needs in addition a simple way to evaluate the rates $k_i$ (with a more explicit formula than the integral formulation in (16)). We will come back to this in Sect. 3, where the Eyring-Kramers formulas will be introduced to approximate these rates, in the small temperature regime.

## 2.4   Estimating the Convergence Time to the Quasi-Stationary Distribution in Practice

We have seen in the previous section that if the process $(X_t)_{t\geq 0}$ starts from the QSD in $S$, one can model the exit event from $S$ exactly using a kMC model. In addition, in view of Proposition 1, the QSD is reached for the process conditioned to stay in $S$ in the longtime limit. A natural question is then: how long the process $(X_t)_{t\geq 0}$ should remain in $S$ so that one can assume it is sufficiently close to the QSD? In the original paper (Voter 1998), this time is called the correlation time, denoted by $\tau_{\mathrm{corr}}$, and is typically fixed as a constant for all the states, this constant being estimated using some physical intuition on the system at hand or an harmonic approximation. When the dynamics enters a state $S$, one thus waits for some time $\tau_{\mathrm{corr}}$ before assuming that the QSD has been reached: this is called the decorrelation step in Voter (1998). Let us now discuss two ways to estimate the time needed to reach the QSD: one theoretical and one numerical.

From a theoretical viewpoint, the following result proven in Le Bris et al. (2012) gives a first estimate of $\tau_{\mathrm{corr}}$.

**Proposition 4.** *Let* $(X_t)_{t\geq 0}$ *satisfies* (5) *with* $X_0 \in S$. *Let us consider* $-\lambda_2 < -\lambda_1 < 0$ *the first two eigenvalues of the operator* $L^*$ *on* $S$ *with homogeneous Dirichlet boundary conditions on* $\partial S$ *(see Proposition 2 for the definition of* $L^*$*). Then, there exists a constant* $C > 0$ *which depends on the law of* $X_0$*, such that, for all* $t \geq \frac{C}{\lambda_2-\lambda_1}$,

$$\sup_{f,\, \|f\|_{L^\infty}\leq 1} \left| \mathbb{E}(f(T_S - t, X_{T_S})|T_S \geq t) - \mathbb{E}^{\nu_S}(f(T_S, X_{T_S})) \right| \leq C \exp(-(\lambda_2 - \lambda_1)t). \tag{17}$$

In other words, the total variation norm between the law of $(T_S - t, X_{T_S})$ conditioned to $T_S \geq t$ (for any initial condition $X_0 \in S$) and the law of $(T_S, X_{T_S})$ when $X_0$ is distributed according to the QSD $\nu_S$ decreases exponentially fast with rate $\lambda_2 - \lambda_1$. This means that $\tau_{\text{corr}}$ should be chosen of the order $1/(\lambda_2 - \lambda_1)$. There are however two difficulties with this result. First, this is not a very practical result since computing the eigenvalues $\lambda_1$ and $\lambda_2$ is in general impossible. Second, the constant $C$ in the righthand side of (17) and in the inequality $t \geq \frac{C}{\lambda_2 - \lambda_1}$ depends in a complicated way on the law of the initial condition $X_0 \in S$. And one indeed expects the convergence time to the QSD to strongly depend on the initial condition.

A more practical approach to estimate the convergence time $\tau_{\text{corr}}$ to the QSD has been proposed in Binder et al. (2015). The method uses two ingredients:

- The Fleming-Viot particle process (Ferrari and Maric 2007), which consists in $N$ replicas $(X_t^1, \ldots, X_t^N)_{t \geq 0}$ which are evolving and interacting in such a way that the empirical distribution $\frac{1}{N} \sum_{n=1}^N \delta_{X_t^n}$ is close (in the large $N$ limit) to the law of the process $X_t$ conditioned on $t < T_S$.
- The Gelman-Rubin convergence diagnostic (Gelman and Rubin 1992) to estimate the correlation time by the convergence time to a stationary state for the Fleming-Viot particle process.

Roughly speaking, the Fleming-Viot particle process consists in the following: each replica $(X_t^i)_{t \geq 0}$ evolves according to the original dynamics (5) driven by independent Brownian motions (starting from the same initial conditions $X_0$), and, each time one of the replicas leaves the domain $S$, another one taken at random is duplicated. The Gelman-Rubin convergence diagnostic consists in comparing the average of a given observable over replicas at a given time, with the average of this observable over time and replicas: when the two averages are close (up to a tolerance, and for a well-chosen list of observables), the process is considered at stationarity. The interest of this approach is that it gives a practical way to approximate $\tau_{\text{corr}}$ which explicitly takes into account the initial condition of $(X_t)_{t \geq 0}$ in $S$. Of course, one should be cautious when using this technique in practice, since bad choices of the observables may lead to false convergence. We refer to Binder et al. (2015) for examples of applications.

In the following, even though the correlation time $\tau_{\text{corr}}$ depends in principle on the state under consideration $S$ and on the initial condition of the process in $S$, we do not indicate explicitly this dependency and stick to the simple notation $\tau_{\text{corr}}$.

## 3    Eyring-Kramers Law and the Harmonic Transition State Theory

In the previous section, we explained that if the process $(X_t)_{t \geq 0}$ remains sufficiently long in the state $S$, then the exit event can be exactly modeled using a kMC model, with the definitions (16) for the rates associated with exits through local minima of

$V$ on $\partial S$. As will become clear below, some accelerated algorithms will require in addition formulas for the rates, which explicitly depend on the potential $V$ and the temperature $\beta$. This is used in particular in the temperature accelerated dynamics (see Sect. 4.4) to infer the exit event at low temperature from exit events observed at a higher temperature. Such formulas are given by the so-called Eyring-Kramers laws, which are introduced in Sect. 3.1. A mathematical result showing that the exit rates from a state $S$ can indeed be approximated by the Eyring-Kramers laws will then be presented in Sect. 3.2, for the overdamped Langevin dynamics (5).

## 3.1   Eyring-Kramers Laws

The Eyring-Kramers laws give formulas which are used in many contexts as approximations of the rates modeling the exit event from the state $S$ in the small temperature regime ($\beta \to \infty$). Let us consider again the situation of Fig. 2, and let us introduce the global minimum $x_1$ of $V$ in $S$ and the local minima $(z_i)_{i=1,\ldots,I}$ of $V$ on $\partial S$. We assume in the following that they are ordered such that

$$V(z_1) \leq V(z_2) \leq \ldots \leq V(z_I).$$

Notice that we also assume in the following that all the critical points of $V$ and $V|_{\partial S}$ are nondegenerate, which implies in particular that there are a finite number of local minima of $V|_{\partial S}$. The Eyring-Kramers formula gives estimates for the exit rates $(k_j)_{j=1,\ldots,I}$ through neighborhoods of the local minima $(z_j)_{j=1,\ldots,I}$, namely:

$$\forall j \in \{1, \ldots, I\}, \; k_j = \nu_j \exp\big(-\beta[V(z_j) - V(x_1)]\big) \tag{18}$$

where $\nu_j > 0$ is a prefactor which depends on the dynamic under consideration and on $V$ around $x_1$ and $z_j$. Let us give a few examples. If $S$ is taken as the basin of attraction of $x_1$ for the dynamics $\dot{x} = -\nabla V(x)$ so that the points $z_j$ are order one saddle points, the prefactor writes for the Langevin dynamics (3) (assuming $M = \mathrm{Id}$ for simplicity):

$$\nu_j^L = \frac{1}{4\pi} \left( \sqrt{\gamma^2 + 4|\lambda^-(z_j)|} - \gamma \right) \frac{\sqrt{\det(\nabla^2 V)(x_1)}}{\sqrt{|\det(\nabla^2 V)(z_j)|}} \tag{19}$$

where $\nabla^2 V$ is the Hessian of $V$ (which, we recall, is assumed to be nondegenerate) and $\lambda^-(z_j)$ denotes the negative eigenvalue of $\nabla^2 V(z_j)$. This formula was derived in Kramers (1940) in a one-dimensional situation. The equivalent formula for the overdamped Langevin dynamics (5) is:

$$\nu_j^{OL} = \frac{1}{2\pi} |\lambda^-(z_j)| \frac{\sqrt{\det(\nabla^2 V)(x_1)}}{\sqrt{|\det(\nabla^2 V)(z_j)|}}. \tag{20}$$

Notice that $\lim_{\gamma \to \infty} \gamma \nu_j^L = \nu_j^{OL}$, as expected from the rescaling in time used to go from Langevin to overdamped Langevin (see Sect. 1). The formula (20) has again been obtained in Kramers (1940), but also by many authors previously (see the exhaustive review of the literature reported in Hänggi et al. 1990).

Using the Eyring-Kramers rates (18) in the kinetic Monte Carlo model introduced in Sect. 2.1, one can then model the exit event from $S$ as follows. The exit event from $S$ is modeled by the couple of random variables $(T, Y)$ where $T$ is the first exit time from $S$ and $Y = j$ if the process exits from $S$ in a neighborhood of $z_j$. This couple has the following law:

1. $T$ and $Y$ are independent.
2. $T$ is exponentially distributed with parameter

$$\sum_{j=1}^{n} k_j \sim \left( \sum_{j'=1}^{I_0} \nu_{j'} \right) \exp(-\beta[V(z_1) - V(x_1)]) \tag{21}$$

3. $Y$ takes the value $j \in \{1, \ldots n\}$ with probability

$$\frac{k_j}{\sum_{j'=1}^{n} k_{j'}} \sim \frac{\nu_j}{\sum_{j'=1}^{I_0} \nu_{j'}} \exp(-\beta[V(z_j) - V(z_1)]). \tag{22}$$

where the equivalents $\sim$ are valid in the small temperature regime $\beta \to \infty$ and where $I_0 \in \{1, \ldots, I\}$ denotes the number of global minima of $V$ on $\partial S$:

$$V(z_1) = \ldots = V(z_{I_0}) < V(z_{I_0+1}) \leq \ldots \leq V(z_I).$$

The modeling of the exit event using a kMC model parameterized by the Eyring-Kramers laws is sometimes called the harmonic transition state theory in the literature. We refer, for example, to Voter (2007) for an introduction to this theory and relevant references.

As already explained in Sect. 2.1, using such a model rather than the Langevin or overdamped Langevin dynamics to model the exit event from $S$ is useful either to simulate the evolution of the dynamics over very long time using the kMC model or to accelerate the sampling of metastable trajectories of the Langevin or overdamped Langevin dynamics, as will be explained in Sect. 4.

This raises the following theoretical question: are the Eyring-Kramers rates (18) a valid approximation to model the exit event from $S$ using a kMC model, for the Langevin or overdamped Langevin dynamics? To be more precise, let us consider the overdamped Langevin dynamics (5). We have already seen in Sect. 2.3 that if the stochastic process $(X_t)_{t \geq 0}$ remains for a sufficiently long time in $S$, then it is indeed valid to use a kMC model to simulate the exit event from $S$, with associated rates defined using the eigenvalue-eigenfunction pair $(\lambda_1, u_1)$ (see Eq. (16)). The question is then: can these rates defined by (16) be approximated using the Eyring-Kramers laws (18)?

## 3.2   Approximating the Exit Rates by the Eyring-Kramers Laws: A Mathematical Framework

Let us consider the dynamics (5) with an initial condition distributed according to the QSD $\nu_S$ in a domain $S$. We assume the following:

- The domain $S$ is an open smooth bounded domain in $\mathbb{R}^d$.
- The function $V : \overline{S} \to \mathbb{R}$ is a Morse function with a single critical point $x_1$ (A Morse function is a function such that, at any critical point, the Hessian is nonsingular. Notice that this is in particular required to define the prefactors in the Eyring-Kramers laws.). Moreover, $x_1 \in S$ and $V(x_1) = \min_{\overline{S}} V$.
- The normal derivative $\partial_n V$ is strictly positive on $\partial S$, and $V|_{\partial S}$ is a Morse function with local minima reached at $z_1, \ldots, z_I$ with

$$V(z_1) = \ldots = V(z_{I_0}) < V(z_{I_0+1}) \le \ldots \le V(z_I).$$

- The height of the barrier is large compared to the saddle point height discrepancies: $V(z_1) - V(x_1) > V(z_I) - V(z_1)$.
- For all $i \in \{1, \ldots I\}$, consider $B_{z_i} \subset \partial S$ the basin of attraction for the dynamics in the boundary $\partial S$: $\dot{x} = -\nabla_T V(x)$ (where $\nabla_T V$ denotes the tangential gradient of $V$ along the boundary $\partial S$, see Eq. (15)). We assume that

$$\inf_{z \in B_{z_i}^c} d_a(z_i, z) > \max(V(z_I) - V(z_i), V(z_i) - V(z_1)) \qquad (23)$$

where $B_{z_i}^c = \partial S \setminus B_{z_i}$.

Here, $d_a$ is the Agmon distance:

$$d_a(x, y) = \inf_{\gamma \in \Gamma_{x,y}} \int_0^1 g(\gamma(t))|\gamma'(t)| \, dt$$

where $g = \begin{cases} |\nabla V| \text{ in } S \\ |\nabla_T V| \text{ in } \partial S \end{cases}$, and the infimum is taken over the set $\Gamma_{x,y}$ of all piecewise $C^1$ paths $\gamma : [0, 1] \to \overline{S}$ such that $\gamma(0) = x$ and $\gamma(1) = y$. The Agmon distance is useful in order to measure the decay of eigenfunctions away from critical points. These are the so-called semiclassical Agmon estimates (see Simon 1984 and Helffer and Sjöstrand 1984). Under the assumptions stated above, the following result is proven in Di Gesù et al. (2017).

**Theorem 1.** *Under the assumptions stated above, in the limit* $\beta \to \infty$*, the exit rate is:*

$$\lambda_1 = \sqrt{\frac{\beta \det(\nabla^2 V)(x_1)}{2\pi}} \sum_{k=1}^{I_0} \frac{\partial_n V(z_k)}{\sqrt{\det(\nabla^2 V_{|\partial S})(z_k)}} e^{-\beta(V(z_1)-V(x_1))}(1 + O(\beta^{-1})).$$

$$(24)$$

*Moreover, for any open set $\Sigma_i$ containing $z_i$ such that $\overline{\Sigma}_i \subset B_{z_i}$,*

$$\mathbb{P}^{\nu_S}(X_{T_S} \in \Sigma_i) = \frac{\frac{\partial_n V(z_i)}{\sqrt{\det(\nabla^2 V|_{\partial S})(z_i)}}}{\sum_{k=1}^{I_0} \frac{\partial_n V(z_k)}{\sqrt{\det(\nabla^2 V|_{\partial S})(z_k)}}} e^{-\beta(V(z_i)-V(z_1))}(1 + O(\beta^{-1})). \quad (25)$$

Formula (24) (resp. (25)) should be compared with (21) (resp. (22)) introduced above. We refer to Di Gesù et al. (2017) for a proof and for other related results (see also Helffer and Nier (2006) for a proof of (24)). The proof uses techniques developed in particular in the previous works: Helffer et al. (2004), Helffer and Nier (2006), Le Peutrec (2010), and Lelièvre and Nier (2015). The analysis requires to combine various tools from semiclassical analysis to address new questions: sharp estimates on quasimodes far from the critical points for Witten Laplacians on manifolds with boundary, a precise analysis of the normal derivative on the boundary of the first eigenfunction of Witten Laplacians, and fine properties of the Agmon distance on manifolds with boundary.

Using the two results of Theorem 1 and the formula (16) for the definition of the exit rates, one obtains that the exit rate associated with an exit in the neighborhood $\Sigma_i$ of $z_i$ is

$$k_i = \lambda_1 \mathbb{P}^{\nu_S}(X_{T_S} \in \Sigma_i)$$
$$= \widetilde{\nu}_i^{OL} e^{-\beta(V(z_i)-V(x_1))}(1 + O(\beta^{-1})) \quad (26)$$

where the prefactors $\widetilde{\nu}_i^{OL}$ are given by

$$\widetilde{\nu}_i^{OL} = \sqrt{\frac{\beta}{2\pi}} \partial_n V(z_i) \frac{\sqrt{\det(\nabla^2 V)(x_1)}}{\sqrt{\det(\nabla^2 V|_{\partial S})(z_i)}}. \quad (27)$$

This should be compared to the formulas (18) and (20) of the previous section (see Remark 2 below for a discussion on the precise values of the prefactors). This gives a rigorous framework to use a kMC model parameterized using Eyring-Kramers laws to model the exit event from $S$, as introduced in the previous section. Let us emphasize that Theorem 1 provides estimates on the probability $\mathbb{P}^{\nu_S}(X_{T_S} \in \Sigma_i)$ and not only on the logarithm of these probabilities (as obtained, e.g., using large deviation results, see Eq. (28) below). Notice that Theorem 1 also gives error estimates (actually, it can be shown that the terms $O(\beta^{-1})$ in (24), (25), and (26) admit full expansions in positive powers of $\beta^{-1}$).

Let us finish this section with a few important remarks.

*Remark 2 (From generalized saddle points to real saddle points).* As stated in the assumptions, Theorem 1 is proven under the assumption that $\partial_n V > 0$ on $\partial S$: the local minima $z_1, \ldots, z_I$ of $V$ on $\partial S$ are therefore not saddle points of $V$ but so-called generalized saddle points (see Helffer and Nier 2006 and Le Peutrec 2010).

In a future work, we intend to extend these results to the case where the points $(z_i)_{1 \le i \le I}$ are saddle points of $V$ (This is indeed natural if $S$ is taken as the basin of attraction of $x_1$ for the gradient dynamics $\dot{x} = -\nabla V(x)$, as in Sect. 3.1.), in which case we expect to prove the same result (26) for the exit rates, with the prefactor $\widetilde{v}_i^{OL}$ being $\dfrac{1}{\pi} |\lambda^-(z_j)| \dfrac{\sqrt{\det(\nabla^2 V)(x_1)}}{\sqrt{|\det(\nabla^2 V)(z_j)|}}$ (this formula can be obtained using formal expansions on the exit time and the Laplace's method). Notice that the latter formula differs from (20) by a multiplicative factor $1/2$. This is due to the fact that $\lambda_1$ is the exit rate from $S$ and not the transition rate to one of the neighboring state (see, e.g., the remark on page 408 in Bovier et al. (2004) on this multiplicative factor $1/2$ and the results on asymptotic exit times in Maier and Stein 1993). One way to understand this multiplicative factor $1/2$ is that once on the saddle point, in the limit $\beta \to \infty$, the process has a probability one half to go back to $S$ and a probability one half to effectively leave $S$. This multiplicative factor does not have any influence on the law of the next visited state which only involves a ratio of the rates $k_i$ (see Eq. (8)).

*Remark 3 (On the importance of prefactors).* The importance of obtaining a result including the prefactors in the rates is illustrated by the following result, which is also proven in Di Gesù et al. (2017). Consider a simple situation with only two local minima $z_1$ and $z_2$ on the boundary $\partial S$, with $V(z_1) < V(z_2)$. Compare the two exit probabilities:

- The probability to leave through $\Sigma_2$ such that $\overline{\Sigma_2} \subset B_{z_2}$ and $z_2 \in \Sigma_2$;
- The probability to leave through $\Sigma$ such that $\overline{\Sigma} \subset B_{z_1}$ and $\inf_\Sigma V = V(z_2)$.

By classical results from the large deviation theory (see, e.g., (28) below), the probability to exit through both $\Sigma$ and $\Sigma_2$ scales like a prefactor times $e^{-\beta(V(z_2)-V(z_1))}$: the difference can only be read from the prefactors. Actually, it can be proven that, in the limit $\beta \to \infty$,

$$\frac{\mathbb{P}^{\nu_S}(X_{T_S} \in \Sigma)}{\mathbb{P}^{\nu_S}(X_{T_S} \in \Sigma_2)} = O(\beta^{-1/2}).$$

The probability to leave through $\Sigma_2$ (namely, through the generalized saddle point $z_2$) is thus much larger than through $\Sigma$, even though the two regions are at the same potential height. This result explains why the local minima of $V$ on the boundary (namely, in our setting the generalized saddle points) play an important role when studying the exit event.

*Remark 4 (On the geometric assumption (23)).* Among the assumptions required to prove Theorem 1, the geometric assumption (23) involving the Agmon distances is probably the most unexpected one. Such an assumption indeed never appeared

before in any mathematical works on Eyring-Kramers laws or on the analysis of the exit event. In Di Gesù et al. (2017), we investigated numerically this assumption, and we observed in some simple geometric settings that if it is not satisfied, the results of Theorem 1 indeed do not hold (more precisely, by computing the exit probabilities (25), we observed that the prefactors are not those predicted by the Eyring-Kramers formulas).

*Remark 5 (From overdamped Langevin to Langevin).* The results of Theorem 1 have been obtained for the overdamped Langevin dynamics (5), and it is then natural to ask whether similar results could be obtained for the Langevin dynamics (3). Indeed such estimates on the rates are actually assumed to be correct for Langevin dynamics in many models and numerical methods using harmonic transition state theory and in particular in the temperature accelerated dynamics algorithm (see Sect. 4.4). We already mentioned in Remark 1 that the existence of the QSD for Langevin requires some additional investigations compared to overdamped Langevin. This is all the more true for the analysis of the exit event starting from the QSD in the small temperature regime. There is hope to obtain similar properties by combining results on the operator associated with Langevin dynamics with absorbing boundary conditions (Nier 2018) and works on the semiclassical analysis of Langevin dynamics (Hérau et al. 2011).

*Remark 6 (On the mathematical results on the Eyring-Kramers law).* Given the importance of the Eyring-Kramers laws in the physics literature, many mathematical approaches have been proposed in order to justify these formulas. Some authors adopt a global approach: they look at the spectrum of the infinitesimal generator of the overdamped Langevin dynamics in the small temperature regime $\beta \to \infty$ (see, e.g., the work by Helffer et al. (2004) based on semiclassical analysis results for Witten Laplacian and the articles by Bovier et al. (2004, 2005) and Eckhoff (2005) where a potential theoretic approach is adopted). These global approaches give the cascade of relevant timescales to reach from a local minimum any other local minimum which is lower in energy. However, they do not give the law of the exit event from a metastable state.

    In the context of this chapter, we are more interested in a local approach: we consider the exit event from a state $S \subset \mathbb{R}^d$, and we would like to relate continuous state-space Markov dynamics such as (5) and (3) and kinetic Monte Carlo model to describe this exit event. In the mathematical literature, the most famous approach to study the exit event is the large deviation theory (Freidlin and Wentzell 1984). In the small temperature regime, large deviation results provide the exponential rates (18), but without the prefactors and without precise error bounds. For the dynamics (5), a typical result on the exit point distribution is the following (see Freidlin and Wentzell 1984, Theorem 5.1): for all $S'$ compactly embedded in $S$, for any $\gamma > 0$, for any $\delta > 0$, there exists $\delta_0 \in (0, \delta]$ and $\beta_0 > 0$ such that for all $\beta > \beta_0$, for all $x \in S'$ such that $V(x) < \min_{\partial S} V$, and for all $y \in \partial S$,

$$\mathrm{e}^{-\beta(V(y)-V(z_1)+\gamma)} \leq \mathbb{P}^x(X_{T_S} \in \mathscr{V}_{\delta_0}(y)) \leq \mathrm{e}^{-\beta(V(y)-V(z_1)-\gamma)} \tag{28}$$

where $\mathscr{V}_{\delta_0}(y)$ is a $\delta_0$-neighborhood of $y$ in $\partial S$. The strength of large deviation theory is that it is very general: it applies to any dynamics (reversible or nonreversible) and in a very general geometric setting, even though it may be difficult in such general cases to make explicit the rate functional and thus to determine the exit probabilities.

Theorem 1 thus differs from all these previous results in the following ways: it gives precise asymptotic estimates of the distribution of $X_{T_S}$; the approach is local, justifies the Eyring-Kramers formula (18) with the prefactors, and provides sharp error estimates.

## 4 Accelerated Dynamics Algorithms

The aim of this section is to explain how the mathematical analysis of metastability and metastable states presented in Sects. 2 and 3 can be used to build efficient algorithms to sample metastable dynamics such as (3) or (5). We present for the sake of simplicity the algorithms in the setting of the overdamped Langevin dynamics (5). The algorithms can be generalized to the Langevin dynamics (3) and actually to many Markov dynamics, under some assumptions that will be discussed below. We will present four algorithms together with their mathematical foundations: parallel replica (Sect. 4.1), parallel trajectory splicing (Sect. 4.2), hyperdynamics (Sect. 4.3), and temperature accelerated dynamics (Sect. 4.4). Finally, we will discuss in Sect. 4.5 how to define in practice the metastable states.

### 4.1 Parallel Replica

The idea of the parallel replica algorithm is to evolve a reference replica following (5) and, if it remains trapped for a long time in a state, to simulate in parallel the exit event from this state. The original parallel replica algorithm (see Voter 1998) consists in iterating three steps:

- *The decorrelation step*: As already explained in Sect. 2.4, in this step, a reference replica evolves according to the original dynamics (5), until it remains trapped for a time $\tau_{\mathrm{corr}}$ in one of the states. During this step, no error is made, since the reference replica evolves following the original dynamics (and there is of course no computational gain compared to a naive direct numerical simulation). Once the reference replica has been trapped in one of the states (that we denote generically by $S$ in the following two steps) for a time $\tau_{\mathrm{corr}}$, the aim is to generate very efficiently the exit event. This is done in two steps.
- *The dephasing step*: In this preparation step, $(N-1)$ configurations are generated within $S$ (in addition to the one obtained from the reference replica) as follows. Starting from the position of the reference replica at the end of the decorrelation step, some trajectories are simulated in parallel for a time $\tau_{\mathrm{corr}}$. For each trajectory, if it remains within $S$ over the time interval of length $\tau_{\mathrm{corr}}$, then its

end point is stored. Otherwise, the trajectory is discarded, and a new attempt to get a trajectory remaining in $S$ for a time $\tau_{\text{corr}}$ is made. This step is pure overhead. The objective is only to get $N$ configurations in $S$ which will be used as initial conditions in the parallel step.

- *The parallel step*: In the parallel step, $N$ replicas are evolved independently and in parallel, starting from the initial conditions generated in the dephasing step, following the original dynamics (5) (with independent driving Brownian motions). This step ends as soon as one of the replica leaves $S$. Then, the simulation clock is updated by setting the residence time in the state $S$ to $N$ (the number of replicas) times the exit time of the first replica which left $S$. This replica now becomes the reference replica, and one goes back to the decorrelation step above.

The computational gain of this algorithm is in the parallel step, which (as explained below) simulates the exit event in a wall clock time $N$ times smaller in average than the wall clock time needed to simulate the exit of the reference walker. This of course requires a parallel architecture able to handle $N$ jobs in parallel. (For a discussion on the parallel efficiency, communication and synchronization, we refer to the papers Voter 1998; Perez et al. 2015b; Le Bris et al. 2012; Binder et al. 2015.) This algorithm can be seen as a way to parallelize in time the simulation of the exit event, which is not trivial because of the sequential nature of time.

In view of the results presented in Sect. 2, the parallel replica is indeed a consistent algorithm (it generates in a statistically correct way the exit event from metastable states) for the following reasons. First, in view of the first property (10) of the QSD, the decorrelation step is simply a way to decide whether or not the reference replica remains sufficiently long in one of the states so that it can be considered as being distributed according to the QSD (see also Sect. 2.4 for an analysis of the error introduced by choosing $\tau_{\text{corr}}$ too small (see in particular Proposition 4) and a discussion on how to evaluate $\tau_{\text{corr}}$ on the fly). Second, by the same arguments, the dephasing step is simply a rejection algorithm to generate many configurations in $S$ independently and identically distributed with law the QSD $\nu_S$ in $S$. Finally, the parallel step generates an exit event which is exactly the one that would have been obtained considering only one replica. Indeed, up to the error quantified in Proposition 4, all the replica are i.i.d. with initial condition, the QSD $\nu_S$. Therefore, according to the third property of the QSD stated in Proposition 3 (see item 1), their exit times $(T_S^n)_{n\in\{1,...N\}}$ are i.i.d. with law an exponential distribution ($T_S^n$ being the exit time of the $n$-th replica) so that

$$N \min_{n\in\{1,...,N\}} (T_S^n) \stackrel{\mathscr{L}}{=} T_S^1. \tag{29}$$

This explains why the exit time of the first replica which leaves $S$ needs to be multiplied by the number of replicas $N$. This also shows why the parallel step gives a computational gain in terms of wall clock: the time required to simulate the exit event is divided by $N$ compared to a direct numerical simulation. Moreover, since

starting from the QSD, the exit time and the exit point are independent (see item 2 in Proposition 3), one also has

$$X^{N_0}_{T_S^{N_0}} \overset{\mathscr{L}}{=} X^1_{T_S^1},$$

where $(X_t^n)_{t \geq 0}$ is the $n$-th replica and $N_0 = \arg\min_{n \in \{1, \ldots, N\}} (T_S^n)$ is the index of the first replica which exits $S$. The exit point of the first replica which exits $S$ is statistically the same as the exit point of the reference walker. Finally, by the independence property of exit time and exit point, one can actually combine the two former results in a single equality in law on couples of random variables, which shows that the parallel step is statistically exact:

$$\left( N \min_{n \in \{1, \ldots, N\}} (T_S^n), X^{N_0}_{T_S^{N_0}} \right) \overset{\mathscr{L}}{=} (T_S^1, X^1_{T_S^1}).$$

We presented the results in the context of the overdamped Langevin dynamics (5) for simplicity. The mathematical analysis actually shows that the parallel replica is a very versatile algorithm. In particular, it can be applied to both energetic and entropic barriers, and it does not assume a small temperature regime (in contrast with the analysis, we will present below for hyperdynamics and temperature accelerated dynamics). In addition, it can also be used for nonequilibrium system (driven by nonconservative forces) and for any Markovian dynamics as soon as a QSD exists. We refer, for example, to Wang et al. (2018) for recent applications to continuous-time Markov chains.

The only errors introduced in the algorithm are related to the rate of convergence to the QSD of the process conditioned to stay in the state. The algorithm is efficient if the convergence time to the QSD is small compared to the exit time (in other words, if the states are metastable). Equation (17) gives a way to quantify the error introduced by the whole algorithm. In the limit $\tau_{\text{corr}} \to \infty$, the algorithm generates exactly the correct exit event. This implies that the resulting dynamics is exact in terms of the laws on trajectories (and not only of the time marginals – master equation – or the stationary state, for example). It gives the correct transition times and trajectories to go from one state to another, for example. The price to pay is that the details of the dynamics within the states are lost.

*Remark 7 (Parallel replica for discrete-time Markov process).* As a remark, let us notice that in practice, discrete-time processes are used (since the Langevin or overdamped Langevin dynamics are discretized in time). Then, the exit times are not exponentially but geometrically distributed. It is however possible to generalize the formula (29) to this setting by using the following fact: if $(\sigma_n)_{n \in \{1, \ldots N\}}$ are i.i.d. with geometric law, then

$$N (\min(\sigma_1, \ldots, \sigma_N) - 1) + \min (n \in \{1, \ldots, N\}, \sigma_n = \min(\sigma_1, \ldots, \sigma_N)) \overset{\mathscr{L}}{=} \sigma_1.$$

We refer to Aristoff et al. (2014) for more details.

*Remark 8 (Generalized parallel replica dynamics).* In view of the analysis above, the crucial parameter of the parallel replica algorithm is the correlation time $\tau_{\text{corr}}$. As explained in Sect. 2.4, Binder et al. (2015) propose an approach to estimate $\tau_{\text{corr}}$ on the fly by combining the Fleming-Viot particle process to simulate the law of the process $X_t$ conditioned on $t < T_S$ and the Gelman-Rubin convergence diagnostic to estimate the convergence time to a stationary state for the Fleming-Viot particle process, which thus gives an estimate of the correlation time. Using this idea, a generalized parallel replica algorithm is introduced in Binder et al. (2015), as follows. Each time the reference replica enters a new state, a Fleming-Viot particle process is launched using $(N - 1)$ replicas simulated in parallel (with initial condition the configuration of the reference replica). Then the decorrelation step consists in the following: if the reference replica leaves $S$ before the Fleming-Viot particle process reaches stationarity, then a new decorrelation step starts (and the replicas generated by the Fleming-Viot particle process are discarded); if otherwise the Fleming-Viot particle process reaches stationarity before the reference replica leaves $S$, then one proceeds to the parallel step. Notice indeed that the final positions of the replicas simulated by the Fleming-Viot particle process can be used as initial conditions for the processes in the parallel step, since they are (approximately) distributed according to the QSD. This procedure thus avoids the choice of a correlation time $\tau_{\text{corr}}$ a priori: it is in some sense estimated on the fly, depending on the state under consideration, and on the initial condition within this state. For more details, discussions on the correlations included by the Fleming-Viot particle process between the replicas and numerical experiments (in particular in cases with purely entropic barriers), we refer to Binder et al. (2015).

## 4.2    Parallel Trajectory Splicing

Parallel trajectory splicing (abbreviated as ParSplice) is a variant of the parallel replica algorithm which has been introduced in Perez et al. (2015a). The idea of the algorithm is to generate in parallel many trajectory segments, which spent at least a time $\tau_{\text{corr}}$ in one state before the beginning of the segment, and ends in a state where it again spends at least a time $\tau_{\text{corr}}$ before the end of the segment. A trajectory segment ending in a state $S$ is then appended to a trajectory segment starting in the same state $S$. The analysis of this algorithm is very similar to the one described above for parallel replica: if $\tau_{\text{corr}}$ is sufficiently large, the trajectory segments start under the QSD in a state and end in a state being again distributed according to the QSD. Therefore, the exit event from the ending state can be simulated by considering any segment which starts under the QSD within the same state. This justifies the fact that these trajectory segments can be appended to form a long molecular dynamics trajectory.

The main difficulty when implementing this technique is to manage the concurrent generation of the segments from many molecular dynamics instances. A database of segments is populated as the simulation proceeds, and this database is used at the same time to generate the molecular dynamics trajectory. This should

be done carefully in order to introduce no bias. For example, segments generated from a given state should not be used in increasing order of their generation time, but using a first-in-first-out queue (otherwise short segments would be favored). In addition, in order to schedule the production of new segments to be added to the database, one uses some prediction of the future trajectory, based on the current knowledge of the visited states. For more details, we refer to Perez et al. (2015a).

## 4.3    Hyperdynamics

As in parallel replica, let us assume that a reference replica $(X_t)_{t \geq 0}$ following the overdamped Langevin dynamics (5) remains trapped for a time $\tau_{\text{corr}}$ is a metastable state $S$. If $\tau_{\text{corr}}$ is sufficiently large, one can assume that the process is distributed according to the QSD. The principle of the hyperdynamics algorithm is then to raise the potential inside the state in order to accelerate the exit from $S$. The algorithm thus requires a biasing potential $\delta V : S \to \mathbb{R}$, which satisfies appropriate assumptions detailed below. The algorithm then proceeds as follows:

- Equilibrate the dynamics on the biased potential $V + \delta V$, namely, run the dynamics (5) on the process $(X_t^{\delta V})_{t \geq 0}$ over the biased potential conditionally to stay in the well, up to the time the random variable $X_t^{\delta V}$ has distribution close to the QSD $\nu_S^{\delta V}$ associated with the biased potential. This first step is a preparation step, which is pure overhead. The end point $X_t^{\delta V}$ will be used as the initial condition for the next step.
- Run the dynamics (5) over the biased potential $V + \delta V$ up to the first exit time $T_S^{\delta V}$ from the state $S$. The simulation clock is updated by adding the effective exit time $B \times T_S^{\delta V}$ where $B$ is the so-called boost factor defined by:

$$B = \frac{1}{T_S^{\delta V}} \int_0^{T_S^{\delta V}} \exp\left(\beta \, \delta V(X_t^{\delta V})\right) dt. \tag{30}$$

The exit point is then used as the starting point for a new decorrelation step.

Roughly speaking, the assumptions required on $\delta V$ in the original paper (Voter 1997) are twofold:

- $\delta V$ is sufficiently small so that the exit event from the state $S$ can be modeled by a kinetic Monte Carlo models parameterized by the Eyring-Kramers laws.
- $\delta V$ is zero on a neighborhood of the boundary $\partial S$.

The derivation of the method relies on explicit formulas for the laws of the exit time and exit point, using the harmonic transition state theory, as explained in Sect. 3.
The algorithm we present here is actually slightly different from the way it is introduced in the original paper (Voter 1997). Indeed, in the original version, the

local equilibration steps (decorrelation step and equilibration step on the biased potential) are omitted: it is assumed that the states are sufficiently metastable (for both the original potential and the biased potential) so that these local equilibrations are immediate. It would be interesting to check if the modifications we propose here improve the accuracy of the method.

Let us now discuss the mathematical foundations of this technique and, in particular, a way to understand the formula (30) for the boost factor. We actually need to compare two exit events. The first one is the exit event for the original process $X_t$ following the dynamics (5), starting from the QSD $\nu_S$ associated with the state $S$ and the dynamics with potential $V$. The second one is the exit event for the process $X_t^{\delta V}$ following the dynamics (5) on the biased potential $V + \delta V$, starting from the QSD $\nu_S^{\delta V}$ associated with the state $S$ and the dynamics with potential $V + \delta V$. Referring to Sect. 3, one way to justify the algorithm is to use the fact that, both on the original potential $V$ and the biased potential $V + \delta V$, a kMC model with transition rates defined by (18) with prefactors such as (19), (20), or (27) can be used to model the exit event (see in particular Theorem 1). Indeed, if this is the case, by using the biasing potential $V + \delta V$, one easily checks that the ratio of exit rates $k_j / k_i$ (which gives the relative probability to exit through a neighborhood of $z_j$ compared to the probability to exit through a neighborhood of $z_i$) does not depend on $\delta V$ since, by assumption, $\delta V$ is zero on $\partial S$: this gives the consistency of the algorithm in terms of the distribution of the first exit point. Concerning the exit time, we know that it is exponentially distributed with parameter $\sum_{i=1}^{I} k_i$, with explicit dependency on $V$ (or $V + \delta V$ for the biased potential) in the small temperature regime thanks again to the formulas (18) (and (19), (20), or (27)). For example, in the framework of Theorem 1, the parameter of the exponential law is $\lambda_1$, where the dependency of $\lambda_1$ on the potential $V$ is explicitly given by formula (24). In particular, one easily checks that (indicating the dependency of $\lambda_1$ on the underlying potential in parenthesis)

$$\frac{\lambda_1(V + \delta V)}{\lambda_1(V)} = \sqrt{\frac{\det\big(\nabla^2(V + \delta V)\big)(x_1)}{\det\big(\nabla^2(V)\big)(x_1)}} e^{\beta \delta V(x_1)}(1 + O(\beta^{-1}))$$

(we again used the fact that $\delta V$ is assumed to be zero on $\partial S$). The righthand side is equal, in the regime $\beta \to \infty$, to $\frac{\int_S \exp(-\beta V)}{\int_S \exp(-\beta(V + \delta V))}(1 + O(\beta^{-1}))$, which is indeed well approximated by the boost factor $B$ (in the limit of a sufficiently large residence time $T_S^{\delta V}$, using the ergodicity of the dynamics). This shows that Theorem 1 applied to $V$ and to $V + \delta V$ justifies the use of hyperdynamics.

Let us mention that in Theorem 1, the relative error on the law of the exit event scales like $O(\beta^{-1})$. It is actually possible to show that the relative error for hyperdynamics scales like $O(\exp(-c\beta))$ for some positive $c$, and to prove this result under less stringent geometric conditions than Theorem 1, see Lelièvre and Nier (2015). Again, generalizing these results to the Langevin dynamics, (3) is an open problem that we are currently investigating (see Remark 5).

Notice that, contrary to the parallel replica method, the hyperdynamics is limited to energetic barriers and a small temperature regime, at least for our mathematical analysis. On the other hand, for very high energetic barriers, hyperdynamics is in principle much more efficient: the parallel replica method only divides the exit time by $N$ (the number of replicas), while for deep wells, the boost factor $B$ is very large.

*Remark 9 (On the biasing potential).* A practical aspect we did not discuss so far is the effective construction of the biasing potential $\delta V$. In the original article (Voter 1997), A.F. Voter proposes a technique based on the Hessian $\nabla^2 V$. Alternatively, a well-known method in the context of materials science is the bond-boost method introduced by Miron and Fichthorn (2003). More recently, some authors proposed to build the biasing potential on the fly, by using adaptive biasing techniques (see, e.g., Tiwary and Parrinello (2013), Bal and Neyts (2015), and Dickson (2017)). Let us also mention the recent variant called *local hyperdynamics* (Kim et al. 2013) which does not enter the previous framework since the bias is actually a nonconservative biasing force (which does not derive from a biasing potential).

## 4.4   Temperature Accelerated Dynamics

Let us finally introduce the temperature accelerated dynamics (TAD) (see Sørensen and Voter 2000). Let us assume again that a reference replica $(X_t)_{t \geq 0}$ following the overdamped Langevin dynamics (5) remains trapped for a time $\tau_{corr}$ in a metastable state $S$, so that one can assume that the process is distributed according to the QSD. The principle of TAD is to increase the temperature (namely, increase $\beta^{-1}$ in (5)) in order to accelerate the exit from $S$. The algorithm consists in:

- Simulating many exit events from $S$ at high temperature, starting from the QSD at high temperature,
- Extrapolating the high-temperature exit events to low-temperature exit events using the Eyring-Kramers law (18).

As for the hyperdynamics algorithm, in the original paper by Sørensen and Voter (2000), no equilibration step is used: it is assumed that the states are sufficiently metastable at both high and low temperatures so that the convergence to the QSD is immediate. In particular, in the simulations at high temperature, the replica is simply bounced back into the state $S$ when it leaves $S$ (and not resampled from the QSD in $S$). Let us now describe more precisely how the extrapolation procedure is made.

Let us consider the exit event from $S$, at a given temperature. Using the results of Sect. 2, the exit event can be modeled using a kMC model with transition rates $(k_i)_{i=1,...,I}$ through the local minima $(z_i)_{i=1,...,I}$ of $V$ on $\partial S$. More precisely, let us consider the process evolving in $S$ which is resampled according to the QSD within $S$ after each exit event. For $i \in \{1, \ldots, I\}$, let us denote by $\tau_i$ the first exit time through a neighborhood of $z_i$ for this process. One readily checks that $\tau_i$ is exponentially distributed with parameter $k_i$ and that the $\tau_i$'s are independent.

Therefore, using the notation of Sect. 2.1, the exit time $T_S$ and exit local minimum $Y_S$ ($Y_S = i$ if the exit point is in $B_{z_i}$) satisfies:

$$(T_S, Y_S) \overset{\mathscr{L}}{=} (\min(\tau_1, \dots, \tau_I), \arg\min(\tau_1, \dots, \tau_I)).$$

Now, using the results of Sect. 3 (see in particular Theorem 1), namely, using the Eyring-Kramers law to parameterize the kMC model, one can compute, in the small temperature regime, the ratios $\frac{k_i^{hi}}{k_i^{lo}}$, where $k_i^{hi}$ (resp. $k_i^{lo}$) denotes the rate at high-temperature $\beta^{hi}$ (resp. low-temperature $\beta^{lo}$). For example, if one considers real saddle points on the boundary, with the prefactors (19) (for Langevin) or (20) (for overdamped Langevin), one obtains:

$$\frac{k_i^{hi}}{k_i^{lo}} \simeq \exp\left(-(\beta^{hi} - \beta^{lo})(V(z_i) - V(x_1))\right). \tag{31}$$

Likewise, in the framework of Theorem 1 (namely, for generalized saddle points), one obtains:

$$\frac{k_i^{hi}}{k_i^{lo}} \simeq \sqrt{\frac{\beta^{hi}}{\beta^{lo}}} \exp\left(-(\beta^{hi} - \beta^{lo})(V(z_i) - V(x_1))\right). \tag{32}$$

Using these formulas, one can infer the exit events at inverse temperature $\beta^{lo}$ from the exit events observed at inverse temperature $\beta^{hi}$, since:

$$(\tau_1^{lo}, \dots, \tau_I^{lo}) \overset{\mathscr{L}}{=} (\Theta^1 \tau_1^{hi}, \dots, \Theta^I \tau_I^{hi}) \tag{33}$$

where

$$\Theta^i = \frac{k_i^{hi}}{k_i^{lo}}$$

is a multiplicative factor constructed from the ratio of the rates. In the equality in law in (33), the random variables $\tau_i^{hi/lo}$ are, as described above, exponential random variables with parameter $k_i^{hi/lo}$. To have analytical formula for the correction factors $\Theta_i$ and make the algorithm practical, the Eyring-Kramers law is assumed to be exact, and one uses in practice $\Theta^i = \exp\left(-(\beta^{hi} - \beta^{lo})(V(x_i) - V(x_0))\right)$, see (31) (or $\Theta^i = \sqrt{\beta^{hi}/\beta^{lo}} \exp\left(-(\beta^{hi} - \beta^{lo})(V(x_i) - V(x_0))\right)$, see (32)).

The TAD algorithm thus consists in running the dynamics at high temperature, observing the exit events through the saddle points on the boundary of the state, and updating the exit time and exit region that would have been observed at low temperature. More precisely, if, at a given time, exits through the saddle points $\{s_1, \dots, s_k\} \subset \{1, \dots, I\}$ have been observed, one computes $\min(\Theta^{s_1} \tau_{s_1}^{hi}, \dots, \Theta^{s_k} \tau_{s_k}^{hi})$ and $\arg\min(\Theta^{s_1} \tau_{s_1}^{hi}, \dots, \Theta^{s_k} \tau_{s_k}^{hi})$ to get the corresponding exit time and exit region at low temperature.

The interest of TAD compared to a brute force saddle point search is that it is not required to observe exits through all the saddle points in order to obtain a statistically correct exit event. Indeed, a stopping criterion is introduced to stop the calculations at high temperature when the extrapolation procedure will not modify anymore the low-temperature exit event (namely, will not modify $\min(\Theta^{s_1}\tau_{s_1}^{hi}, \ldots, \Theta^{s_k}\tau_{s_k}^{hi})$, $\{s_1, \ldots, s_k\} \subset \{1, \ldots, I\}$ being the saddle points discovered up to the time the stopping criterion is fulfilled). This stopping criterion requires to provide some a priori knowledge, typically a lower bound on the barriers $V(z_j) - V(x_1)$ ($j \in \{1, \ldots, I\}$) or a lower bound on the prefactors $\nu_j$ in (18) (see, e.g., Aristoff and Lelièvre (2014) for a discussion). In some sense, TAD can be seen as a clever saddle point search, with a rigorous way to stop the searching procedure.

From the above discussion, the mathematical analysis of the TAD algorithm thus requires to prove that the exit event from $S$ can be modeled using a kMC model parameterized by the Eyring-Kramers formulas. This is exactly the content of Theorem 1 for the overdamped Langevin dynamics (5) with generalized saddle points on $\partial S$. See also Aristoff and Lelièvre (2014), for the case of a one-dimensional potential. The generalization of Theorem 1 to real saddle points on $\partial S$ and to the Langevin dynamics (3) is a work under progress (see Remarks 2 and 5).

Notice that, compared to the hyperdynamics, TAD is really based on the Eyring-Kramers formulas, with relative error terms which scales like $1/\beta$, while for hyperdynamics, one can prove that the error is exponentially small in $\beta$. On the other hand, the interest of TAD compared to the hyperdynamics is that it does not require a biasing potential, which may be complicated to build in some situation.

## 4.5   How to Choose the Metastable States?

Let us finally make a few comments on how the metastable states can be defined in practice. As explained above, the overall efficiency of the accelerated dynamics methods depends on the choice of these metastable states: the algorithms indeed provide an acceleration after assuming that the QSD has been reached in a metastable state. The efficiency of the algorithms thus depends on the choice of the states, which should be metastable regions, so that the stochastic process generically reaches the local equilibrium (the QSD) before leaving the state. How to define the metastable states is a difficult question, very much related to the definition of good reaction coordinates (or good reduced degrees of freedom) for molecular dynamics. Notice that choosing good metastable states also implies being able to estimate the correlation time $\tau_{\text{corr}}$ within each state either from some a priori knowledge or some on the fly estimates, as already explained in Sect. 2.4.

In the original papers by Voter (1997, 1998), Sørensen and Voter (2000), and Perez et al. (2015a), the states are defined as the basins of attraction of the gradient dynamics:

$$\frac{dq}{dt} = -\nabla V(q). \tag{34}$$

For almost every initial conditions, this dynamics converges to a local minimum of $V$: there are thus as many states as local minima of $V$, and the states define (up to a negligible set of points) a partition of the state-space $\mathbb{R}^d$. This means that in practice, a steepest descent is performed at regular time intervals to identify the state in which the system is. One big advantage of this definition is that the states do not need to be defined a priori: they can be numbered as they are discovered by the dynamics, when new local minima of $V$ are identified. Formally, in such a case, one can introduce a map

$$\mathscr{S} \colon \mathbb{R}^d \to \mathbb{N}$$

which to a given position associates a label of a basin of attraction of (34). Accelerated dynamics then aim at efficiently simulating the so-called state-to-state dynamics $(\mathscr{S}(q_t))_{t\geq0}$ or $(\mathscr{S}(X_t))_{t\geq0}$.

For a system with more diffusive or entropic barriers (this is typically the case for biological applications), one could think of defining the states using relevant reaction coordinates (see, e.g., Kum et al. (2004) where the states are defined in terms of the molecular topology of the molecule of interest). This requires to identify the states before starting the simulation.

An important point to make is that since the numerical methods are local in nature, one does not need a partition of the state space to apply these techniques. Two situations can then be considered. One can first define metastable states $(S_i)_{i\geq1}$ which are disjoint open subsets of $\mathbb{R}^d$ (they are called milestones by Faradjian and Elber 2004, target sets, or core sets by Schütte et al. 2011). Each time the process enters one of these states, one checks if the QSD is reached before leaving (this is the decorrelation step, see Sect. 2.4), and then parallel replica, hyperdynamics, or temperature accelerated dynamics can be used to efficiently sample the exit event. Parallel trajectory splicing can also be applied in such a situation. These techniques thus do not require a partition. On the other hand, since one has to simulate the original dynamics outside $\cup_{i\geq1}S_i$, if the time spent outside $\cup_{i\geq1}S_i$ is large, the algorithms are less efficient.

Another possibility is to introduce again an ensemble $(C_i)_{i\geq1}$ of disjoint open subsets of $\mathbb{R}^d$ and to define the state $S_i$ as follows:

$$S_i = \mathbb{R}^d \setminus \cup_{j\neq i} C_j.$$

(The state is then unbounded, which raises some mathematical question about the existence and uniqueness of the QSD, which could be addressed under appropriate assumptions on the growth of the potential $V$ at infinity.) The dynamics then goes as follows: when the process enters one of the core set $C_i$, one considers the exit event from the associated state $S_i$, namely, the next visited core set which is different from $C_i$. In terms of kMC dynamics, this corresponds to projecting the dynamics $(X_t)_{t\geq0}$ (or $(q_t)_{t\geq0}$) onto a discrete state-space dynamics obtained by considering the last visited core set as in Vanden-Eijnden et al. (2008) and Schütte et al. (2011). The interest of such an approach is that the time to reach the QSD starting from

$\partial C_i$ in $S_i$ should be quite small if the $C_i$'s are well chosen. In such a setting, the process thus should decorrelate very quickly before exiting, and an approximation using a global kMC algorithm becomes relevant. However, one drawback is that the description of the underlying continuous state-space dynamics may become poor, especially for very small core sets (since the information of the last visited core set may not be very informative about the actual state of the system).

In summary, one should keep in mind that there is possibly room for improvements in the way the metastable states are defined, compared to the original papers where a partition of the state space in basins of attraction of the gradient dynamics (34) is considered (see also Perez et al. (2015b) for a recent discussion). This is particularly relevant since there are now techniques to approximate the convergence time to the QSD which can be applied for sets which are not basins of attractions of (34) (see Binder et al. (2015) and Sect. 2.4).

## 5    Conclusion and Perspectives

We presented a mathematical analysis of the accelerated dynamics proposed by A.F. Voter and coworkers in order to efficiently generate exit events from metastable states. The analysis is based on the notion of quasi-stationary distribution (QSD), which gives a natural framework to prove that the exit event from a state $S$ for the Langevin or overdamped Langevin dynamics can be modeled by a kinetic Monte Carlo (kMC) model, if the QSD is reached before exiting from $S$. Moreover, under some assumptions, we reported on recent mathematical results which show that the Eyring-Kramers formula can be used to parameterize the kMC model.

From a theoretical viewpoint, we already mentioned above that the mathematical analysis proving that the Eyring-Kramers formulas are good approximations of the exit rates is for the moment restricted to the overdamped Langevin dynamics (5) and to a domain $S$ such that $\partial_n V > 0$ on $\partial S$, which prevents us from considering real saddle points $z_i$ on $\partial S$. The generalization of the results presented in Sects. 2 and 3 to the Langevin dynamics (3) and real saddle points on $\partial S$ is a work in progress. It would also be interesting to investigate Langevin or overdamped Langevin dynamics with nongradient forces (nonequilibrium systems).

From a numerical viewpoint, the mathematical analysis shows the versatility and the limitations of the accelerated dynamics algorithms. The parallel replica and the parallel trajectory splicing algorithms, for example, are very general, and can be applied in many contexts: general Markov dynamics, general definitions of states, etc. Likewise, the principle of the temperature accelerated dynamics algorithm can be used as soon as formulas approximating the exit rates are available (one could think, for example, of versions of TAD where the potential is modified, in the spirit of hyperdynamics but without the assumption that the biasing potential is zero on $\partial S$). Generally speaking, the investigation of the performance of these algorithms to new physical settings and general Markov dynamics is a very promising research direction.

# Temporal Acceleration in Coupled Continuum-Atomistic Methods

# 37

Woo Kyun Kim  and Ellad B. Tadmor

## Contents

### Abstract

In order to speed up molecular simulations, coupled continuum-atomistic methods have been developed in which atomistic resolution is only retained in regions of interest with the rest of the model approximated as a continuum.

In parallel, there have been efforts to extend the time scale accessible in molecular simulations by filtering out atomic vibrations and focusing on the more interesting dynamics associated with the formation and motion of defects. This article focuses on a current research trend to combine these two complementary approaches into a unified framework that can simultaneously span multiple length and time scales from the microscopic to the macroscopic. As a specific example, the combination of the spatial quasicontinuum (QC) method with the temporal hyperdynamics method to create "hyper-QC" is described.

## 1    Introduction

In typical engineering simulations of macroscopic systems, no limitations are placed on length or time scales. Using high-performance computing, a system being modeled can be as large as needed and can be simulated for as long as needed. For example, continuum finite element (FE) simulations of an entire aircraft during flight, or a crash test of a vehicle, are routinely performed. However, the situation is very different when simulating systems on microscopic length scales. In this case, the atoms constituting the material introduce an inherent length and time scale into the problem; these are the separation between atoms on the order of an Angstrom ($10^{-10}$ m) and atomic vibrations that set a characteristic time on the order of a femtosecond ($10^{-15}$ s). This severely limits the size and times that can be modeled, with most simulations restricted to a tiny fraction of the full system on sub-microsecond time scales.

Two parallel efforts have been pursued to address the length and time scale limitations in microscopic simulations. To overcome the length problem, spatial coarse-graining methods have been introduced in which the atoms in the system are strategically thinned in a manner that retains the physics of interest. This can be traced back to the work of Kirkwood (1935) on the potential of mean force and to earlier work on statistical mechanics. More recently, a class of computational partitioned-domain methods have been introduced in which atomistic resolution is retained in regions of interest (e.g., near a crack tip or dislocation core), while a continuum approximation is used elsewhere (Miller and Tadmor 2009). Thus a coupled continuum-atomistic approach is adopted.

Among the various partitioned-domain methods (many of which are reviewed in Miller and Tadmor 2009; Curtin and Miller 2003; Tadmor and Miller 2011), the quasicontinuum (QC) method of Tadmor and co-workers (Tadmor et al. 1996; Shenoy et al. 1999) is one of the earliest and has been widely adopted in various domains. The original static QC method was extended to study finite temperature effects in dynamics simulations; this approach is referred to as "hot-QC" (Dupuy et al. 2005; Tadmor et al. 2013). An alternative "fully nonlocal" version of the QC method (which we refer to as "cluster-QC" (CQC)) was developed by Knap and Ortiz (2001). In CQC, summation in continuum regions is conducted node-by-node using nodal clusters, as opposed to the original QC method that adopts element-by-element summation using the Cauchy-Born rule (see Sect. 3.1).

In parallel to the spatial coarse-graining efforts, different methods for extending the time scale accessible in microscopic simulations have been pursued. These efforts can be traced back to work on the kinetic Monte Carlo (KMC) method in the 1960s (Voter 2007) and earlier work on rate kinetics and transition state theory (TST). A variety of methods have been introduced since then to accelerate dynamics in microscopic simulations. These include hyperdynamics (Voter 1997), the parallel replica method (Voter 1998), temperature-accelerated dynamics (Sørensen and Voter 2000), on-the-fly KMC (Henkelman and Jónsson 2001), metadynamics (Laio and Parrinello 2002), and diffusive molecular dynamics (Li et al. 2011). Briefly, hyperdynamics adds a bias potential to reduce energy barriers and expedite the escape from potential energy wells. In the parallel replica method, several statistical copies of the original system are simultaneously evolved to increase the probability for transitions. Temperature-accelerated dynamics seeks transition pathways at elevated temperatures. The on-the-fly KMC approach constructs the KMC rate table at each state by searching for escape pathways across saddle points. In metadynamics, the potential energy is modified by adding Gaussian potentials defined by several "collective variables" to discourage revisits to previously sampled configurations. In diffusive molecular dynamics, diffusion is simulated by evolving the occupation probabilities of the mean positions of atomic sites by minimizing a free energy expression based on the Gibbs-Bogoliubov inequality.

The spatial coarse graining and temporal acceleration methods described above have largely been developed separately. A current research focus is to formulate methods that combine these efforts into a single framework to enable simulations of large microscopic systems over long times. In this article, we discuss methods where both length and time scales are extended simultaneously. We focus on the "hyper-QC" method, which is an extension of hot-QC based on hyperdynamics. We also briefly describe a second approach that employs the maximum entropy (max-ent) formalism of Jaynes (1957a, b) within CQC, which we refer to as "finite-temperature CQC." (The term "hot-QC" is sometimes applied to this approach as well, which can be confusing.)

We begin in Sect. 2 with general background on the mechanics of systems of particles including the Hamiltonian formulation and statistical mechanics. The hot-QC approach for spatial coarse graining is discussed in Sect. 3. The integration of temporal acceleration into spatial coarse-graining methods, with emphasis on hyper-QC, is in Sect. 4. This includes a discussion of infrequent events and the hyperdynamics method for accelerating molecular dynamics. We end in Sect. 5 with brief concluding remarks.

## 2  Background: Mechanics of Systems of Particles

### 2.1  Hamiltonian Formulation

Consider a material system consisting of $N$ atoms. The total energy of the system, which is called the "Hamiltonian" and denoted by $\mathcal{H}$, is given by

$$\mathcal{H}(\boldsymbol{q}, \boldsymbol{p}) = \mathcal{V}(\boldsymbol{q}) + \mathcal{K}(\boldsymbol{p}), \tag{1}$$

where $\boldsymbol{q} = (\boldsymbol{q}_1, \ldots, \boldsymbol{q}_N)$ and $\boldsymbol{p} = (\boldsymbol{p}_1, \ldots, \boldsymbol{p}_N)$ represent the positions and momenta of all atoms, $\mathcal{V}$ is the potential energy due to interactions between atoms (see, e.g., Tadmor and Miller 2011), and $\mathcal{K} = \sum_{i=1}^{N} ||\boldsymbol{p}_i||^2/(2m_i)$ is the kinetic energy, where $m_i$ is the mass of particle $i$. It is assumed that the potential energy can be represented as a sum over individual atom energies $V_i$:

$$\mathcal{V} = \sum_{i=1}^{N} V_i(\boldsymbol{q}). \tag{2}$$

Then, the Hamiltonian can also be written as a sum over individual atom Hamiltonians $h_i$:

$$\mathcal{H} = \sum_{i=1}^{N} h_i(\boldsymbol{q}, \boldsymbol{p}_i), \tag{3}$$

where $h_i = V_i(\boldsymbol{q}) + ||\boldsymbol{p}_i||^2/(2m_i)$. Note that the potential energy of atom $i$ will in general depend on some subset of positions in $\boldsymbol{q}$ in the vicinity of $\boldsymbol{q}_i$, whereas the kinetic energy of atom $i$ only depends on $\boldsymbol{p}_i$.

The dynamical trajectories of the atoms are governed by Newton's equations of motion, which in terms of the Hamiltonian are given by

$$\dot{\boldsymbol{q}}_i = \frac{\partial \mathcal{H}}{\partial \boldsymbol{p}_i}, \qquad \dot{\boldsymbol{p}}_i = -\frac{\partial \mathcal{H}}{\partial \boldsymbol{q}_i}, \tag{4}$$

where the dot represents differentiation with respect to time. The first equation in Eq. (4) enforces the connection between momentum and position, and the second is Newton's equation of motion (second law). The dynamical trajectories of all atoms $(\boldsymbol{q}(t), \boldsymbol{p}(t))$ are obtained by integrating the equations of motion subject to any existing macroscopic constraints. This is the method of "molecular dynamics" (MD).

## 2.2   Statistical Mechanics

In practice, it is not possible to integrate the equations of motion in Eq. (4) for a macroscopic system due to the huge numbers of atoms involved, due to lack of knowledge of initial conditions, and due to the exponential sensitivity of trajectories to these conditions. Instead in statistical mechanics, a probabilistic approach is adopted. The probability of finding the system in microstate $(\boldsymbol{q}, \boldsymbol{p})$ is given by a distribution function $\rho(\boldsymbol{q}, \boldsymbol{p})$ satisfying macroscopic constraints. Any macroscopic observable $A$ is then represented as an ensemble average of a corresponding phase function $\mathcal{A}(\boldsymbol{q}, \boldsymbol{p})$:

$$A = \langle \mathcal{A}(\boldsymbol{q}, \boldsymbol{p}) \rangle = \iint \mathcal{A}(\boldsymbol{q}, \boldsymbol{p}) \, \rho(\boldsymbol{q}, \boldsymbol{p}) \, d\boldsymbol{q} \, d\boldsymbol{p}, \tag{5}$$

where the integration is over the entire phase space of the system (i.e., all possible values of $\boldsymbol{q}$ and $\boldsymbol{p}$) and $d\boldsymbol{q} \, d\boldsymbol{p} = d\boldsymbol{q}_1 \ldots d\boldsymbol{q}_N d\boldsymbol{p}_1 \ldots d\boldsymbol{p}_N$. The distribution function $\rho$ satisfies the normalization condition:

$$\iint \rho(\boldsymbol{q}, \boldsymbol{p}) \, d\boldsymbol{q} \, d\boldsymbol{p} = 1. \tag{6}$$

Under equilibrium conditions, for a system of $N$ atoms at constant volume $V$ and in contact with a heat bath at temperature $T$ (the so-called canonical or $NVT$ ensemble), the distribution function has the Boltzmann form:

$$\rho(\boldsymbol{q}, \boldsymbol{p}; \beta) = \frac{1}{\mathcal{Z}(\beta)} e^{-\beta \mathcal{H}(\boldsymbol{q}, \boldsymbol{p})}, \tag{7}$$

where $\beta = (k_B T)^{-1}$, $k_B$ is the Boltzmann constant, and the canonical partition function is

$$\mathcal{Z}(\beta) = \iint e^{-\beta \mathcal{H}(\boldsymbol{q}, \boldsymbol{p})} \, d\boldsymbol{q} \, d\boldsymbol{p}. \tag{8}$$

## 2.3  Harmonic Approximation

The partition function in Eq. (8) can be evaluated approximately by employing the quasi-harmonic (QH) approximation, whereby the potential energy $\mathcal{V}(\boldsymbol{q})$ (which is part of $\mathcal{H}(\boldsymbol{q}, \boldsymbol{p})$) is expanded to second order about mean atom positions $\bar{\boldsymbol{q}}$:

$$\mathcal{V}_{\mathrm{QH}}(\boldsymbol{q}; \bar{\boldsymbol{q}}) = \mathcal{V}(\bar{\boldsymbol{q}}) + \frac{1}{2}(\boldsymbol{q} - \bar{\boldsymbol{q}})^{\mathrm{T}} \mathbf{H}(\boldsymbol{q})(\boldsymbol{q} - \bar{\boldsymbol{q}}). \tag{9}$$

Here $\mathbf{H}$ is the $3N \times 3N$ Hessian (stiffness) matrix, and the positions $\bar{\boldsymbol{q}}$ are free parameters to be determined later. At sufficiently low temperatures (below half the melting temperature according to LeSar et al. 1989), the off-diagonal terms in $\mathbf{H}$ can be neglected, which leads to the local harmonic (LH) approximation:

$$\mathcal{V}_{\mathrm{LH}}(\boldsymbol{q}; \bar{\boldsymbol{q}}) = \mathcal{V}(\bar{\boldsymbol{q}}) + \sum_{i=1}^{N} \frac{1}{2}(\boldsymbol{q}_i - \bar{\boldsymbol{q}}_i)^{\mathrm{T}} \boldsymbol{\Phi}_i(\boldsymbol{q})(\boldsymbol{q}_i - \bar{\boldsymbol{q}}_i), \tag{10}$$

where $\boldsymbol{\Phi}_i$ is the force constant matrix for atom $i$ given by

$$\boldsymbol{\Phi}_i = \begin{bmatrix} \dfrac{\partial^2 \mathcal{V}}{\partial q_{i1} \partial q_{i1}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i1} \partial q_{i2}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i1} \partial q_{i3}} \\[2mm] \dfrac{\partial^2 \mathcal{V}}{\partial q_{i2} \partial q_{i1}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i2} \partial q_{i2}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i2} \partial q_{i3}} \\[2mm] \dfrac{\partial^2 \mathcal{V}}{\partial q_{i3} \partial q_{i1}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i3} \partial q_{i2}} & \dfrac{\partial^2 \mathcal{V}}{\partial q_{i3} \partial q_{i3}} \end{bmatrix}, \tag{11}$$

and $\boldsymbol{q}_i = (q_{i1}, q_{i2}, q_{i3})$. The LH approximations for the canonical distribution function and partition function follow as

$$\rho_{\mathrm{LH}}(\boldsymbol{q}, \boldsymbol{p}; \beta, \bar{\boldsymbol{q}}) = \frac{1}{\mathcal{Z}_{\mathrm{LH}}} e^{-\beta \mathcal{V}(\bar{\boldsymbol{q}})} \prod_{i=1}^{N} e^{-\beta \left\{ \frac{(\boldsymbol{q}_i - \bar{\boldsymbol{q}}_i)^T \boldsymbol{\Phi}_i (\boldsymbol{q}_i - \bar{\boldsymbol{q}}_i)}{2} + \frac{\|\boldsymbol{p}_i - \bar{\boldsymbol{p}}_i\|^2}{2m_i} \right\}}, \tag{12}$$

$$\mathcal{Z}_{\mathrm{LH}}(\beta, \bar{\boldsymbol{q}}) = e^{-\beta \mathcal{V}(\bar{\boldsymbol{q}})} \prod_{i=1}^{N} \sqrt{\frac{1}{\det \boldsymbol{\Phi}_i}} \left( \sqrt{\frac{2\pi}{\beta}} \right)^3 \left( \sqrt{\frac{2\pi m_i}{\beta}} \right)^3. \tag{13}$$

The identification of $\bar{\boldsymbol{q}}$ with the mean positions of the atoms is confirmed since

$$\langle \boldsymbol{q}_i \rangle_{\mathrm{LH}} = \bar{\boldsymbol{q}}_i \quad (i = 1, \ldots, N). \tag{14}$$

The internal energy and Helmholtz free energy can also be calculated:

$$U_{\mathrm{LH}}(\beta, \bar{\boldsymbol{q}}) = -\frac{\partial \ln \mathcal{Z}_{\mathrm{LH}}}{\partial \beta} = \mathcal{V}(\bar{\boldsymbol{q}}) + \frac{3N}{\beta} = \sum_{i=1}^{N} \left( V_i(\bar{\boldsymbol{q}}) + \frac{3}{\beta} \right), \tag{15}$$

$$\Psi_{\mathrm{LH}}(\beta, \bar{\boldsymbol{q}}) = -\frac{1}{\beta} \ln \mathcal{Z}_{\mathrm{LH}} = \sum_{i=1}^{N} \psi_i(\beta, \bar{\boldsymbol{q}}), \tag{16}$$

where

$$\psi_i(\beta, \bar{\boldsymbol{q}}) = V_i(\bar{\boldsymbol{q}}) + \frac{1}{\beta} \ln \frac{\sqrt{\det \boldsymbol{\Phi}_i(\bar{\boldsymbol{q}})}}{(2\pi \sqrt{m_i}/\beta)^3}. \tag{17}$$

For a quasistatic process, $\bar{\boldsymbol{q}}$ is determined by minimizing $\Psi_{\mathrm{LH}}$, i.e., by solving

$$\frac{\partial \Psi_{\mathrm{LH}}}{\partial \bar{\boldsymbol{q}}_i} = \frac{\partial}{\partial \bar{\boldsymbol{q}}_i} \left( \sum_{i=1}^{N} \psi_i \right) = 0, \quad (i = 1, \ldots, N), \tag{18}$$

and ensuring the solution corresponds to a minimum.

## 3      Spatial Coarse Graining

The atomistic methods described in the previous section can in principle be used to obtain the dynamics of a system of atoms (Sect. 2.1) and its equilibrium properties (Sects. 2.2 and 2.3). However in practice, such simulations become prohibitively expensive when the number of atoms is too large. Spatial multiscale methods, like the hot-QC method (Dupuy et al. 2005; Tadmor et al. 2013), address this by systematically reducing the number of atoms in a manner that retains the physics of interest – a process referred to as "coarse graining." A description of the hot-QC approach to coarse graining follows.

### 3.1      Finite-Temperature Quasicontinuum (Hot-QC)

As a first step to developing a rigorous coarse-graining procedure, one must introduce a well-defined design principle. In the static QC method, the objective is to approximate the total potential energy of the fully atomistic system in a manner that ensures convergence to the exact result as the atomistic region is increased in size (Tadmor et al. 1996). For a dynamical method at finite temperature, a different design principle is required. Hot-QC assumes equilibrium thermodynamic conditions and sets as its goal to approximate phase averages of the system in a controlled fashion. The exact expression being approximated is provided below after some preliminary definitions.

Consider an atomistic system of $N$ atoms that is partitioned into an atomistic region where the deformation changes appreciably on atomic length scales (this is where the interesting physics is occurring) and a continuum region where the deformation varies slowly on the atomic scale (Fig. 1a). The atoms in each region are distinguished using the superscripts "at" and "c" so that $q = (q^{at}, q^c) = (q^{at}_1, \ldots, q^{at}_{N^{at}}, q^c_1, \ldots, q^c_{N^c})$, where $N^{at}$ and $N^c$ are the number of atoms in the atomistic and continuum regions ($N = N^{at} + N^c$). Note that at this stage no coarse graining has taken place.

Returning to the hot-QC design principle, equilibrium properties of this system in the canonical ensemble are given by (Sect. 2.2):

$$A = \frac{1}{\mathcal{Z}} \iiiint \mathcal{A}(q^{at}, p^{at}) e^{-\beta \mathcal{H}(q^{at}, q^c, p^{at}, p^c)} \, dq^{at} \, dp^{at} \, dq^c \, dp^c, \qquad (19)$$

where the dependence on the atoms in the atomistic and continuum regions has been made explicit. Since the intent is to coarse grain the system by removing the atoms in the continuum region, only phase functions that depend on the atoms retained in the atomistic region are considered in Eq. (19). It is straightforward to show that, by reordering the sequence of integrations, Eq. (19) is *exactly* given by the following expression (Shenoy et al. 1999; Tadmor et al. 2013):
**Fig. 1** A portion of a QC model for an atomically sharp crack. Frame (**a**) shows the atoms in the vicinity of the crack tip. The colored square is the "atomistic region" of QC. The continuum region encompasses all atoms outside this square and extends beyond the boundaries of the figure. Frame (**b**) shows the corresponding QC model. Atoms retained in the model are called "repatoms" and shown as filled circles. The repatoms serve as the nodes of an FE mesh. The positions of unfilled atoms are then obtained through FE interpolation

$$A = \frac{1}{\mathcal{Z}} \iint \mathcal{A}(\boldsymbol{q}^{\text{at}}, \boldsymbol{p}^{\text{at}}) e^{-\beta \mathcal{H}^{\text{at}}(\boldsymbol{q}^{\text{at}}, \boldsymbol{p}^{\text{at}}; \beta)} \, d\boldsymbol{q}^{\text{at}} \, d\boldsymbol{p}^{\text{at}}, \tag{20}$$

where $\mathcal{H}^{\text{at}}$ is the effective Hamiltonian of the atomistic region

$$\mathcal{H}^{\text{at}}(\boldsymbol{q}^{\text{at}}, \boldsymbol{p}^{\text{at}}; \beta) = \mathcal{V}^{\text{at}}(\boldsymbol{q}^{\text{at}}; \beta) + \mathcal{K}^{\text{at}}(\boldsymbol{p}^{\text{at}}; \beta), \tag{21}$$

and $\mathcal{V}^{\text{at}}$ and $\mathcal{K}^{\text{at}}$ are the corresponding effective potential and kinetic energies:

$$\mathcal{V}^{\text{at}}(\boldsymbol{q}^{\text{at}}; \beta) = -\frac{1}{\beta} \ln \int e^{-\beta \mathcal{V}(\boldsymbol{q}^{\text{at}}, \boldsymbol{q}^{\text{c}})} \, d\boldsymbol{q}^{\text{c}}, \tag{22}$$

$$\mathcal{K}^{\text{at}}(\boldsymbol{p}^{\text{at}}; \beta) = -\frac{1}{\beta} \ln \int e^{-\beta \mathcal{K}(\boldsymbol{p}^{\text{at}}, \boldsymbol{p}^{\text{c}})} \, d\boldsymbol{p}^{\text{c}}. \tag{23}$$

The effective potential energy $\mathcal{V}^{\text{at}}$ corresponds to the potential of mean force introduced by Kirkwood (1935).

The hot-QC approach is based on an approximate computation of $\mathcal{H}^{\text{at}}$. The effective kinetic energy in Eq. (23) can be computed analytically. (See Dupuy et al. (2005) for details on how coarse graining is handled for this term.) The effective potential energy $\mathcal{V}^{\text{at}}$ in Eq. (22) can be approximated by expanding the potential energy about mean positions of the continuum atoms $\bar{\boldsymbol{q}}^{\text{c}}$ and applying the LH approximation (Sect. 2.3):

$$\mathcal{V}_{\text{LH}}^{\text{at}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}; \beta) = \sum_{i=1}^{N^{\text{at}}} V_i^{\text{at}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}) + \sum_{i=1}^{N^{\text{c}}} \psi_i^{\text{c}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}; \beta), \qquad (24)$$

where $V_i^{\text{at}}$ is the potential energy of atom $i$ in the atomistic region and $\psi_i^{\text{c}}$ follows in similar fashion to Eq. (17):

$$\psi_i^{\text{c}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}; \beta) = V_i^{\text{c}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}) + \frac{1}{2\beta} \ln \left[ \det \boldsymbol{\Phi}_i^{\text{c}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}) \right], \qquad (25)$$

where $V_i^{\text{c}}$ refers to the potential energy of continuum atom $i$. (Note that $\psi_i^{\text{c}}$ only includes the potential part of the free energy, since the kinetic part is included in $\mathcal{K}^{\text{at}}$.) The LH expression in Eq. (24) depends on the mean positions of the continuum atoms. Treating the continuum as a heat bath that occupies an equilibrium state as the atomistic region evolves, $\mathcal{V}^{\text{at}}$ in Eq. (22) is identified with the minimum of the LH expression:

$$\mathcal{V}^{\text{at}}(\boldsymbol{q}^{\text{at}}; \beta) \approx \min_{\bar{\boldsymbol{q}}^{\text{c}}} \mathcal{V}_{\text{LH}}^{\text{at}}(\boldsymbol{q}^{\text{at}}, \bar{\boldsymbol{q}}^{\text{c}}; \beta). \qquad (26)$$

The expression in Eq. (24) still involves a sum over all $N^{\text{c}}$ atoms in the continuum region making it prohibitively expensive. To reduce the computational cost, a small subset of atoms is selected from the continuum region to represent the remainder. The set of all atoms in the atomistic region and the selected atoms in the continuum region are called "representative atoms" or "repatoms" for short. The atoms in the atomistic region are "nonlocal" repatoms (since their energy depends nonlocally on other repatoms in their vicinity), whereas the retained continuum atoms are "local" (since their energy is computed using a local continuum approximation).

The repatoms constitute the nodes of an FE mesh as shown in Fig. 1b. Note that for computational convenience the mesh is continued into the atomistic region, although it serves no purpose there. The positions of discarded continuum atoms (appearing as open circles in Fig. 1b) are determined by FE interpolation:

$$\bar{\boldsymbol{q}}_i^{\text{c}} = \boldsymbol{Q}_i^{\text{c}} + \sum_{J=1}^{N_{\text{node}}} N_J(\boldsymbol{Q}_i^{\text{c}}) \, \boldsymbol{u}_J, \qquad (27)$$

where $\boldsymbol{Q}_i^{\text{c}}$ is the reference position of continuum atom $i$, $N_J$ is the FE shape function associated with node $J$, $\boldsymbol{u}_J$ is the displacement of node $J$, and $N_{\text{node}}$ is the number of nodes. Thus, the total number of degrees of freedom is reduced from $3N$ to $3N_{\text{node}}$.

Using the FE discretization, the sum over continuum atoms in Eq. (24) is approximated by employing the Cauchy-Born rule, which maps the continuum deformation to the motion of the underlying continuum atoms (Tadmor and Miller 2011):

$$\sum_{i=1}^{N^{\mathrm{c}}} \psi_i^{\mathrm{c}}(\boldsymbol{q}^{\mathrm{at}}, \bar{\boldsymbol{q}}^{\mathrm{c}}; \beta) \approx \sum_{e=1}^{N_{\mathrm{elem}}} \nu_e\, \psi^{\mathrm{CB}}(\boldsymbol{F}_e; \beta). \tag{28}$$

Here $\nu_e$ is the number of continuum atoms associated with element $e$ that fall within the continuum region, $\boldsymbol{F}_e$ is the deformation gradient of element $e$ (computed from the FE interpolation), and $\psi^{\mathrm{CB}}(\boldsymbol{F}_e; \beta)$ is the potential part of the Helmholtz free energy per atom computed for an infinite crystal deformed by $\boldsymbol{F}_e$ at inverse temperature $\beta$. (Note that for multilattice crystals, the displacement of basis atoms must be accounted for; see Tadmor et al. 1999.)

Putting everything together, the QC effective potential is given by

$$\mathcal{V}^{\mathrm{QC}}(\boldsymbol{q}^{\mathrm{at}}; \beta) = \min_{\boldsymbol{u}^{\mathrm{c}}} \left\{ \sum_{i=1}^{N^{\mathrm{at}}} V_i^{\mathrm{at}}(\boldsymbol{q}^{\mathrm{at}}, \boldsymbol{u}^{\mathrm{c}}) + \sum_{e=1}^{N_{\mathrm{elem}}} \nu_e\, \psi^{\mathrm{CB}}(\boldsymbol{F}_e; \beta) \right\}. \tag{29}$$

The hot-QC Hamiltonian is then

$$\mathcal{H}^{\mathrm{QC}}(\boldsymbol{q}^{\mathrm{at}}, \boldsymbol{p}^{\mathrm{at}}; \beta) = \mathcal{V}^{\mathrm{QC}}(\boldsymbol{q}^{\mathrm{at}}; \beta) + \mathcal{K}^{\mathrm{at}}(\boldsymbol{p}^{\mathrm{at}}; \beta). \tag{30}$$

A hot-QC simulation corresponds to an MD simulation of the atoms in the atomistic region using the QC Hamiltonian in Eq. (30).

The hot-QC formulation derived so far involves the minimization in Eq. (29) at every time step as $\boldsymbol{q}^{\mathrm{at}}$ is updated. A further approximation referred to as "hot-QC-dynamic" allows both nonlocal atoms and continuum nodes to evolve simultaneously by adding a correction term to account for artificial entropy associated with the mesh. With this correction, second-order accuracy in $k_{\mathrm{B}}T$ is retained. See Dupuy et al. (2005) and Tadmor et al. (2013) for details.

## 4    Integrating Temporal Acceleration into Spatial Coarse Graining

The hot-QC approach presented in the previous section significantly reduces the number of degrees of freedom in a system, thereby reducing the computational cost, but remains limited by the very short time step ($\sim 1\,\mathrm{fs}$) required for integrating the equations of motion of the nonlocal repatoms (i.e., atoms in the atomistic region). This severely limits the duration of hot-QC simulations. As a result, the loading rates in hot-QC simulations (as in MD simulations) are typically far larger than in experiments (otherwise no appreciable deformation would occur). For example, the hot-QC simulations of nanoindentation reported in Dupuy et al. (2005) were performed with an indenter velocity of about $5 \times 10^6\,\mu\mathrm{m/s}$, whereas the experimental loading rate is typically in the range of $0.001$–$1\,\mu\mathrm{m/s}$. Such large differences in rates can strongly influence the response of material systems, even leading to qualitative changes in some cases. Methods are therefore needed to accelerate the dynamics

occurring on the molecular scale. One approach suited for solid systems takes advantage of the separation between atomic vibrations and the far larger time scales associated with the nucleation and motion of defects. The idea is to skip over the uninteresting vibrations directly to the more infrequent defect-related events that evolve the system. Below is a description of this approach in a fully atomistic setting, followed by a discussion of how it can be incorporated into hot-QC.

## 4.1   Infrequent Events and Transition State Theory

The energetics of a system of $N$ particles can be represented in terms of a potential energy surface (PES). The PES is a conceptual plot of the energy of the system as a function of the positions of the atoms. Think of it as a topographical map in $3N + 1$ dimensions. The PES includes energy minima that are associated with equilibrium states of the system, separated from each other by dividing surfaces. The low points on the dividing surfaces are saddle points through which the system can most easily cross from one minimum to another; these are the transition states of the system. A two-dimensional schematic of a PES is shown in Fig. 2.

A solid system at a sufficiently low temperature spends most of its time vibrating within the basins of attraction of equilibrium states with occasional, rapid, thermally activated transitions between states. The trajectory of a typical system is represented as the black line in Fig. 2. The transition rate $R_{A \to B}$ is defined as the frequency of transitions from state A to state B (i.e., the number of transitions from A to B per

**Fig. 2** A PES for a system with two degrees of freedom represented by the horizontal and vertical axes. The colors represent the energy of the system with blue being lowest and red highest. Two equilibrium states (minima) are shown, denoted as A and B. The dashed lines are the dividing surfaces separating the region associated with one equilibrium state ("basin of attraction") from surrounding states. The low points on the dividing surfaces are saddle points denoted by S. The black line represents a trajectory of the system

unit time). It is important to understand that this rate is defined in the thermodynamic limit where the system spends an infinite amount of time transitioning back and forth between A and B. It is given by

$$R_{A \to B} \equiv \lim_{t \to \infty} \frac{N_{A \to B}(t)}{t_A(t)}, \tag{31}$$

where $N_{A \to B}(t)$ is the number of crossings from A to B during time $t$ and $t_A(t)$ is the portion of time spent in state A during time $t$. Inverting Eq. (31) gives the average waiting time that the system spends in state A before escaping:

$$\bar{t}_A^{\text{wait}} \equiv \lim_{t \to \infty} \frac{t_A(t)}{N_{A \to}(t)} = \frac{1}{R_{A \to}}. \tag{32}$$

This expression has been generalized to the case where there can be multiple escapes out of A. The total number of escapes out of state A during time $t$ is $N_{A \to}(t)$.

Under the assumption that every crossing of the dividing surface corresponds to a transition between states, the transition rate in Eq. (31) can be computed within the TST formalism of statistical mechanics (see, e.g., Vanden-Eijnden and Tal 2005). This is an approximation since dynamical trajectories that cross the dividing surface may return back to their original state instead of equilibrating in the new state (see Fig. 2 where the trajectory briefly crosses the dividing surface twice before making a true transition to state B). Neglecting these dynamical recrossings, the TST expression for Eq. (31) is

$$R_{A \to B}^{\text{TST}} = \frac{1}{2} \frac{\int_{\Sigma_{AB}} d\boldsymbol{q} \int d\boldsymbol{p} \ |v_n| \, e^{-\beta \mathcal{H}(\boldsymbol{q}, \boldsymbol{p})}}{\int_{\Omega_A} d\boldsymbol{q} \int d\boldsymbol{p} \ e^{-\beta \mathcal{H}(\boldsymbol{q}, \boldsymbol{p})}} = \langle |v_n| \, \delta_{AB}(\boldsymbol{q}) \rangle_A, \tag{33}$$

where $\Sigma_{AB}$ is a portion of the dividing surface separating A and B, $\Omega_A$ is a region in the configuration space (basin of attraction) associated with A, and $v_n$ is the velocity normal to the dividing surface. In the second expression, $\delta_{AB}$ is the Dirac delta, which is zero everywhere except on the dividing surface between A and B, and the subscript A indicates that the phase average is computed over $\Omega_A$. The TST rate defined in Eq. (33) is an equilibrium property of the system.

At low temperatures, the TST rate can be evaluated analytically by expanding the potential energy in the numerator about the saddle point configuration S and the potential energy in the denominator about A and applying the harmonic approximation (Sect. 2.3). The result is the famous Arrhenius equation that governs many physical processes:

$$R_{A \to B}^{\text{hTST}} = \nu e^{-\beta \mathcal{E}_a}, \tag{34}$$

where $\nu$ is an attempt frequency related to the curvatures at states A and S and $\mathcal{E}_a = \mathcal{V}(\boldsymbol{q}_S) - \mathcal{V}(\boldsymbol{q}_A)$ is the activation energy (the energy barrier for crossing from A to B across S).

## 4.2    Transitions in Hot-QC

As explained in Sect. 3.1, hot-QC is designed to reproduce equilibrium phase averages. As a result hot-QC simulations should exhibit transition behavior that is consistent with TST (since the TST rate itself is an equilibrium property as noted in Sect. 4.1). This is indeed correct provided that two conditions are satisfied (Kim et al. 2014):

1. All atoms significantly affected by the transition are inside the atomistic region.
2. The dividing surface can be approximated as a function of only atoms in the atomistic region.

Both assumptions are consistent with the basic hot-QC ansatz in Eq. (19) of limiting consideration to phase averages over degrees of freedom in the atomistic region. Under these conditions, it can be shown that

$$
\left( R_{\mathsf{A}\to\mathsf{B}}^{\mathrm{TST}} \right)_{\mathcal{V}} = \frac{1}{2} \frac{\int_{\Sigma_{\mathsf{AB}}(\boldsymbol{q}^{\mathrm{at}})} d\boldsymbol{q}^{\mathrm{at}} \int d\boldsymbol{p} \, |v_{\mathrm{n}}| \, e^{-\beta \mathcal{H}(\boldsymbol{q},\boldsymbol{p})}}{\int_{\Omega_A(\boldsymbol{q}^{\mathrm{at}})} d\boldsymbol{q}^{\mathrm{at}} \int d\boldsymbol{p} \, e^{-\beta \mathcal{H}(\boldsymbol{q},\boldsymbol{p})}}
$$

$$
= \frac{1}{2} \frac{\int_{\Sigma_{\mathsf{AB}}(\boldsymbol{q}^{\mathrm{at}})} d\boldsymbol{q}^{\mathrm{at}} \int d\boldsymbol{p}^{\mathrm{at}} \, |v_{\mathrm{n}}^{\mathrm{at}}| \, e^{-\beta \mathcal{H}^{\mathrm{QC}}(\boldsymbol{q}^{\mathrm{at}},\boldsymbol{p}^{\mathrm{at}})}}{\int_{\Omega_A(\boldsymbol{q}^{\mathrm{at}})} d\boldsymbol{q}^{\mathrm{at}} \int d\boldsymbol{p} \, e^{-\beta \mathcal{H}^{\mathrm{QC}}(\boldsymbol{q}^{\mathrm{at}},\boldsymbol{p}^{\mathrm{at}})}} = \left( R_{\mathsf{A}\to\mathsf{B}}^{\mathrm{TST}} \right)^{\mathrm{QC}}. \qquad (35)
$$

Thus TST rates in the QC system equal those in the fully atomistic system for transitions occurring in the atomistic region. This analytical result was verified numerically by Kim et al. (2014).

## 4.3    Accelerated Molecular Dynamics (Hyperdynamics)

Equation (34) provides guidance on how to increase transition rates in systems governed by TST; one can either decrease the activation energy $\mathcal{E}_{\mathrm{a}}$ or increase the temperature (i.e., reduce $\beta$). These two approaches are adopted in hyperdynamics (Voter 1997) and temperature-accelerated dynamics (Sørensen and Voter 2000), respectively. Here we focus on hyperdynamics.

Consider a system with positions $\boldsymbol{q}$ that is within the basin of attraction $\Omega_{\mathsf{A}}$ of state $\mathsf{A}$. To expedite the escape from this state, the true potential energy of the system $\mathcal{V}(\boldsymbol{q})$ is modified by the addition of a nonnegative "bias potential" $\Delta \mathcal{V}(\boldsymbol{q})$, such that

$$
\mathcal{V}_{\mathrm{b}}(\boldsymbol{q}) = \mathcal{V}(\boldsymbol{q}) + \Delta \mathcal{V}(\boldsymbol{q}), \qquad (36)
$$

in which

$$
\Delta \mathcal{V}(\boldsymbol{q}) = \begin{cases} > 0 & \text{if } \boldsymbol{q} \in \Omega_{\mathsf{A}}, \\ = 0 & \text{if } \boldsymbol{q} \in \Sigma_{\mathsf{A}}, \end{cases} \qquad (37)
$$

where $\Sigma_A$ is the dividing surface separating state A from surrounding states. (Methods for constructing bias potentials are discussed below.)

An MD simulation using $\mathcal{V}_b(\boldsymbol{q})$ in Eq. (36) will by design escape from state A more quickly than the original system with potential $\mathcal{V}(\boldsymbol{q})$. However, since the biased system has a different potential energy, it is in fact a different material. Why then would the results obtained with $\mathcal{V}_b$ be relevant to the original material? The key lies in the condition in Eq. (37) that requires $\Delta\mathcal{V}$ to vanish on the dividing surfaces. It is shown next that if this is satisfied, then the state-to-state dynamics of the original and biased systems will be the same. In other words, if both systems were simulated for a very long time, they would visit each state with the same relative probability, even though the dynamics within each state would be different. All of this holds only within the TST formalism (Sect. 4.1); thus the state-to-state dynamics of the biased and original systems *would* differ due to dynamic recrossings, an effect that becomes more pronounced with increasing temperature (Vanden-Eijnden and Tal 2005).

In order to prove the state-to-state dynamics assertion, recall the TST rate expression in Eq. (33). Separating the Hamiltonian into kinetic and potential contributions and multiplying the denominator and numerator by $\exp(+\beta\Delta\mathcal{V})\exp(-\beta\Delta\mathcal{V}) = 1$, the following relation is obtained:

$$R_{A\to B}^{TST} = \frac{1}{2}\frac{\int_{\Sigma_{AB}} d\boldsymbol{q}\int d\boldsymbol{p}\ |v_n|\ e^{-\beta(\mathcal{K}+\mathcal{V}+\Delta\mathcal{V})}e^{\beta\Delta\mathcal{V}}}{\int_{\Omega_A} d\boldsymbol{q}\int d\boldsymbol{p}\ e^{-\beta(\mathcal{K}+\mathcal{V}+\Delta\mathcal{V})}e^{\beta\Delta\mathcal{V}}} = \frac{\langle|v_n|\,\delta_{AB}(\boldsymbol{q})\rangle_{A_b}}{\langle e^{\beta\Delta\mathcal{V}}\rangle_{A_b}}. \qquad (38)$$

In the second expression, the subscript $A_b$ indicates a phase average on the biased PES. This expression follows from the first by dividing the numerator and denominator by the biased partition function restricted to state A:

$$\int_{\Omega_A} d\boldsymbol{q}\int d\boldsymbol{p}\ e^{-\beta(\mathcal{K}+\mathcal{V}+\Delta\mathcal{V})}.$$

Next, enforcing the condition in Eq. (37) that $\Delta\mathcal{V} = 0$ on $\Sigma_{AB}$ and rearranging, Eq. (38) becomes

$$R_{A_b\to B}^{TST} = \left\langle e^{\beta\Delta\mathcal{V}}\right\rangle_{A_b} R_{A\to B}^{TST}, \qquad (39)$$

where the definition in Eq. (33) was used. This result shows that the escape rate from the biased state $A_b$ is boosted by the exponential factor $\left\langle e^{\beta\Delta\mathcal{V}}\right\rangle_{A_b}$. (Since $\Delta\mathcal{V} \geq 0$, the boost is always greater or equal to one.) Further, considering two possible escapes, $A \to B$ and $A \to C$, the relative probabilities are preserved on the biased PES since

$$\frac{R_{A_b\to B}^{TST}}{R_{A_b\to C}^{TST}} = \frac{\left\langle e^{\beta\Delta\mathcal{V}}\right\rangle_{A_b} R_{A\to B}^{TST}}{\left\langle e^{\beta\Delta\mathcal{V}}\right\rangle_{A_b} R_{A\to C}^{TST}} = \frac{R_{A\to B}^{TST}}{R_{A\to C}^{TST}} \qquad (40)$$

This is the basis for the statement that state-to-state dynamics are preserved by the biased system (Voter 1997).

The remaining step is to relate the time scale of the biased system dynamics to the original system. For example, if the biased system escapes from a basin in 1 ns, what does this correspond to in the original system? This is a subtle question. To understand this, recall the TST definition of the average waiting time in Eq. (32). Using Eq. (39) and rearranging, the true waiting time is related to the biased waiting time by

$$\bar{t}_A^{wait} = \left\langle e^{\beta \Delta \mathcal{V}} \right\rangle_{A_b} \bar{t}_{A_b}^{wait}. \tag{41}$$

Converting from a phase average to the time average performed in an MD simulation, one can relate the MD time step of the biased system $\Delta t_{MD}$ to the corresponding boosted time step for the real system:

$$\Delta t_{boosted}^k = e^{\beta \Delta \mathcal{V}(\boldsymbol{q}^k)} \Delta t_{MD}, \tag{42}$$

where $k$ is the time step index and $\boldsymbol{q}^k$ is the corresponding atomic configuration. The stepwise definition in Eq. (42) will give statistics that are consistent with Eq. (41) (Voter 1997).

The key step in setting up and running a hyper-QC simulation is the construction of a bias potential that is zero on dividing surfaces (as stated in Eq. (37)) and provides good boost. In the original hyperdynamics method (Voter 1997), the lowest eigenvalues and corresponding eigenvectors of the Hessian were used to construct the bias potential. However, this approach can be computationally expensive. Later, a bias potential without significant computational overhead, called the "bond-boost method," was proposed by Miron and Fichthorn (2003). The bond-boost method is based on the increased changes in bond lengths that occur when a system makes transitions. In particular, a bias potential $\Delta \hat{\mathcal{V}}(e_n)$ can be defined in terms of the fractional bond length change, $e_n = |l_n - l_n^{ref}| / l_n^{ref}$, where $l_n$ is the bond length of the $n$th bond and $l_n^{ref}$ is the bond length in the reference configuration (usually taken as the potential energy minimum). The functional form $\Delta \hat{\mathcal{V}}(e_n)$ is selected to guarantee that if any $e_n$ exceeds a threshold value (which can be empirically estimated by preprocessing simulations), the total bias potential vanishes. Other bias potentials have been proposed including one which uses the hyperdistance from a reference configuration (Kim and Falk 2010) and a "mechanism-based bias potential" that makes use of the specific physics being modeled to obtain better boosts (Kim and Tadmor 2017).

## 4.4 Temporal Acceleration in Hot-QC (Hyper-QC)

The last step is to integrate hyperdynamics within the hot-QC framework to create the hyper-QC method. Adopting the conditions outlined in Sect. 4.2, it is straightforward to show that the hyperdynamics derivation carries over to hot-QC

with a bias potential that is a function of only atoms retained in the atomistic region (Kim et al. 2014):

$$\mathcal{V}_b^{QC}(\boldsymbol{q}^{at}; \beta) = \mathcal{V}^{QC}(\boldsymbol{q}^{at}; \beta) + \Delta\mathcal{V}^{QC}(\boldsymbol{q}^{at}; \beta). \qquad (43)$$

A hyper-QC simulation corresponds to doing MD with $\mathcal{V}_b^{QC}$. Analogous to standard hyperdynamics, hyper-QC preserves the original state-to-state dynamics of hot-QC under the TST assumptions (Kim et al. 2014). See Kim and Tadmor (2017) for a detailed discussion of the practical issues in setting up and performing hyper-QC simulations.

Hyper-QC was first applied to a one-dimensional system to verify the formulation (Kim et al. 2014). A chain of 1000 atoms undergoing a transition from a bonded state to an unbonded state at constant temperature was studied. The hyper-QC simulations exactly recovered the TST rates of the fully atomistic model, running 77 to 92 times faster in terms of computation time.

A hyper-QC application to nanoindentation of a face-centered cubic (fcc) nickel crystal is described in Kim and Tadmor (2017). The single crystal is of size $2000 \times 100$ Å with periodic boundary conditions corresponding to the minimal repeated distance of 4.31 Å applied in the out-of-plane direction. The indenter is cylindrical with a diameter of 100 Å. The hyper-QC model contains 6,135 repatoms, which represent a fully atomistic system of 79,461 atoms. The atomic interactions are modeled by an embedded atom method (EAM) potential (Zhou et al. 2004). A mechanism-based bias potential designed to accelerate slip events in fcc is employed.

Simulations were performed at three temperatures, $T = 100, 200$, and $300$ K, and indenter velocities ranging from $10^6$ to $10^2$ μm/s. Results for the critical force required to nucleate the first dislocation under the indenter are plotted in Fig. 3. A typical logarithmic dependence on the indenter velocity is observed, indicating that the dislocation nucleation is thermally activated. Based on this observation,

**Fig. 3** The indentation force at which the first partial dislocation nucleates as a function of indenter velocity at temperatures of 100, 200, 300 K. The straight lines are obtained from the Tomlinson-Prandtl model. (Reprinted with permission from Kim and Tadmor 2017)
a simple Prandtl-Tomlinson model is constructed (Tomlinson 1929; Gnecco et al. 2000; Tadmor et al. 2013). The predictions of the model are shown as the straight lines in Fig. 3. (In Fig. 3, the model was fit separately at each temperature, and a fit over all temperatures shows more scatter but is still good overall; see Kim and Tadmor 2017.)

The smallest indentation rate of $10^2 \, \mu$m/s achieved in the hyper-QC simulation is significantly lower than that attainable using hot-QC and is approaching experimental loading rates (see start of Sect. 4). This is possible due to speedups in hyper-QC ranging from 1000 (at $T = 300$ K) to 10,000 (for $T = 100$ and 200 K) compared with hot-QC. This speedup includes both the spatial coarse graining and temporal acceleration.

## 4.5   Other Approaches: Finite-Temperature CQC

The extension of QC to finite temperature, dynamics, and temporal acceleration described above (i.e., hot-QC and hyper-QC) is based on equilibrium statistical mechanics. A different approach is adopted in the CQC method. Based on the maximum entropy principle of Jaynes (1957a, b) and a mean field approximation (Kulkarni et al. 2008; Venturini et al. 2014), the finite-temperature CQC method seeks a probability distribution $\rho(\mathbf{q}, \mathbf{p})$ of the form:

$$\rho \propto \exp\left[ -\sum_{i=1}^{N} \beta_i \left\{ \frac{m_i \omega_i^2 ||\mathbf{q}_i - \bar{\mathbf{q}}_i||^2}{2} + \frac{||\mathbf{p}_i - \bar{\mathbf{p}}_i||^2}{2m_i} \right\} \right], \tag{44}$$

which maximizes the entropy functional $S$ defined as

$$\mathcal{S}[\rho] \equiv -k_{\mathrm{B}} \langle \ln \rho \rangle = -k_{\mathrm{B}} \int \rho \ln \rho \, dq \, dp. \tag{45}$$

The maximum is sought subject to local constraints, $\langle h_i \rangle = e_i$ $(i = 1, \ldots, N)$, where $e_i$ is regarded as the energy of atom $i$ observed on a macroscopic time scale. In Eq. (44), $\beta_i$, $\bar{\mathbf{q}}_i$, and $\bar{\mathbf{p}}_i$ are the local temperature, mean position, and mean momentum of atom $i$, respectively, and $\boldsymbol{\omega}$ are free parameters to be determined.

For a quasistatic process, $\bar{\mathbf{q}}$, $\bar{\mathbf{p}}$, and $\boldsymbol{\omega}$ are determined by maximizing the canonical free entropy $\Phi$ given by (Venturini et al. 2014)

$$\Phi(\boldsymbol{\beta}; \bar{\mathbf{q}}, \bar{\mathbf{p}}, \boldsymbol{\omega}) = -k_{\mathrm{B}} \sum_{i=1}^{N} \left[ \beta_i \left( \frac{||\bar{\mathbf{p}}_i||^2}{2m_i} + \langle V_i \rangle \right) - \frac{3}{2} + 3 \ln \left( \frac{\beta_i \omega_i}{2\pi} \right) \right]. \tag{46}$$

A Hamiltonian dynamics is postulated for the evolution of the mean positions and momenta $(\bar{\mathbf{q}}, \bar{\mathbf{p}})$ (Ponga et al. 2015, 2016):

$$\dot{\bar{\mathbf{q}}}_i = \frac{\partial \mathcal{H}_{\mathrm{ME}}}{\partial \bar{\mathbf{p}}_i}, \qquad \dot{\bar{\mathbf{p}}}_i = -\frac{\partial \mathcal{H}_{\mathrm{ME}}}{\partial \bar{\mathbf{q}}_i}, \tag{47}$$

where $\mathcal{H}_{\text{ME}}$ is the max-ent Hamiltonian:

$$\mathcal{H}_{\text{ME}} = -\sum_{i=1}^{N} \frac{1}{k_{\text{B}}} \frac{\partial \Phi}{\partial \beta_i}. \tag{48}$$

Next, an FE-based coarse-graining scheme is introduced to reduce the number of degrees of freedom using the fully nonlocal cluster-based summation method of Knap and Ortiz (2001).

In contrast to hot-QC, which is based on equilibrium statistical mechanics and assumes a system at constant uniform temperature, the finite-temperature CQC method can be applied to nonequilibrium systems with nonuniform temperature fields. As such, Eqs. (46) and (47) can be coupled with a phenomenological atomic-level heat conduction equation to determine $\beta$ (Venturini et al. 2014). Moreover, since the equations of motion are for the *mean* positions and momenta, where the short-time thermal vibrational modes are averaged out, the resultant trajectory will be smooth on microscopic time scales enabling much larger time steps than those used in conventional MD simulations (Ponga et al. 2015).

## 5    Concluding Remarks

The size of systems that can be simulated using fully atomistic MD continues to increase as computing power grows, with the current world record well above one trillion atoms (Germann and Kadau 2008). Given this, one may wonder regarding the need for accelerated continuum-atomistic methods that aim to reduce degrees of freedom and extend time scales in molecular simulations. There are several reasons why such methods remain of interest. First, as more complex materials are modeled, the computational expense of interatomic models greatly increases, dramatically reducing the size of systems that can be studied. This is the case for state-of-the-art reactive force fields, bond-order potentials, and machine learning-based potentials that are of current interest (Tadmor and Miller 2011). Second, without acceleration techniques, the time scales attainable in molecular simulations are typically very short leading to loading rates that are many orders of magnitude higher than experiments except under extreme conditions. Third, the reduction in computation time promised by the methods described in this article will make it possible to perform multiple simulations of a given system and thereby obtain uncertainty estimates in terms of the various physical and numerical parameters in the problem. Finally, there is the philosophical view that expending huge amounts of effort and energy to simulate the dynamics of trillions of atoms that are mostly obeying continuum field theories is not the best use of resources. The challenge lies in developing robust and predictive multiscale methods that are able to span multiple length and time scales and are applicable to a broad range of materials under both equilibrium and nonequilibrium conditions. These topics remain an exciting and ongoing area of research.

# Long-Timescale Simulations: Challenges, Pitfalls, Best Practices, for Development and Applications

# 38

Graeme Henkelman, Hannes Jónsson, Tony Lelièvre,
Normand Mousseau, and Arthur F. Voter

**Abstract**

In this chapter, we examine the practice of developing, implementing, and applying long-timescale simulation methods. In contrast to standard molecular dynamics, the performance, and sometimes the accuracy, of long-timescale atomistic methods can vary greatly from one application to another. Therefore, for the practitioners, it is particularly important to understand the strengths and weaknesses of the methods, in order to assess their respective potential for

specific problems, as well as maximize their efficiency. For the method developer, clearly assessing the challenges faced by current methods as well as the areas of opportunities for future development is paramount.

In the following, we present the opinion of five leaders in the field regarding best practices, challenges, and pitfalls in the use and development of such methods. Their answers both provide a roadmap to how best to approach the field and deliver insight into areas that need addressing in the future.

## Question 1: In your experience, what are the biggest challenges associated with extending the timescale of atomistic simulations? What pitfalls does one need to be aware of?

AFV: Biggest challenges: Low barriers, low barriers, low barriers! In general, the lowest barriers in a system may be substantially lower than the relevant higher barriers, those barriers one needs to surmount to reach the timescale of interest. In this case, although there may be good acceleration compared to direct molecular dynamics, the gap between the fast rates (low barriers) and slow rates (high barriers) might prevent observation of the desired very-long-time dynamics, because a huge number of the lower-barrier events need to take place before a high-barrier event occurs. Especially frustrating is when the lowest barriers are actually so low, relative to $k_B T$, that there is very little absolute acceleration.

The very worst case is "persistent low barriers," in which the system keeps visiting new states, and each of these new states has low-barrier pathways that inhibit acceleration. For a state that has been visited previously (especially if it was visited many times previously), accumulated information can be used to improve the performance on the revisit. This cannot be done very effectively on the first visit, however, so that for this type of system the acceleration will be very low.

For systems with a serious low-barrier problem, there is hope for being able to combine many states that are connected by low barriers into a single superbasin state. The quasi-static distribution (QSD) formalization of parallel-replica dynamics offers a framework for this kind of generalization. In some cases, we have been able to improve the boost substantially by using our understanding of the system to apply such an approach. So far, however, it has proved challenging to develop an automated approach to this problem, one that would work, e.g., for proteins.

NM: I totally agree with this problem. At one point, however, the low-barrier problem mixes with the configuration entropy problem. In the case of proteins, for example, many barriers have a significant entropic contribution, meaning that the transition state cannot be well described with a single point on the energy landscape.

In materials, where the problem is simpler, we have to consider two types of low barriers: those that do not evolve the system, which are generally referred to as flickers, and those that are an intrinsic part of the evolution. Distinguishing between those requires a deep knowledge of the problem. Moreover, it is not always possible to draw a clear line between the two.

For kinetic Monte Carlo (KMC), the main problem is that every time one leaves a basin, it becomes necessary to reconstruct it, which means a lot of effort for a relatively short time step. When barriers remain energy-activated, it is nevertheless

possible to see a solution where basins, incorporating multiple states separated by low barriers, are generated on a local basis and merged if needed. As long as those states are distinct, KMC is efficient. When this is not the case, however, one can get overloaded by the cost of rebuilding the basin.

AFV: Unfortunately, pitfalls also abound. For example, the shape of the bias potential in hyperdynamics is a very subtle problem. In hyperdynamics, one must take care to design a bias potential that is zero at all dividing surfaces, so that it does not "block" any pathways (i.e., slow them down). A problem is that there is typically not any obvious signature when a pathway is being blocked. In principle, one can check for a nonzero bias at a dividing surface for an escape mechanism that has been observed, but for a mechanism that has not been observed because the rate was slowed down too much, no such check can be performed – then the dynamics are just wrong.

Another pitfall is the high dimensionality of typical problems in materials. Our intuition can be easily misled by drawings in one or two dimensions when the real system is 3N dimensional. An example is the flat bias potential of Steiner, Genilloud, and Wilkins (1998), in which the potential energy is replaced with a flat potential for energies lower than some threshold, with this threshold chosen to be lower than the energy of the lowest saddle point bounding the state (picture a frozen lake in the mountains). In one dimension, or a few dimensions, this simple form of bias potential can indeed give good acceleration, and it is natural to think that this characteristic would persist to high-dimensional systems. However, it does not. Although it is a valid bias, because the bias is guaranteed to be turned off whenever the potential energy is higher than the lowest barrier, it is no longer an effective bias because the typical potential energy in a system with N atoms is roughly $3Nk_BT/2$, which for large N will be much higher than the threshold energy, so that the instantaneous boost is rarely turned on. This is difficult or impossible to draw in a one-dimensional diagram.

Another example of where our intuition can fail us in higher dimension is for a bias potential that is constructed from space-filling objects in a low-dimensional collective-variable space, as in an approach based on metadynamics, for example. Then, although the acceleration can remain large as N increases, the bias form itself may no longer be valid for hyperdynamics. This is because any reaction coordinate that is orthogonal to the collective variable space will be blocked. Thus, extreme care must be exercised.

NM: This problem is not limited to hyperdynamics. Methods such as ART nouveau and the dimer evolve the system through this high-dimension landscape to find saddle points. Yet, this search does not always work and, often, it is clear that the failure to find a saddle point is related to the structure of the energy landscape, a structure that is almost impossible to figure out given the high-dimensionality of the problem. Similarly, without a detailed knowledge of the energy landscape, it is not possible to ensure that these methods can find, even in principle, all connected saddle points.

HJ: In my opinion, the most basic pitfall is to assume some transition mechanism(s), some reaction coordinate, and base the time acceleration scheme on that assumption. This can lead to incorrect time evolution of the system. There is a

myriad of cases where the mechanism for atomic scale transitions turned out to be entirely different from what one might guess a priori. The simulation should show what the relevant transition mechanism is, and not rely on a preconceived notion of the mechanism. There are many schemes that are based on such preconceived notion, metadynamics being one of them that is used frequently. It is also important to realize that full free energy sampling using such an assumed reaction coordinate is not going to make up for a bad choice of the reaction coordinate. If the sampling is carried out in a subspace (e.g., hyperplane) that is not lined up with the transition state of the relevant mechanism, then no matter how much sampling is carried out, the deduced rate of the transition will be wrong and the simulated time evolution incorrect.

**Question 2: What are the main limitations of current methods and what needs to be done to address them?**

NM: There has been considerable development over the last two decades regarding accelerated methods. While they have opened up new regimes of physics that had been out of reach until now, significant challenges remain.

(I) Cost-effective accurate force fields. Long-time simulations in materials typically require relatively large systems, as following kinetics often implies displacement. Ab initio calculations being still limited to boxes of 1000 atoms or less, they cannot be used directly in these simulations. For lattice-based atomistic KMC methods, it is possible to construct an event catalog using small cells and density functional theory (DFT). Yet, for complex systems with significant deformations or a large number of configurations, even catalog building becomes too costly with ab initio. When dealing with elemental systems, especially pure metals, empirical potentials can offer a decent level of precision. These potentials cannot be relied upon, however, for conformations far away from the close-packed states, in the presence of many elements or when considering semiconductors, magnetic elements, etc. Over the last decade, statistical-derived potentials, using neural networks or other automatic learning methods, have shown significant promise. There is still work to be done, however, before these methods can be used regularly. Moreover, these new approaches remain very costly, limiting their application.

(II) Entropic effects. KMC methods, whether off-lattice or lattice-based, are effectively run at zero K. Most of the time, entropic contributions are included through a constant prefactor that supposes that the local environments remain relatively similar throughout the simulation. Some groups go beyond this simple approximation and evaluate the local entropic contributions for each environment using the harmonic approximation of transition state theory (TST), which supposes a temperature-independent prefactor, an approximation also made in temperature accelerated dynamics (TAD), one of the accelerated MD (AMD) approaches. Yet, this is not always valid. For example, an atom moving in a three-vacancy cluster in an FCC metal forms a tetrahedral vacancy cluster centered around an atom, a structure stable at high temperature. As it turns out, this structure is very unstable at low temperature, although it exists. In Ni, this state is at an energy 0.4 eV above ground state, separated

from it by a barrier of only 0.08 eV. Its stabilization at high temperature is clearly due to an increase in thermal vibrations that prevent the atom from moving back into its original position, a feature that might not be captured by the harmonic approximation (S. Mahmoud, et al., Acta Materialia (in press)). It is therefore likely necessary to go beyond the harmonic approximation with thermodynamic integration methods that can be automated.

(III) Going beyond TST. Most accelerated methods rely on TST at some level. There is a need to work on this theory and see how one can expand it to complex systems without having to use the heavy tools developed in systems dominated by entropy, such as transition path sampling.

(IV) Handling flickers and energy barrier distributions efficiently. In spite of considerable advances over the last years, handling systems with a wide distribution of relevant barriers remains a challenge. Yet, following the evolution of a grain boundary, the formation of a nanostructure, or the aging of a multicomponent glass, involves working with continuous energy distributions.

(V) A more efficient cataloging. Recognizing local environments, whether using KMC or MD-based methods is an essential part of recycling previous efforts. Over the years, a number of approaches have been proposed – geometrical, lattice-based, and topological. Yet, all of them suffer from some limitations that decrease the recycling. There is a need to carefully study this aspect and identify methods that are flexible, can be applied to wide range of environments, provide useful comparison, and facilitate the reconstruction.

HJ: Current methods are mainly based on the identification of local minima on the potential energy surface (with the exception of parallel replica dynamics, though even there, in practice, states are often defined in terms of local energy minima). There is a large set of problems, where entropy plays a central role and energy barriers are small and numerous. The definition of states needs to be more in terms of subspaces where the system spends enough time to locally equilibrate and for which the time evolution can be described as a Markov chain. Full TST, as opposed to the harmonic approximation to TST, coupled with the variational principle can, I believe, deal with these kinds of systems, the problem is coming up with an efficient algorithm for representing and optimizing the dividing surface that defines a state. Very little work has been done on this so far. Is it timely now to give it a try?

TL: I think that in some sense, AMD methods can be seen as a way to go beyond the TST, especially parallel replica dynamics or parallel trajectory splicing. Indeed, the decorrelation step is a way to check if first order kinetics can be applied to model the exit event, and then, these algorithms do not require knowledge of the exit rates. However, the efficiency in parallel replica is limited by the decorrelation time within the state. Parallel trajectory splicing is a nice idea to overcome this problem, but we need to think more about algorithms that are able to exploit massively parallel machines.

AFV: Normand, Tony, and Hannes make good points. As discussed under question 1, in my mind the main limitation of the methods is how hard it is to get

good acceleration for systems with persistent low barriers. Although some progress has been made on this front by various groups, I have been surprised by how difficult this challenge has remained. Ever greater cleverness will be required.

Amplifying Normand's point on the difficulty in using electronic structure forces, although in principle AMD methods can be used as easily with an expensive first-principles force call as it can with an empirical potential, in practice this may be far from the truth. For electronic structure forces, it may take so much computer time to advance the dynamics that the system will still be in its initial state when the computer budget runs out. In this situation, while formally the boost factor may be high, if the system has not yet jumped to a new state, the effective boost factor is zero.

**Question 3: Are there specific issues or challenges associated with applying these methods as opposed to their development? What could be done to further their widespread adoption?**

GH: Echoing Normand's point above, perhaps the most important challenge associated with a more widespread application of accelerated methods is that they cannot, at present, be used with standard DFT. There is an enormous community of scientists using DFT to model dynamics in chemical and material science applications, but we have not provided accelerated methods which are sufficiently efficient to be used routinely with energies and forces from DFT. While current methods can be based upon empirical potentials, for example as implemented in parallel codes such as LAMMPS, there are a vanishingly small number of applications for which we have accurate potentials as compared to those which can be described by DFT.

Some of the problem, I believe, can be attributed to the electronic structure community, which puts a greater emphasis on the accuracy of each energy calculation rather than an accurate sampling of configuration space. Recent developments of surrogate models, including those based upon machine learning, have the potential to change this bias if sampling could be done at a fraction of the cost of DFT. Additionally, there is a potential application for more approximate methods which can be used directly with DFT. Regardless of which direction the connection is made, either more approximation and efficient methods or more approximate and efficient potentials, providing tools in a form which can be used directly by the community of people running DFT calculations is key to their widespread adoption.

TL: I have the feeling that one of the major difficulties when applying AMD techniques in a general setting is the definition of good metastable states. It would be great to be able to define automatically or adaptively (as the simulation runs) good metastable states. These metastable states should be such that:

(I) The time to leave these states is much larger than the time to reach local equilibrium (quasi-stationary distribution QSD), for a generic initial condition obtained when entering the state.

(II) The discrepancy between the transition rates associated with these states is not too large (otherwise the algorithm spends much of the time switching over low barriers).

(III)  The states give a reasonable description of the macroscopic state of the system (since the details of the dynamics within states are lost).
(IV)  There is a way to estimate the convergence time to local equilibrium faithfully.

The list is rather long, but one could think of using modern statistical techniques to extract from the trajectories "good" states. The fact that these states do not need to define a partition of the state space could be used to make the construction easier. This is very much related to discussions about choosing good reaction coordinated or collective variables, which is obviously a difficult question, but the interest of AMD methods is that even if some of the states are not really well chosen, the methods can still give reliable results, e.g., with parallel replica dynamics.

AFV: I have been somewhat surprised that effective application of the AMD methods seems to require serious dedication on the part of the user. In essence, the user must become an expert; this takes time, and some users become discouraged before reaching this stage. Further automation of the methods, as discussed above, should help, and we may achieve this in the future, so that for a nonexpert user, applying an AMD code could be a "turnkey" operation.

NM: In addition to the challenges already mentioned, with which I totally agree, I would add that the current accelerated methods, based on high energy barriers with respect to $k_B T$, are restricted to solids well below melting. This is a considerable limitation as it prevents us from looking at molecules in solvent, including biomolecules, many catalytic and growth processes and a number of other fundamental questions. Overcoming this limitation is not impossible but it will require rethinking the approach and, more important, reworking TST.

HJ: Transition state theory actually works fine in cases where the free energy barrier is mainly of entropic origin. The effusion through a hole in a cavity is a nice example of how TST can give exact results even where there is no energy barrier. What is missing, however, is an efficient implementation of full TST where the dividing surface is systematically optimized (using the variational principle) to obtain the free energy barrier and thereby the mechanism(s) of the transition. But, I want to emphasize that I agree with all that has been written here above.

**Question 4: In developing or applying an approach, what are the best practices you recommend?**

HJ: The first rule is to have one or more test problems that are simple enough or well enough established so that the answer that should be obtained from the calculation is known. For example, when testing a method for estimating a transition rate, choose a system where the energy barrier is low enough and the temperature high enough that relatively long, but not too long, simulations of the dynamics using basic equations of motion can be used for comparison. When finding saddle points, use a test system where the energy surface can be visualized and the search path illustrated. Also, when it comes to implementation of a previously developed approach, do a calculation on a system that has been studied with the method previously and where the performance has been documented. Here, the web site OptBench.org is of great help. There, various benchmark problems have

been documented and the performance of various methods reported by experts. There are too many articles in the literature where performance of a method is reported but the implementation is not optimal. It is important to compare performance reported by those who developed or are knowledgeable about the method.

The challenge in atomic scale simulations is typically the large number of degrees of freedom. While a system with only a few degrees of freedom can be valuable to test and illustrate a method, performance should not be measured with application to such systems. A method that works well for a system with only a few degrees of freedom may not work well for a realistic system with many degrees of freedom. The opposite can also be the case. It is important to document performance on challenging systems for which the method has been developed.

When documenting performance, it does not make sense to report CPU time. Computers change rapidly and such information is quickly obsolete. Identify the most computationally intensive operation and report the number of such operations needed to reach the desired results from the simulation. In most simulations of atomic scale systems, the evaluation of the energy and atomic forces is the most computationally intensive operation. A natural measure of computational effort in calculations of transition rate, identification of a reaction mechanism or a saddle point search is the number of times the energy and force needs to be evaluated.

It is also important to keep focus on the ultimate goal of the calculation, not intermediate steps. The question whether an approach is useful and how large the computational effort is should be answered by evaluating the quantity of interest.

Performance in terms of computational effort is of course not the only criterion for evaluating the appropriateness of a method. A method that is not reliable in that the answer obtained cannot be trusted is not useful even if it is fast. The results obtained using a fast method should be compared with results obtained using a slower but safer method on a range of problems similar to the application of interest.

GH: The points raised, including the recommendations to compare new methods to existing methods through benchmarks and the strategy of developing methods on model system with known results and then demonstrating how well they work in complex high dimensional systems are spot-on. Adopting these recommendations as best practices would benefit the community of method developers and the people who aim to apply the methods. An additional recommendation, which is gaining traction in the community, is that computational methods that are developed in the public domain should be made available in the form of open source code. There are many details associated with computational methods which are not easily described in publications. To make our methods transparent and our calculations reproducible, other developers and users should be able to see the algorithms at the level of the source code and reproduce published results and benchmarks directly from the code. The adoption of an open-source policy for computational material science is, in my opinion, encouraging collaboration in the field and facilitating the development of computational frameworks that are larger than the scope of a single research group, such as the Materials Project.

Finally, I think that there is an opportunity in the field to consider how computational methods compare with respect to more than one objective. Taking the example of modeling molecular dynamics over long timescales, for example, we have efficient methods based upon harmonic transition state theory (e.g., temperature accelerated dynamics and off-lattice kinetic Monte Carlo), which have the inherent limitations associated with that approximation, and other methods for which the harmonic approximation is relaxed (e.g., parallel replica dynamics and hyperdynamics), that may have additional computational costs. What is not typically considered is the pareto-optimal set of methods which can deliver the highest accuracy for the minimum computational cost. In other words, the community of developers can establish a set of tools which can most efficiently accelerate dynamics for a specified level of accuracy. There is similar multiobjective optimization problem between the accuracy of the energy and force evaluations (e.g., empirical potentials vs. density functional theory) and the degree to which the energy landscape can be sampled. Research groups that focus on the accuracy of electronic structure calculations can neglect the potential importance of exploring the energy landscape. On the other hand, a focus on highly accurate sampling will typically put little emphasis on the accuracy of the potential landscape. A set of efficient methods for modeling dynamics or sampling potential surfaces targeting a wide range of available sample sizes would facilitate the use of methods such as accelerated dynamics for the large community of scientists modeling systems of interest with density functional theory.

AFV: Graeme and Hannes have covered this well; I will add just a few general points. As with any careful computational work (or any careful science for that matter), one should always be on the lookout for indications that something is not working correctly or not making sense. This is especially important for simulation methods that are capable of giving results for timescales that cannot be reached in any other way. For example, perhaps there is a nonlinearity that only causes significant inaccuracy at very large boost factors, which means it might not show up until the simulated timescales are beyond what can be checked with MD.

Although I think most readers of this chapter will already understand this, there is a general principle I feel is important for developing any method of this type – a method that is tied to an interatomic potential and that attempts to improve the efficiency of the simulation of a physical, material, or chemical property. When testing the method, the accuracy should be gauged by how well the method reproduces accurate simulation results for that same interatomic potential, *not* an experimental result. For long-time dynamics methods, the correct reference is direct molecular dynamics, and the benchmark systems must be chosen with some care, as MD may not be capable of directly reaching the long timescales (as Hannes pointed out).

Finally, on this issue of common codes, while I agree that standard software packages make development faster and easier than ever, one should absolutely not be afraid of developing one's own code from scratch. This can take longer, but sometimes it opens possibilities for creativity in the development that would be steered in a different direction, or inhibited, by using existing packages. Moreover,

the developer typically gains a deeper understanding of the methodology by proceeding in this way. And standard codes are not totally bug- or mistake-free, so the developer may uncover such problems by having a redundant code with which to compare, thereby doing the community a favor.

NM: Previous advice is excellent and I agree with all those. Developing methods is a risky business. It is generally impossible to tell how well it will perform on realistic systems before the method is in place. For a method to be useful, it has to be beyond what is available, either by doing faster or allowing access to new regimes of physics. This is why, I would also suggest that you make sure that the method that you are developing can go beyond what other approaches can do by applying it, as soon as possible, on nontrivial problems. So: yes, do check on simple systems that can allow you to compare results with other approaches, but make sure that also apply your algorithm to something nontrivial that demonstrate the interest of your method; too many methods are demonstrated on simple well-understood systems but have failed to produce any new significant physics.

It is also worth remembering that few computational physicists today write extensive codes. Most will use standard packages and write analysis or extension bits. If your algorithm has any degree of complexity, it is therefore essential that you write a code that is portable and useable by others, if you want your approach to gain exposure and have the impact you expect. This means that your code should be easy to read, modular, and adaptable. Be aware of this requirement from the day you start planning your software; this will decrease the time you will have to spend getting your code ready for distribution.

TL: Let me make two points along those lines. First, I would like to mention here that it is actually very difficult for nonspecialists to have access to test problems which are simple enough to have reference values, but not considered overly simple by the applied community. It would be very useful for the development of new approaches to agree on a sequence of test problems with graded difficulty, where the problem would be only a timescale problem (and not a modeling problem related to the force field for example). Second, when very long timescales are reached, weird results may be observed because of two reasons: (i) the algorithm gives incorrect estimates or (ii) the model is incorrect. Concerning the second item, notice indeed that many force fields have been parameterized and checked using only short-timescales simulations: when looking at very long trajectories, one is thus visiting unexplored territories. In such situations, it is very important to have rigorous ways to assess the quality of the numerical results in order to distinguish between the two sources of errors. This shows the importance of deriving certified error bounds for such algorithms (which is indeed sometimes a challenge!).

**Abstract**

Spanning over a wide range of length and time scales, magnetism is one of the most fascinating states of matter and one that poses many challenges to theory. Here we briefly review how different state-of-the-art approaches to the modeling of the magnetic order interface with each other and provide a complete toolset to explore this fascinating area of condensed matter theory. Methods include accurate quantum-mechanical approaches, such as density functional theory both in its static and dynamical version, atomistic spin dynamics tools, and continuum models to be solved in a finite difference framework.

## 1    Modeling Magnetism

Magnetism is one of the most fascinating macroscopic orders of matter. It is deeply rooted in quantum mechanics and spans over many different scales in time, space, and energy (see Fig. 1). At its core magnetism is based on the $m$-$J$-$\kappa$ paradigm. The Hund's coupling is responsible for the formation of the magnetic moment, $m$, often localized close to the atomic nuclei. This is active in open shell ions; hence

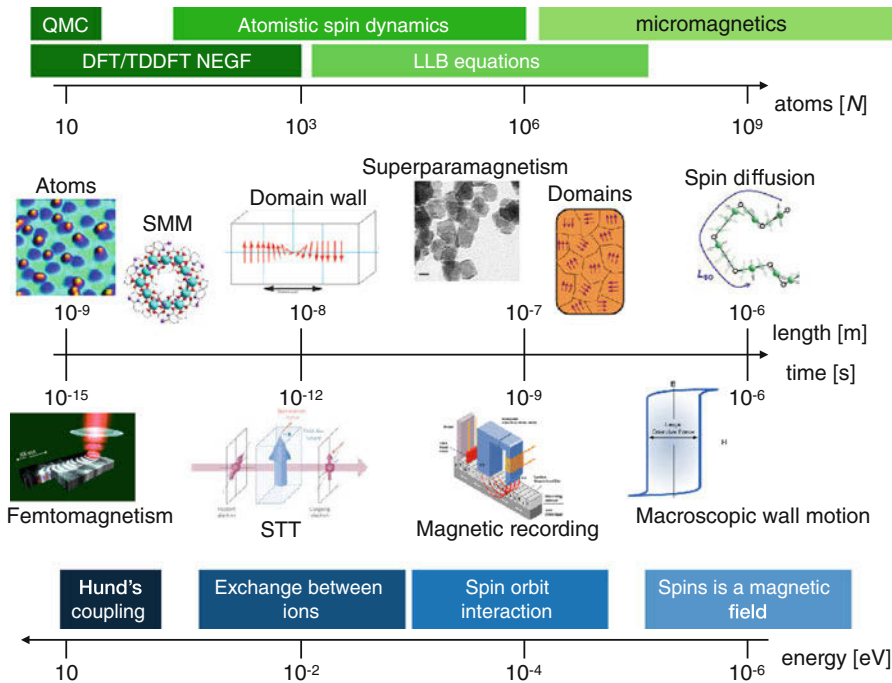

**Fig. 1** Length, time and energy scales of magnetism. At the atomic level, the high-energy Hund's coupling is responsible for the formation of the local moments, which are then coupled to each other through exchange interaction. Finally, magnetic anisotropy aligns the moment along particular directions in space. The computational tools needed to explore and explain magnetism range from quantum mechanics-rooted methods, such as density functional theory (DFT) and Quantum Monte Carlo (QMC), to atomistic spin dynamics, and to effective theories allowing large-scale coarse graining, such as the Landau-Lifshitz-Bloch (LLB) and the micromagnetic approach

$m$ forms in $2p$ radicals, among the elements in the $3d$ period, in rare earths and some $4d$ ions. Then the exchange interaction, $J$, makes the moments interacting with each other. At the microscopic level, a large variety of mechanisms is active in generating $J$ at both sides of the metal/insulator boundary. These range from direct exchange to ion-mediated mechanisms and to those where the magnetic interaction is mediated by free electrons. Finally, the magnetic anisotropy, $\kappa$, is responsible for the interplay between spatial and spin degrees of freedom and ties the local moment to specific directions in space. The anisotropy, at the atomic level, is determined by the spin-orbit coupling.

The interplay and competition among the different interactions participating to the $m$-$J$-$\kappa$ paradigm guide the formation of a multitude of magnetic orders. Locally exchange and anisotropy contribute to establish an alignment among the local moments, thus that often a microscopic order emerges. In simple cases, this can have the same periodicity of the crystal unit cell, but most frequently the crystal and magnetic cells are different. Then, classical magnetostatics imposes the formation

of macroscopically ordered regions (domains), separated by others where the order changes (domain walls). Symmetry breaking, for example through the presence of a surface, introduces additional complexity. In general the exchange and anisotropy get altered and, as a result, so does the macroscopic order.

Excitations of different energy can tip the various interactions and probe magnetism over many time scales. Intense, femtosecond-long, laser pulses interact directly with the electronic degrees of freedom (femtomagnetism). At this energy and time scale, the Hund's coupling, the exchange interaction, and the magneto-crystalline anisotropy are all functions of time, and the short-time dynamics is determined by their evolution. As time passes, the most energetic of the interactions, the Hund's coupling, returns $m$ to its ground state value, meaning that the local moment recovers first. The dynamics is then determined by electronic currents interacting with local spins via exchange interaction. The same dynamics can also be engineered by passing spin-polarized electrical currents through magnets of various order. This is the realm of spin-transfer-torque devices. Now the exchange and the anisotropy are perturbed, and the magnetic order can be manipulated, both locally and globally. The energy scale of this phenomena is lower than that needed to alter the local moment, and the typical times vary between picoseconds and nanoseconds. In the slower limit of this range operates magnetic data storage technologies. Finally, when the dynamics is governed by macroscopic domain walls motion, magnetism slows down further, the exchange interaction becomes constant, and the time scale may approach the macroscopic range.

It is then clear that magnetism is both an atomic and a macroscopic phenomenon, and as such, it necessitates computational tools spanning a broad range of time and length scales. This chapter wishes to provide a map of the theoretical methodologies used to date to describe and understand the magnetic interaction.

At the atomic level, density functional theory (DFT) is usually the theory of choice, since it can describe all the interactions on the same footing and does not require any parameters from experiments. DFT for magnetism will be reviewed in ▶ Chap. 42, "Density Functional Theory for Magnetism and Magnetic Anisotropy" by Bihlmayer, while Friedrich, Müller, and Bluegel in ▶ Chap. 43, "Spin Excitations in Solid from Many-Body Perturbation Theory" will present how it can be applied to the description of magnetic excitations. Beyond-DFT methods usually require computational resources significantly larger than DFT itself. However, in some cases, they provide a more accurate description of both the moment formation and the exchange. Recent progress in Monte Carlo technique for $d$ and $f$ ions will be reviewed by Wagner in ▶ Chap. 46, "Quantum Monte Carlo for Electronic Systems Containing $d$ and $f$ Electrons". Finally, the DFT description of magnetism can be extended to time-dependent phenomena, as discussed by Elliott and co-workers in ▶ Chap. 40, "Time-Dependent Density Functional Theory for Spin Dynamics", and to open systems in the presence of a steady-state current, as described by Rungger and collaborators in ▶ Chap. 44, "Non-equilibrium Green's Function Methods for Spin Transport and Dynamics".

The next level of description is obtained by neglecting an explicit description of the electronic degrees of freedom. Namely, one can represent a magnet by

using local spins of constant magnitude associated to each atom. This provides an atomistic view of spin phenomena, at a course-graining scale analogous to that used in classical molecular dynamics for the ionic motion. These methods, reviewed by Ma and Dudarev in ▶ Chap. 47, "Atomistic Spin-Lattice Dynamics", can describe magnetic phase transitions for systems including up to several millions atoms and require parameters extracted either from experiments or from DFT calculations. Intriguingly, the interplay between the spin and the vibrational degrees of freedom can be described on the same footing. One can then integrate the dynamics over larger regions of space and move to a continuous description. This is the domain of micromagnetic methods, which allow to reach time and length scales approaching the macroscopic limit. The foundation of micromagnetic theory and and its connection to spintronics are discussed by Abert in ▶ Chap. 45, "Spintronics in Micromagnetics". In its most conventional form, only the transverse component of the magnetization can vary, while its longitudinal part is constant. However, a formalism based on the Landau-Lifshitz-Bloch equations allows to go beyond this approximation. Such range of methods is presented by Chubykalo-Fesenko and Nieves in ▶ Chap. 41, "Landau-Lifshitz-Bloch Approach for Magnetization Dynamics Close to Phase Transition".

## 2 Conclusion

We have briefly reviewed the state of the art in the modeling of the magnetic order both in the static and time-dependent domains. This develops over a range of computational schemes capable of bridging many length and time scales. In particular we have discussed the approximations that allow one to connect the various levels of theory, where a progressively smaller number of degrees of freedom are treated explicitly. Such a body of work gives us a complete toolset to tackle this fascinating area of materials science.

**Abstract**

With the development of ultrashort sub-picosecond laser pulses, the last two decades have witnessed the emergence of a new field of magnetism, namely, femtomagnetism. This consists of controlling the magnetic interactions by using purely optical stimuli at sub-picosecond timescales, where both the exchange interaction and the magnetic anisotropy cannot be considered constant. The modeling of such phenomena is at present populated by semiempirical theories, which heavily rely on assumptions about the dominant interactions responsible for the dynamics and the system intrinsic properties (e.g., the conductivity). However, in the last few years, there have been a few attempts to look at the problem from a purely ab initio point of view, namely, by using time-dependent density functional theory. Here we will review the progress in this field and show how a theory not biased by assumptions can shed light into the fundamental aspects of the laser-induced magnetization dynamics. In particular we will discuss the ultrafast demagnetization of transition metals both in their cluster and bulk form and the possibility of spin transfer between sublattices in compounds containing magnetic ions. The chapter is also complemented by a short review of time-dependent spin density functional theory in the context of spin dynamics.

# 1    Introduction

In 1996 it was first demonstrated that an intense laser pulse could generate ultrafast light-induced demagnetization (in Ni), with typical demagnetization times faster than a few picoseconds (Beaurepaire et al. 1996). Recently, these spin-manipulation times have been reduced to a few femtoseconds, owing to the great advances made in the production of short-time laser pulses. As the control of spin moments by light may strongly impact several technological applications such as magnetic storage, spintronics, all-optical switching, heat-assisted magnetic recording, just to name a few, the field of femtomagnetism has recently become intensively active. To date several experimental methods are available to study magnetism at high speed. These include THz emission (Kampfrath et al. 2011; Walowski and Münzenberg 2016), time-resolved X-ray circular dichroism (Stamm et al. 2007; Boeglin et al. 2010), and high harmonic generation (La-O-Vorakiat et al. 2009).

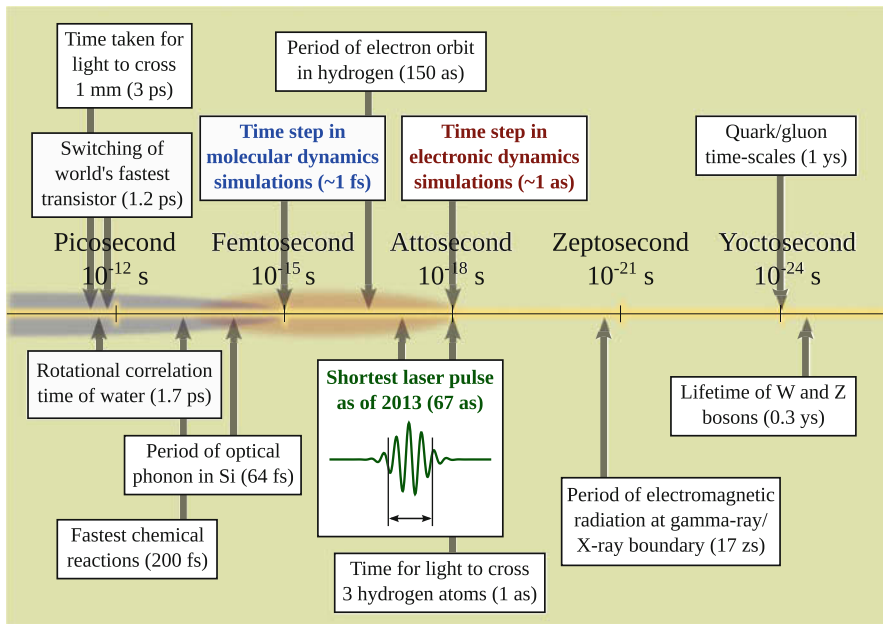
Femtomagnetism has two ultimate goals: (i) to understand the physics of light-induced spin dynamics and, on this basis, (ii) to manipulate the spin in a fully controlled manner using designed materials and/or tailored laser pulses. However, a complete understanding of the underlying physics of light-induced spin dynamics is hard to reach. In fact, since there is not strong direct coupling between light and spins, laser-induced spin dynamics is an indirect phenomenon, driven by spin-charge and spin-lattice interactions. A variety of distinct and simultaneous physical mechanisms thus underpins the observed magnetization dynamics. Some of these, such as interatomic spin transfer or spin-flips, begin early after the laser pulse, while other processes such as spin canting, spin currents (spin diffusion), or spin-lattice-induced spin-flips make significant contributions only at a later time (Fig. 1).


**Fig. 1** Comparison of timescales for sub-nanosecond physical phenomena, where we have also included the characteristic times for time-dependent molecular and electronic dynamics

Disentangling these processes and identifying the relevant timescales are among the first outstanding challenges of this field.

## 2    Models of Ultrafast Spin Dynamics

There have been several distinct attempts at explaining optically induced spin dynamics. At the thermodynamical level, three-temperature models (3TMs), which assume the ultrafast demagnetization to be a thermal process, are widely used (Beaurepaire et al. 1996). For times earlier than picoseconds, the magnetic system cannot be considered in thermal equilibrium with electrons and phonons. The laser-induced initial hot electron distribution initiates spin dynamics, which is driven by a spin temperature different from the electronic and lattice ones. Thus the electronic and lattice degrees of freedom act as energy reservoirs for the spin system. From a practical point of view, one solves three coupled differential equations representing the electronic, spin, and lattice dynamics. The demagnetization then crucially depends upon the coupling strengths between the three subsystems, coupling strengths that remain free parameters. Fitting is performed against experimental data usually with good success (Vodungbo et al. 2012; Ostler et al. 2012).

At the dynamical level, there is a vast range of approaches depending on the material type and conditions. These include lattice models using the Landau-Lifshitz-Gilbert equation with effective magnetic fields and damping parameters (Kazantseva et al. 2008) and direct spin-photon interaction models derived from

a lower-order nonrelativistic expansion of the Dirac Hamiltonian (Hinschberger and Hervieux 2012; Jean-Yves Bigot and Beaurepaire 2009). This type of description usually neglects many-body electron-electron interactions by assuming that during the application of the laser pulse, the demagnetization process occurs through the interplay between the spin-laser and spin-orbit interactions.

When electron transport takes place, the Elliott-Yafet mechanism describes scattering-induced spin-flips (Koopmans et al. 2010) modulated by phonons, which may lead to a global momentum loss. The speed of such demagnetization process is, however, bound to the slow lattice dynamics and hence cannot be used to explain early-femtosecond ($\sim$10–20 fs) demagnetization. The super-diffusive spin-transport mechanism (Battiato et al. 2010) instead completely neglects spin-orbit coupling (SOC) and relies on spins diffusing away and thus causing a local reduction in the material moment. These assumptions are controversial, and the literature is populated by experimental results confirming them (Vodungbo et al. 2012) and others contesting their validity (Schellekens et al. 2013).

## 3    Why Time-Dependent Spin Density Functional Theory?

Given the wide range of theoretical approaches and the uncertainty over their assumptions and range of validity, it is desirable to look into an ab initio method to describe ultrafast spin dynamics. Time-dependent density functional theory (TDDFT) is an in-principle exact approach for calculating electron, and thus spin, dynamics induced by external fields. It builds on ground-state (GS) density functional theory and has been successfully applied in the linear-response regime. We will first review the basic foundations of TDDFT before detailing several recent applications of TDDFT to spin dynamics. For simplicity we will introduce TDDFT for the spin-unpolarized case and use atomic units throughout unless otherwise specified.

### 3.1    Basic TDDFT Concepts

We begin with the nonrelativistic time-dependent Schrödinger equation:

$$i \frac{\partial}{\partial t} \Psi(\mathbf{r}_1, \mathbf{r}_2 \ldots \mathbf{r}_N, t) = \hat{H}(t) \Psi(\mathbf{r}_1, \mathbf{r}_2 \ldots \mathbf{r}_N, t), \qquad \Psi(t_0) \text{ given,} \qquad (1)$$

which governs the dynamics of $N$ electrons, starting from a given initial state, $\Psi(t_0)$, and under the influence of a time-dependent Hamiltonian, $\hat{H}(t)$. In the spatial representation, the Hamiltonian is written as

$$\hat{H}(t) = \sum_{i=1}^{N} \left[ -\frac{1}{2} \nabla_i^2 + v_{\text{ext}}(\mathbf{r}_i, t) \right] + \frac{1}{2} \sum_{i \neq j}^{N} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}, \qquad (2)$$

where the first term is the kinetic energy, the last is the electron-electron interaction, and $v_{ext}(\mathbf{r}, t)$ is the time-dependent external potential, which contains both the electron-nuclear interaction and any external electric fields (e.g., a laser pulse). The time-dependent one-electron density is defined as

$$n(\mathbf{r}, t) = N \int d^3 r_2 \ldots \int d^3 r_N |\Psi(\mathbf{r}, \mathbf{r}_2, \ldots \mathbf{r}_N, t)|^2 . \tag{3}$$

TDDFT is based on the Runge-Gross (RG) theorem (Runge and Gross 1984), which proves that the knowledge of $n(\mathbf{r}, t)$, rather than the full wavefunction, is sufficient to determine all the observables of the system. The RG theorem states that, if two time-dependent Taylor-expandable (around the initial time $t_0$) external potentials, $v_{ext}(\mathbf{r}, t)$ and $v'_{ext}(\mathbf{r}, t)$, differ by more than a purely time-dependent function, then the associated time-dependent densities, $n(\mathbf{r}, t)$ and $n'(\mathbf{r}, t)$, evolving from a common initial state, must be different. In other words, there is a one-to-one mapping between the density and the external potential and hence all the observables.

The proof of the RG theorem is split into two parts. First we consider the difference $\Delta\mathbf{j}(\mathbf{r}, t) = \mathbf{j}(\mathbf{r}, t) - \mathbf{j}'(\mathbf{r}, t)$ between two current densities evolving in the potentials $v_{ext}(\mathbf{r}, t)$ and $v'_{ext}(\mathbf{r}, t)$, respectively. The time evolution of this difference is

$$\left.\frac{\partial \Delta\mathbf{j}(\mathbf{r}, t)}{\partial t}\right|_{t=0} = -n_0(\mathbf{r})\nabla\Delta v_{ext}(\mathbf{r}, 0) , \tag{4}$$

where $\Delta v_{ext}(\mathbf{r}, 0) = v_{ext}(\mathbf{r}, 0) - v'_{ext}(\mathbf{r}, 0)$ and $n_0(\mathbf{r})$ is the initial density (which is the same for both systems due to the common initial wavefunction). Equation (4) was derived by inserting the paramagnetic current density operator:

$$\hat{\mathbf{j}}_p(\mathbf{r}) = \frac{1}{2i} \sum_{j=1}^{N} \left[\nabla_j \delta(\mathbf{r} - \mathbf{r}_j) + \delta(\mathbf{r} - \mathbf{r}_j)\nabla_j\right] , \tag{5}$$

into the Heisenberg equation of motion. At this point, we make use of the restriction to the class of external potential, which are Taylor expandable around the initial time, $t_0$, namely:

$$v_{ext}(\mathbf{r}, t) = \sum_{j=0}^{\infty} \frac{1}{j!} v_j(\mathbf{r})(t - t_0)^j , \tag{6}$$

where $v_j(\mathbf{r})$ are the Taylor coefficients of this expansion. If $v_{ext}(\mathbf{r}, t)$ and $v'_{ext}(\mathbf{r}, t)$ differ by more than a time-dependent constant, then there must be some order, $k$, at which the Taylor expansion coefficient of $\Delta v_{ext}(\mathbf{r}, t)$ is not a constant

$$u_k(\mathbf{r}) - u'_k(\mathbf{r}) = \left. \frac{\partial^k}{\partial t^k} \left[ v_{\text{ext}}(\mathbf{r}, t) - v'_{\text{ext}}(\mathbf{r}, t) \right] \right|_{t=t_0} \neq \text{constant} . \tag{7}$$

Thus, if we take $k$ additional time derivatives of Eq. (4), we can see that the time evolution of the two current densities must be different. This establishes the one-to-one correspondence between external potential and the current density. The second step of the RG proof utilizes the continuity equation:

$$\frac{\partial n(\mathbf{r}, t)}{\partial t} = -\mathbf{\nabla} \cdot \mathbf{j}(\mathbf{r}, t) , \tag{8}$$

along with Eq. (4) to relate the charge density to the external potential and prove that the mapping between them is unique. Thus we can write $v_{\text{ext}}[n, \Psi_0](\mathbf{r}, t)$, i.e., the external potential is a functional of the density and the initial wavefunction.

We can also apply the RG theorem to a noninteracting system, referred to as the Kohn-Sham (KS) system. There is then a potential, $v_{\text{S}}[n, \Phi_0](\mathbf{r}, t)$, such that the evolution of noninteracting fermions in this potential reproduces the exact time-dependent density. This requires various assumptions about the $N$- and $v$-representability of the density and potential, a discussion that is beyond the scope of this review, but can be explored in van Leeuwen (1999), Li and Ullrich (2008), and Ruggenthaler and van Leeuwen (2011). The time-dependent Kohn-Sham equations are

$$i \frac{\partial \phi_j(\mathbf{r}, t)}{\partial t} = \left[ -\frac{\nabla^2}{2} + v_0(\mathbf{r}, t) + v_{\text{H}}[n](\mathbf{r}, t) + v_{\text{xc}}[n](\mathbf{r}, t) \right] \phi_j(\mathbf{r}, t) , \tag{9}$$

where $\phi_j(\mathbf{r}, t)$ denotes the single-particle Kohn-Sham orbitals. The density is given by:

$$n(\mathbf{r}, t) = \sum_{j=1}^{N/2} \left| \phi_j(\mathbf{r}, t) \right|^2 , \tag{10}$$

and the Hartree potential is

$$v_{\text{H}}[n](\mathbf{r}, t) = \int d^3 r' \frac{n(\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|} . \tag{11}$$

The exchange-correlation (XC) potential, $v_{\text{XC}}$, is defined as

$$v_{\text{xc}}[n, \Psi_0, \Phi_0](\mathbf{r}, t) \equiv v_{\text{s}}[n, \Phi_0](\mathbf{r}, t) - v_{\text{ext}}[n, \Psi_0](\mathbf{r}, t) - v_{\text{H}}[n](\mathbf{r}, t) \tag{12}$$

and has a functional dependence on the density of the system at the current and at all previous times, as well as the initial interacting and noninteracting wavefunctions. These initial states need not be the GS or an eigenstate of the initial potential,

$v_{\text{ext}}(\mathbf{r}, t_0)$. However, if we start from the GS, then all initial-state dependence is subsumed into the initial density due to the Hohenberg-Kohn theorem (Hohenberg and Kohn 1964). In practice, the XC potential must be approximated, with the most commonly used being the adiabatic approximation. This simply inserts the density at each time into a ground-state DFT XC functional.

## 3.2   TDSDFT for Ultrafast Spin Dynamics

TDDFT can be extended to include the electron spin degree of freedom and its interaction with an external magnetic field, $\mathbf{B}_{\text{ext}}(\mathbf{r}, t)$, via the Zeeman interaction. Hence, in addition to the exact density $n(\mathbf{r}, t)$, TD spin DFT (TDSDFT) will also reproduce the exact magnetization (or spin) density, $\mathbf{m}(\mathbf{r}, t) = \text{Tr}\left[\hat{\rho}(\mathbf{r}, t)\boldsymbol{\sigma}\right]$, where $\hat{\rho}$ is the single-particle density matrix, i.e., $n(\mathbf{r}, t) = \text{Tr}\left[\hat{\rho}(\mathbf{r}, t)\right]$, and $\boldsymbol{\sigma}$ is the vector of Pauli matrices. The TD-KS equations become (from Eq. (9)):

$$
i\frac{\partial \phi_j(\mathbf{r}, t)}{\partial t} = \left[\frac{1}{2}\left(-i\boldsymbol{\nabla} + \frac{1}{c}\mathbf{A}_{\text{ext}}(t)\right)^2 + v_{\text{S}}(\mathbf{r}, t) + \frac{1}{2c}\boldsymbol{\sigma}\cdot\mathbf{B}_s(\mathbf{r}, t)\right.
$$
$$
\left. + \frac{1}{4c^2}\boldsymbol{\sigma}\cdot(\boldsymbol{\nabla}v_s(\mathbf{r}, t) \times -i\boldsymbol{\nabla})\right]\phi_j(\mathbf{r}, t) , \tag{13}
$$

where $\mathbf{B}_{\text{S}}(\mathbf{r}, t) = \mathbf{B}_{\text{ext}}(\mathbf{r}, t) + \mathbf{B}_{\text{XC}}(\mathbf{r}, t)$ is the KS effective magnetic field and $\mathbf{B}_{\text{XC}}$ is the XC magnetic field, which may be approximated for non-collinear systems according to the method of Kübler (Kubler et al. 1988). In Eq. (13), the external laser field is written as a purely time-dependent vector potential, $\mathbf{A}_{\text{ext}}(t)$. If gauge transformed to the length gauge, it recovers the dipole approximation to the electric field of a laser. This form is necessary for periodic systems so that the Hamiltonian retains lattice periodicity. The last term of Eq. (13) is the SOC. If we assume $v_{\text{S}}(\mathbf{r}, t)$ to be spherically symmetric around each atom, then this term reduces locally to the more familiar form, $\xi(r)\,\hat{\mathbf{L}}_e \cdot \hat{\mathbf{S}}$, where $\hat{\mathbf{L}}_e$ is the electronic angular momentum operator, $\hat{\mathbf{S}} = 1/2\hat{\boldsymbol{\sigma}}$ is the spin operator, and $\xi(r) = \partial_r v_{\text{S}}(r)/2c^2 r$. SOC typically provides small contributions to the GS energy, but, as we will see, it has dramatic effect on the dynamics.

### 3.2.1   Spin Continuity Equation
A spin continuity equation for the local magnetization density can be derived using the Heisenberg equation of motion (EOM) along with the Hamiltonian in Eq. (13):

$$
\frac{d}{dt}\mathbf{m}(\mathbf{r}, t) = -\boldsymbol{\nabla}\cdot\overset{\leftrightarrow}{\mathbf{J}}_{\text{S}}(\mathbf{r}, t) + \frac{1}{2c}\mathbf{m}(\mathbf{r}, t) \times \mathbf{B}_s(\mathbf{r}, t) + \frac{1}{4c^2}\langle(\boldsymbol{\nabla}v_s(\mathbf{r}) \times -i\boldsymbol{\nabla}) \times \hat{\boldsymbol{\sigma}}\rangle \tag{14}
$$

where the first term on the right-hand side represents the spin current divergence of the noninteracting Kohn-Sham system. Here we defined the spin current operator to be $\overset{\leftrightarrow}{\hat{\mathbf{J}}}_{\text{S}}(\mathbf{r}, t) = \hat{\boldsymbol{\sigma}} \otimes \hat{\mathbf{j}}$ or, equivalently, $\hat{\mathbf{j}}_\nu = \hat{\sigma}_\nu\hat{\mathbf{j}}$, where $\nu = \{x, y, z\}$ and

$\hat{\mathbf{j}}(\mathbf{r}, t) = \hat{\mathbf{j}}_p(\mathbf{r}) + \hat{n}(\mathbf{r}) A_{\text{ext}}(t)/c$ is the usual current density operator (which includes a diamagnetic term in order to be gauge invariant). The middle term is a precessional term due to the effective KS magnetic field, and the last term is the magnetization torque due to SOC.

We may integrate Eq. (14) to find the equation of motion for the global spin moment, $\mathbf{M}(t) = \int d^3r \; \mathbf{m}(\mathbf{r}, t)$. After some algebra and in the absence of an external magnetic field, one can write:

$$\frac{\partial}{\partial t}\mathbf{M}(t) = \frac{1}{2c^2} \int d^3r \begin{bmatrix} \hat{x} \\ \hat{y} \\ \hat{z} \end{bmatrix} \times \begin{bmatrix} \boldsymbol{\nabla} v_s(\mathbf{r}, t) \times \mathbf{j}_x(\mathbf{r}, t) \\ \boldsymbol{\nabla} v_s(\mathbf{r}, t) \times \mathbf{j}_y(\mathbf{r}, t) \\ \boldsymbol{\nabla} v_s(\mathbf{r}, t) \times \mathbf{j}_z(\mathbf{r}, t) \end{bmatrix} , \tag{15}$$

where we used Gauss' theorem and the TDSDFT zero-torque theorem (Capelle et al. 2001). Equation (15) demonstrates that only SOC can change the global spin moment.

## 4 Ultrafast Demagnetization of Small Magnetic Clusters

We will now review some of the results obtained with TDSDFT towards the understanding of ultrafast spin dynamics by starting from transition-metal clusters and then moving to bulk magnets. TDSDFT simulations have shown that, similarly to ferromagnetic films, a number of small iron clusters (i.e., $Fe_2$, $Fe_4$ and $Fe_6$) demagnetize rapidly when excited by a strong electric field pulse a few femtosecond long (Stamenova et al. 2016). The real-time evolution of the system described by TDSDFT simulations allows one to gain unparalleled microscopical insights into the physical processes, driving the ultrafast dissipation of spin angular momentum. It is understood that, in the absence of direct light-to-spin coupling, the demagnetization onset is triggered by the electronic charge response to the electric field component of the laser pulse. A more transparent microscopic interpretation of the observed first-principles spin dynamics can be sought in the spin continuity equation, which in turn leads to a set of coupled magnetohydrodynamical equations (Simoni et al. 2017). This will allow us to understand the demagnetization process through the following mechanism: the charge and spin currents generated by the electric pulse in the magnetic media give rise to an effective magnetic field that, in combination with the SOC, facilitates spin-flip and a global spin decay. We will elaborate on this picture bellow.

### 4.1 TDSDFT Simulations

The TDSDFT platform of choice is the OCTOPUS code (Castro et al. 2006), which uses a real-space representation of the wavefunctions and is particularly suited for an accurate treatment of small atomistic systems and shaped time-dependent
**Fig. 2** (**a**) A typical pulse used in the TDSDFT simulation and isosurface snapshots of the spin density variation with respect to the GS at given times after the initiation of the pulse for two different directions of the electric field relative to the cluster geometry. Red and blue isosurfaces correspond, respectively, to positive and negative variation of the same magnitude with respect to the GS spin density. (**b**) The evolution of the net spin of the cluster for the two directions of the electric field

excitations. SOC is included at the level of pseudopotential, $v_{PP}(r)$, i.e., it is part of the KS potential, $v_0(r)$, of Eq. (9):

$$v_{PP}(r) = \sum_I \sum_l \sum_{m=-l}^{l} \left( \bar{V}_l^{ion}(r) + \frac{1}{4} V_l^{SO}(r) + \alpha V_l^{SO}(r) \hat{\mathbf{L}}_I \cdot \hat{\mathbf{S}} \right) |l, m\rangle \langle l, m| \, , \tag{16}$$

where $\hat{\mathbf{S}}$ is the spin operator, $\hat{\mathbf{L}}_I$ is the angular momentum operator associated to the atomic center "$I$," while the scalar part of the pseudopotential, $\bar{V}_l^{ion}(r)$, includes the effect of the mass shift and the Darwin term. Here $V_l^{SO}(r)$ defines the range of the SOC term, and $\alpha$ is a scaling parameter used to enhance/reduce the contribution of the SOC from the regular value $\alpha = 1$. In the following the adiabatic local spin density approximation (ALSDA) to the XC functional has been used with the Perdew and Wang parameterization.

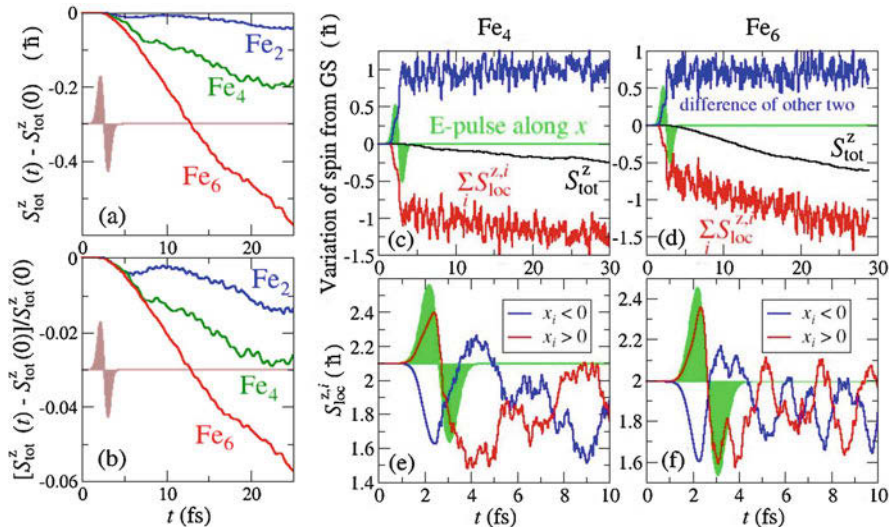
Any TDSDFT simulation starts with a GS SDFT calculation. We then consider a strong bipolar pulse of an homogeneous electric field as illustrated in Fig. 2a and applied as per Eq. (13) in length gauge. In the case of $Fe_6$, which has the shape of an (almost) square-based bipyramid (Gutsev and Beuschlicher 2003), the direction of the electric field with respect to the cluster affects the net demagnetization process. The snapshots from such TDSDFT simulations, presented in Fig. 2, highlight the local variation of the spin density of $Fe_6$ for two pulses differing only by the E-field direction. It is clear that at the pulse onset, there is charge transfer, accompanied by spin transfer (as the cluster is spin-polarized), in the direction of the electric field. Soon after that a spin decay for the entire cluster is established (the predominant color in the plots is blue). For both field directions, this results in demagnetization, which continues long after the pulse has died out (Fig. 2b). For $Fe_6$ the effect is


**Fig. 3** Comparison of the absolute (**a**) and relative (i.e., per unpaired electron in the cluster) (**b**) demagnetization in three Fe clusters: $Fe_2$, $Fe_4$, and $Fe_6$. Panels (**c**) and (**d**) show the evolution of the total spin of the cluster (black curve) compared to the *local spin*, integrated over spheres of radius $r_{sph} = 0.5$ Å (red curves) centered at the atoms (see text) and the difference of the latter. Panels (**e**) and (**f**) display a comparison of average local spins for the two pairs of atoms in the plane along the direction of the pulse ($x$-axis) for $Fe_4$ and $Fe_6$, respectively

very anisotropic with the cluster demagnetizing more when the E-field is along the shortest bond in the basal plane. This anisotropy is an indication of the crucial rôle played by the SOC in the spin dissipation. Indeed, switching off the SOC (setting $\alpha = 0$ in Eq. (16)) results in net spin conservation during and following the optical excitation.

A further observation is that clusters of different sizes demagnetize at different rates for the same pulse, as shown in Fig. 3. In fact, the $Fe_2$, $Fe_4$, and $Fe_6$ clusters investigated also represent atomic structures of increasing dimensionality: going from linear ($Fe_2$) to planar ($Fe_4$) to full three dimensional ($Fe_6$). All structures, simulated in large ideally-reflecting cuboid simulation boxes, show ultrafast demagnetization, namely, a decrease of the total spin, $S_{tot}^z(t) = \int d^3r\, m^z(\mathbf{r}, t)$, when excited by a fs E-field pulse along a non-zero dimension (i.e., for $Fe_2$ along the bond and for $Fe_4$ in the cluster plane). Interestingly, the long-term rate of demagnetization increases with the cluster size (see Fig. 3a) which is suggestive of a nonlocal mechanism (see Eq. 15). However, in the early times after the pulse, the TDSDFT simulations show very similar relative demagnetization rate in all three clusters. This is an indication of a common demagnetization onset mechanism, and it corroborates the key rôle played by the SOC close to the Fe nuclei.

A spatial analysis of the spin density evolution shows that after the pulse, nearly all the spin drop takes place in the vicinity of the atomic centers (see Fig. 3c, d) for
**Fig. 4** Time evolution of (**a**) the total spin, (**b**) the total TDSDFT energy, and (**c**) the total KS orbital momentum, defined as $L_{tot}^z(t) = \int d^3r\, L_{KS}^z(\mathbf{r}, t)$ for the $Fe_6$ cluster excited by pulses of different shapes (see inset of panel (**a**) with the corresponding color code). (Figure adapted from Stamenova et al. 2016)

both $Fe_4$ and $Fe_6$. We define local atom-based spin as the integral of the spin density, $\mathbf{m}(\mathbf{r}, t)$, inside a sphere $\Sigma_i$ centered on the $i$-th nucleus, $\mathbf{S}_{loc}^i(t) = \int_{\Sigma_i} d^3r\, \mathbf{m}(\mathbf{r}, t)$. The total local spin is obtained by summing up over all atomic centers $i$. During the pulse it appears that spin and charge rapidly spill out from the atomic centers and occupy the interatomic regions. This is not accompanied by a total (net) spin variation as practically no spin flipping occurs during this ultrafast excitation stage. After this the spin starts to decay, and all the SOC-driven spin-flip events take place in the vicinity of the atomic cores. The bipolar pulse excites a coherent antiphase oscillation of the local spins along the direction of the pulse, which persists as all local spins continue to decay (see Fig. 3e, f). The very high frequency oscillations of the local spin quantities in Fig. 3 are due to sloshing spin currents and include some minor numerical noise from the spatial integration.

The demagnetization rate depends strongly also on the shape and amplitude of the pulse, as shown in Fig. 4. A small unipolar pulse is shown to generate very little demagnetization (even exhibiting time intervals of small total momentum enhancement), while bipolar pulses of increasing amplitude tend to demagnetize the cluster more. After the pulse, the total TDSDFT energy reaches a new higher value, which is kept constant for the rest of the simulation. This means that the cluster remains in an excited state, since there is no energy dissipation mechanism in the method. However, unlike the total energy, the total angular momentum is not a constant of motion after the pulse. Figure 4d shows the rapidly oscillating total orbital momentum of the cluster, defined as $\mathbf{L}_{tot} = \int d^3r\, \mathbf{r} \times \mathbf{p}$. This does not mirror the smooth decay of the total spin. The reason for that lies in the

rotational symmetry breaking due to the superimposed ionic potentials of the six frozen atom cores. What is seen after the pulse is a transfer of spin into the orbital angular momentum, which in turn is not conserved and develops high frequency oscillations due to the elastic scattering of the excited electrons onto the immobile atomic cores. Note that the lack of total angular momentum conservation of the valence electron subsystem is physical and it stems from their interaction with the lattice. The TDSDFT simulations are aimed at describing the early stages of the demagnetization process, when other relaxation mechanisms (e.g., phonons) can be ignored.

## 4.2 Hydrodynamical Formulation of the Spin Continuity Equation

In order to understand the dynamics better, it is useful to rewrite the continuity equation, Eq. (14), in terms of the following set of hydrodynamical variables:

$$\boldsymbol{\mu}(\mathbf{r}, t) \equiv \frac{\mathbf{m}(\mathbf{r}, t)}{n(\mathbf{r}, t)} \qquad \text{and} \qquad \mathbf{v}(\mathbf{r}, t) \equiv \frac{\mathbf{j}_\mathrm{p}(\mathbf{r}, t)}{n(\mathbf{r}, t)}, \qquad (17)$$

leading to:

$$\frac{D}{Dt}\mathbf{m}(\mathbf{r}, t) + \sum_i \nabla \cdot \mathbf{v}_i(\mathbf{r}, t)\mathbf{m}_i(\mathbf{r}, t) =$$

$$= \nabla \cdot \mathscr{D}(\mathbf{r}, t) + \frac{1}{2c}\mathbf{m}(\mathbf{r}, t) \times \mathbf{B}_\mathrm{eff}(\mathbf{r}, t) + \frac{1}{4c^2}\langle (\nabla v_\mathrm{s}(\mathbf{r}, t) \times -i\nabla) \times \hat{\boldsymbol{\sigma}}\rangle \quad (18)$$

where $\mathbf{v}_i(\mathbf{r}, t)$ and $\mathbf{m}_i(\mathbf{r}, t)$ are the velocity field and the magnetization density associated to the single KS state $\psi_i^\mathrm{KS}(\mathbf{r}, t)$ and $\nabla \cdot \mathscr{D}(\mathbf{r}, t)$ is a new spin current flux term. Now, in addition to the spin-orbit, we have a torque due to the effective magnetic field:

$$\mathbf{B}_\mathrm{eff}(\mathbf{r}, t) = \mathbf{B}_\mathrm{s}(\mathbf{r}, t) + \frac{1}{\bar{\mathscr{F}}}\left[\frac{\nabla n \cdot \nabla \boldsymbol{\mu}}{n} + \nabla^2 \boldsymbol{\mu}\right], \qquad (19)$$

where $\bar{\mathscr{F}} = \frac{\langle \psi_i^\mathrm{KS}(\mathbf{r}, t)^* \psi_i^\mathrm{KS}\rangle}{n(\mathbf{r}, t)}$ defines an average occupation number of the KS states. This effective field is responsible for generating a torque upon the magnetization vector as we will see in the next sections. Furthermore it has been shown (see Simoni et al. 2017 for details) that the spin current divergence also contributes to the magnetization torque following an ultrafast optical excitation. It locally increases spin non-collinearity and enables the SOC to dissipate spins more effectively in the orbital momentum channel. Note that globally the total spin deflection from the quantization axis, $z$, in these simulations is negligible.

### 4.3   Identifying the Role of the Spin-Orbit Interaction

In order to quantify the effect of the SOC in the early stage of the demagnetization process, we have investigated the spin dynamics for different values of the scaling factor $\alpha$ (see Eq. (16)). Depicted in Fig. 5 is the effect on the global spin variation trajectory from tuning $\alpha$ between 0 and 4. Clearly, the spin loss rate is strongly affected by the SOC strength with the limit of $\alpha = 0$ (no SOC), resulting in global spin conservation. In panel (b) we have plotted the same spin trajectories after removing their GS offset and scaling them by a factor $1/\alpha^2$. The overlap of the curves demonstrates that in the initial coherent stage, the spin-decay rate scales as the square of the SOC strength.

Since a SOC scaling factor is just a theoretical tool, a number of different atomic species have been also considered. In response to the same laser pulse, clusters geometrically identical to $Fe_6$ (Gutsev and Beuschlicher 2003) but composed of Co and Ni (although this is not their GS geometry, it is chosen as to exclude structural factors from the comparison.) demagnetize at different rates, as shown in Fig. 5. We quantify their ionic SOC strength as

$$\lambda_{\text{eff}} = \sum_{l \in \text{occ.}} \frac{n_l}{n_{\text{tot}}} \int V_l^{\text{SO}}(\mathbf{r}) R_l^2(\mathbf{r}) d^3 r \;, \tag{20}$$

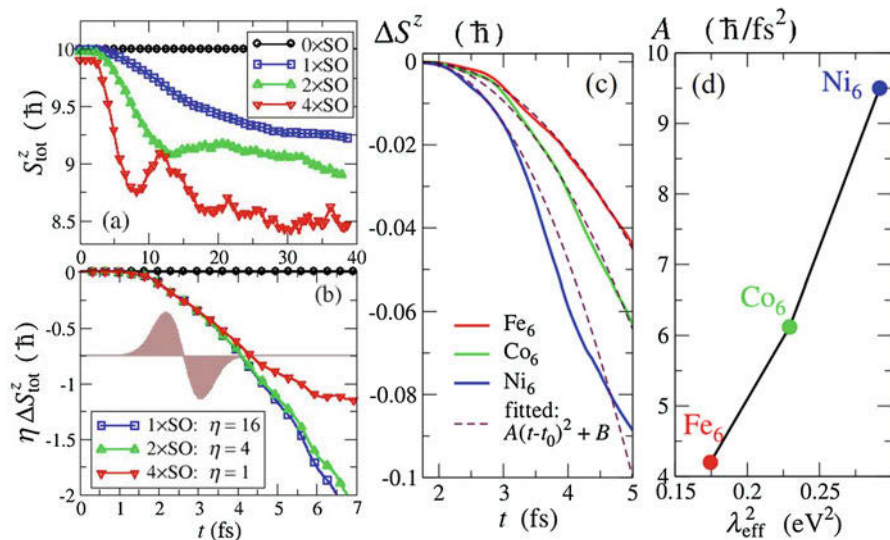

**Fig. 5** (a) Evolution of global spin expectation value for different values of the factor $\alpha = 0, 1, 2, 4$ scaling the SOC term in Eq. (16). (b) Same as in panel (a) but having the GS spin subtracted and a multiplication factor $\eta = (\alpha_{\text{max}}/\alpha)^2$. (c) TDSDFT trajectories of the variation of $S_{\text{tot}}^z(t)$ with respect of the GS spin for three different clusters: $Fe_6$, $Ni_6$, and $Co_6$ (all sharing the same $Fe_6$ geometry) fitted to $y = A(t - t_0)^2 + A_0$ (dashed curves). (d) The fitting coefficients $A$ from panel (c) versus the effective atomic SOC from Eq. (20) for each material. (Figure adapted from Stamenova et al. 2016)

where $n_l$ are the KS state occupations with $l$ spanning the valence states (in this case $3s$, $3p$, $3d$, and $4s$), $n_{\text{tot}} = \sum_{l \in \text{occ.}} n_l$, $R_l(\mathbf{r})$ are the radial pseudo-atomic wavefunctions, and $V_l^{\text{SO}}(\mathbf{r}) = \frac{2l}{2l+1} \left[ V_{\text{PP}}^{l+1/2}(\mathbf{r}) - V_{\text{PP}}^{l-1/2}(\mathbf{r}) \right]$ is the same object as in Eq. 16. Those are all obtained from LSDA calculations for isolated atoms. By fitting the first few femtoseconds of the demagnetization curve to a quadratic time decay $S^z(t) \propto A(t - t_0)^2$ with $t_0$ in the rise of the laser pulse (around 1.5 fs), we extract the demagnetization rate $A$ for each of the three different clusters. Such extracted demagnetization rates show a systematic (quasi-linear) dependence on their ionic SOC strength $\lambda_{\text{eff}}^2$ (see Fig. 5c).

## 4.4    Simple Model

A minimal model involving SOC and resulting in a local variation of the spin expectation value is described by Stamenova et al. (2016):

$$\hat{H}(t) = \lambda \hat{\mathbf{L}} \cdot \hat{\mathbf{S}} + \mathbf{B}_{\text{eff}}(t) \cdot \hat{\mathbf{S}}, \tag{21}$$

where $\mathbf{B}_{\text{eff}}(t)$ represents a generic time-dependent magnetic field, $\hat{\mathbf{S}}$ is the spin operator, and $\hat{\mathbf{L}}$ is the orbital momentum operator. This model is designed to mimic the local TDSDFT spin dynamics at a given spatial point, but it does not reproduce the full ab initio simulations in all their features.

By solving the model for a simple two-level system, we observe that a temporal change of the magnetic field, $\mathbf{B}_{\text{eff}}(t)$, combined with finite SOC leads to the transfer of part of the spin expectation value into the orbital momentum channel more efficiently than when $\mathbf{B}_{\text{eff}}$ is constant. The amount of spin lost after the action of $\mathbf{B}_{\text{eff}}(t)$ is not the same for different SOC coefficients $\lambda$, and, in particular, higher $\lambda$ values lead to faster momentum transfers, i.e., faster spin decays.

A numerical integration of the Schrödinger equation with the Hamiltonian of Eq. (21) in the case of no SOC (i.e., $\lambda = 0$) returns, as expected, no observable spin dynamics, if the effective magnetic field $\mathbf{B}_{\text{eff}}(t)$ stays parallel to the spin expectation value $\langle \hat{\mathbf{S}} \rangle$. In contrast, when $\lambda \neq 0$ and the initial state has not the maximum or minimum $j_z = l_z + s_z$, a steplike variation of $\mathbf{B}_{\text{eff}}(t)$ produces a sharp variation in the spin expectation value $\langle \hat{S}_z \rangle$ (see Fig. 6). In particular, for an initial spin-up state ($s_z = 1/2$), we observe a decrease of $\langle \hat{S}_z \rangle$ after the drop of $|\mathbf{B}_{\text{eff}}(t)|$, while an initial spin-down state ($s_z = -1/2$) results in an increase of the spin expectation value.

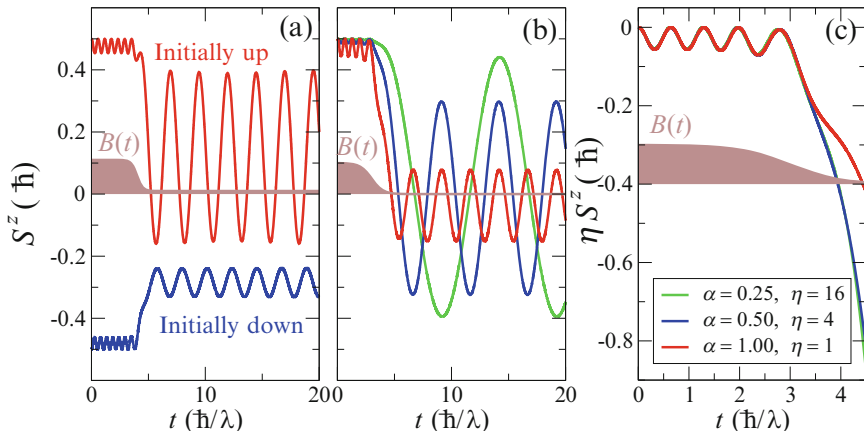
This simple model demonstrates that a change in the magnetic field $\mathbf{B}_{\text{eff}}(t)$, combined with SOC, leads to a transfer of part of the spin expectation value into the orbital momentum more efficiently than when $\mathbf{B}_{\text{eff}}(t) = 0$. Figure 6b further reveals that the amount of spin lost after the action of $\mathbf{B}_{\text{eff}}(t)$ depends strongly on the value of the SOC coefficient $\lambda$. In particular, larger values of $\lambda$ lead to faster spin-decay rates. Furthermore, it can be established numerically (and analytically, see Stamenova et al. (2016)) that there is a quadratic dependence of the spin-decay rate on the SOC strength (see Fig. 6c).


**Fig. 6** Trajectories of $\left\langle \hat{S}_z \right\rangle$ under the action of the Hamiltonian of Eq. (21) in the case of (**a**) having an initial spin-up or spin-down state, (**b**) for different values of a multiplicative factor $\alpha$ to the SOC ($\lambda \rightarrow \alpha\lambda$) and for an initial spin-up state, (**c**) the trajectories rescaled by a factor $1/\alpha^2$. The shaded area describes the temporal profile of the applied magnetic field $[0, 0, B_{\text{eff}}(t)]$. The initial orbital configuration is a linear combination of $l_z = 0, 1$ states. (Figure adapted from Stamenova et al. 2016)

The insights drawn from the simple model map out a possible interpretation for the ultrafast demagnetization observed in the TDSDFT simulations. An effective magnetic field provides the connection between the light pulse and the spin dynamics. This is $\mathbf{B}_{\text{eff}}(\mathbf{r}, t)$, identified in Eq. (19). Such field is directly coupled to the spin density and dependents on the density gradients and hence couples the spins with the laser-induced charge dynamics. In order to show that $\mathbf{B}_{\text{eff}}(\mathbf{r}, t)$ initiates the spin demagnetization, as suggested by the simple model, we compare the variation of the spin density in the $(x-y)$ plane for the $Fe_6$ cluster averaged over the simulation time and the axial direction (see Fig. 7). Together with highlighting the localized character of the demagnetization effect in small areas close to nuclei, Fig. 7 also shows the spatial correlation between regions of high spin loss with regions of high $\mathbf{B}_{\text{eff}}$ variation.

## 5    Ultrafast Spin Dynamics in Bulk Materials

TDSDFT simulations may also be performed for bulk systems using the formulation of Eq. (13), which has been implemented in the all-electron electronic structure code ELK `elk.sourceforge.net` for *two*-component Pauli spinors, allowing systems with non-collinear magnetism to be simulated.

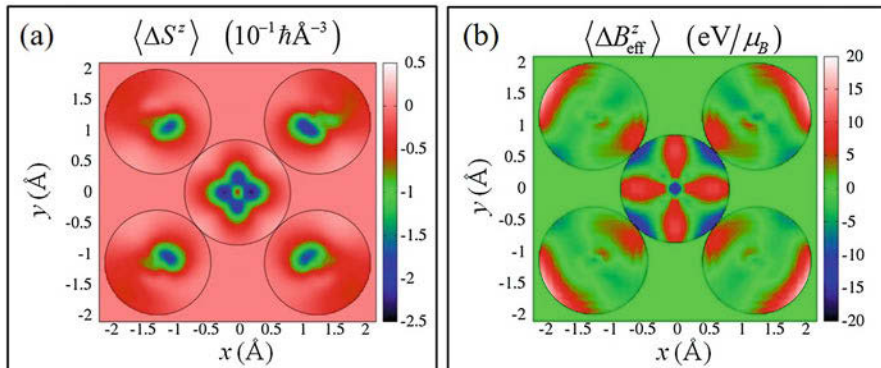
The ELK basis set consists of linearized augmented plane waves (LAPW). These decompose the system into so-called muffin-tin regions centered on each atom and the interstitial region (IR) in between them. The calculations discussed below used


**Fig. 7** Contour plots of computed observables averaged in time (entire simulation of 30 fs) and along the $z$-direction (perpendicular to the page and only within the marked spheres of radius $0.85$ Å around each atom). Here we present the variation from the GS values for (**a**) the spin density $S^z(\mathbf{r})$ and (**b**) the effective magnetic field $B_{\text{eff}}^z(t)$. (Figure adapted from Stamenova et al. 2016)

a $8 \times 8 \times 8$ $k$-points grid and a timestep $\Delta t = 0.1$ au. Further computational details can be found in references Krieger et al. (2015); Elliott et al. (2016a, b). In all cases we begin the simulation from the GS with the global spin moment parallel to the $z$-axis.

We will discuss in detail two forms of spin dynamics observed in bulk systems, namely, ultrafast demagnetization and ultrafast spin transfer between sublattices.

## 5.1 Ultrafast Demagnetization of Bulk Materials

The first experimental observation of ultrafast demagnetization consisted in measuring the rotation of the light polarization reflected by bulk Ni [magneto-optical Kerr effect (MOKE)] (Beaurepaire et al. 1996; Hohlfeld et al. 1997; Scholl et al. 1997; Koopmans et al. 2000). Such change in the MOKE signal, induced by a strong laser pulse, was found to take place in under 100 fs. Since then, subsequent experiments have found changes as fast as 10 s of fs and have been observed also in bulk Fe (Carpene et al. 2008; La-O-Vorakiat et al. 2009), Co (Cinchetti et al. 2006), and Gd (Lisowski et al. 2005; Eschenlohr et al. 2014). Thus, it is natural to ask what spin dynamics are seen in TDDFT simulations for these systems.

In Fig. 8 we show the relative change in the global spin moment, $M(t)$, for bulk Fe, Ni, and Co following the application of a laser pulse (frequency 2.72 eV, FWHM 2.5 fs, peak intensity $10^{15}$ W/cm$^2$), also shown in the figure. The same simulations run in the absence of SOC return no demagnetization, indicating once again that SOC is the interaction responsible for the loss of global spin moment. This confirms the analytic result derived in Eq. (15). Note that in Fig. 8 we plot the absolute value $M(t) = |\mathbf{M}(t)|$, which rules out any canting of the moment that leaves $M(t)$ unchanged but reduces $\mathbf{M}_z(t)$.
**Fig. 8** Demagnetization of bulk Ni, Fe, and Co. In the left-hand side plot, we show the total magnetic moment $M(t) = |\mathbf{M}(t)|$ as a function of time, while in the right-hand side one, we trace in space the vector field position of the spin current, $\mathbf{j}_x$. (Figure adapted from Krieger et al. (2015) and Krieger et al. 2017)

Another interesting feature that may be seen in Fig. 8 is the separation of timescales between the laser excitation and the demagnetization process. During the laser pulse, electrons are excited into higher energy states, but the global spin moment does not change significantly. It is only in the $\approx 10 - 20$ fs following the laser pulse peak that the demagnetization takes place. Only by utilizing such a short laser pulse are we able to disentangle these two physical phenomena. For pulses of longer duration, the two occur together. We will now study the EOM, Eq. (15), for the global moment in order to explain why this time lag is present and what causes the demagnetization.

Focusing on the $z$-component of Eq. (15):

$$\frac{\partial}{\partial t} M_z(t) = \frac{1}{2c^2} \int d^3r \left[\nabla v_s(\mathbf{r}, t) \times \mathbf{j}_y(\mathbf{r}, t)\right]_x - \left[\nabla v_s(\mathbf{r}, t) \times \mathbf{j}_x(\mathbf{r}, t)\right]_y , \quad (22)$$

where $\mathbf{j}_\mu$ is the spin current density, defined previously, which describes the flow of the $\mu$ spin component throughout the system. We see that the demagnetization can only occur when the $\mathbf{j}_x$ spin current circulates about the $y$-axis and/or $\mathbf{j}_y$ circulates around the $x$-axis. In Fig. 8, we plot the streamlines found by following the vector field of $\mathbf{j}_x$. This allows us to visualize the flow of spin current at a particular time during the demagnetization process. Indeed we see exactly the circulation required by Eq. (22). From this analysis, we understand that the role of the laser pulse is to excite the system (including changing the exchange coupling) and to cause such spin currents to appear (note similar spin currents exist in the GS due to the spin texture induced by the SOC). The SOC can then rotate the spin components, causing a decrease in $M_z(t)$ leading to the demagnetization observed. These processes operate on different timescales, primarily dictated by the strength of the SOC, the exchange field, and the laser pulse duration.

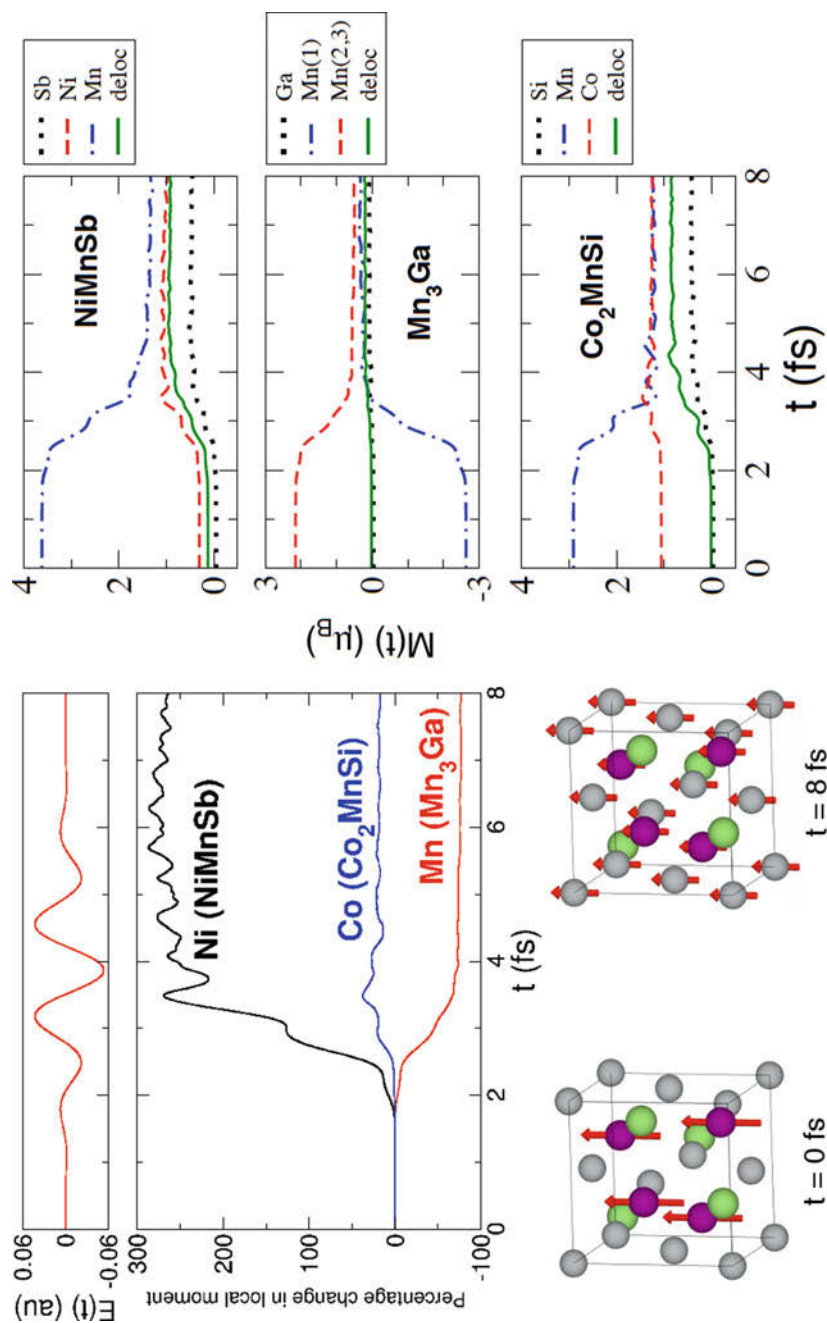
Ultrafast demagnetization experiments are generally performed with the ferromagnetic material grown on top of a conducting substrate. This allows spin current


**Fig. 9** (continued)

to transport moment away from the probed region, also leading to an ultrafast demagnetization of this region, as in the super-diffusive spin-transport model (Battiato et al. 2010). Due to computational restrictions on the size of supercell possible, it is difficult to include this form of demagnetization in our TDSDFT simulations. However, recent experiments (Razdolski et al. 2017) used an insulating substrate to eliminate any super-diffusive mechanism, yet ultrafast demagnetization of Ni, Fe, and Co was still observed, suggesting that the SOC-orbit mediated spin-flips observed in our simulations have been experimentally observed.

Finally, we should comment on the fact that we purposefully used an ultrashort, ultrastrong laser for the simulations presented. As discussed, this is to disentangle the many physical processes involved in ultrafast demagnetization. However, if we use laser parameters taken from experiments, we still observe significant demagnetization, as can be seen in Krieger et al. (2017).

## 5.2   Optical Inter-sublattice Spin Transfer

The magnetization dynamics studied so far have all involved a decrease in the global spin-magnetic moment driven by SOC. However, another interesting phenomenon seen in TDSDFT calculations for systems with more than one magnetic sublattice is an increase of the local moment, driven by spin currents transferring angular momentum from one sublattice to another (Elliott et al. 2016b). This form of magnetization dynamics can have a dramatic effect on the local magnetic moments, as can be seen in Fig. 9. Here we plot the percentage change in the local spin moment (defined as the integral of the magnetization density inside an appropriately sized sphere around each atom) for a particular atom (Ni, Co, Mn) in three Heusler alloys, NiMnSb, $Co_2MnSi$, and $Mn_3Ga$. It is clear that the local moment reacts to the incoming laser pulse completely different in each of the three cases: it may be strongly enhanced (Ni), relatively unchanged (Co), or completely destroyed (Mn). Having the ability to selectively control these local magnetic moments could be of great technological importance, particularly for magnetic storage and spintronic devices. We now investigate the underlying physical mechanism for such inter-sublattice spin transfer, with the goal of identifying a strategy for tailoring the material and/or the pulse for a particular purpose.

Heusler alloys are compounds consisting of four interpenetrating $fcc$ sublattices with stoichiometry $X_2YZ$ (or $XYZ$ in the case of half-Heuslers), where $X$ and $Y$

**Fig. 9** Laser-induced magnetization dynamics in Heusler alloys. The left-hand side panel presents the relative change in local magnetic moment of the given atom within NiMnSb, $Co_2MnSi$, and $Mn_3Ga$ and the shape of the electric field pulse used to initiate the dynamics. We also show two snapshots of the local spin configuration of NiMnSb at $t = 0$ (ground state) and $t = 8$ fs. Mn atoms are in purple, Ni in green, and Sb in gray. The exact values can be deduced from the right-hand side panels which display the dynamics of the local moment and of the interstitial region ("deloc") for the three studied compounds. (Figure adapted from Elliott et al. 2016b)

are usually transition metals and $Z$ is a main group element. We choose to illustrate the inter-sublattice spin transfer dynamics using Heusler alloys as they exhibit a wide range of magnetic behavior and thus can be a convenient playground for understanding the phenomenon. As already mentioned, the three compounds we will focus on are NiMnSb, $Co_2MnSi$, and $Mn_3Ga$. The first two are ferromagnets, while $Mn_3Ga$ is a ferrimagnet with antiferromagnetic coupling between the two different Mn sublattices. For more information on the crystal structure of these compounds, see Elliott et al. (2016b) and references therein.

The local spin dynamics for each atom and for the interstitial region (shown in Fig. 9) reveal why an increase or a reduction of the local magnetization was observed. Starting with NiMnSb, the main features to observe are a large Mn moment loss and an increase in moment for both Ni and the IR. Due to the small initial moment on Ni, an increase of $0.7\mu_B/f.u.$ due to the laser pulse manifests itself as a huge change in the percentage moment seen in Fig. 9. A similar picture emerges for $Co_2MnSi$ with a loss of Mn moment and a gain in the IR moment. However in contrast to NiMnSb, there is not a large increase in Co moment. Finally, in $Mn_3Ga$ there are two symmetry positions that the Mn atoms can occupy, labeled as Mn(1) (Wyckoff position 2b of the $I4/mmm$ symmetry group) and Mn(2,3) (4d). In the ground state, Mn(1) and Mn(2,3) are coupled antiferromagnetically. The laser pulse then strongly decreases the moment on each Mn atom. In fact, for Mn(1) this is completely destroyed, although for less intense laser fields, it simply decreases but does not vanish. Note that the global spin moment during this time remains unchanged. For longer times, the spin-orbit mediated demagnetization discussed previously may also take place. Again by using an ultrashort laser pulse (frequency 2.72 eV, FWHM 2.42 fs, peak intensity $1 \times 10^{14}$ W/cm$^2$) in these simulations, we were able to separate the SOC-induced effects from purely optical effects, which we wish to focus on. From these three examples, it is clear that the laser pulse induces spin moment to flow from one sublattice to another, a phenomenon that we term as *optical inter-sublattice spin transfer*.

We can make use of the TDSDFT simulation to understand in more detail the inter-sublattice spin transfer process. In particular, we can distinguish between majority and minority spin transfer, information not available from the magnetization density alone. For example, consider the transfer of moment between Ni and Mn in NiMnSb. We observed that the Ni moment increases while that of Mn decreases. This could be explained as a transfer of majority spins from Mn to Ni. However, it can also be explained as a transfer of minority spin from the Ni to Mn. In order to distinguish those processes, we plot in Fig. 10 the change in the number of majority and minority spins for each atomic specie, as defined by:

$$\Delta N_{\uparrow\downarrow}(t) = \frac{1}{2}\left(\Delta N(t) \pm \Delta M_z(t)\right) , \tag{23}$$

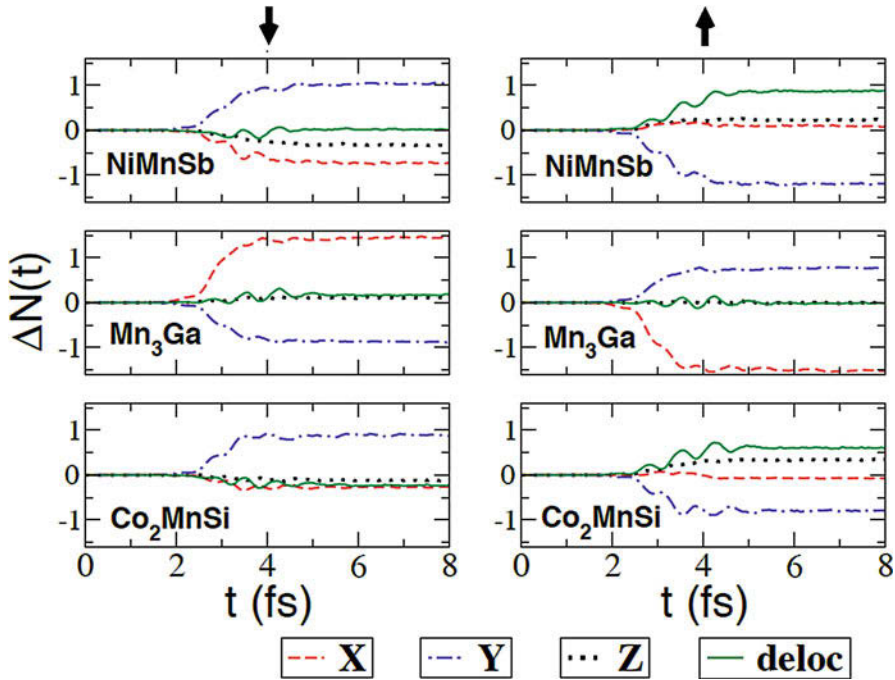
where $\Delta N(t)$ is the change in local charge and $\Delta M_z(t)$ is the change in the $z$-component of the local magnetic moment (the $z$-direction is that of the ground-state moment). If the system remains approximately collinear during the laser pulse


**Fig. 10** The change in majority (↑) and minority (↓) local population for each atoms of the Heusler alloys considered. The spin direction is defined from the ground-state magnetic structure. The labels of the different atoms follow the general formula unit definition $X_2YZ$ ($XYZ$ for half-Heusler alloys)

and no spin-flip transitions take place, then the sum of $\Delta N_{\uparrow\downarrow}(t)$ over all atoms (and the IR) will be zero (i.e., the total number of majority/minority electrons is conserved). Again starting with NiMnSb, we see a gain of minority electrons on Mn, which is accompanied by a loss of minority electrons on Ni. This is a transfer of minority electrons from Ni to Mn. Thus, we find the perhaps counter-intuitive answer of how the Ni local moment increases. In the majority channel, we see a further loss of Mn moment due to transfer of majority electrons from the Mn to the IR. This picture of inter-sublattice spin transfer is further validated by the cases of $Co_2MnSi$ and $Mn_3Ga$. The Mn atom in $Co_2MnSi$ behaves similarly as in NiMnSb, in that it gains minority and losses majority electrons, leading to a loss of its moment. However, now Co loses a similar amount of majority and minority electrons, leaving its moment unchanged. In $Mn_3Ga$, Mn(1) and Mn(2,3) behave opposite to each other, with Mn(1) transferring majority electrons to the two Mn(2,3) atoms and the two Mn(2,3) atoms transferring minority electrons to Mn(1). This causes the local moment to be reduced in magnitude at all Mn sites.

In quantum mechanics we are used to the idea of electrons transitioning from an occupied state to an unoccupied one, due to the application of a laser pulse. When
**Fig. 11** The ground-state DOS for NiMnSb, $Co_2FeSi$, and $Mn_3Ga$. The solid line is the total DOS, while the colored areas are the contributions from the $d$ shell of the various magnetic transition metals

considering magnets with different magnetic sublattices, for each spin channel, we can think of transitions from states primarily located on one atom to states primarily located on another, similar to the charge-transfer processes of molecular chemistry. Therefore, in order to determine what transitions are possible, it is useful to consider the GS density of states (DOS). This can only be a zero-th order approximation to the transition energies and states, as it is known from linear-response TDDFT (e.g., Sharma et al. 2014) that the KS response is corrected to the true response via the Hartree-XC kernel. Furthermore, the DOS does not tell us the probability of a particular transition. Keeping this in mind, we now ask if these inter-sublattice transitions can be understood from the DOS.

In Fig. 11 we plot the total DOS and the $d$-state atom-projected DOS for the three systems under investigation. As would be expected for magnets, we see in all cases minority $d$ bands above the Fermi energy, $\varepsilon_F$. This leads to a significant unoccupied DOS, which is available to the laser-excited electrons. For example, Mn in NiMnSb has a large moment of $3.62\,\mu_B$ in our GS DFT calculations, which leads to a large density of unoccupied Mn $d$-states centered approximately 1 eV above $\varepsilon_F$. Ni, by contrast, has no strong features above $\varepsilon_F$ but does present occupied $d$-states from 0 to 3 eV below $\varepsilon_F$ in both spin channels. Thus, in this simple picture of transitions from occupied to unoccupied state, we would anticipate minority spin transfer from Ni to Mn, as it is the transition with the highest density of both unoccupied and occupied states. This is precisely the transition we have observed in our simulations, demonstrating the usefulness of the DOS for interpretation of results.

Clearly, we observe several other features in our time-dependent calculations that lie outside the DOS picture due to many-body and nonlinear effects, but the DOS still provides an initial interpretation tool. This is confirmed by looking at $Co_2MnSi$ and $Mn_3Ga$ in Fig. 11. The situation for $Co_2MnSi$ is very similar to that of NiMnSb except that there is a large number of unoccupied Co minority states above $\varepsilon_F$. This reduces the net amount of minority electrons transferred from Co to Mn, reducing any increase in the Co moment. The antiferromagnetic coupling in $Mn_3Ga$ makes the DOS interpretation quite simple. On Mn(1) there are occupied majority states and unoccupied minority ones ($d^5$ configuration), while Mn(2) and Mn(3) have fractional occupation for both majority and minority spins. The laser then excites majority electrons from Mn(1) to Mn(2,3) and minority from Mn(2,3) to Mn(1), decreasing the amount of moment on each ion. In Elliott et al. (2016b), the dependence on the laser intensity and frequency was investigated, and the results were found to be consistent with the DOS picture. In particular, the frequency dependence can be inferred by observing the energy difference between the bulk of the occupied and unoccupied DOS.

The inter-sublattice spin transfer observed in our TDSDFT simulations can now be explained using the GS DOS, which provides a simple picture for this phenomenon. Although we choose to illustrate this mechanism in Heusler compounds, the DOS interpretation suggests that this is general to any system with inequivalent magnetic sublattices. The strength and frequency of the transitions depend on the material details and on the laser intensity (as nonlinear processes likely contribute). Most importantly our predictions can be validated experimentally by using element-specific techniques such as X-ray magnetic circular dichroism or XUV TR-MOKE.

## 6    Conclusion

In this chapter we have shown the most recent advances in the study of laser-induced magnetization dynamics in both magnetic clusters and periodic solids, showing different magnetic orders. In particular we have focused our attention on the early dynamical evolution, namely, on the first few tens of femtoseconds following the laser excitation. This is the timescale where the dynamics is entirely driven by the electronic degrees of freedom and where the magnetic moment, the exchange coupling, and the spin-orbit interaction are all fast-varying time-dependent quantities. As such it is a regime in which models that do not explicitly account for the electrons are incapable to make predictions.

The theory of choice in this limit is time-dependent density functional theory. TDDFT has a rigorous foundation, which is reviewed here, and represents the only viable approach to the dynamics. In fact, it is fully quantitative and parameter free, but at the same time, it is computationally light enough to guarantee long simulations for real materials. In general we have shown that the application of an intense laser field is capable of producing ultrafast demagnetization. This, however, takes place only in presence of spin-orbit interaction and when the system investigated is able to sustain a local current (an atom in vacuum does not

demagnetize). The loss of magnetization, following the laser excitation, is the result of the angular momentum transfer between the spin and the orbital components. Firstly, part of the spin moment is transferred to the electronic angular momentum. This is a rapid process, whose timescale is set by the strength of the spin-orbit interaction. As a second step, the electronic angular momentum is dissipated to the angular momentum of the nuclei, which are described as stationary at our level of theory.

Being a fully quantitative theory, TDDFT allows us to investigate complex magnetic orders. For instance, we have discussed the case of antiferromagnetic metals and shown that the laser can produce inter-lattice spin transfer. This is an active channel for spin dynamics, which may result in an increase of one or more of the sublattice magnetizations. In conclusion we have shown that TDDFT may be a powerful tool for the study of ultrafast spin dynamics in complex magnetic systems. Although in its present form the theory is non-dissipative, namely, it cannot describe the long-time magnetization recovery, it still represents the only fully atomistic approach to spin dynamics available. We envision that TDDFT will have a crucial role in the understanding of complex spin phenomena, with applications to materials science, spintronics, and quantum computing.

# Landau-Lifshitz-Bloch Approach for Magnetization Dynamics Close to Phase Transition

# 41

Oksana Chubykalo-Fesenko and Pablo Nieves

## Contents

### Abstract

Micromagnetic modeling has recommended itself as a useful tool for the design of magnetic nanostructures in multiple applications. The standard micromagnetics based on the integration of the Landau-Lifshitz-Gilbert equation is a valid approach at low temperatures only. In multiple recent applications such as heat-assisted magnetic recording or ultrafast magnetic dynamics, the temperatures often go close to the Curie temperature $T_c$ and above. Here we review the micromagnetic approach valid in this temperature range, based on the use

of the Landau-Lifshitz-Bloch equation. The essential part of this approach is the presence of the temperature-dependent longitudinal relaxation with the characteristic time diverging at $T_c$. We review this approach in its classical and quantum formulations and for one- and two-component materials. The behavior of longitudinal relaxation time is discussed. Finally, we present examples of the use of this micromagnetics related to the modeling of ultrafast magnetization dynamics.

# 1    Introduction

Recent advances in magnetism including the design of novel nanostructured magnetic materials, better theoretical understanding of magnetic phenomena, and the development of nanoscale experimental techniques have driven the progress of nanotechnology in general but specially in the data storage industry. Recently, novel high-temperature magnetic phenomena have been discovered and attracted a lot of researchers. One of them is the laser-induced ultrafast magnetization dynamics (see, e.g., Beaurepaire et al. 1996; Vahaplar et al. 2009; Kirilyuk et al. 2010) where a subpicosecond dynamics is observed when a femtosecond laser pulse is applied to magnetic materials. Another example is the spin Seebeck effect (Uchida et al. 2008) where spin currents and spin accumulation are observed in a ferromagnet due to a temperature gradient. Apart from their fundamental interest, these phenomena are very appealing from technological perspectives that range from increasing the speed of the magnetization switching to the production of spin-voltage generators. It has been also found that a good strategy to improve the performance of hard disk devices and magnetic random-access memories is to increase the temperature of the magnetic thin film during the writing process. Therefore, it is necessary to search for models that can describe the magnetic behavior in these novel high-temperature phenomena, in which temperature is often raised up to and above the Curie temperature $T_c$.

In magnetism, micromagnetic modeling is a very useful complement to experimental measurements, especially for calculations of hysteresis and dynamics of magnetic nanostructures such as magnetic thin films, dots, stripes, etc. (Brown 1963a; Fidler and Schrefl 2000; Chantrell et al. 2001). The micromagnetics is essentially a macroscopic continuous theory. It uses a discretization of continuous magnetization function in finite elements or finite differences. The dynamics of each unit in standard micromagnetics is based on the integration of the classical Landau-Lifshitz-Gilbert (LLG) equation of motion (Landau and Lifshitz 1935; Gilbert 2004). It is essentially a zero-temperature equation, although the micromagnetic parameters could be taken as experimentally measured values at a given temperature $T$. The temperature effects are typically included by adding random fields acting on each discretization element with properties consistent with the thermodynamical equilibrium (Brown 1963b; Chubykalo et al. 2003). However, this approach is correct only for low temperatures and largely overestimates the transition temperature $T_c$ (Grinstein and Koch 2003), since the magnitude

of the magnetization vector in each element is constant. At high temperatures, high-frequency spin waves, responsible for longitudinal magnetization fluctuations near the Curie temperature $T_c$, are cut, and the value of the Curie temperature is strongly overestimated. To solve this issue, an alternative micromagnetic approach for higher temperatures based on the Landau-Lifshitz-Bloch (LLB) equation has been proposed (Garanin 1997; Chubykalo-Fesenko et al. 2006) where the magnitude of the magnetization vector is not conserved at each discretization element and the longitudinal magnetization fluctuations are introduced.

Furthermore, a complete description of the material's magnetic behavior requires very different spatial scales going from Ångström (like microscopic interactions at atomic level) to macroscale (magnetic domains typically have micrometer sizes) and also very different timescales going from femtoseconds (as in the ultrafast magnetization dynamics) to years (thermal stability in magnetic storage media). The ab initio models typically calculate microscopic parameters of the material, while atomistic spin (Heisenberg) models are good to describe the phase transitions. However, to model realistic devices such as sensors or magnetic recording head performance, large-scale modeling based on the micromagnetics is used. One way to include the effects of the microscopic properties on the magnetic macroscopic behavior is the multiscale approach (Kazantseva et al. 2008a; Atxitia et al. 2010b; Hinzke et al. 2015). Namely, ab initio calculations (the most widely used formalism is density functional theory (DFT)) are used to calculate the intrinsic parameters as magnetic moment ($\mu$), exchange constants ($J$), on-site magnetocrystalline anisotropy ($k$), etc...; then these parameters are used in atomistic classical (Heisenberg-like) models where the temperature dependence of the equilibrium magnetization $M_s(T)$, anisotropy $K(T)$, and exchange stiffness $A(T)$ among other properties can be calculated; and finally the temperature dependence of these parameters is included in the micromagnetic approach which can model the magnetic behavior at large spatial scale (see the sketch in Fig. 1). The temperature is an essential part of this approach, and the correct micromagnetic description is based on the LLB equation (Kazantseva et al. 2008a).

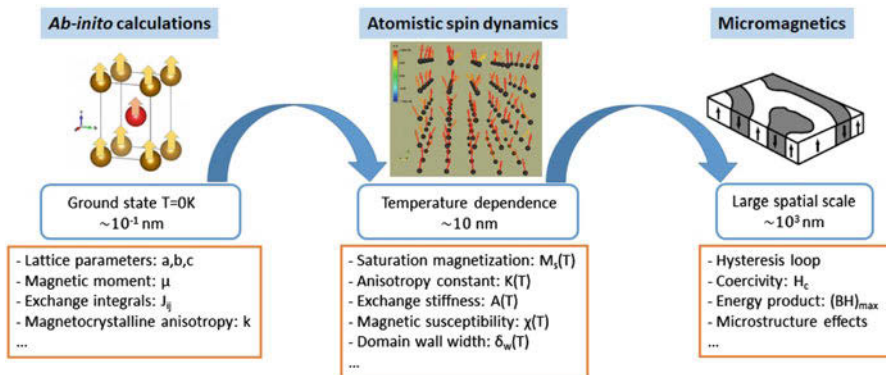

**Fig. 1** The sketch of the multiscale approach

The micromagnetic modeling based on the LLB equation has manifested itself as a good approach to model new phenomena such as the ultrafast magnetization dynamics (Kazantseva et al. 2008a; Sultan et al. 2012; Atxitia et al. 2007, 2010a, 2016; Mendil et al. 2014), spin caloritronics (Hinzke and Nowak 2011; Schlickeiser et al. 2014), and heat-assisted magnetic recording (McDaniel 2012; Greaves et al. 2015; Takano et al. 2011; Vogler et al. 2014, 2016) processes.

## 2 Classical Micromagnetic Models

### 2.1 The Classical Heisenberg (Atomistic) Modeling

The magnetic moments in the solid state can be localized or semi-localized, carried by the conduction electrons (itinerant magnetism) like in metals. However, models based on a classical Heisenberg Hamiltonian of localized spins are currently used to describe the magnetic properties in both situations. Typically, the generalized Heisenberg Hamiltonian for a uniaxial magnet in these atomistic models is written as

$$\mathcal{H} = -\sum_i \mathbf{H} \cdot \boldsymbol{\mu}_i - \sum_i k_i s_{i,z}^2 - \frac{1}{2} \sum_{i,j} J_{ij} \mathbf{s}_i \cdot \mathbf{s}_j, \tag{1}$$

where $\mathbf{H}$ is the external magnetic field, $\boldsymbol{\mu}_i$ is the magnetic moment per atom at site $i$, $\mathbf{s}_i = \boldsymbol{\mu}_i / \mu_i$, $k_i$ is the uniaxial atomic-site anisotropy constant, and $J_{ij}$ is the exchange constant between the spins $i$ and $j$. The first term in Eq. (1) corresponds to the Zeeman energy, the second term is the on-site uniaxial magnetocrystalline anisotropy energy (where the uniaxial axis is along the z-axis), and the last one is the exchange energy. The exchange energy may be long-range corresponding to the RKKY interactions and site-dependent. The dynamics of each normalized classical atomic magnetic moment $\mathbf{s}_i$ is described using the phenomenological Landau-Lifshitz-Gilbert (LLG) equation given by

$$\frac{d\mathbf{s}_i}{dt} = -\frac{\gamma}{1+\lambda^2} (\mathbf{s}_i \times \mathbf{H}_{\mathrm{eff},i}) - \frac{\gamma\lambda}{(1+\lambda^2)} \mathbf{s}_i \times (\mathbf{s}_i \times \mathbf{H}_{\mathrm{eff},i}), \tag{2}$$

where $\gamma$ is the gyromagnetic ratio, $\lambda$ is called atomic coupling to the bath (atomistic damping) parameter, $\mathbf{H}_{\mathrm{eff},i} = -\partial \mathcal{H}/\partial \boldsymbol{\mu}_i$ is the effective field, and $\mathcal{H}$ is the Hamiltonian given by Eq. (1). Equation (2) is a deterministic equation; it means that given the same initial conditions, one obtains always exactly the same dynamics. However, the atomic magnetic moment in a solid follows a stochastic dynamics due to the interaction with its surroundings. This fact is included in Eq. (2) adding a stochastic field $\boldsymbol{\zeta}_i$ to the effective field $\mathbf{H}_{\mathrm{eff},i}$, that is,

$$\frac{d\mathbf{s}_i}{dt} = -\frac{\gamma}{1+\lambda^2} (\mathbf{s}_i \times (\mathbf{H}_{\mathrm{eff},i} + \boldsymbol{\zeta}_i)) - \frac{\gamma\lambda}{(1+\lambda^2)} \mathbf{s}_i \times (\mathbf{s}_i \times (\mathbf{H}_{\mathrm{eff},i} + \boldsymbol{\zeta}_i)), \tag{3}$$

where the stochastic field has the following time average properties following the Brown's theory for nanoparticles (Brown 1963b)

$$\langle \zeta_{i,k} \rangle = 0, \quad \langle \zeta_{i,k}(0) \zeta_{i,k'}(t) \rangle = 2 \frac{\lambda k_B T}{\gamma \mu_i} \delta_{kk'} \delta(t), \quad k, k' = x, y, z, \tag{4}$$

where $k_B$ is the Boltzmann constant and $\delta$ is Kronecker delta symbol. This approach is called atomistic spin dynamics (ASD) (Skubic et al. 2008; Evans et al. 2014; Eriksson et al. 2017). The macroscopic magnetization at time $t$ is obtained as an average of the atomic magnetic moments over some volume $V$

$$\mathbf{M}(t) = \frac{1}{V} \sum_{i=1}^{N} \boldsymbol{\mu}_i(t), \tag{5}$$

where $N$ is the total number of atomic magnetic moments inside the volume $V$.

Simulations based on ASD is a powerful tool to describe the magnetic behavior of magnetic materials. Importantly, the ASD simulations lead to a good agreement with the experimentally measured Curie temperatures. Unfortunately, the size of a magnetic material that can be simulated using ASD is very limited (typically up to $(20-30 \, \text{nm})^3$ due to a large number of differential equations that must be numerically integrated.

## 2.2   Classical Micromagnetic Models at Low Temperatures

A suitable approach to study the behavior of magnetic materials at large scale is micromagnetics. It is based on the continuum approximation where the length scales considered are large enough for the atomic structure of the material to be ignored and small enough to resolve magnetic structures such as domain walls or vortices. In the continuum approximation the macroscopic magnetization is assumed to be a spatial continuous function over the material

$$\mathbf{M}(\mathbf{r}) = M_s \mathbf{m}(\mathbf{r}), \tag{6}$$

where $|\mathbf{m}(\mathbf{r})| = 1$ and $M_s$ is the saturation magnetization. In this approach the energy of a uniaxial magnetic system reads (e.g., Coey 2009)

$$E = \int_V d\mathbf{r} \{ -\mathbf{M} \cdot \mathbf{H} - K m_z^2 + A(\nabla \mathbf{m})^2 - \frac{1}{2} \mathbf{M} \cdot \mathbf{H}_d \}, \tag{7}$$

where $K$ is the macroscopic uniaxial anisotropy constant, $A$ is the exchange stiffness parameter, $(\nabla \mathbf{m})^2 = (\nabla m_x)^2 + (\nabla m_y)^2 + (\nabla m_z)^2$, $\nabla$ is the gradient operator, and $\mathbf{H}_d$ is the magnetostatic field which must be calculated self-consistently.
**Fig. 2** Illustration of the relation between atomistic model and micromagnetics. (Reprinted from Nieves 2015)

In order to solve micromagnetic problems numerically, the system is divided in cells of volume $V_i$ (typically around few nm$^3$), and then the average magnetization of the cell at position $\mathbf{r}_i$ is represented by vector called macrospin (see Fig. 2), $\mathbf{M}(\mathbf{r}_i) = \mathbf{M}_i = M_s \mathbf{m}_i$. In a coarse-grained (multiscale) approach, the mascrospin is the average of atomic spin moments in the sense of Eq. (5). In order to choose a suitable volume cell, it is important to take into account the domain wall width parameter $\delta$ and the exchange length $l_{\text{ex}}$ which are given by

$$\delta = \pi \sqrt{\frac{A}{K}} \ , \qquad l_{\text{ex}} = \sqrt{\frac{A}{M_s^2}}. \tag{8}$$

The domain wall width parameter corresponds to the width of a Bloch wall that is found in magnetic materials with a large magnetocrystalline anisotropy. The exchange length is the length below which atomic exchange interactions dominate typical magnetostatic fields, and it is proportional to the Néel domain wall width. The discretization length must be less than the domain wall width but includes enough atoms to be valid as the continuous approximation. The main difficulty of micromagnetics is the correct calculation of the long-range magnetostatic fields.

The standard dynamic micromagnetics is based on the same LLG equation as in the atomistic approach (however with more justified damping form) for the macrospin $\mathbf{M}_i$ given by

$$\frac{d\mathbf{M}_i}{dt} = -\frac{\gamma}{1 + \alpha_{\text{LLG}}^2}(\mathbf{M}_i \times \mathbf{H}_{\text{eff},i}) - \frac{\gamma \alpha_{\text{LLG}}}{(1 + \alpha_{\text{LLG}}^2)M_s}\mathbf{M}_i \times (\mathbf{M}_i \times \mathbf{H}_{\text{eff},i}), \tag{9}$$

where $\alpha_{\text{LLG}}$ is called the LLG damping (not to be confused with the microscopic damping in the atomistic approach, often designated with the same letter $\alpha$ but called

here $\lambda$ in order to stress the difference) and $\mathbf{H}_{\text{eff},i}$ is the effective field which is given by

$$\mathbf{H}_{\text{eff},i} = -\frac{1}{V_i}\frac{\partial E}{\partial \mathbf{M}_i} = \mathbf{H}_i + \frac{2K_i m_{i,z}}{M_s}\mathbf{e}_z + \frac{2A_i}{M_s}\nabla^2 \mathbf{m}_i + \mathbf{H}_{d,i}. \tag{10}$$

The temperature effects in micromagnetism are typically included in the following way:

(i) *Via temperature-dependent parameters:* The parameters $M_s(T)$, $A(T)$, $K(T)$, $\alpha_{\text{LLG}}(T)$ are taken at given temperature. Importantly the damping parameter $\alpha_{\text{LLG}}$ is also temperature-dependent which is frequently forgotten. As it was mentioned in the introduction, their temperature dependence can be calculated numerically using ASD within the multiscale approach; a detailed explanation of this calculation can be found, for example, in Kazantseva (2008) for FePt. They can also be obtained theoretically, for example, using the mean-field approximation (MFA) or measured experimentally.

(ii) *Via thermal field:* In 1963 W.F. Brown (1963b), considering the superparamagnetism problem in a collection of non-interacting nanoparticles, suggested to include thermal fluctuations in the LLG dynamical equation as stochastic fields whose properties are defined by the equilibrium solution of the corresponding Fokker-Planck (FP) equation. Importantly, these fields are just formal quantities and do not have physical sense; they are used in order to produce stochastic deviations of different magnetization trajectories from their averaged value with correct statistical properties. In 1993 Lyberatos and Chantrell (1993) for the first time studied the dynamics of two interacting magnetic dipoles including these fluctuating thermal fields. This idea was further developed by many authors (Nakatani et al. 1997; García-Palacios and Lázaro 1998; Scholz et al. 2001; Chubykalo et al. 2002). It was shown that the stochastic fields remain uncorrelated and with the same properties for the interacting case (Chubykalo et al. 2003). These developments lead to Langevin dynamics micromagnetics where a fluctuating thermal field $\boldsymbol{\zeta}_i$ is added to the effective field given by Eq. (10) with the following time average properties (the same as used in the ASD dynamics)

$$\langle \zeta_{i,k}\rangle_t = 0, \quad \langle \zeta_{i,k}(0)\zeta_{i,k'}(t)\rangle_t = 2\frac{\alpha_{\text{LLG}}k_B T}{\gamma M_s V_i}\delta_{kk'}\delta(t), \quad k, k' = x, y, z. \tag{11}$$

The main feature of this approach is that the magnitude of every macrospin is conserved in all dynamical processes, that is, $|\mathbf{M}_i| = $const. However, the direct comparison with the ASD shows that thermal simulations of the magnetization dynamics based on the micromagnetic LLG equation are not suitable for high temperatures (Chubykalo-Fesenko et al. 2006). This is due to the fact that micromagnetic simulations do not include the high-frequency spin waves, and, thus, the Curie temperature is seriously overestimated (Grinstein and Koch 2003). Additionally, in recent ASD simulations (Chubykalo-Fesenko et al. 2006; Kazantseva et al. 2007),

it has been demonstrated that at high temperatures several important effects occur which cannot be taken into account in the micromagnetic LLG approach. Namely, during the magnetization dynamics, (i) the magnetization vector magnitude is not conserved, (ii) longitudinal magnetization relaxation occurs with the longitudinal relaxation time increment approaching $T_C$ (known as critical slowing down), and (iii) at the same time the transverse relaxation time decreases (Chubykalo-Fesenko et al. 2006). Therefore, a different micromagnetic approach is required at elevated temperatures.

## 2.3    Thermal Micromagnetics at High Temperatures

In 1997 an alternative approach was suggested by D. Garanin (1997). Based on the Fokker-Planck equation, he derived a classical macroscopic equation of motion for the magnetization called Landau-Lifshitz-Bloch (LLB) equation. The name was chosen in order to stress that the magnetization behavior interpolates between the Landau-Lifshitz equation at low temperatures (micromagnetic LLG Eq. (9)) and the well-known Bloch equation (Bloch 1946) at high temperatures. The Bloch equation is a phenomenological equation frequently used in the nuclear spin resonance description, for example, for protons in a water molecule. The dynamical equation for the ensemble of paramagnetic spins involves the same precessional term and two phenomenological relaxational parameters describing the longitudinal relaxation (defined by the characteristic time $T_1$) and the transverse relaxation ($T_2$). In the nuclear spin resonance case $T_2 \ll T_1$, for ferromagnetic materials of the interest here, the situation is the opposite due to a dominant role of large exchange interactions.

The derivation of the classical LLB assumes the classical atomistic approach (ASD) of Sect. 2.1, only based on the Landau-Lifshitz (LL) equation instead of the LLG (i.e., disregarding the term $\lambda^2$ in Eq. (2), which anyway is small). First, the Fokker-Planck equation corresponding to many-spin Eq. (9) was calculated in Garanin (1997) (see also details in Atxitia 2012). Using the dynamics of the probability function, governed by this equation and disregarding the third-order moment distribution, one obtains an equation for thermal average of the spin polarization, i.e., the reduced magnetization $\mathbf{m} = < \mathbf{s}_i >$ in a paramagnetic state. For the treatment of ferromagnet, the external field is substituted by the mean field.

The corresponding LLB equation for $\mathbf{m}$ has the following form (see details in Garanin 1997 and Atxitia 2012):

$$\frac{d\mathbf{m}}{dt} = -\gamma[\mathbf{m} \times \mathbf{H}^{\text{MFA}}] - \Gamma_\parallel \left(1 - \frac{\mathbf{m}\mathbf{m}_0}{m^2}\right)\mathbf{m} - \Gamma_\perp \frac{[\mathbf{m} \times [\mathbf{m} \times \mathbf{m}_0]]}{m^2}, \qquad (12)$$

where

$$\mathbf{m}_0 = L(\xi)\frac{\boldsymbol{\xi}}{\xi}, \quad \boldsymbol{\xi} \equiv \beta\mu\mathbf{H}^{\text{MFA}}, \quad \mathbf{H}^{\text{MFA}} = \frac{zJ}{\mu}\mathbf{m} + \mathbf{H}'. \qquad (13)$$

Here $\xi \equiv |\boldsymbol{\xi}|$, $L(\xi) = \coth(\xi) - 1/\xi$ is the Langevin function, $\beta = 1/k_B T$, $k_B$ is the Boltzmann constant; $\mu$ is the atomic magnetic moment; $z$ is the number of nearest neighbors; $J$ is the Heisenberg exchange interaction parameter; $\mathbf{H}'$ contains the external magnetic field and the nonhomogeneous part of the exchange interaction;

$$\Gamma_{\parallel} = \Lambda_N \frac{L(\xi)}{\xi L'(\xi)}, \quad \Gamma_{\perp} = \frac{\Lambda_N}{2} \left( \frac{\xi}{L(\xi)} - 1 \right) \tag{14}$$

describe parallel and perpendicular relaxation rates, respectively; $\Lambda_N = 2\gamma \lambda k_B T/\mu$ is the characteristic diffusion relaxation rate or, for the thermo-activation escape problem, the Néel attempt frequency; and $L'(\xi) = dL/d\xi$ is the derivative of the Langevin function. This equation can be already used for modeling and in many cases gives even a better agreement with the ASD than a more conventional LLB equation presented below.

To put this equation in the form, similar to the LLG one, the homogeneous part of the exchange field is assumed to be much larger than all other fields acting in the system ($[zJ/\mu]m \gg H'$). This leads to the conventional form of the LLB equation which in micromagnetics is written for each discretization element (macrospin) $i$

$$\frac{d\mathbf{m}_i}{dt} = -\gamma \left[ \mathbf{m}_i \times \mathbf{H}_{\text{eff}}^i \right] + \frac{\gamma \alpha_{\parallel}}{m_i^2} \left( \mathbf{m}_i \cdot \mathbf{H}_{\text{eff}}^i \right) \mathbf{m}_i - \frac{\gamma \alpha_{\perp}}{m_i^2} \left[ \mathbf{m}_i \times \left[ \mathbf{m}_i \times \mathbf{H}_{\text{eff}}^i \right] \right], \tag{15}$$

where $\mathbf{m}_i = \mathbf{M}_i/M_e(0)$ with $M_e(0) = M_s(0)$ being the equilibrium saturation magnetization at $T = 0K$. The longitudinal and transverse relaxation parameters are

$$\alpha_{\parallel} = \lambda \frac{2T}{3T_c}, \qquad \alpha_{\perp} = \lambda \cdot \begin{cases} \left[ 1 - \frac{T}{3T_c} \right] & T \lesssim T_c, \\ \frac{2T}{3T_c} & T \gtrsim T_c. \end{cases} \tag{16}$$

Note that in the alternative representation, the magnetization can be normalized at its value at $T$, i.e., using $\mathbf{n}_i = \mathbf{M}_i/M_e(T)$ as is typically done for the LLG micromagnetics. This leads to the same form of the LLB equation but now for the variable $\mathbf{n}_i$. The only difference is the renormalization of the damping parameters by the factor $m_e = M_e(T)/M_e(0)$. Since $m_e \to 0$ at $T_c$, this form of the LLB equation is obviously not useful for modeling near the phase transition but should be used for the comparison with the LLG micromagnetic modeling.

In the LLB-based micromagnetic approach, the effective fields are given by

$$\mathbf{H}_{\text{eff}}^i = \mathbf{H} + \mathbf{H}_{i,\text{EX}} + \mathbf{H}_{i,A} + \begin{cases} \frac{1}{2\tilde{\chi}_{\parallel}} \left( 1 - \frac{m_i^2}{m_e^2} \right) \mathbf{m}_i & T \lesssim T_c, \\ \frac{J_0}{\mu} \left( 1 - \frac{T}{T_c} - \frac{3m_i^2}{5} \right) \mathbf{m}_i & T \gtrsim T_c, \end{cases} \tag{17}$$

where $\widetilde{\chi}_{\parallel} = (\partial m/\partial H)_{H\to\infty}$ is the reduced longitudinal susceptibility and $J_0$ is the zero Fourier component of the exchange interaction which is related to the Curie temperature $T_c$ in the MFA through $T_c = J_0/(3k_B)$ (in the simple cubic lattice case with nearest interactions only $J_0 = 6J$). The last term in Eq. (17) describes the internal exchange field inside the macrospin. $\mathbf{H}$ is the applied magnetic field and $\mathbf{H}_{i,\mathrm{EX}}$ is exchange interaction between macrospins, and it is given by

$$\mathbf{H}_{i,\mathrm{EX}} = \frac{2A_i(T)}{m_i^2 M_s(0)}\nabla^2\mathbf{m}_i = \frac{2A_i(T)}{m_i^2 M_s(0)\triangle^2}\sum_{\langle i,j\rangle}\left(\mathbf{m}_j - \mathbf{m}_i\right), \tag{18}$$

where $\langle i, j\rangle$ means a sum over neighbors, $\triangle$ is the lateral size of the micromagnetic discretization cell, $A_i(T)$ is the micromagnetic exchange also called stiffness parameter, and $\mathbf{H}_{i,A}$ is the anisotropy field given by

$$\mathbf{H}_{i,A} = -\frac{1}{\widetilde{\chi}_{\perp}}\left(m_{i,x}\mathbf{e}_x + m_{i,y}\mathbf{e}_y\right), \tag{19}$$

where $\widetilde{\chi}_{\perp}$ is the reduced transverse susceptibility. Note that the use of the transverse susceptibility is more physically correct as that of the anisotropy (see discussion in Garanin and Chubykalo-Fesenko 2004). However, in practice the anisotropy notion is still used in most of cases, i.e., one assumes $\widetilde{\chi}_{\perp}(T) = M^2/[2K(T)]$.

The LLB equation contains six temperature-dependent parameters: $\lambda(T)$, $M_e(T)$, $A(T)$, $K(T)$, $\widetilde{\chi}_{\parallel}(T)$, and $\widetilde{\chi}_{\perp}(T)$. Typically, the parameter $\lambda$ is considered in ASD temperature independent. This however is not true in the ab initio modeling (see also discussion in Nieves et al. 2014). In principle other parameters can be measured experimentally. In the multiscale approach the temperature dependence of $M_e(T)$, $A(T)$ and $K(T)$ is calculated using ASD (Kazantseva et al. 2008a; Atxitia et al. 2010b; Nieves et al. 2017), and the scaling with magnetization relations can be used for the last two of them (Kazantseva 2008; Atxitia et al. 2010b; Moreno et al. 2016; Asselin et al. 2010). The parameter $M_e(T)$ can be also obtained using the MFA as the solution of the equation $m_e = L(\beta J_0 m_e)$ where $L(x) = \coth(x) - 1/x$ is the Langevin function. The exchange parameter $J_0$ can be calculated by first principles or roughly estimated by MFA expression $J_0 = 3k_B T_c$ using experimental Curie temperature. The reduced longitudinal susceptibility can be calculated either by using MFA as

$$\widetilde{\chi}_{\parallel}(T) = \begin{cases} \dfrac{\mu_{at}\beta L'}{1 - \beta J_0 L'} & T \lesssim T_c, \\[2mm] \dfrac{\mu_{at}T_c}{J_0(T - T_c)} & T \gtrsim T_c, \end{cases} \tag{20}$$

where $L'$ is the derivative of the Langevin function evaluated at $\beta J_0 m_e$, or by ASD simulations (Hinzke et al. 2000).

The first term in Eq. (15) describes the precession of magnetization vector $\mathbf{m}$ around its effective field $\mathbf{H}_{\mathrm{eff}}$ (see Fig. 3a), and the second and the third terms
**Fig. 3** Diagram illustrating the meaning of three terms in the LLB equation: (**a**) precession, (**b**) longitudinal dynamics, and (**c**) transverse dynamics. (Reprinted from Nieves 2015)

describe the longitudinal (see Fig. 3b) and the transverse (see Fig. 3c) dynamics, respectively. Comparing the LLB equation (15) with LLG equation (9), we notice that the former contains an extra term which describes the longitudinal relaxation, that is, it drives the dynamics of the magnitude of **m** giving a more accurate description of the magnetic dynamics at elevated temperatures. In particular this extra term plays a crucial role in ultrafast magnetization dynamics, i.e., at the timescale below 1 ps. At low temperatures the additional internal field in Eq. (17) is very large (since the susceptibility is very small) and keeps the magnetization length constant. Since the LLB equation contains the LLG one, it also describes the damped precession which typically takes place between 0.1 and 10 ns (see Fig. 3a).

The effective field of the LLB equation given by Eq. (17) can be also obtained as

$$\mathbf{H}_{\text{eff}}^i = -\frac{1}{V_i} \frac{\partial \mathcal{F}}{\partial \mathbf{M}_i}, \tag{21}$$

where $\mathcal{F}$ is the free energy given by

$$\mathcal{F}(\mathbf{M}, T) = \mathcal{F}_0 + \int_V d\mathbf{r} \{-\mathbf{M} \cdot \mathbf{H} + \frac{1}{2\chi_\perp}(M_x^2 + M_y^2) + A \left( \nabla \left[ \frac{\mathbf{M}}{M} \right] \right)^2$$

$$+ \frac{1}{8 M_e^2(T)\chi_\parallel}[M^2 - M_e^2(T)]^2\}, \tag{22}$$

where $\mathcal{F}_0$ is the equilibrium free energy in the absence of anisotropy and magnetic field, $\chi_\parallel = M_s(0)\widetilde{\chi}_\parallel$ and $\chi_\perp = M_s(0)\widetilde{\chi}_\perp$. In Kachkachi and Garanin (2001) derived this free energy in the whole temperature range using a procedure based on the MFA. Obviously close to the transition temperature, this functional is reduced to the well-known Landau-Ginzburg expression. This derivation further justifies the thermodynamic consistency of the LLB equation.

Similarly as it was done in the micromagnetic LLG equation, Garanin and Chubykalo-Fesenko (2004) included stochastic thermal fields into the LLB equation. However, Evans et al. (2012) noticed that this approach doesn't recover the Boltzmann distribution close to $T_c$ at equilibrium. In order to solve this issue, they suggested an alternative stochastic LLB equation of the form

$$\frac{d\mathbf{m}_i}{dt} = -\gamma \left[ \mathbf{m}_i \times \mathbf{H}_{\text{eff}}^i \right] + \frac{\gamma \alpha_\parallel}{m_i^2} \left( \mathbf{m}_i \cdot \mathbf{H}_{\text{eff}}^i \right) \mathbf{m}_i$$

$$- \frac{\gamma \alpha_\perp}{m_i^2} \left[ \mathbf{m}_i \times \left[ \mathbf{m}_i \times \left( \mathbf{H}_{\text{eff}}^i + \boldsymbol{\zeta}_{i,\perp} \right) \right] \right] + \boldsymbol{\zeta}_{i,ad}, \qquad (23)$$

with two thermal fields: a multiplicative transverse $\boldsymbol{\zeta}_{i,\perp}$ and an additive longitudinal $\boldsymbol{\zeta}_{i,ad}$ given by

$$\left\langle \zeta_{i,\perp}^k(0) \zeta_{j,\perp}^l(t) \right\rangle = \frac{2\gamma k_B T \left( \alpha_\perp - \alpha_\parallel \right)}{M_e(0) V_i \alpha_\perp^2} \delta_{ij} \delta_{kl} \delta(t) \qquad (24)$$

$$\left\langle \zeta_{i,ad}^k(0) \zeta_{j,ad}^l(t) \right\rangle = \frac{2\gamma k_B T \alpha_\parallel}{M_e(0) V_i} \delta_{ij} \delta_{kl} \delta(t), \qquad (25)$$

where $i$ and $j$ denote macrospin index and $k$ and $l$ denote the Cartesian components x, y, and z. Thus in order to describe the thermal dispersion of the magnetization trajectories, we now have a Langevin dynamics simulations based on the LLB equation. The dispersion of magnetization trajectories is very important for modeling of magnetization dynamics under the action of thermal laser pulse (Kazantseva et al. 2008a). Note that not very close to $T_c$ the approaches of Garanin and Chubykalo-Fesenko (2004) and Evans et al. (2012) are indistinguishable.

The comparison of the macrospin LLB equation with direct ASD simulations gives a very good agreement (Chubykalo-Fesenko et al. 2006; Kazantseva et al. 2008a). Note that a typical problem of the thermal micromagnetics is the presence of finite-size effects, i.e., the dependence of the average magnetization on the discretization size. Comparatively to the LLG approach, thermal micromagnetics based on the LLB equation have these effects largely reduced (Atxitia et al. 2007). This happens due to the fact that the LLB equation forces the equilibrium solution to be $M_e$. However, the finite-size effects are an inherent part of the thermal micromagnetic approach and are always present (Atxitia et al. 2007). If these effects are taken into account, the agreement between the atomistic and LLB-based micromagnetics can be even better (Vogler et al. 2014, 2016).

## 3 The Quantum (Semiclassical) Landau-Lifshitz-Bloch Equation

The above LLB equation is based on the ASD approach. There is also a quantum derivation, which was published even earlier than the classical one by Garanin et al. (1990) and Garanin (1991). Obviously, the quantum derivation can be made for simplified models only. In the original derivation, this was done for an isolated spin interacting with a phonon bath via direct and Raman processes with the Hamiltonian presented in Fig. 4. Lately, this was also done for a spin interacting with a simple electron bath by Nieves et al. (2014) following a simple model of Koopmans et al. (2005) conceived for ultrafast magnetization dynamics.

Hamiltonian:

Scattering probabilities

$$\hat{H} = -\mathrm{H}(t)\cdot\hat{\mathrm{S}} + \sum_q w_q \hat{a}_q^+ \hat{a}_q - \sum_q V_q(\eta\cdot\hat{\mathrm{S}})(\hat{a}_q^+ + \hat{a}_{-q}) - \sum_{p,q} V_{p,q}(\eta\cdot\hat{\mathrm{S}})\hat{a}_p^+ \hat{a}_q$$

$|\sigma\rangle \qquad |\sigma\rangle \quad |-q\rangle \qquad |\sigma\rangle \qquad |q\rangle$
**Fig. 4** The sketch of the quantum model based on the spin-phonon scattering. (Reprinted from Nieves 2015)

The derivation of the quantum LLB (qLLB) equation by Garanin (1991) is based on a standard density matrix approach (see, e.g., Blum 1981; Garanin 2012) for a system interacting weakly with a bath. The sketch for the spin-phonon model is presented in Fig. 4, and the spin-electron model can be found in Nieves et al. (2014). Namely, starting from the Schrödinger equation, one can obtain a Liouville equation for the time evolution of the density operator $\hat{\rho} = |\Psi\rangle\langle\Psi|$, where $|\Psi\rangle$ is the wave function of the whole system (spin and phonons or spin and electrons). Next, the bath is assumed to be in a quasi-equilibrium meaning that at this timescale the phonon (electron) distribution can be described by the Bose-Einstein (Fermi-Dirac) one with a defined temperature (Nieves et al. 2014) although the temperature is still slow varying in time. The temperature dynamics can be external, for example, described by the two-temperature model (Atxitia et al. 2007; Nieves and Chubykalo-Fesenko 2016; John et al. 2017; Mendil et al. 2014). Note that in the self-consistent description, the magnetization dynamics also produces a temperature dynamics and vice versa (Nieves et al. 2016).

Furthermore, the interactions with the bath are assumed to be small so that they cannot cause a significant entanglement between both systems; this allows to factorize the density operator by its spin and bath part $\hat{\rho}(t) \cong \hat{\rho}_s(t)\hat{\rho}_b^{eq}$ and average over the bath variable (Garanin 2012). The following approximations are also made: (i) the Markov or short memory approximation assuming that the spin dynamics is slower than the phonon (electron) dynamics; (ii) the secular approximation, which consists in neglecting the fast oscillating terms; (iii) as in the classical case, the interactions are taken into account in the MFA, the homogeneous part of the exchange field is considered to be much larger than all other approximations, and close to $T_c$ the expansion $H_\mathrm{E} \simeq (J_0/\mu_\mathrm{at})(m_e + \widetilde{\chi}_\parallel h)$ is used.

The final formal form of the qLLB equation is the same as in the classical case (15), the equilibrium magnetization is defined now by the Brillouin function for the spin S: $m_e = B_S(\beta J_0 m_e)$, and the MFA longitudinal susceptibility $\widetilde{\chi}_\parallel$ follows from it at $T < T_c$ as $\widetilde{\chi}_\parallel = \mu_{at}\beta B'_S/(1 - \beta B'_S J_0)$ where $B'_S(x) = dB_S/dx$ is

evaluated at the equilibrium $B'_S = B'_S(\beta J_0 m_e)$. The parameters $\alpha_\parallel$ and $\alpha_\perp$ are different and can be conveniently expressed in a form which is suitable for the comparison with the classical LLB equation. Below $T_c$ the damping parameters are written as

$$\alpha_\parallel = \lambda \frac{2T}{3T_c} \frac{2q_s}{\sinh(2q_s)} \tag{26}$$

$$\alpha_\perp = \lambda \left[ \frac{\tanh(q_s)}{q_s} - \frac{2T}{3T_c} \left( 1 - \frac{K_1}{2K_2} \right) \right], \tag{27}$$

where $q_s = 3T_c m_e / (2(S+1)T)$ and

$$\lambda = K_2 \frac{(S+1)}{S} \frac{\mu_{at}}{\gamma k_B T}. \tag{28}$$

has the sense of atomistic damping (coupling to the bath) parameter. The parameters $K_1$ and $K_2$ are related to the microscopic scattering probabilities (see Nieves et al. 2014).

Below $T_c$ the effective field used in Eq. (15) is given by Eq. (17). Above $T_c$ we also rewrite the effective field in terms of the longitudinal susceptibility at $T > T_c$, i.e., $\tilde{\chi}_\parallel = \mu T_c / [J_0(T - T_c)]$, and the field reads as

$$\mathbf{H}_{\text{eff}} = -\frac{1}{\tilde{\chi}_\parallel} \left( 1 + \frac{3T_c m^2}{5A_s(T - T_c)} \right) \mathbf{m} + \mathbf{h} \ , \ \frac{T_c}{T - T_c} \gg 1, \tag{29}$$

where $A_s = 2(S+1)^2 / ([S+1]^2 + S^2)$ and $\mathbf{h}$ contains all other fields (Zeeman, anisotropy, (external) inter-macrospin exchange, and magnetostatic). Note that although $\tilde{\chi}_\parallel$ is divergent at $T_c$ as it corresponds to the second-order phase transition, the internal exchange field is the same for any $T_c - \varepsilon$ and $T_c + \varepsilon$ insuring that under the integration of the LLB equation, $\mathbf{m}(t)$ rests continuous through the critical point. In the region just above $T_c$, $q_s = 0$ and $K_1 \cong K_2$, so that the damping parameters become approximately the same and equal to the one presented in Eq. (16), where the dependence on the spin value $S$ is included implicitly through $\lambda$ (see Eq. (28)).

In the special case with $S = 1/2$ and pure longitudinal dynamics, the qLLB equation is reduced (see details in Nieves et al. 2014) to the so-called self-consistent Bloch equation (see Xu and Zhang 2012)

$$\frac{d\mathbf{m}}{dt} = -\gamma \mathbf{m} \times \mathbf{h} - \frac{\mathbf{m} - \mathbf{m}_0}{\tau_s}, \tag{30}$$

where $\mathbf{m}_0 = B_{1/2}(\xi)\boldsymbol{\xi}/\xi$ and $\tau_s = 1/K_2$ the spin relaxation time. This equation may be further simplified taking into account that the exchange field is large in which case it is reduced to

$$\frac{dm}{dt} = \frac{m}{\tau_s}\left[1 - m\coth\left(\frac{mT_c}{T}\right)\right].$$  (31)

The above equation was used as a part of the so-called three-temperature model (M3TM) by Koopmans et al. (2010), in which $\tau_s$ is related to the Elliott-Yafet scattering probability.

## 4    The Two-Sublattice Landau-Lifshitz-Bloch Equation

For the treatment of a two-sublattice ferro- or ferrimagnet by Atxitia et al. (2012), two Eq. (12) are written for each sublattice separately, and the mean field contains inter- and intra-sublattice contributions. For the disordered case with different concentrations of the species (such as the case of $Gd_xCo_{1-x}$, see Fig. 5), the MFA field reads:

$$\mathbf{H}_v^{MFA} = \frac{J_{0,v}}{\mu_v}\mathbf{m}_v + \frac{J_{0,v\kappa}}{\mu_v}\mathbf{m}_\kappa + \mathbf{h}_v,$$  (32)

where $J_{0,v} = x_v z J_{vv}$, $J_{0,v\kappa} = x_\kappa z J_{v\kappa}$; $z$ is the number of nearest neighbors in the ordered lattice; $J_{vv}$ and $J_{v\kappa}$ are the Heisenberg intra- and intersublattice exchange interaction parameters; $x_v$ and $x_\kappa = 1 - x_v$ are the concentrations of the sublattices $v$ and $\kappa$, respectively; and $\mathbf{h}_v$ contains the external applied and the anisotropy fields acting on the sublattice $v$. With the same approximations as in the case of the classical one sublattice LLB equation, one arrives at two coupled LLB equations of the form Eq. (15) for each sublattice, where the effective field is given by

$$\mathbf{H}_{eff,v} = \mathbf{H} + \mathbf{H}_{A,v} + \frac{J_{0,v\kappa}}{\mu_v}\mathbf{\Pi}_\kappa$$  (33)

$$- \left[\frac{1}{\Lambda_{vv}}\left(m_v - m_{e,v}\right) - \frac{1}{\Lambda_{v\kappa}}\left(|\tau_\kappa| - |\tau_{e,\kappa}|\right)\right]\frac{\mathbf{m}_v}{m_v},$$

**Fig. 5** Sketch of a disordered magnetic alloy from the point of view of the atomistic model (left panel) and the micromagnetic LLB model (right panel). (Reprinted from Atxitia et al. 2012)
where $\mathbf{H}_{A,v}$ is the anisotropy field, $\mathbf{H}$ is the applied field, $\mathbf{\Pi}_\kappa = -[\mathbf{m}_v \times [\mathbf{m}_v \times \mathbf{m}_\kappa]]/m_v^2$, $\tau_v = (\mathbf{m}_v \cdot \mathbf{m}_\kappa)/m_\kappa$, $\tau_{e,v} = (\mathbf{m}_{e,v} \cdot \mathbf{m}_{e,\kappa})/m_{e,\kappa}$, and

$$\Lambda_{vv}^{-1} = \frac{1}{\widetilde{\chi}_{v,||}} \left( 1 + \frac{J_{0,v\kappa}}{\mu_v} \widetilde{\chi}_{\kappa,||} \right), \quad \Lambda_{v\kappa}^{-1} = \frac{|J_{0,v\kappa}|}{\mu_v}. \tag{34}$$

The longitudinal susceptibility can be calculated in the MFA as in Atxitia et al. (2012)

$$\widetilde{\chi}_{v,||} = \frac{\mu_\kappa \beta L'_v J_{0,v\kappa} \beta L'_\kappa + \mu_v \beta L'_v \left( 1 - J_{0,\kappa} \beta L'_\kappa \right)}{\left( 1 - J_{0,v} \beta L'_v \right) \left( 1 - J_{0,\kappa} \beta L'_\kappa \right) - J_{0,\kappa v} \beta L'_v J_{0,v\kappa} \beta L'_\kappa}, \tag{35}$$

where $L'_v = L'(\xi_{e,v})$ with $\xi_{e,v} = \beta(J_{0,v} m_{e,v} + |J_{0,v\kappa}| m_{e,\kappa})$. The damping parameters are

$$\alpha_{||}^v = \frac{2\lambda_v}{\beta \widetilde{J}_{0,v,e}}, \quad \alpha_\perp^v = \lambda_v \left( 1 - \frac{1}{\beta \widetilde{J}_{0,v,e}} \right), \tag{36}$$

where $\widetilde{J}_{0,v,e} = J_{0,v} + |J_{0,v\kappa}| (m_{e,\kappa}/m_{e,v})$. Note that all the expressions above are the same for two-sublattice ferrimagnetic and ferromagnetic alloys.

The quantum case only differs by the damping parameters which now have the forms (see Nieves 2015):

$$\alpha_{||}^v = \frac{2\lambda_v}{\beta \tilde{J}_{0,v,e}} \left( \frac{S_v}{S_v + 1} \right) \frac{2q_v}{\sinh(2q_v)}, \tag{37}$$

$$\alpha_\perp^v = \lambda_v \left[ \frac{\tanh(q_v)}{q_v} - \frac{2S_v}{(S_v + 1)\beta \tilde{J}_{0,v,e}} \left( 1 - \frac{K_{1,v}}{2K_{2,v}} \right) \right], \tag{38}$$

where $q_v = (\beta \tilde{J}_{0,v,e} m_{e,v})/(2S_v)$ and $\lambda_v = [\beta \mu_v K_{2,v}(S_v + 1)]/[\gamma_v S_v]$.

In the equations above the longitudinal susceptibility $\widetilde{\chi}_{v,||}$ should be evaluated in MFA using the Brillouin function.

Taking the limits $S_v \to \infty$ and $S_\kappa \to \infty$ in the quantum version, we arrive to the classical LLB equation for disordered magnetic alloys. On the other hand, if we take the limit $x_\kappa \to 0$ (i.e., the impurities are removed), then we obtain the qLLB equation for a ferromagnet. Very recently, Vogler et al. (2018) incorporated stochastic fluctuations to the classical two-sublattice LLB.

## 4.1    The Relaxation Rates

The main difference of the high-temperature micromagnetics based on the LLB equation and the conventional micromagnetics is the temperature-dependent relaxation. It is defined by the two main characteristic times, obtained by the linearization. These are the longitudinal relaxation time

$$\tau_{\parallel} = \frac{\widetilde{\chi}_{\parallel}}{\gamma \alpha_{\parallel}}, \tag{39}$$

which defines the speed of the change of the magnetization length and the transverse relaxation time $\tau_{\perp}$, i.e., the characteristic time taken by the transverse component of magnetization to relax to the effective field **h** including the external field and the anisotropy contributions

$$\tau_{\perp} = \frac{\gamma \, h \, m_e}{\alpha_{\perp}}. \tag{40}$$

The corresponding transverse relaxation below $T_c$ may be put in the more common form of the macroscopic LLG equation. For this instead of the normalization of magnetization to the total spin polarization, one should use its normalization to the saturation magnetization value, i.e., $M_e(T)$. The resulting equation is the same LLB one but with a different damping parameters, called here $\alpha_{\text{LLG}}$.

$$\alpha_{\text{LLG}} = \frac{\alpha_{\perp}}{m_e}. \tag{41}$$

Note that while both $\alpha_{\parallel}$ and $\alpha_{\perp}$ are continuous through $T_c$, $\tau_{\parallel}$ and $\alpha_{LLG}$ diverge at $T_c$, corresponding to the critical behavior at the phase transition. At the same time the perpendicular relaxation time goes to zero which constitutes one of the main differences between the LLG and the LLB dynamics.

The most important manifestation of the high-temperature dynamics is the longitudinal relaxation time. It will show itself only close to the phase transition due to the fact that at relatively low temperatures the longitudinal susceptibility is small. At $T_c$ the susceptibility diverges as well as the longitudinal relaxation time. This divergence is only visible very close to $T_c$ so that for practical reasons the longitudinal timescale is still at femtosecond scale for $T/T_c = 0.9$. However, this timescale is now accessible with the ultrafast magnetization dynamics exited by fs laser or THz radiation.

An example of the temperature dependence of the longitudinal relaxation time is presented in Fig. 6. It has the following asymptotic behavior:

$$\tau_{||} \cong \frac{\mu_{at}}{2\gamma \lambda k_B T_c} \frac{S+1}{S} \begin{cases} \frac{T_c}{T S} & T \ll \min(T_c, \frac{T_c}{S}), \\ \frac{1}{3}\left[1 + \left(\frac{S}{S+1}\right)\frac{T}{T_c}\right] & \frac{T_c}{S} \ll T \ll T_c, \\ \frac{T_c}{2(T_c - T)} & \frac{T_c}{T_c - T} \gg 1, \\ \frac{T_c}{T - T_c} & \frac{T_c}{T - T_c} \gg 1. \end{cases} \tag{42}$$

Note that its behavior is in agreement with the well-known relation, proposed by Koopmans et al. (2010), that the ultrafast demagnetization time scales with the ratio $\mu_{at}/T_c$ and proposed by Kazantseva et al. (2008b) and Ostler et al. (2012) that it scales as a ratio $\mu_{at}/\lambda$. As was pointed out elsewhere by Atxitia and Chubykalo-Fesenko (2011) and Atxitia et al. (2014), the complete expression involves the
**Fig. 6** Longitudinal relaxation time (Eq. (39)) versus temperature using constant $\lambda = 0.02$, $T_c = 650$ K, and $\mu_{at} = 0.5\mu_B$ in the three spin cases with $S = 1/2$, $S = 9/2$, and $S = \infty$. The case $S = \infty$ is done by taking the limit $S \rightarrow \infty$ in Eq. (39), which is equivalent to the classical LLB equation. (Reprinted from Nieves et al. 2014)

combination of both. The two last lines in Eq. (42) describe the effect of the critical slowing down near the critical temperature. Note that the relaxation time is twice large above $T_c$ than below it. Furthermore, the relaxation time decreases with the increase of the quantum number $S$. This is due to the fact that for larger $S$ one increases the number of scattering possibilities. Furthermore, there is also an increase of the longitudinal relaxation time for low temperatures, visible especially for $S = 1/2$. This is due to the well-known fact of the freezing of fluctuations at low temperature in the quantum case and is reflected also in the fact that the perpendicular damping parameter goes to zero in the quantum case (see Eq. (27)), while it tends to a constant value in the classical case. In any case, there is an additional temperature dependence not considered above due to the fact that $\lambda(T)$ is a function of temperature itself since it contains the scattering probabilities. This dependence is specific for the scattering mechanism (see Nieves et al. 2014, Nieves 2015).

While in the LLB equation we use the longitudinal susceptibility at zero field (diverging at $T_c$), the resulting susceptibility at constant field does not diverge. In Fig. 7 we present the longitudinal relaxation time as a function of the temperature in constant applied field for the two limiting cases $S = 1/2$ and $S = \infty$. The longitudinal relaxation time was evaluated by direct integration of the qLLB equation with initial conditions $m_0 - m_e = 0.1m_e$. The longitudinal relaxation time for $S = 1/2$ is smaller in the classical case than for the quantum one, and, as expected, the maximum is displaced for larger values at larger fields.

For the two-sublattice case, it is also possible to analyze the relaxation rates of the two sublattices. However, the equations are coupled and the situation depends
**Fig. 7** The in-field longitudinal relaxation time calculated via direct integration of the qLLB equation with small deviation from the equilibrium. The following parameters are used $T_c = 650\,$K, $\mu_{at} = 0.5\mu_B$, $\lambda = 0.02$, and zero anisotropy constant. (Reprinted from Nieves et al. 2014)

**Fig. 8** Longitudinal relaxation time of the (**a**) transition metal (TM), strong intersublattice exchange and (**b**) rare earth (RE), weak intersublattice exchange, evaluated for the $Gd_{0.25}Fe_{0.75}$ compound and different intersublattice strengths $J_{TR}$. The parameter $J_1$ corresponds to a typical (relatively weak) intersublattice strength of this material (see Suarez et al. 2015 and Ostler et al. 2011 for the values). (Reprinted from Suarez et al. 2015)

strongly on the coupling strength. Typically the divergence of the longitudinal relaxation time is suppressed by interactions (as in the case of the external field), and individual longitudinal relaxation times simply have maximum at different critical temperatures for each sublattice. An example of the longitudinal relaxation time for different intersublattice exchange strengths is presented in Fig. 8. In weakly coupled ferrimagnets, only the material with the largest exchange value slows down at the common Curie temperature (see Suarez et al. 2015).

If the coupling is not very strong and for relatively low temperatures, we can estimate the longitudinal relaxation time as defined by the exchange field acting on each sublattice as

$$\tau_v^{\|} \approx \frac{1}{2\gamma_v \lambda_v m_{v,e} H_{v,e}^{ex}}, \tag{43}$$

where

$$H_{v,e}^{ex} = \frac{\widetilde{J}_{0,v,e}}{\mu_v} m_{e,v}, \tag{44}$$

is the homogeneous exchange field evaluated at the equilibrium. Note that in this approximation, the relaxation time is independent on the sign of the coupling between sublattices (ferro or antiferro).

Interestingly that varying the initial temperature, the demagnetization speed of the initially slower material may become faster than that of the high-speed material. For example, Gd in GdFe may become faster than Fe at high initial temperatures (Atxitia et al. 2014). The temperatures at which the longitudinal relaxation times are maximum coincide for each sublattice in the case of strongly coupled alloys.

The extension of the two-sublattice LLB above the Curie temperature can be found in Nieves et al. (2015) and Nieves (2015). Here the longitudinal and the transverse damping parameters become the same and defined by the formula (Eq. (16)) for each sublattice.

## 5 Examples of Modeling Magnetization Dynamics Close to the Phase Transition

The main difference of the LLG and LLB magnetization dynamics is the presence of the longitudinal relaxation. This relaxation manifests itself close to the Curie temperature only and especially at picosecond-femtosecond timescale. In fact, close to this temperature, the magnetization can be switched by a so-called linear reversal, i.e., when the macroscopic magnetization changes its length instead of rotating the magnetization vector as it happens at low temperatures. In the intermediate region the reversal is so-called elliptical, i.e., the magnetization vector rotates together with the change of its magnitude. For the analysis of elliptical and linear reversal within the LLB model, see Kazantseva et al. (2009). The high-temperature magnetization dynamics close to $T_c$ is also characterized by the presence of the linear domain walls in which the magnetization changes its length rather than rotates (see, e.g., Hinzke et al. 2007).

To illustrate the appearance and importance of linear magnetization reversal path, we present in Fig. 9 the modeling results for the magnetization reversal time versus temperature for a magnetic nanoparticle with $S = 1/2$ (pure quantum case) and $S = \infty$ (classical case) under applied field $\mu_0 H_z = -1T$ for two different initial
**Fig. 9** Reversal time versus temperature for a magnetic nanoparticle with magnetic moment $\mu = 0.5\mu_B$ ($\mu_B$ is the Bohr magneton), $T_c = 650$ K, and the coupling to the bath parameter $\lambda = 0.02$ under applied field $\mu_0 H_z = -1T$ modeled with the LLB equation with $S = 1/2$ and $S = \infty$. In the pure longitudinal dynamics, the initial magnetization is set to $\mathbf{m} = (0, 0, 0.2)$, and in the longitudinal plus transverse dynamics, the initial magnetization is set to $\mathbf{m} = (0.05, 0, 0.2)$. (Reprinted from Nieves et al. 2014)

conditions: (i) pure longitudinal dynamics where we put the initial magnetization of nanoparticle parallel to the field so that it cannot precess and (ii) longitudinal plus transverse dynamics where the initial magnetization is slightly tilted from the field axis. We define the reversal time as time elapsed between the initial state and the instant of time at which the magnetization begins to reverse its direction, i.e., crosses $m_z = 0$ point. One can observe that slightly below and above $T_c$, the magnetization reversal becomes completely linear, i.e., occurs by a pure change of the magnetization magnitude. However, at 5 degrees from $T_c$, the path is elliptical and at 10 degrees, it is completely precessional.

The longitudinal relaxation especially manifests itself in the laser-induced magnetization dynamics which recently has become an essential part of the novel field of opto-magnetism (Kimel et al. 2007; Kirilyuk et al. 2010). Indeed the timescale in these experiments goes down to the femtosecond range, and the energies are such that the electronic temperature often exceeds the Curie temperature of the materials. One of the main acting mechanisms has a pure heat origin (see Ostler et al. 2012), and during the femtosecond timescale, the exchange interaction energy is probed. The modeling of the ultrafast laser-induced magnetization dynamics based on the LLB equation has been successfully performed in Ni (Atxitia et al. 2010a), in FeNi (Hinzke et al. 2015), Gd (Sultan et al. 2012), and FePt (Mendil et al. 2014) with a very good agreement with experiment. For this purpose the LLB equation is coupled with the electronic temperature of the two-temperature model assuming the electron scattering mechanism.
**Fig. 10** (left panel) The measured Kerr angle rotation (solid line) and the modeled magnetization dynamics (circles) for various laser fluencies $F$ on Ni. The right panels represent experimental (circles) and modeled (squares) timescales for demagnetization $\tau_m$ and recovery $\tau_E$. (Reprinted from Atxitia 2012)

The main consequence of the longitudinal relaxation is the slowing down of the first laser-induced demagnetization timescale. An example of this is illustrated in Fig. 10 where we present a comparison between the experiment performed in Atxitia et al. (2010a) on Ni and the micromagnetic modeling based on the LLB equation. The right panels represent the behavior of the demagnetization $\tau_m$ and the recovery $\tau_E$ times as a function of the laser fluency. The slowing down of the demagnetization timescale is the consequence of the slowing down of the longitudinal relaxation time, while the slowing down of the recovery timescale is the consequence of the electronic temperature dynamics. The comparison of the experimental measurements with the modeling based on the LLB has allowed to conclude the pure thermal origin of the laser-induced demagnetization. This was later confirmed by atomistic modeling and experiments on different FeCoGd thin films and dots by Ostler et al. (2012).

Another prominent example is the magnetization dynamics measured and modeled in FePt thin film with a linearly polarized laser pulse by Mendil et al. (2014). Here as the laser pulse intensity increases and the quasi-equilibrium electron temperature approaches the Curie temperature, the slowing down of the demagnetization time of FePt in the picosecond timescale is observed experimentally and in modeling. At large pulse intensity the quasi-equilibrium electron temperature stays near $T_c$, and the recovery does not take place in the 100 ps timescale. The result of the modeling is presented in Fig. 11. The experiment and LLB-based modeling with circularly polarized laser pulse can be found in John et al. (2017). The circular polarized light produces an additional effect based on the inverse Faraday one (Hertel 2005; Vahaplar et al. 2012; Battiato et al. 2014). This suppresses the slowing

**Fig. 11** Magnetization dynamics in FePt under the linearly polarized laser pulse obtained by the integration of the qLLB equation with $S = 3/2$ coupled with the two-temperature model with the parameters from Mendil et al. (2014), Nieves (2015) and for several laser intensities measured in fluence $F$. (Reprinted from Nieves 2015)
down and makes the reversal probabilities from up to down and from down to up to become non-equal. A similar effect is produced treating the inverse Faraday effects as an additional short timescale field (Nieves and Chubykalo-Fesenko 2016). In John et al. (2017) the reversal probabilities were modeled within the multiscale approach based on the DFT calculations, LLB approach, and the rate equations. The modeling results explained the recently observed by Lambert et al. (2014) switching of FePt granular media by circularly polarized pulses.

The two-sublattice LLB approach was successfully used to explain the temperature dependence of the frequencies and damping parameter of ferro- and antiferromagnetic modes in GdFe ferrimagnet (Schlickeiser et al. 2012) and to explain the different demagnetization speeds in Fe and Ni in permalloy (Hinzke et al. 2015).

Furthermore the LLB approach is currently extensively used as a framework for modeling of heat-assisted magnetic recording (McDaniel 2012; Vogler et al. 2014, 2016). It is especially useful for a coarse-grained modeling when one magnetic grain can be represented as the LLB macrospin (Vogler et al. 2014, 2016).

Recently several extensions of the LLB model also appeared, to mention the introduction of the spin-torque effects into the LLB model by Schieback et al. (2009) or Janda et al. (2017), of the colored noise (Atxitia 2012) or the self-consistent modeling of magnetization and temperature dynamics (Nieves et al. 2016) useful for modeling of magnetocaloric effect and magnetic hyperthermia.

## 6   Conclusions

The LLB approach is a valuable micromagnetic framework to model magnetization dynamics close to $T_c$ and in general where rapid temperature changes appear. First, it correctly reproduces the temperature dependence of relaxational parameters and is in agreement with atomistic modeling. Second, it has proved its viability in modeling of several important research areas such as the heat-assisted magnetic

recording, spin caloritronics, and ultrafast laser-induced magnetization dynamics and was validated via the experimental measurements. It is an important part of the multiscale framework, especially when the model should include the temperature effects. The introduction of the quantum LLB equation allows one to pass directly from ab initio modeling to the micromagnetic one without going through the atomistic part and avoiding the classical temperature dependencies of the micromagnetic parameters as opposed to the more correct quantum dependencies. This, however, needs future investigation on the relevant scattering mechanisms and their spin-flip probabilities. The generalization of the LLB equation for the case of alloys allows one to describe separately the dynamics of each species, in agreement with experimental predictions that these dynamics are different on the ultrashort timescale.

## Abstract

Density functional theory and its application for the simulation of magnetic properties of condensed matter is introduced. This includes vector-spin density functional theory for the evaluation of spin-spin interactions and relativistic extensions to capture effects like the magnetocrystalline anisotropy. The role of the different approximations to the exchange-correlation functional, e.g., the local density approximation, or the generalized gradient approximation, is investigated, showing successes and limitations of the present functionals. Special techniques to determine, e.g., the magnetic ground state or finite temperature properties based on density functional theory are shortly discussed.

# 1 Introduction

Being a material-specific theory, density functional theory (DFT) has gained enormous popularity in the last few decades for the investigation of structural, electronic, or optical properties of condensed matter and is valued as "approximate practical method" in many other areas as well (Jones 2015). In the field of magnetism the value of DFT calculations is widely accepted: only few input parameters have to be known (the chemical composition and, maybe, some information on the crystal structure) to calculate ground state properties like the magnetic order (ferro- or antiferromagnetic, non-collinear structures etc.), spin- and orbital magnetic moments, magnetic interaction parameters (e.g., the spin-stiffness), or the easy axis (or plane) of magnetization. These "ab-initio" parameters can further be used to determine properties beyond the ground state, for example spin-wave spectra or ordering temperatures. In many cases, the results are of excellent quality, in particular in the field of itinerant magnets DFT results usually have predictive power.

To illustrate these statements, magnetic moments and ordering temperatures of several Co-based Heusler compounds are compiled in Table 1 (Thoene et al. 2009). The structure of these compounds consists of four interpenetrating face-centered cubic (fcc) lattices where the atoms of the formula $Co_2YZ$ are located. Here, $Y$ is another transition metal element, while $Z$ is from the $p$-block of the main group. The DFT calculations give access not only to the total magnetic moment in the unit cell, $M_{tot}$, which is in good agreement with the experimental values, but also to locally resolved quantities. E.g., one can see a considerable variation of the Co moments for the listed $Co_2YZ$ structures, depending on their neighboring atoms. With increasing total moment also the Curie-temperatures rises in the shown series, a trend that is also confirmed experimentally.

Despite the many successes of DFT in the field of magnetism, one has to be aware of possible complications that can arise due to the specific nature of some materials. This can be e.g., correlation effects that are difficult to capture in DFT calculations (Galler et al. 2015) or zero-point fluctuations that have to be accounted for (Ibáñez Azpiroz et al. 2016). However, also in these cases DFT can be used as a starting point to explore the magnetic properties of materials.

All specific examples shown in this chapter are bulk magnets that can be reliably calculated with different basis sets, e.g., planewaves, augmented plane

**Table 1** Magnetic moment, $M$, in $\mu_B$ per site (Co or $Y$) or unit cell (tot) and Curie temperature ($T_C$, in Kelvin) of several Heusler compounds: The moments and exchange interactions were obtained in DFT, while $T_C$ is calculated from these DFT results in the mean-field approximation. Experimental values are listed for comparison. (From Thoene and coworkers 2009)

| $Co_2YZ$ | $M_{Co}^{calc}$ | $M_Y^{calc}$ | $M_{tot}^{calc}$ | $M_{tot}^{exp}$ | $T_C^{calc}$ | $T_C^{exp}$ |
|---|---|---|---|---|---|---|
| $Co_2TiAl$ | 0.48 | −0.08 | 0.85 | 0.74 | 148 | 134 |
| $Co_2VGa$ | 0.89 | 0.20 | 1.95 | 1.92 | 343 | 352 |
| $Co_2MnGa$ | 0.79 | 2.80 | 4.29 | 4.11 | 698 | 685 |
| $Co_2FeSi$ | 1.30 | 2.76 | 5.34 | 6.00 | 1134 | 1100 |

waves, muffin-tin orbitals, etc. assuming three-dimensional periodicity. For other material classes (like molecular magnets or adatoms on surfaces) other basis sets (localized orbitals) or formalisms (Green function methods) might be better suited. Relativistic calculations (to obtain e.g., spin-orbit coupling effects) or problems dealing with electron-nucleus interaction might profit from an all-electron treatment of the DFT problem, while for obtaining other quantities (spin moments, scalar exchange interactions) a pseudopotential treatment can be sufficient. In most cases, however, the diversity of available DFT implementations will make it easy to find a suitable solution for a specific problem.

## 2    Methodological Framework

To calculate the electronic structure of an atom, a molecule or a solid, it is necessary to solve the Schrödinger- or Dirac-equation that governs the behavior of the electrons in the system. This behavior is encoded in the wavefunction, $\Psi$, that is a complex quantity in $3N$-dimensional space if $N$ is the number of electrons. Even for a moderate amount of particles (e.g., 26 electrons in an Fe atom) this many-particle wavefunction is impossible to handle numerically. If spin comes into play, or a time-dependence has to be included, the problem even worsens. Therefore, a straightforward solution is – in most cases – out of reach.

The key idea of density functional theory is to work, instead of the many-body wavefunction, with the density, $n(\mathbf{r})$, as the basic variable. The latter can be obtained by the former by integration over all but one spatial variables:

$$n(\mathbf{r}) = N \int d\mathbf{r}_2 \dots \int d\mathbf{r}_N \Psi^*(\mathbf{r}, \mathbf{r}_2, \dots, \mathbf{r}_N) \Psi(\mathbf{r}, \mathbf{r}_2, \dots, \mathbf{r}_N). \tag{1}$$

Surprisingly, the total energy, $E$, turns out to be a unique functional of this density and this functional is stationary with respect to variations of $n(\mathbf{r})$. This theorem was worked out by Hohenberg and Kohn (1964), together with the observation that in a non-degenerate ground state the many-body wavefunction $\Psi$ that describes electrons in an external potential, $v(\mathbf{r})$ (caused by e.g., nuclei), is uniquely determined by the particle density distribution $n(\mathbf{r})$ (The charge density is obtained by multiplying $n$ with the electron's charge $-e$. In atomic units this is normalized to unity and in the following $e$ is not written explicitly, unless in the context of some relativistic terms.). The energy functional can be written as

$$E[n(\mathbf{r})] = \int v(\mathbf{r})n(\mathbf{r})d\mathbf{r} + F[n(\mathbf{r})], \tag{2}$$

where the first term on the right side describes the Coulomb interaction of the density with the external potential and the functional $F$ captures the kinetic energy of the electrons and their mutual Coulomb repulsion. Since Hohenberg and Kohn could show that the density determines $v(\mathbf{r})$ to within a constant, all terms in Eq. (2) can be determined for a given $n(\mathbf{r})$, provided that $F$ is known.

It was the achievement of Kohn and Sham (1965) to find a representation of this functional that allowed to split it into large, known parts and a small, unknown remainder. Their idea was to consider a fictitious system of independent electrons that have the same density, $n(\mathbf{r})$, as the true electron system: Then, the kinetic energy, $T_0$, and the Coulomb interaction of these electrons can be separated out:

$$F[n(\mathbf{r})] = T_0[n(\mathbf{r})] + \frac{1}{2} \int \int \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}' + E_{\text{xc}}[n(\mathbf{r})] \qquad (3)$$

and the remaining so-called exchange-correlation (XC) functional, $E_{\text{xc}}[n(\mathbf{r})]$, is just a small correction to be determined. In reality, the movement of the electrons is correlated due to their Coulomb interaction, not independent, and $E_{\text{xc}}$ has to account for this difference. The exchange energy, arising from the fact that the density is derived from a Slater determinant of wavefunctions that will be defined below, is also contained in $E_{\text{xc}}$.

With this decomposition, it is possible to evaluate the (large) term $T_0$, assuming that the fictitious independent electrons are described by wavefunctions $\phi$ so that $n(\mathbf{r}) = \sum_{i=1}^{N} |\phi_i(\mathbf{r})|^2$. Hereby, an Aufbau principle is used to occupy the $\phi_i$, ensuring that the total wavefunction of the Kohn-Sham system satisfies the Pauli principle. The kinetic energy of the electrons with the mass $m$ is given by $T_0 = -\frac{\hbar^2}{2m} \sum_{i=1}^{N} \phi_i^*(\mathbf{r})\nabla^2 \phi_i(\mathbf{r})d\mathbf{r}$. Now, requiring that $E[n(\mathbf{r})]$ is stationary with respect to variations of the ground state density and requiring particle conservation, the resulting Euler-Lagrange equation can be recast in the form of an effective single particle Schrödinger equation, the Kohn-Sham equation:

$$\left[ -\frac{\hbar^2}{2m}\nabla^2 + \int \frac{n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}d\mathbf{r}' + v(\mathbf{r}) + V_{\text{xc}}(\mathbf{r}) \right] \phi_i(\mathbf{r}) = \varepsilon_i \phi_i(\mathbf{r}) . \qquad (4)$$

Here, the exchange correlation potential, $V_{\text{xc}}$, is the derived as $\frac{\delta E_{\text{xc}}}{\delta n(\mathbf{r})}$, the $\varepsilon_i$ are strictly speaking just Lagrange parameters that follow from the normalization condition; In practice they are often used as "single particle energies" to describe spectral properties. Equation (4) has to be solved self-consistently since it contains the density (both explicitly and implicitly via the exchange correlation potential) that depends on the single particle wavefunctions. Nevertheless, the numerical effort is rather moderate, comparable to the well-known Hartree equation, i.e., it scales normally with the third power of the system size. In particular, this is much faster than wave-function based methods (Friesner 2005).

## 2.1 Vector-Spin DFT

Since the magnetic ground-state properties are uniquely determined by the many-body wavefunction that is in turn determined by the density, in principle DFT allows finding out the magnetic order, magnetic moments etc., provided that a method is known to extract these properties from the density. In practice, however, it turns out
**Fig. 1** (110) cuts through the density and magnetization of bcc Fe and bcc Cr. The left and middle columns show the densities in the nonmagnetic (NM) and magnetic (M) state, respectively, where blue color indicated low density and green/yellow high density. In the right column the magnetization is plotted, where red (blue) color encodes positive (negative) values. The plots were obtained using the FLEUR-code for the DFT calculations (Kurz et al. 2004) and XCrysDen for plotting (Kokalj 2003)

to be easier to extend DFT in a way that explicitly includes the spin-density, $s(\mathbf{r})$, in the formalism. This has the additional advantage that it gives a handle to calculate not only the magnetic ground state, but also other, metastable, magnetic orders. E.g., it is possible to initialize a DFT calculation of body-centered cubic (bcc) Fe such that ferromagnetic (FM), antiferromagnetic (AFM) or nonmagnetic (NM) solutions and their relative stability are obtained. This turns out to be very useful to access the strength of magnetic interactions in a system.

As an example, in Fig. 1 cuts through the (spin-) density of Fe and Cr are shown in the NM state and in the magnetic ground state that is FM for Fe and AFM for Cr. Clearly, the density alone is not very sensitive to variations of the magnetic state, although for FM Fe a small decrease of hybridization, which is due to the spin-splitting of the states, can be seen in the images. However, in both cases only the spin-density gives a clear picture of the magnetic order.

The spin-dependent version of DFT works with spinor wavefunctions to define the spin density $\mathbf{s}(\mathbf{r})$:

$$\mathbf{s}(\mathbf{r}) = \left\langle \phi(\mathbf{r}) | \underline{\boldsymbol{\sigma}} | \phi(\mathbf{r}) \right\rangle ; \quad \phi(\mathbf{r}) = \begin{pmatrix} \phi_\uparrow(\mathbf{r}) \\ \phi_\downarrow(\mathbf{r}) \end{pmatrix} . \tag{5}$$

(The magnetization density is obtained by multiplying $-\mathbf{s}$ with the Bohr magneton, $\mu_B = \frac{e\hbar}{2mc}$.) Here, the Pauli matrices (underlined symbols denote $2 \times 2$ matrices) are given as:

$$\underline{\sigma_x} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \underline{\sigma_y} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \underline{\sigma_z} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} . \tag{6}$$

With this, a density matrix can be introduced that is composed of a scalar and a vectorial part, corresponding to the particle and spin density:

$$\underline{n}(\mathbf{r}) = \frac{1}{2} \left( n(\mathbf{r})\underline{I} + \underline{\boldsymbol{\sigma}} \cdot \mathbf{s}(\mathbf{r}) \right) = \frac{1}{2} \begin{pmatrix} n(\mathbf{r}) + s_z(\mathbf{r}) & s_x(\mathbf{r}) - i s_y(\mathbf{r}) \\ s_x(\mathbf{r}) + i s_y(\mathbf{r}) & n(\mathbf{r}) - s_z(\mathbf{r}) \end{pmatrix}, \quad (7)$$

where $\underline{I}$ denotes a $2 \times 2$ unit matrix. It is easy to see that the components of the density matrix are given by $n_{\alpha\beta}(\mathbf{r}) = \phi_\alpha^*(\mathbf{r})\phi_\beta(\mathbf{r})$ where $\alpha, \beta$ are spin labels. Analogously, a potential matrix, denoted as $\underline{v}(\mathbf{r})$, can be written in terms of a scalar potential, $v$, and magnetic field, $\mathbf{B}(\mathbf{r})$:

$$\underline{v}(\mathbf{r}) = v(\mathbf{r})\underline{I} - \mu_B \underline{\boldsymbol{\sigma}} \cdot \mathbf{B}(\mathbf{r}) . \quad (8)$$

In terms of these quantities, von Barth and Hedin (1972) extended DFT to spin-polarized systems. They derived an analog to Eq. (4) in the form:

$$\left[ \left( -\frac{\hbar^2}{2m}\nabla^2 + \int \frac{n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' \right) \underline{I} + \underline{v}(\mathbf{r}) + \underline{V}_{\mathrm{xc}}(\mathbf{r}) \right] \begin{pmatrix} \phi_i^\uparrow(\mathbf{r}) \\ \phi_i^\downarrow(\mathbf{r}) \end{pmatrix} = \varepsilon_i \begin{pmatrix} \phi_i^\uparrow(\mathbf{r}) \\ \phi_i^\downarrow(\mathbf{r}) \end{pmatrix}, \quad (9)$$

where $\underline{V}_{\mathrm{xc}}$ is now defined as the functional derivative of the exchange-correlation energy with respect to the density matrix. If $\underline{v}(\mathbf{r})$ and $\underline{V}_{\mathrm{xc}}(\mathbf{r})$ are diagonal matrices, Eq. (9) clearly decomposes into two equations of type (4) for spin-up and spin-down wavefunctions.

Naturally the quality of the results obtained with Eq. (9) depends heavily on the approximation for $\underline{V}_{\mathrm{xc}}$. In the local density approximation (LDA) or, for the spin-polarized case, the local spin density approximation (LSDA), the exchange correlation energy is assumed to be of the form

$$E_{\mathrm{xc}}^{LSDA} = \int n(\mathbf{r})\varepsilon_{\mathrm{xc}} \left[ n_\uparrow(\mathbf{r}), n_\downarrow(\mathbf{r}) \right] d\mathbf{r}, \quad (10)$$

where $\varepsilon_{\mathrm{xc}}$ is the exchange correlation energy density of the homogeneous, spin-polarized electron gas. Already before the formulation of DFT several approximations have been known for the exchange energy of the homogeneous electron gas, e.g., from the Thomas-Fermi-Dirac theory (Dirac 1930) or derived from Hartree-Fock theory (Slater 1951). In all these cases it was observed that $\varepsilon_{\mathrm{x}} \propto [n(\mathbf{r})]^{1/3}$ and, surprisingly, the first LDA functionals based on this approximations performed rather well.

Although modern exchange correlation functionals are more sophisticated, many properties of spin-polarized DFT calculations can be studied already in the simple LSDA form. Suppose, there is a collinear magnet with the orientation of the magnetization in $z$-direction (actually, the Hamiltonian in Eq. (9) is invariant under spin-rotations). Then, the density matrix is diagonal and $\underline{V}_{\mathrm{xc}}$ has only two terms: $V_{\mathrm{xc}}^{\uparrow\uparrow} = \frac{\delta E_{\mathrm{xc}}}{\delta n_{\uparrow\uparrow}} \propto \left[ n_{\uparrow\uparrow}(\mathbf{r}) \right]^{1/3}$ and $V_{\mathrm{xc}}^{\downarrow\downarrow} = \frac{\delta E_{\mathrm{xc}}}{\delta n_{\downarrow\downarrow}} \propto \left[ n_{\downarrow\downarrow}(\mathbf{r}) \right]^{1/3}$. This means that Eq. (9)

**Table 2** Magnetic moments (in $\mu_B$ per atom) of ferromagnetic elements in the bulk. The experimentally determined total magnetization, $M_{\text{tot.}}$, consists of spin- and orbital moment contributions. The LSDA results for Fe, Co and Ni are taken from Moruzzi et al. (1978), the GGA values of the magnetic moments from Shallcross and coworkers (2005), the experimental values are quoted from Trygg et al. (1995). The calculated Gd moments are from Kurz et al. (2002), the experimental one is taken from White and coworkers (1975)

| Property | Source | Fe (bcc) | Co | Ni (fcc) | Gd (hcp) |
|---|---|---|---|---|---|
| $M_{\text{spin}}$ | LSDA | 2.15 | 1.56 (fcc) | 0.59 | 7.63 |
| $M_{\text{spin}}$ | GGA | 2.22 | 1.62 (fcc) | 0.62 | 7.65 |
| $M_{\text{spin}}$ | Experiment | 2.13 | 1.52 (hcp) | 0.57 | |
| $M_{\text{tot.}}$ | Experiment | 2.21 | 1.66 (hcp) | 0.62 | 7.63 |

consists of two equations, one for $\phi_\uparrow$ and one for $\phi_\downarrow$ that are identical if $n_{\uparrow\uparrow} = n_{\downarrow\downarrow}$, i.e., if the charge density is not spin-polarized. If a self-consistent calculation starts from a non-magnetic density it remains in this state, even if a spin-polarized solution gives a lower total energy. This shows that the spin-polarized version of DFT can lead to metastable solutions and it is necessary to break the symmetry of the spin-channels to arrive at a magnetic ground state.

Some DFT results for ferromagnetic elements are shown in Table 2, where both the LSDA moments are listed and values obtained within the generalized gradient approximation (GGA) to the exchange-correlation potential. Although the more sophisticated GGA functionals usually lead to better predictions of the atomic structure or lattice constants, the magnetic properties are in most cases not improved (Singh and Ashkenazi 1992). Systematic studies of magnetic properties with modern XC potentials are rather scarce, but it seems that at least in some cases care has to be taken (Koller et al. 2011). This is not surprising, since most efforts are devoted to improving the description of structural parameters or binding energies in these functionals and often the performance with respect to magnetic properties is not tested. There are developments of new functionals that can, in principle, improve also the description of non-collinear magnetism (Eich and Gross 2013), however with considerably increased numerical efforts.

## 2.2   Spin-Orbit Coupling

It was already mentioned in the last section that the Hamiltonian in Eq. (9) has several shortcomings: Since it is derived from the Schrödinger equation, there is no spin-dependent term in this Hamiltonian; Spin enters just through the wavefunction and the Pauli-principle that is encoded in the exchange part of the XC potential. This is enough to find out that Fe is ferromagnetic and has a (spin-) moment of $2.2\,\mu_B$, but this moment has no preferential direction. The concept of easy and hard magnetic directions enters only if further, spin-dependent terms are added to the Hamiltonian. Thinking in terms of a general interaction between two classical spins, $\mathbf{S}$, of the form $\mathbf{S}_\nu \underline{J}_{\nu\nu'} \mathbf{S}_{\nu'}$, where $\underline{J}$ is a $3 \times 3$ matrix, only the trace of $\underline{J}$ can be accessed by

Eq. (9). This gives rise to Heisenberg-type interactions of the form $J_{\nu\nu'}\mathbf{S}_\nu \cdot \mathbf{S}_{\nu'}$ that are in many cases responsible for the magnetic order and, for $\nu = \nu'$, it describes the intra-atomic exchange interaction that is responsible for the formation of the magnetic moment.

To go beyond this description, it is necessary to start from the Dirac-equation or, if one wants to keep two-component wavefunctions, the Pauli-equation that can be derived from the Dirac-equation keeping terms up to second order in $c$, the velocity of light. (We consider here the single-particle equations, adopting the view that the Kohn-Sham equations are also in a single-particle form that can be extended by relativistic terms.) The Hamiltonian of the Pauli-equation can be written as (Bethe and Salpeter 1977):

$$H_{\text{Pauli}} = H_{\text{NR}} + H_{\text{SR}} + \frac{\hbar}{(2mc)^2}\underline{\boldsymbol{\sigma}} \cdot (\boldsymbol{\nabla} V(\mathbf{r}) \times \mathbf{p}) - \frac{e\hbar}{2mc}\underline{\boldsymbol{\sigma}} \cdot \mathbf{B}(\mathbf{r}).\qquad(11)$$

Here, $H_{\text{NR}}$ is the usual Schrödinger-type Hamiltonian (with the momentum operator $\mathbf{p}(\mathbf{r})$ extended by the vector potential $\frac{e}{c}\mathbf{A}(\mathbf{r})$) and $H_{\text{SR}}$ contains scalar-relativistic terms that do not contain spin-operators:

$$H_{\text{SR}} = -\frac{1}{2mc^2}(E + eV(\mathbf{r}))^2 + \frac{\hbar^2}{8m^2c^2}\nabla^2 V(\mathbf{r}).\qquad(12)$$

These are the mass-velocity correction containing the non-relativistic energy $E$ and the Darwin term, relevant mostly for $s$ electrons. The last two terms in Eq. 11 represent the spin-orbit interaction and the interaction of the spin with an external magnetic field. This last term was already included ad hoc in the potential matrix $\underline{v}(\mathbf{r})$. It may seem odd that in DFT calculations the magnetic field is normally considered via this B-field, while the mentioned vector potential contribution is neglected. Indeed, the latter is responsible for diamagnetic effects and has been discussed in the context of calculating NMR shielding tensors (Pickard and Mauri 2001), but requires a rather special treatment that goes beyond this introduction.

The physical interpretation of the spin-orbit coupling (SOC) term in Eq. (11) is most easily seen in an atom, where the gradient of the central potential can be written $\boldsymbol{\nabla} V(\mathbf{r}) = \frac{\partial V(r)}{\partial r}\frac{\mathbf{r}}{r}$. Then,

$$\frac{\hbar}{(2mc)^2}\underline{\boldsymbol{\sigma}} \cdot (\boldsymbol{\nabla} V(\mathbf{r}) \times \mathbf{p}) = \frac{\hbar}{(2mc)^2}\frac{1}{r}\frac{\partial V(r)}{\partial r}\underline{\boldsymbol{\sigma}} \cdot (\mathbf{r} \times \mathbf{p}) = \xi\underline{\boldsymbol{\sigma}} \cdot \mathbf{L},\qquad(13)$$

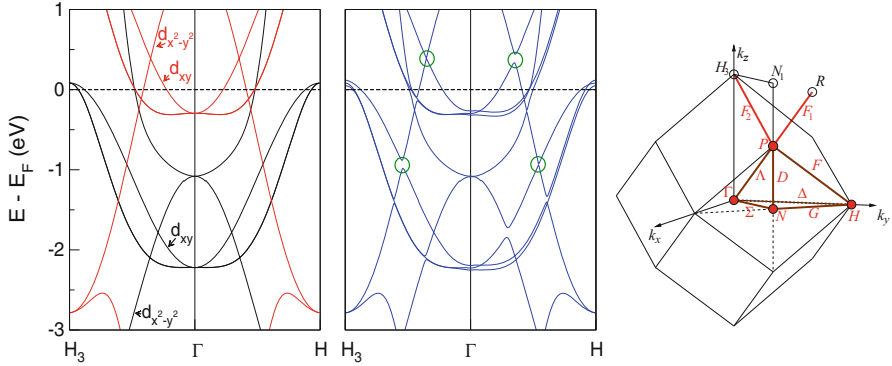
where $\xi$ is called the SOC constant and $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ is the (angular) orbital momentum operator. In this form, the SOC term resembles a coupling between spin- and orbital momentum, although one has to keep in mind that it is rather the (orbital) motion of the electron in a potential gradient (i.e., an electric field that is Lorentz-transformed into a magnetic field) that couples to the spin. This also applies to a linear motion of an electron, where the SOC term manifests in the so-called Rashba-effect (Bychkov and Rashba 1984).


**Fig. 2** Band structure of bcc Fe without (left) and with (middle) SOC effects. The Brillouin zone is shown on the right. (From the Bilbao Crystallographic Server, http://www.cryst.ehu.es). Left: Majority and minority spin states are shown in black and red, respectively. The character of the orbitals forming the bands along $H_3 - \Gamma$ is indicated. With SOC the spin-character of the states is mixed and some band degeneracies are lifted. Crossings discussed in the text are marked with green circles. The magnetization is assumed to point in $y$ direction

Due to this coupling between the potential landscape (as, e.g., formed by the atomic lattice in a solid) and the electron spin, the orientation of the magnetization in the solid is no longer arbitrary but certain directions are preferred. This is one source of magnetic anisotropy, the so-called magnetocrystalline anisotropy, that determines the "easy axis" of magnetization. (Other sources, like the dipole-dipole interaction are not included in the single particle equation (11) and have to be added, e.g., from a classical calculation of the dipole sum.)

The effect of spin-orbit interaction in a magnetic system can be seen as a certain symmetry breaking that leads not only to a magnetic anisotropy, but also other effects like magnetostriction. This can be seen most clearly from a consideration of the band structure in two directions that are equivalent without SOC, but get non-equivalent when SOC is taken into account. As an example Fig. 2 shows the band structure of bulk bcc Fe along a high-symmetry direction in reciprocal space ($\Gamma - H$). In this direction, without SOC, several band crossings can be detected, e.g., between $d_{x^2-y^2}$ states and $d_{xy}$ states of same and different spin. The SOC term, Eq. (13), allows now hybridization between these states of the same spin to form an orbital moment in the direction of magnetization ($\Gamma - H$ corresponding to $y$) and these states of opposite spin in $\Gamma - H_3$ direction. Thus, gaps form at different positions in the formerly equivalent directions, which leads to a symmetry reduction from cubic to tetragonal in this case. These gap openings were recently also seen experimentally (Młyńczak et al. 2016).

Moreover, the spin-orbit terms gives rise to a finite orbital momentum that can be easily obtained in the vicinity of an atom $\nu$ as

$$\mathbf{M}_\nu^{\mathrm{orb}} = -\mu_B \sum_i \langle \phi_i | \mathbf{L} | \phi_i \rangle_\nu \tag{14}$$

where the integration is performed in a sphere around the atom. To obtain the orbital moment in an infinite periodic solid a more involved theory is necessary (Thonhauser et al. 2005). It should be noted that the orbital moments obtained by LSDA (and also GGA) calculations are typically too small, e.g., for Fe and Co values of 0.05 and 0.08 $\mu_B$ have been obtained (Beiden et al. 1998). Compared to experimental values (i.e., the difference between total and spin-momentum in Table 2) these values are reduced by almost 50%.

In absence of spin-flip terms (i.e., when the majority and minority band are well separated by the exchange interaction), SOC changes the total energy of a system in second-order perturbation theory as (van der Laan 1998):

$$\delta E = \sum_{i,j} \frac{\langle \phi_i | H_{so} | \phi_j \rangle \langle \phi_j | H_{so} | \phi_i \rangle}{\varepsilon_i - \varepsilon_j} f(\varepsilon_i) \left[ 1 - f(\varepsilon_j) \right] \approx -\frac{1}{4} \xi \hat{\mathbf{S}} \cdot \left[ \left\langle \mathbf{L}^\downarrow \right\rangle - \left\langle \mathbf{L}^\uparrow \right\rangle \right] \tag{15}$$

where $H_{so}$ is the SOC Hamiltonian, $f$ is the Fermi function giving the occupation of the state, $\hat{\mathbf{S}}$ is the direction of the spin moment, and $\mathbf{L}^{\downarrow(\uparrow)}$ is the orbital moment of the spin-down (up) bands. If the spin-up band is completely filled, we see that energy change, $\delta E$, is proportional to the size of the orbital moment. The magnetocrystalline anisotropy energy (MAE), i.e., the difference of $\delta E$ for two different magnetization directions, will be proportional to the difference in the orbital moments as first derived by Bruno (1989).

When calculating the MAE from DFT one has to keep in mind that the resulting energy differences are often very small, for cubic metals like Fe or Ni even in the $\mu$eV per unit cell range (see Table 3). Therefore, the numerical parameters, in particular those determining the sampling of reciprocal space, have to be extremely well converged (Trygg et al. 1995). To make the numerical effort tractable, often these calculations are not performed self-consistently, but SOC is added on top of a non- or scalar-relativistic calculation using the so-called force theorem (Weinert et al. 1985). Although the experimental values of the MAE for the cubic elements listed in Table 3 are hard to reproduce quantitatively, the easy axis is correctly reproduced in LSDA (Halilov et al. 1998).

**Table 3** Magnetic anisotropy energy (in $\mu$eV per atom) of the ferromagnetic elements obtained by DFT calculations with spin-orbit (SO) coupling included as obtained by Trygg et al. (1995) [1] and Halilov et al. (1998) [2]. In addition, the results including the orbital polarization correction (OP) are cited from [1]. The experimental data (exp.) are quoted from both references. For the fcc structures the anisotropy between [001] and [111] direction is given and positive values indicate that the latter magnetization direction is preferred. The values for Co (hcp) show the energy difference between the [0001] and [10$\bar{1}$0] direction

| Element | SO[1] | OP[1] | SO[2] | exp. |
|---------|-------|-------|-------|------|
| Fe (bcc) | –0.5 | –1.8 | –2.6 | –1.4 |
| Co (hcp) | –29 | –110 | | –65 |
| Co (fcc) | 0.5 | 2.2 | 2.4 | 1.3–1.8 |
| Ni (fcc) | –0.5 | –0.5 | 1.0 | 2.7 |

**Table 4** Magnetic anisotropy energy (in meV per formula unit) of the $L1_0$ phases of FePt and CoPt obtained in LSDA with spin-orbit (SO) coupling and orbital polarization (OP) by Ravindran et al. (2001) [1], Shick and Mryasov (2003) [2] and Kota and Sakuma (2014) [3], where perturbation theory (PT) and force theorem (FT) were used. Positive numbers indicate that the [001] direction is preferred (relative to [100]). The experimental data (exp.) are quoted from Ravindran et al. (2001)

| Element | SO[1] | OP[1] | SO[2] | PT[3] | FT[3] | Exp. |
|---------|-------|-------|-------|-------|-------|------|
| FePt    | 2.73  | 2.89  | 2.68  | 2.41  | 1.90  | 0.88 |
| CoPt    | 1.05  | 1.64  | 1.03  | 0.77  | 0.68  | 1.0–1.67 |
| FePd    | 0.15  | 0.34  |       | 0.33  | 0.29  | 0.48–0.63 |

As suggested by Eq. (15), the underestimation of the orbital moments in LSDA also leads to MAEs that are systematically too small. Techniques like the orbital polarization correction (OP) were introduced that increase both quantities leading to better agreement with experimental values (Trygg et al. 1995). Another way to improve results is to tale into account strong correlation effects via the Hubbard $U$ approximation (LSDA+$U$), as shown by Yang et al. (2001) or, for binary alloys by Shick and Mryasov (2003). For uniaxial systems, where the energies go up to the meV scale, the agreement is generally better as can be seen from Table 4.

Although in the examples listed above only the energies of two magnetization directions were compared, the MAE describes more generally the dependence of the energy on the spin orientation. In terms of the general two-spin interaction, $\underline{J}_{\nu\nu'}$, the magnetic anisotropy can be expressed as the traceless symmetric on-site part ($\nu = \nu'$) denoted as $\underline{K}_\nu$. It is a matrix with (at most) six coefficients that can be obtained by independent calculations.

One should keep in mind that a DFT calculation with SOC also gives rise to interactions described by the symmetric part of the $\underline{J}$ matrix (so-called pseudodipolar interactions) and the antisymmetric part of the $\underline{J}$ [Dzyaloshinskii-Moriya interaction (Dzialoshinskii 1957)] where the strength of the latter is first order in SOC, while the former arises in second order (Moriya 1960). Although small, these interactions can be extracted from DFT calculations as will be outlined below.

# 3 Ground State Calculations

## 3.1 Magnetic Order

It was shown that spin-polarized versions of DFT allow calculating also metastable magnetic (or non-magnetic) configurations and the result depends on the initial configuration. This makes determining the magnetic ground state of a specific system by DFT a rather challenging problem. Different strategies can be applied: like in molecular-dynamics calculations, (ab initio) spin-dynamics allows exploring the magnetic degrees of freedom and finding the global energy minimum that corresponds to the ground state configuration. A different possibility is to determine

the magnetic interactions between the atoms by DFT calculations which are then mapped onto a model (in the simplest case a classical Heisenberg model) that is solved analytically or numerically. In both cases a discretization of the (vector) magnetization density in terms of magnetic moments is introduced. Assume that at the positions of the magnetic atoms the intra-atomic exchange interaction is large and there are robust magnetic moments that can be assigned to each lattice site, e.g., within some sphere centered at the nucleus, $\nu$ (at a position $\mathbf{R}_\nu$). Then the magnetization density, $\mathbf{m}(\mathbf{r})$, can be approximated as

$$\mathbf{m}(\mathbf{r}) = M_\nu \hat{\mathbf{e}}_\nu, \tag{16}$$

where $M_\nu$ is the magnetization and $\hat{\mathbf{e}}_\nu$ is the magnetization direction at that site. A magnetic state is in this case characterized by a set of directions, $\{\hat{\mathbf{e}}_\nu\}$, of all the atoms in the magnetic unit cell. Of course there are the well-known ferromagnetic (FM) and antiferromagnetic (AFM) states, but already for the latter several possible unit cells come in mind. E.g., in an face-centered cubic (fcc) material, an AFM order can occur for ferromagnetically ordered planes in (001), (111), or (110) directions (type I, II or III AFM order, respectively) to name just the few possibilities that can be realized by a Heisenberg model with nearest-neighbor (nn) and next-nearest-neighbor (nnn) interactions.

On a simple level, one can "relax" the directions of the magnetization at the atoms like a relaxation of the atomic structure (e.g., at a surface) is done. In the DFT self-consistency cycle the output magnetizations $\{\hat{\mathbf{e}}_\nu^{\text{out}}\}$ in general deviate from the input values $\{\hat{\mathbf{e}}_\nu^{\text{in}}\}$. The magnetization directions change to minimize the total energy (cf. Fig. 3). The final magnetic state, that is reached, in general depends on the starting point of the calculation and a more elaborate technique is needed to avoid being trapped in some local minimum of $E[\{\hat{\mathbf{e}}_\nu\}]$.

To this end one can develop an equation of motion for the magnetization of an atom. To keep things simple it is again assumed that the magnetization stays collinear within the vicinity of the atom. Starting from the Hamiltonian of Eq. (9) and assuming that the external potential matrix, $\underline{v}(\mathbf{r})$, has been chosen to be diagonal and the exchange-correlation potential is separated into diagonal and off-diagonal parts, following Antropov et al. (1995, 1996) it is possible to set up a time-dependent analog of Eq. (9):

$$i\frac{d\Phi}{dt} = \left[ H_d - \underline{\boldsymbol{\sigma}} \cdot \mathbf{B}(\mathbf{r}, t) \right] \Phi \quad \text{where} \quad \Phi = \begin{pmatrix} \phi_\uparrow(\mathbf{r}, t) \\ \phi_\downarrow(\mathbf{r}, t) \end{pmatrix}, \tag{17}$$

and $H_d$ is the Hamiltonian that contains now only diagonal parts.

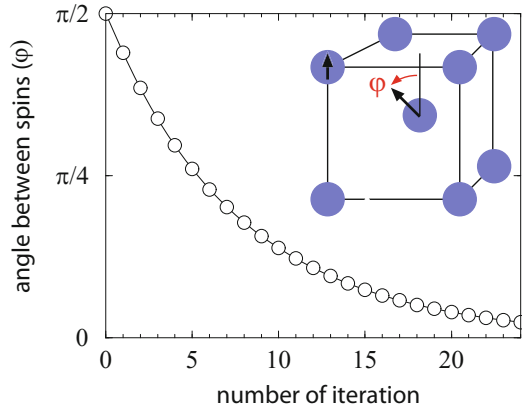
Separating the evolution of the magnetization into fast (value of the magnetization) and slow (direction of the magnetization) degrees of freedom the fast part are described quantum-mechanically, while the latter can be treated on a semiclassical level. At a given time, $t$, the time-independent version of Eq. (17) can be solved for a given magnetization characterized by $\{\hat{\mathbf{e}}_\nu\}$. An equation of motion for the


**Fig. 3** Relaxation of the spin direction of a Fe atom in bulk bcc Fe calculated in a simple cubic unit cell. The evolution of the angle $\varphi$ between the magnetic moments of two Fe atoms is shown as a function of the number of the self-consistency steps of the DFT calculation. Starting from a 90° canting of the spins, the FM ground state is reached after approx. 30 iterations. It is important to avoid high-symmetry states (e.g., AFM) as starting points. (Adapted with permission from Kurz et al. 2004. Copyrighted by the American Physical Society)

magnetization $\mathbf{m}(\mathbf{r}, t)$ can be obtained by multiplying Eq. (17) from the left with $-\mu_B \Phi^* \underline{\boldsymbol{\sigma}}$ and adding the complex conjugate equation. Comparing to the time derivative of the magnetization (cf. Eq. (5)), the equation of motion reads

$$\frac{d\mathbf{m}(\mathbf{r}, t)}{dt} = 2\mathbf{m} \times \mathbf{B} + \frac{i}{2}\nabla(\Phi^* \underline{\boldsymbol{\sigma}} \cdot \nabla\Phi - c.c.). \tag{18}$$

The second term on the right side is complicated and describes longitudinal changes of the magnetization, which will not be considered on this level. Omitting this term, Eq. (18) describes the precession of the magnetization direction at an atom under the influence of the magnetic field generated by the atom itself and other atoms of the crystal.

Equation (18) can be simplified using Eq. (16) and one can write for the evolution of the magnetization direction in atom $\nu$

$$\frac{d\hat{\mathbf{e}}_\nu}{dt} = -\frac{2}{\mu_B}\hat{\mathbf{e}}_\nu \times \mathbf{I}_\nu, \tag{19}$$

where $\mathbf{I}_\nu = \mu_B \mathbf{B}$. If the effect of other fields acting on a magnetization direction has to be taken into account explicitly, they can be included in Eq. (19). E.g., for contributions stemming from the spin-orbit interaction (magnetic anisotropy) or dipole-dipole interaction, these fields can be added in the form $\mathbf{I} = \mathbf{I}_\nu + \mathbf{I}_{SO} + \mathbf{I}_{d-d}$. More general expressions of Eq. (19), suitable for spin-dynamics with finite temperatures included, can be found in the paper of Antropov et al. (1996). It should

be noted that these equations are the starting point to describe many properties beyond the ground state on an ab initio basis e.g., shown by Skubic et al. (2008).

## 3.2    Magnetic Interactions

Although spin-dynamic simulations are a good way to explore magnetic ground states, they are computationally rather expensive and require additional analysis to get insight into the interactions leading to a specific magnetic order. For an interpretation of the results the system is usually mapped to a classical model spin Hamiltonian, e.g.,

$$H_{\mathrm{mod}} = - \sum_{\langle \nu\nu' \rangle} J_{\nu\nu'} \mathbf{M}_\nu \cdot \mathbf{M}_{\nu'} + \sum_\nu \mathbf{M}_\nu \underline{K}_\nu \mathbf{M}_\nu + \sum_\nu \mathbf{B} \cdot \mathbf{M}_\nu, \qquad (20)$$

where the first term on the right side captures the Heisenberg-like (scalar, two-spin) interactions and the sum runs over all pairs of atoms $\langle \nu, \nu' \rangle$, the second term is the magnetic anisotropy and the last term represents the interaction of the spins with an external $\mathbf{B}$ field (if needed). As mentioned above, the magnetic moments $\mathbf{M}_\nu$ are directly available from the DFT results and the anisotropy $\underline{K}_\nu$ can be obtained from relativistic total energy calculations.

To extract the $J_{\nu\nu'}$ coefficients in Eq. (20), it is in principle possible to compare the total energies of ferromagnetic and different antiferromagnetic states from non-relativistic DFT calculations and fit these differences to a classical spin Hamiltonian. As example in Fig. 4 the case of a square lattice is shown, as e.g., realized by an Fe monolayer on a (001) oriented bcc substrate. Ferriani et al. (2007) studied this system for Ta and W as substrate and found a transition from a FM ground state for Ta to a $c(2 \times 2)$ AFM state for Fe/W(001). In a nearest-neighbor (nn) Heisenberg model this transition corresponds to a sign change of the nn coupling constant $J_1$. Including also next-nearest-neighbor (nnn) interactions, this model also allows (for negative $J_2$) for another ground state, a row-wise AFM state with a $p(2 \times 1)$ unit cell

**Fig. 4** Two antiferromagnetic (AFM) and the ferromagnetic (FM) structure on a square lattice. The magnetic unit cells are indicated by the shaded areas. The phase diagram for the classical Heisenberg model with nearest-neighbor (nn) and next-nearest-neighbor (nnn) interaction is shown on the right. The red dashed line indicates a phase transition as discussed in the text. (Adapted with permission from Ferriani et al. 2007. Copyrighted by the American Physical Society)
**Fig. 5** Total energy of bcc-Eu as a function of the spin-spiral **q**-vector (in units of $\frac{2\pi}{a}$ where $a$ is the lattice constant) in (110) and (100) direction calculated in the LDA+$U$ method. The symbols represent calculated values, the lines are a fit of $E(q) = \sum_{n=0}^{5} c_n \cos(n\pi q)$. The energy minimum at **q** $= (1.63, 0, 0)/a$ (also visualized in the inset) corresponds quite well to the experimental ground state (Turek et al. 2003b)

as shown in Fig. 4. By calculating these three magnetic states for alloyed substrates, $Ta_x W_{1-x}$, one can see that from $x = 1$ to $x = 0$ $J_1$ changes from about $+20$ to $-20$ meV while $J_2$ remains rather constant at $-5$ meV. In the phase diagram in Fig. 4 this corresponds to a change along the red dashed line and one can see that for $x = 0.5$ a $p(2 \times 1)$ AFM structure can be expected as magnetic ground state (Ferriani et al. 2007) (Fig. 5).

Of course, more magnetic structures can be added to the analysis and further interactions, $J_i$ for $i > 2$, can be extracted. A systematic way to obtain these $J$'s is given by the calculation of so-called spiral spin-density waves (SSDWs), general solutions of the classical Heisenberg model. The magnetic moments in a spiral with propagation vector **q** are given as:

$$\mathbf{M}_\nu = M \left( \hat{\mathbf{e}}_x \cos(\mathbf{q} \cdot \mathbf{R}_\nu) + \hat{\mathbf{e}}_y \sin(\mathbf{q} \cdot \mathbf{R}_\nu) \right), \tag{21}$$

where the unit vectors $\hat{\mathbf{e}}_x$ and $\hat{\mathbf{e}}_y$ just have to be perpendicular to each other, otherwise their directions are (in absence of SOC) arbitrary. For simplicity it is assumed that the size of the magnetic moment, $M$, is not site dependent. The wave-length of the spin-spiral is given by $\lambda = \frac{2\pi}{q}$ and it seems that huge super-cells are necessary to capture these SSDWs. But using the generalized Bloch theorem (Herring 1966; Sandratskii 1991) these magnetic structures can be conveniently calculated in the chemical unit cell as long as no spin-orbit coupling is considered. In this way the total energy $E(\mathbf{q})$ can be calculated on a grid of **q** vectors and, assuming that $M$ remains constant, directly related to $J(\mathbf{q})$ which is the Fourier transform of the Heisenberg interaction constants in real space. By

Fourier transformation the constants $J_{\nu\nu'}$ can thus be recovered. This procedure can be generalized to systems with different atomic species in the unit cell, where intra-sublattice $J$'s and inter-sublattice $J$'s have to be considered (Ležaić et al. 2013).

Spin-spiral structures, as given by Eq. (21), also occur as ground states in many magnetic systems. A well-investigated system is bcc Eu, a member of the lanthanides, where the spins are rotated between neighboring (001) planes by 47° (Turek et al. 2003b). DFT calculations of SSDWs with $\mathbf{q}$ along the $(1, 0, 0)$ direction indeed show a minimum of $E(\mathbf{q})$ at the experimentally observed position. Also along the $(1, 1, 0)$ direction a local minimum is found and experiments indeed report that under an external magnetic field such state can be realized (Millhouse and McEwen 1973). It should be further mentioned that in these calculations the so-called LDA+$U$ method (Anisimov et al. 1997) was used to capture the correlated nature of the $4f$ electrons in Eu.

As mentioned above, SSDWs are the general solutions of the classical Heisenberg model (Yosida 1996). Therefore, if a system described by this model, a procedure to find the magnetic ground state was presented. However, for a system with spins larger than $1/2$, higher order interactions are allowed that involve more than two spins, e.g., the biquadratic interaction $B_{\nu\nu'}(\mathbf{S}_\nu \cdot \mathbf{S}_{\nu'})^2$ or other four-spin interactions. These terms can couple two or more spin-spirals and possibly lead to solutions with lower energy than all SSDWs. E.g., the $p(2 \times 1)$ structure in Fig. 6 can be regarded as spin spiral with $\mathbf{q}_1 = \left(0, \frac{1}{2}\right)$ and a 90° rotated SSDW with $\mathbf{q}_2 = \left(\frac{1}{2}, 0\right)$ is degenerate with this structure. A linear combination $\frac{1}{2}(\mathbf{q}_1 + \mathbf{q}_2)$, where the spins of neighboring atoms are 90° rotated to each other (see Fig. 6), is energetically degenerate to the constituting spin spirals in the classical Heisenberg model, but a Hamiltonian that includes the biquadratic interaction can differentiate between the former double-$\mathbf{q}$ and the latter single-$\mathbf{q}$ structures. In a DFT calculation it is found that indeed the double-$\mathbf{q}$ structure has lower total energy (Ferriani et al. 2007). This is a sign for the importance of higher-order interactions that is not unexpected in a system with large spin moment.

p(2x1) AFM (0meV)    2q (−3meV)    p(1x2) AFM (0meV)
**Fig. 6** The 2$\mathbf{q}$ structure shown in the middle is a superposition of the $p(2 \times 1)$ and $p(1 \times 2)$ structure. Alternatively, it can be constructed by rotation of the spins in the collinear structures by 45° as indicated by the blue arrows. For Fe on a Ta/W-alloy substrate, the 2$\mathbf{q}$ structure is 3 meV lower in energy than the two shown antiferromagnetic structures (Ferriani et al. 2007)

All SSDWs and the AFM structures shown in Fig. 4 [that are actually spin spirals with $\mathbf{q}_{c(2\times2)} = \left(\frac{1}{2}, \frac{1}{2}\right)$, $\mathbf{q}_{p(1\times2)} = \left(\frac{1}{2}, 0\right)$ and $\mathbf{q}_{FM} = (0, 0)$] are special in the sense that in these structures there is no torque on the magnetic moments due to symmetry. I.e., in the DFT self-consistency cycle the spin direction does not change in the sense described in Sect. 3.1. This is different for the spin-structures that connect the states shown in Fig. 6. To calculate the total energy of such spin structures correctly, constrained DFT calculations (Dederichs et al. 1984) have to be performed, i.e., a transversal $\mathbf{B}_\perp$ field has to be applied that keeps the local moment in a prescribed direction (Kurz et al. 2004). This constrained DFT scheme can also be used to study longitudinal fluctuations of the magnetic moments, $E(|\mathbf{M}|)$. These so-called fixed spin-moment calculations can be very useful to explore magnetic phases, in particular when multiple solutions (high-spin and low-spin phases) are present (Moruzzi et al. 1986).

It was mentioned above that SSDW calculations using the generalized Bloch theorem can only be performed in the absence of SOC. Nevertheless, it is possible to include SOC in first order perturbation theory to the spin-spiral calculations (Heide et al. 2009). In this way, it is possible to access the Dzyaloshinskii-Moriya interaction (DMI) mentioned at the end of Sect. 2.2 in a rather systematic way. This relativistic interaction can then be added to the model Hamiltonian (20) to describe large-scale spin structures. For example the DMI can stabilize a SSDW with unique rotational sense (Bode et al. 2007) or it leads to chiral magnetic skyrmions in complex superlattices with several nanometers of diameter (Dupé et al. 2016). It can also be used as input for micromagnetic simulations of even larger systems (see Schweflinghaus et al. (2016) for an relation of atomistic and micromagnetic parameters).

# 4 Beyond the Ground State

Although a more detailed account of spin excitations and finite temperature magnetism will follow in the next chapters, this section is intended to show the link between non-collinear DFT calculations, as described above, and the modeling of properties beyond the magnetic ground state. Moreover, the application range and limitations of some simple models are indicated.

## 4.1 Magnetic Fluctuations

Up to now, flat spin-spirals as defined in Eq. (21) were discussed, i.e., the spins were assumed to be rotating in the plane defined by $\hat{\mathbf{e}}_x$ and $\hat{\mathbf{e}}_y$. These SSDWs can be generalized to conical spin-spirals as

$$\mathbf{M}_\nu = M \left( \hat{\mathbf{e}}_x \cos(\mathbf{q} \cdot \mathbf{R}_\nu) \sin(\vartheta) + \hat{\mathbf{e}}_y \sin(\mathbf{q} \cdot \mathbf{R}_\nu) \sin(\vartheta) + \hat{\mathbf{e}}_z \cos(\vartheta) \right), \qquad (22)$$

where $2\vartheta$ defines the opening angle of the cone. Magnetic structures described by Eq. (22) occur as magnetic ground states, e.g., in $LaMn_2Ge_2$ (Di Napoli et al. 2004), or in strong magnetic fields as described by the Hamiltonian (20).

Since conical spin-spirals also resemble snap shots of a single magnon in a ferromagnet at a fixed time, the SSDWs introduced above are sometimes called "frozen magnons". Calculations for different (small) $\mathbf{q}$ values (e.g., using the generalized Bloch theorem) can be used to simulate the effect of temperature on a magnetic system in the adiabatic approximation. At very low temperatures, when magnons with long wavelengths dominate and no Stoner excitations are present, this is a reasonable approximation. In the long wavelength limit, i.e., around $\mathbf{q} = 0$, the spin-wave dispersion behaves almost quadratically and can be described as $E(\mathbf{q}) = Dq^2$. The spin stiffness, $D$, characterizes the magnetic properties of a ferromagnet at low temperatures and can be calculated from SSDW calculations directly or from the exchange coupling constants in real space. Consider e.g., the Heisenberg term of Eq. (20) in one dimension: Then

$$\delta E(\mathbf{q}) = E(\mathbf{0}) - E(\mathbf{q}) = +2M^2 \sum_{\nu>0} J_{0\nu} \left(1 - \cos(\mathbf{q}\mathbf{R}_\nu)\right) \approx 2M^2 q^2 \sum_{\nu>0} J_{0\nu} \mathbf{R}_\nu^2 \tag{23}$$

and $D$ is obtained as $2M^2 \sum_{\nu>0} J_{0\nu} \mathbf{R}_\nu^2$. In more dimensions $D$ is a tensorial quantity and the exact expression depends on the crystal symmetry. Some results of an isotropic $D$ obtained from DFT calculations for cubic systems are given in Table 5. For Fe and Co agreement with experimental data is reasonable, but for Ni most methods fail to reproduce the experimental spin stiffness. More about spin-waves can be found e.g., in the review of Staunton (1994) and in a following chapter. Calculations of the full magnon spectra of Fe and Ni can be found e.g., in the work of Halilov et al. (1997). The agreement with experimental spectra, even for larger $\mathbf{q}$ values is quite satisfactorily, therefore these calculations can also serve as a starting point to calculate finite temperature properties, like the Curie temperature. One has to keep in mind, however, that for other systems it is not guaranteed that they can be treated in such simple model.

In the discussion of spin waves so far the influence of spin-orbit coupling was neglected. Therefore, the so obtained "spin-excitations" are always gapless while in a system with magnetic anisotropy there is an energy to overcome for a finite

**Table 5** Calculated and experimental spin-wave stiffness ($D$) for Fe, Co and Ni. The theoretical values were obtained in different approximations as described by Rosengaard and Johansson (1997) [th.(1)], Kübler (2000) [th.(2)], Shallcross and coworkers (2005) [th.(3)] and Pajda et al. (2001) [th.(4)], experimental data were taken as cited in these references

| $D$ (meV Å$^2$) | th.(1) | th.(2) | th.(3) | th.(4) | Exp. |
|---|---|---|---|---|---|
| Fe (bcc) | 247 | 355 | 322,313 | 250 | 280,314,330 |
| Co (fcc) | 502 | 510 | 480,520 | 663 | 510,580 |
| Ni (fcc) | 739 | 790 | 541,1796 | 756 | 422,550,555 |

**q** value. Moreover, the Dzyaloshinskii-Moriya interaction leads to a finite energy difference between clockwise and anticlockwise rotating magnons (Udvardi and Szunyogh 2009).

## 4.2 Ordering Temperatures

Extending the description of finite-temperature magnetic properties of bulk ferromagnets to the point where transverse fluctuations finally destroy the magnetic order, here the simplest model is presented, the so-called mean field approximation (MFA). A selected site 0 experiences an effective field from all other atoms; At $T = 0$ it is proportional to $M \sum_{\nu \neq 0} J_{0\nu} = M J_0$, while at $T > 0$ this field is reduced by thermal fluctuation on the sites $\nu$:

$$B_{\text{eff}} = \sum_\nu J_{0\nu} \langle M(\mathbf{R}_\nu) \rangle, \tag{24}$$

where the thermal average of the projection of the magnetization at site $\nu$ on the magnetization at site 0 is denoted as $\langle M(\mathbf{R}_\nu) \rangle$. In this model the temperature where the average magnetization vanishes (for ferromagnetic systems the Curie temperature) is given by

$$k_B T_C^{\text{MFA}} = \frac{2}{3} J_0 M^2 \eta, \tag{25}$$

where $\eta \to 1$ in the classical limit (Liechtenstein et al. 1986). In many cases the MFA overestimates $T_C$ and other models, like the random phase approximation (RPA) are preferable. Moreover, in lower-dimensional systems the MFA cannot be applied, e.g., a finite the magnetic anisotropy is essential to stabilize magnetic order in two dimensions (Bander and Mills 1988). However relativistic DFT calculations provide the necessary ingredients to calculate also $T_C$ in two dimensional systems (Udvardi and Szunyogh 2009). Also for antiferromagnets (or, generally spin-spiral states) expressions for the ordering temperature, the Néel temperature $T_N$, can be derived (Turek et al. 2003b). There exist several more methods to calculate critical temperatures from DFT results, e.g., the Monte Carlo technique (MC) allows studying finite-temperature magnetic properties by implementation of a Heisenberg Hamiltonian, possibly with extensions like the magnetic anisotropy like in Eq. (20). Some applications for multi-sublattice systems are shown in the work of Ležaić et al. (2013).

The Curie temperature of Fe, Co, Ni and Gd obtained in different approximations with parameters from DFT calculations are presented in Table 6. Compared to RPA, the MFA overestimates $T_C$ by 25–50% in these cases. For Fe and Co RPA gives quite good estimates of the Curie temperature, while for Ni $T_C$ is underestimated in both approximations. From Table 1 it can be seen that this behavior is not universal and for some materials the MFA results compare very well with experimental data.

**Table 6** Calculated and experimental Curie temperature $T_C$ for some ferromagnetic materials. MFA[1] and RPA data for Fe, Co and Ni taken from Pajda et al. (2001), MFA[2] results and experimental values as quoted by Shallcross and coworkers (2005), while the MC results were obtained by Rosengaard and Johansson (1997). Spin dynamics (SD) calculations have been performed by Antropov (2005). Data for Gd can be found in the papers of Kurz et al. (2002) and Turek and coworkers (2003a)

| $T_C$ (K) | MFA[1] | MFA[2] | RPA | MC | SD | Exp. |
|-----------|--------|--------|-----|-----|-----|------|
| Fe (bcc) | 1414 | 550,1190 | 950 | 1060 | 1070 | 1044 – 1045 |
| Co (fcc) | 1645 | 1120,1350 | 1311 | 1080 | | 1388 – 1393 |
| Ni (fcc) | 397 | 320,820 | 350 | 510 | 470 | 624 – 631 |
| Gd (hcp) | 334 | | | | | 293 |

MC simulations work better for Ni and Fe, but give a too low $T_C$ for Co. Finally, the results of spin dynamics calculations, performed along the line sketched in Sect. 3.1, give results comparable to MC calculations for Fe and Ni, but have the advantage that they do not rely on a model Hamiltonian (Antropov 2005). Also in the work of Skubic et al. (2008) it can be seen that SD and MC results for bcc Fe are very similar.

# 5    Conclusion

Within this small chapter I tried to give an impression of the possibilities that DFT calculations can give to calculate magnetic properties of elemental magnets and some compounds, mainly focusing on bulk materials. I left out many classes of magnetic materials, e.g., transition metal oxides, where correlation effects complicate the picture and extensions like LDA + $U$ (Anisimov et al. 1997) or LDA + DMFT (Held et al. 2002) are required to capture many aspects of their properties. Of course, there are many more magnetic properties where DFT can be very useful for modeling, e.g., the coupling of electrons with the nuclear spin that has been neglected here. Nevertheless, I hope that this chapter gives at least a staring point to explore the power of ab initio methods to model magnetic systems.

# Many-Body Spin Excitations in Ferromagnets from First Principles

Christoph Friedrich, Mathias C. T. D. Müller, and Stefan Blügel

## Contents

**Abstract**

Electronic spin excitations are low-energy excitations that influence the properties of magnetic materials substantially. Two types of spin excitations can be identified, single-particle Stoner excitations and collective spin-wave excitations. They can be treated on the same footing within many-body perturbation theory. In this theory, the collective spin excitations arise from the correlated motion of electron-hole pairs with opposite spins. We present the theory in detail and discuss several aspects of an implementation within the full-potential linearized augmented plane-wave method. The pair propagation is described by the transverse magnetic susceptibility, which we calculate from first principles employing the ladder approximation for the $T$ matrix. The four-point $T$ matrix is represented in a basis of Wannier functions. By using an auxiliary Wannier set with suitable Bloch character, the magnetic response function can be evaluated for arbitrary $\mathbf{k}$ points, allowing fine details of the spin-wave spectra to be studied. The energy of the acoustic spin-wave branch should vanish in the limit $\mathbf{k} \to \mathbf{0}$,

which is a manifestation of the Goldstone theorem. However, this condition is often violated in the calculated acoustic magnon dispersion, which can partly be traced back to the choice of the Green function. In fact, the numerical gap error is considerably reduced when a renormalized Green function is used. As an alternative simple correction scheme, we suggest an adjustment of the Kohn-Sham exchange splitting. We present spin excitation spectra for the elementary ferromagnets Fe, Co, and Ni as illustrative examples and compare to model calculations of the homogeneous electron gas.

# 1 Introduction

Electronic spin excitations span a large range of energies, from high-energy single-particle Stoner excitations to low-energy collective spin-wave excitations. Therefore, they are present at all temperatures and play an important role for the physical properties of magnetic materials. For example, the specific heat (Doniach and Engelsberg 1966), the macroscopic magnetization (Bloch 1930), and the magnetic susceptibility (Moriya 1985) exhibit a characteristic temperature dependence which can be attributed to the low-energy spin waves (magnons) with excitation energies ranging from a few meV up to a few hundreds meV. In low-dimensional magnets, spin-wave excitations can even destroy the long-range magnetic order completely. This happens in the absence of magnetic anisotropy at any finite temperature (Mermin and Wagner 1966). As the temperature increases, in addition to collective magnon modes, single-particle spin-flip processes, so-called Stoner excitations, become increasingly important. They further contribute to the temperature variation of the magnetization and give rise to a damping of the magnon states.

Spin excitations play a role in many fields of fundamental and technological interest. They can contribute to the scattering of a propagating electron or hole in a magnetic material, leading to a renormalization of the quasiparticle band dispersion (Hofmann et al. 2009; Schäfer et al. 2004) and reducing the inelastic mean free path of hot electrons (Hong and Mills 1999, 2000). In magnetic recording applications, the creation of spin waves that accompanies each switching process in the storage medium sets physical limits on data rates and areal recording densities. A strong damping helps in dissipating the energy contained in the spin waves. The spin wave bus, on the other hand, utilizes spin waves as a means for information transmission between distant nanoscale devices (Khitun and Wang 2005). The damping through the creation of Stoner excitations is an undesirable effect in this case, limiting the distance over which information can be transmitted. The power consumption of such a spin wave bus is expected to be considerably lower than in charge-based devices. Finally, it is believed that the electron-electron interaction can become attractive through the exchange of magnons, which is a possible mechanism for the creation of Cooper pairs in high-temperature superconductors (Dagotto 1994; Scalapino 1995).

In quantum mechanics, the spin excited states are eigenstates of the many-body Hamiltonian with a net spin flip with respect to the many-body ground state. The magnetic response function or dynamical spin susceptibility, defined as a two-particle Green function in many-body perturbation theory, exhibits resonances at the corresponding eigenenergies. In an infinite system, these resonances – or poles – are, in general, not discrete but form a continuous distribution when plotted over the eigenenergy. This *spectral function* is given mathematically by the imaginary part of the magnetic response function and can be measured in inelastic neutron scattering experiments (Lowde et al. 1983) where the circularly polarized magnetic field of an incoming neutron beam disturbs the local magnetization density of the sample material. The magnetic response function is thus a central quantity in the theoretical study of magnetic materials.

For a theoretical description of spin dynamics, various formalisms have been established. Most theoretical studies to date employ the Heisenberg model, which relies on a separation of the magnetic degrees of freedom and the fast motion of the electrons. This model is defined in terms of exchange parameters, which can be obtained, for example, from constrained density functional theory (Rosengaard and Johansson 1997; Kübler 2009; Halilov et al. 1997). Spin waves with long wavelengths can be calculated efficiently. Single-particle Stoner excitations are neglected, though, and the linewidths of the spin-wave resonances, which are inversely proportional to the magnon lifetimes, are inaccessible. Furthermore, the Heisenberg model is strictly justified only for systems with localized moments, such as systems with rare-earth magnetic ions, but not for materials which are magnetized by the exchange-driven polarization of the spins of itinerant electrons. While the Heisenberg model still yields reasonable results for long-wavelength excitations in itinerant-electron magnets, results for short-wavelength excitations are unsatisfactory. For example, the multiple branches or gaps in the magnon dispersion of $3d$ ferromagnets cannot be captured (Cooke 1976).

Many-body perturbation theory (MBPT) provides a more general theoretical framework that works for systems with localized moments and for metallic magnets alike. Single-particle Stoner and collective spin excitations appear simultaneously as poles in the transverse magnetic susceptibility, which can be interpreted as describing the correlated motion of an electron-hole pair coupled by an effective electron-electron interaction. First applications to real systems (Cooke 1973; Cooke 1976) employed a tight-binding description. Reasonable agreement with experiment throughout the Brillouin zone was obtained for the spin-wave dispersion of $3d$ ferromagnets. With a similar approach, Tang et al. (1998) examined the spin dynamics in ultrathin ferromagnetic films on nonmagnetic substrates.

Around the turn of the millennium, the first calculations based on ab initio electronic structure methods were carried out: Karlsson and Aryasetiawan (2000) employed MBPT but used a local model potential with an adjustable parameter instead of the nonlocal electron-hole interaction. Savrasov (1998), Buczek et al. (2009), Lounis et al. (2010), and Rousseau et al. (2012) performed calculations

within time-dependent density functional theory (TDDFT). Kotani and van Schilf-
gaarde (2008) studied (anti-)ferromagnets based on quasiparticle self-consistent *GW*
calculations (Faleev et al. 2004), where the effective interaction was determined
from a magnetic sum rule. In 2010, Şaşıoğlu et al. (2010) reported a treatment
within MBPT where the screened Coulomb interaction was explicitly calculated
from the random-phase approximation (RPA) rather than using a model potential or
a parameter fixed by a sum rule. Still an ad hoc scaling of the screened interaction
was required to fulfill the Goldstone condition. Good agreement of the calculated
magnon dispersions in $3d$ ferromagnets with experiment was achieved in both
approaches, MBPT and TDDFT.

In the present chapter, we give a detailed presentation of the theoretical many-
body treatment of spin excitations within MBPT. We adopt a very general viewpoint
that encompasses excitations with and without a spin transfer, so neutral excita-
tions – e.g., excitons, which play an important role in optical absorption – will
appear as a special case. In Şaşıoğlu et al. (2010), a practical computational scheme
was developed to study excitation spectra of magnetic materials from first principles,
in close relation to the formalism of Aryasetiawan and Karlsson (1999). To study
collective magnon excitations, we include vertex corrections in the form of ladder
diagrams, which describe the coupling of electrons and holes with opposite spins via
the screened Coulomb interaction. In analogy to the many-body $T$ matrix defined by
Strinati (1988) for optical absorption, we use the same term for the corresponding
quantity that appears in the Green-function formalism for the transverse magnetic
response function. In order to reduce the numerical cost for the calculation of the
four-point $T$ matrix, we exploit a transformation to maximally localized Wannier
functions (MLWFs), which provide a more efficient basis to study local correlations
than extended Bloch states (Marzari and Vanderbilt 1997; Souza et al. 2001;
Freimuth et al. 2008). Our implementation is based on the full-potential linearized
augmented plane-wave (FLAPW) method.

Section 2 gives a detailed account of the theoretical framework. The numerical
implementation is described in Sect. 3. In particular, we discuss how the magnetic
response function can be calculated for any Bloch vector, even if this Bloch vector
is not an element of the **k**-point set. This allows the calculation of smooth dispersion
curves while keeping the **k**-point set small. Section 4 is devoted to the discussion of
the violation of the Goldstone theorem. This theorem stipulates the existence of an
acoustic magnon branch with vanishing excitation energy in the long-wavelength
limit. In numerical calculations, the excitation energy often remains finite in this
limit. We show – both numerically and mathematically – that this violation is due
to an inconsistency in the choice of the single-particle Green function. In Sect. 5,
we present illustrative magnetic excitation spectra obtained for the elementary
ferromagnets bcc Fe, fcc Co, and fcc Ni. For more practical applications of this
method, we refer the reader to Friedrich et al. (2014) and Şaşıoğlu et al. (2010,
2013). In Sect. 6, we summarize our conclusions. Unless otherwise indicated,
Hartree atomic units are used throughout.

## 2    Theory

When a many-electron system is perturbed by a time-dependent external **B** field, originating, for example, from a neutron beam impinging on a magnetic sample, the system reacts by a change of the electronic density. This electronic redistribution is different for spin-up and spin-down electrons, since the **B** field couples to the electrons' spin, and, to a first approximation, it is the spin density that changes, while the total density remains the same. Therefore, we consider the magnetic response function

$$R^{ij}(\mathbf{r}_1 t_1, \mathbf{r}_2 t_2) = \frac{\delta \sigma^i(\mathbf{r}_1 t_1)}{\delta B^j(\mathbf{r}_2 t_2)} \,, \tag{1}$$

which gives the linear change of the spin density at the position $\mathbf{r}_1$ and time $t_1$ with respect to changes in the external **B** field at $\mathbf{r}_2$ and $t_2$. Here, $\sigma^i$ and $B^j$ are the vector components ($i, j = x, y, z$) of the spin density $\boldsymbol{\sigma}$ and the **B** field. We additionally allow for $i = 0$ and $j = 0$, where $\sigma^0$ is the total electronic density and $B^0$ is an external scalar potential. For example, $R^{00} = \delta\sigma^0/\delta B^0$ then corresponds to the density response function. Equation (1) thus defines a $4 \times 4$ tensor of response functions that are all nonzero in general.

The magnetic response function exhibits resonances (analytical poles) at the spin excitation energies of the unperturbed many-body system, corresponding to the eigen oscillations of the spin system. These "eigen oscillations" are, in general, not discrete and show a spectral distribution given by the imaginary part of the magnetic response function. In order to capture all possible oscillations of the spin system, Eq. (1) defines a microscopic response function in the sense that the perturbing field – and also the response of the electronic (spin) density – can have an arbitrary shape in space. In particular, it can exhibit any wavelength down to interatomic distances. Its determination requires an ab initio description of the electronic structure and a high-level quantum mechanical treatment of the correlated motion of the electrons.

We employ a method based on MBPT similar to the one of Aryasetiawan and Karlsson (1999). However, we do not employ Matsubara frequencies but a formulation at absolute zero that yields the magnetic excitation spectra directly for real frequencies. An implementation within an all-electron Wannier-function formulation was published in Şaşıoğlu et al. (2010) and Friedrich et al. (2014). In the following, we develop the theory in detail.

To simplify the notation, space and time arguments $\mathbf{r}_1 t_1, \mathbf{r}_2 t_2, \ldots$ are abbreviated by the corresponding index $1, 2, \ldots$. The ground-state spin density distribution is given by the expectation value of the spin density operator

$$\sigma^i(1) = \sum_{\alpha,\beta} \sigma^i_{\alpha\beta} \langle \Psi_0 | \psi^\dagger_\alpha(1) \psi_\beta(1) | \Psi_0 \rangle \,, \tag{2}$$

where $\psi_\alpha(1)$ $[\psi_\alpha^\dagger(1)]$ is an annihilation (creation) field operator of an electron with spin $\alpha$ and $\sigma_{\alpha\beta}^i$ are the elements of the Pauli spin matrices for $i = x, y, z$. The expectation value is taken with respect to the interacting many-body ground state $|\Psi_0\rangle$. For example, for the spin density in $z$ direction, the operator is simply $\psi_\uparrow^\dagger(1)\psi_\uparrow(1) - \psi_\downarrow^\dagger(1)\psi_\downarrow(1)$, and the spin density is given by the difference of the spin-up and spin-down number densities. When considering transversal spin-wave excitations later on, the spin Pauli matrices for $i = x$ and $i = y$ will become relevant, but until then the derivation is general. The case $i = 0$ can be taken into account by defining $\sigma_{\alpha\beta}^0 = \delta_{\alpha\beta}$. We rewrite Eq. (2) as

$$\sigma^i(1) = -i \sum_{\alpha,\beta} \sigma_{\beta\alpha}^i G_{\alpha\beta}(11^+) \qquad (3)$$

where $1^+ = \mathbf{r}_1 t_1 + \eta$ with a positive infinitesimal time $\eta$ and $G_{\alpha\beta}(12) = -i\langle\Psi_0|\mathcal{T}[\psi_\alpha(1)\psi_\beta^\dagger(2)]|\Psi_0\rangle$ is the interacting single-particle Green function with the time-ordering operator $\mathcal{T}$ (Mahan 2000), which orders the field operators chronologically from right to left. (A factor $-1$ has to be multiplied for each permutation of field operators.)

We are now in the position to prove that $R^{ij}$ can be written as a spin-spin correlation function. First the Green function is expressed in the interaction picture

$$G_{\alpha\beta}(12) = -i\langle\Psi_0^I(\infty)|U^I(\infty, 1)\psi_\alpha^I(1)U^I(1, 2)\psi_\beta^{I\dagger}(2)U^I(2, -\infty)|\Psi_0\rangle$$

$$= -i\frac{\langle\Psi_0|U^I(\infty, 1)\psi_\alpha^I(1)U^I(1, 2)\psi_\beta^{I\dagger}(2)U^I(2, -\infty)|\Psi_0\rangle}{\langle\Psi_0|U(\infty, -\infty)|\Psi_0\rangle}, \qquad (4)$$

where we have assumed that $t_1 > t_2$, that the Heisenberg state $|\Psi_0\rangle$ is identical to $|\Psi_0^I(-\infty)\rangle$, and that $|\Psi_0^I(\infty)\rangle$ differs from $|\Psi_0\rangle$ only by a phase factor. The time evolution operator depends only on the time arguments and fulfills the Tomonaga-Schwinger equation

$$i\frac{\partial}{\partial t}U^I(t, t') = H^I(t)U^I(t, t') \qquad (5)$$

with the Zeeman term $H^I(t') = \sum_{j,\alpha,\beta} \sigma_{\alpha\beta}^j \int B^j(1)\psi_\alpha^{I\dagger}(1)\psi_\beta^I(1)d1$. Using the solution $U^I(t, t') = \mathcal{T}\exp\left[-i\int_{t'}^t H_j^I(t'')dt''\right]$, one can show that

$$\frac{\delta U^I(t, t')}{\delta B^j(3)} = \begin{cases} -iU^I(t, t_3)\hat{\sigma}^j(3)U^I(t_3, t') & \text{if } t < t_3 < t' \\ 0 & \text{otherwise} \end{cases} \qquad (6)$$

with $\hat{\sigma}^j(3) = \sum_{\alpha,\beta} \sigma_{\alpha\beta}^j \psi_\alpha^{I\dagger}(3)\psi_\beta^I(3)$. This expression replaces the corresponding $U^I$ when Eq. (4) is differentiated. Then, transforming back to the Heisenberg picture,

including the case $t_1 < t_2$, and inserting the result into Eqs. (1) and (3) yields the spin-spin correlation function

$$R^{ij}(12) = -i\langle\Psi_0|\mathcal{T}[\hat{\sigma}^{i\prime}(1)\hat{\sigma}^{j\prime}(2)]|\Psi_0\rangle \tag{7}$$

with $\hat{\sigma}^{i\prime}(1) = \hat{\sigma}^i(1) - \sigma^i(1)$.

The reformulation with the Green function makes Eq. (3) amenable to a treatment within MBPT. The equation of motion of the Green function, the Dyson equation, in the presence of a **B** field reads

$$\left[i\frac{\partial}{\partial t_1} + \frac{1}{2}\nabla_{\mathbf{r}_1}^2 - V^{\text{ext}}(\mathbf{r}_1)\right]G_{\alpha\beta}(12) - \left[\sum_i \sigma_{\alpha\beta}^i B^i(1)\right]G_{\alpha\beta}(12)$$

$$- \sum_\gamma \int M_{\alpha\gamma}(13)G_{\gamma\beta}(32)d3 = \delta(12)\delta_{\alpha\beta}\,, \tag{8}$$

from which we can directly identify the inverse of the Green function

$$G_{\alpha\beta}^{-1}(12) = \left[i\frac{\partial}{\partial t_1} + \frac{1}{2}\nabla_{\mathbf{r}_1}^2 - V^{\text{ext}}(\mathbf{r}_1)\right]\delta(12)\delta_{\alpha\beta} - \left[\sum_i \sigma_{\alpha\beta}^i B^i(1)\right]\delta(12) - M_{\alpha\beta}(12) \tag{9}$$

with the external potential $V^{\text{ext}}(\mathbf{r})$ and the delta function $\delta(12) = \delta(\mathbf{r}_1 - \mathbf{r}_2)\delta(t_1 - t_2)$. We have assumed the **B** field to incorporate a factor $g_e\mu_B/2$ ($g_e/4$ in atomic units) with the electron spin $g$-factor $g_e$ and the Bohr magneton $\mu_B$ so that $\mathbf{B}\cdot\hat{\sigma}$ is the Zeeman term of the Hamiltonian.

In solids, the orbital magnetic moment is usually strongly quenched, which is why we neglect the coupling of the **B** field to the orbital motion. The mass operator

$$M_{\alpha\beta}(12) = V^{\text{H}}(1)\delta(12)\delta_{\alpha\beta} + \Sigma_{\alpha\beta}(12) \tag{10}$$

accounts for the electron-electron interaction. It embodies the Hartree potential

$$V^{\text{H}}(1) = \int n(2)v(21)d2 = -i\sum_\alpha \int G_{\alpha\alpha}(22^+)v(21)d2 \tag{11}$$

with the bare Coulomb interaction $v(12) = \delta(t_1 - t_2)/|\mathbf{r}_1 - \mathbf{r}_2|$ and the self-energy $\Sigma_{\alpha\beta}(12)$, a time-dependent nonlocal potential that incorporates all many-body exchange and correlation effects of the electronic system. The self-energy is the most complex quantity in Eq. (9), and its exact form is unknown. We employ the $GW$ approximation (Hedin 1965)

$$\Sigma_{\alpha\beta}(12) = iG_{\alpha\beta}(12)W(1^+2)\,, \tag{12}$$

where

$$W(12) = v(12) + \iint v(13)P(34)W(42)\,d3\,d4 \qquad (13)$$

is the screened interaction, which is the effective potential at 1 created by a unit charge at 2 (first term) and the induced charge cloud forming around the unit charge (second term). The screened interaction is a dynamical (i.e., time-dependent) quantity, since the screening process requires the electrons to move, and this process takes time. Equation (13) is formally exact. The approximation consists in the choice of the polarization function, for which we use the RPA

$$P(12) = -\mathrm{i} \sum_{\alpha,\beta} G_{\alpha\beta}(12)G_{\beta\alpha}(21^+)\,. \qquad (14)$$

We note that Eq. (12) is defined with the self-consistently renormalized Green function, formally corresponding to a fully self-consistent solution of Hedin's equations (Hedin 1965) where the vertex function is approximated by $\Gamma(12;3) = \delta(12)\delta(13)$. This will become important in Sect. 4.

The derivative of $G$ can be related to that of $G^{-1}$ by differentiating both sides of $\sum_\gamma G_{\alpha\gamma}(13)G_{\gamma\beta}^{-1}(32)d3 = \delta(12)\delta_{\alpha\beta}$, yielding

$$\frac{\delta G_{\alpha\beta}(12)}{\delta B^j(3)} = -\sum_{\gamma,\delta} \iint G_{\alpha\gamma}(14)\frac{\delta G_{\gamma\delta}^{-1}(45)}{\delta B^j(3)}G_{\delta\beta}(52)d4\,d5\,. \qquad (15)$$

Through the derivative of Eq. (9)

$$\frac{\delta G_{\alpha\beta}^{-1}(12)}{\delta B^j(3)} = -\sigma_{\alpha\beta}^j\delta(13)\delta(12) - \frac{\delta M_{\alpha\beta}(12)}{\delta B^j(3)} \qquad (16)$$

and Eqs. (10), (11), and (12), the right-hand side of Eq. (15) can be expressed in terms of $\delta G/\delta B$, and successive insertion will lead to an infinite series expansion. Before we do this step, we have to find a suitable expression for the second term of $\delta\Sigma/\delta B = \mathrm{i}(\delta G/\delta B)W + \mathrm{i}G(\delta W/\delta B)$. Differentiating Eq. (13), solving for the derivative of $W$, and using Eq. (14) gives

$$\frac{\delta W(12)}{\delta B^j(3)} = -\mathrm{i} \sum_{\alpha,\beta} \iint W(14)$$

$$\left[\frac{\delta G_{\alpha\beta}(45)}{\delta B^j(3)}G_{\beta\alpha}(54^+) + G_{\alpha\beta}(45)\frac{\delta G_{\beta\alpha}(54^+)}{\delta B^j(3)}\right] W(52)\,d4\,d5\,. \qquad (17)$$
**Fig. 1** Diagrammatic representations of (**a**) Eq. (18) and (**b**) Eq. (19). Successive reinsertion in (**a**) produces an infinite series of diagrams for $\delta G/\delta B$ and, hence, for $R$. Arrows represent the renormalized Green function, the dotted line the bare, and the wiggly line the screened interaction. (We use the convention that each interaction line carries a factor i.) The spin-flip operator, mathematically described by a Pauli matrix, is shown as $\sigma$

Now, we can combine everything and obtain

$$\frac{\delta G_{\alpha\beta}(12)}{\delta B^j(3)} = \sum_{\gamma,\delta}\left[\sigma^j_{\gamma\delta}G_{\alpha\gamma}(13)G_{\delta\beta}(32^+)\right. \tag{18}$$

$$\left. + \sum_{\varepsilon,\zeta}\iiiint G_{\alpha\gamma}(14)G_{\delta\beta}(52^+)I_{\gamma\delta,\varepsilon\zeta}(45,67)\frac{\delta G_{\varepsilon\zeta}(67)}{\delta B^j(3)}d4\,d5\,d6\,d7\right]$$

with the (irreducible) interaction kernel

$$I_{\alpha\beta,\gamma\delta}(12,34) = \mathrm{i}\left[W(1^+2)\delta(13)\delta(24)\delta_{\alpha\gamma}\delta_{\beta\delta} - v(13)\delta_{\alpha\beta}\delta_{\gamma\delta}\delta(12)\delta(3^+4)\right]$$
$$+ G_{\alpha\beta}(12)\left[W(1^+3)G_{\delta\gamma}(43^+)W(42)+W(1^+4)G_{\delta\gamma}(43^+)W(32)\right]. \tag{19}$$

Equation (18) defines an infinite series expansion for $\delta G/\delta B$ as shown diagrammatically in Fig. 1a. By virtue of the Eqs. (1) and (3), a corresponding series expansion is obtained for $R^{ij}(12)$.

For $i = j = 0$, the above formulas lead to the Bethe-Salpeter equation for optical absorption. The case $i = 0 \neq j$ (or vice versa) describes the coupling of electronic spin and charge. The equations simplify in the absence of spin-orbit coupling. The Green function is then diagonal in spin space, and the inner spin summations in Eq. (18) disappear. We now discuss some specific cases:

**Nonmagnetic case:** We have $G_{\alpha\beta}(12) = \delta_{\alpha\beta}G(12)$, i.e., spin-up and spin-down Green functions are identical. As a result, all degrees of freedom (0, $x$, $y$, and $z$) decouple and $R^{00} = R^{zz}$ and $R^{xx} = R^{yy}$.

**Collinear (anti-)ferromagnetism:** The Green function is still diagonal in spin space, but the two components are different, i.e., $G_{\alpha\beta}(12) = \delta_{\alpha\beta}G_\alpha(12)$. Then, the degrees of freedom 0 and $z$ as well as $x$ and $y$ couple. In particular, we get a coupling of the spin and charge degrees of freedom in $R^{0z}$ (and $R^{z0}$). The diagonal elements $R^{00}$ and $R^{zz}$ are the density response function and the longitudinal spin susceptibility, respectively. They are decoupled from the functions $R^{ij}$ with $i, j \in \{x, y\}$, which give rise to the transverse spin susceptibility. In the latter case, the interaction kernel reduces to the first term $I = iW$.

**Spin-orbit coupling:** In the presence of spin-orbit coupling, the Green function acquires spin-off-diagonal elements. Then all degrees of freedom couple in general and all terms in Eq. (19) and all response functions defined in Eq. (1) must be taken into account.

In the following, we restrict ourselves to the case of spin excitations in a ferromagnet with a collinear magnetic ground state without spin-orbit coupling. For a spin polarization along the $z$ axis, these are generated by an oscillating magnetic field in the $xy$ plane. In particular, in inelastic neutron scattering experiments, the incoming neutron beam is circularly polarized, creating a magnetic field whose $y$ component exhibits a phase shift of $\pi/2$ with respect to the $x$ component (Lowde et al. 1983).

It is instructive to discuss the coupling of the electron's spin to the $\mathbf{B}$ field in terms of semiclassical physics. Without the perturbing field, the electron spin $\mathbf{S}$ precesses around the Weiss (exchange) field $\mathbf{B}_0$ according to the equation of motion $\dot{\mathbf{S}} = \boldsymbol{\mu} \times \mathbf{B}_0$, where $\boldsymbol{\mu} = -g_e\mu_B\mathbf{S}/\hbar$ is the magnetic moment of the electron. (We write the formulas in SI units in this paragraph.) With the majority spin pointing in the positive $\mathbf{z}$ direction, the Weiss field points in the negative $\mathbf{z}$ direction, and $\omega_0 = g_e\mu_B\mathbf{B}_0/\hbar$ is the Larmor frequency of the precession. The two possible circular polarizations of the perturbing $\mathbf{B}$ field – right- and left-handed with respect to the $\mathbf{B}_0$ field – are given by $\mathbf{B}^\pm(t) = B^\pm \mathrm{Re}[(\hat{\mathbf{x}}\mp i\hat{\mathbf{y}})e^{-i\omega t}]$, respectively. The equation of motion in the presence of the perturbing field is $\dot{\mathbf{S}} = \boldsymbol{\mu} \times (\mathbf{B}_0 + \mathbf{B}^\pm)$. If $\mathbf{S}^\pm$ is defined as the spin vector seen in the coordinate system that rotates with the $\mathbf{B}^\pm$ field, we can write $\dot{\mathbf{S}} = \dot{\mathbf{S}}^\pm - \mathbf{S} \times \boldsymbol{\omega}$. Equating the right-hand sides of the last two equations and inserting the formulas for $\boldsymbol{\mu}$ and $\omega_0$ gives $\dot{\mathbf{S}}^\pm = \boldsymbol{\mu} \times \mathbf{B}^\pm + \mathbf{S} \times (\boldsymbol{\omega} - \boldsymbol{\omega}_0)$, which reduces to $\dot{\mathbf{S}}^\pm = \boldsymbol{\mu} \times \mathbf{B}^\pm$ if $\boldsymbol{\omega} = \boldsymbol{\omega}_0$. This is the equation of motion of a spin precessing around $\mathbf{B}^\pm$, i.e., around a direction perpendicular to $\mathbf{B}_0$, making it possible to flip the spin of the electron. The frequency of this precession, the Rabi frequency, is $g_e\mu_B B/\hbar$. The condition that $\boldsymbol{\omega}$ and $\boldsymbol{\omega}_0 = g_e\mu_B\mathbf{B}_0/\hbar$ have the same orientation is fulfilled for the right-handed circular polarization, for which the relevant component is $B^+ = B_x + iB_y$ because $B_x\hat{\mathbf{x}} + B_y\hat{\mathbf{y}} = B^+(\hat{\mathbf{x}} - i\hat{\mathbf{y}}) + B^-(\hat{\mathbf{x}} + i\hat{\mathbf{y}})$ with $B^- = B_x - iB_y$.

Therefore, we consider the transverse magnetic susceptibility

$$R^{+-}(12) = \frac{\delta\sigma^+(1)}{\delta B^+(2)} \tag{20}$$

in the following, where "$+$" and "$-$" refer to the Pauli matrices $\hat{\sigma}^+ = \hat{\sigma}^x + i\hat{\sigma}^y$ and $\hat{\sigma}^- = \hat{\sigma}^x - i\hat{\sigma}^y$ with the matrix representations

$$\sigma^+ = \begin{pmatrix} 0 & 2 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad \sigma^- = \begin{pmatrix} 0 & 0 \\ 2 & 0 \end{pmatrix} \tag{21}$$

for the spin creation and annihilation operators. The Zeeman term of Eq. (9) can be written as

$$\sum_i \sigma_{\alpha\beta}^i B^i(1) = \frac{1}{2} \left[ \sigma_{\alpha\beta}^+ B^-(1) + \sigma_{\alpha\beta}^- B^+(1) \right] + \sigma_{\alpha\beta}^z B^z(1). \tag{22}$$

Because of the mixed products of the form $\sigma^+ B^-$ and $\sigma^- B^+$, the spin-spin correlation function Eq. (7) becomes

$$R^{+-}(12) = \frac{\delta\sigma^+(1)}{\delta B^+(2)} = -i\langle\Psi_0|\mathscr{T}[\hat{\sigma}^+(1)\hat{\sigma}^-(2)]|\Psi_0\rangle, \tag{23}$$

where we have used that $\langle\Psi_0|\hat{\sigma}^+(1)|\Psi_0\rangle = \langle\Psi_0|\hat{\sigma}^-(1)|\Psi_0\rangle = 0$ in a collinear magnetic system. This form of the spin-spin correlation function is intuitive: for a spin in the up channel to be probed, one has to flip its spin with the operator $\hat{\sigma}^-$ before flipping it back with $\hat{\sigma}^+$. Equation (23) also explains the notation $R^{+-}$.

With Eq. (22), a derivation that proceeds in analogy to above leads to

$$i\frac{\delta G_{\downarrow\uparrow}(12)}{\delta B^+(3)} = K_{\downarrow\uparrow}(12, 33) + \iint K_{\downarrow\uparrow}(12, 45)W(4^+5)i\frac{\delta G_{\downarrow\uparrow}(45)}{\delta B^j(3)}d4\,d5 \tag{24}$$

with the (uncorrelated) two-particle propagator

$$K_{\downarrow\uparrow}(12, 34) = iG_{\downarrow}(13)G_{\uparrow}(42^+) \tag{25}$$

($G_{\uparrow} = G_{\uparrow\uparrow}$, $G_{\downarrow} = G_{\downarrow\downarrow}$). We have used that (a) the mass operator Eq. (10) reduces to $\Sigma$ for $\alpha \neq \beta$ and (b) the second term in Eq. (19) vanishes, (c) as do the last two terms because the Green function is diagonal in spin space. Note that Eq. (24) can be obtained from Eq. (18) by setting $i = +$ and $j = -$ except for an additional factor $1/2$ from Eq. (22).

Equation (24) can be written as a matrix equation if we define a generalized four-point magnetic response function (formally giving the response of the spin density matrix with respect to changes of a nonlocal $\mathbf{B}$ field). To this end, we introduce

the auxiliary four-point magnetic response function defined by the Bethe-Salpeter equation

$$R_{\downarrow\uparrow}^{(4)}(12, 34) = K_{\downarrow\uparrow}(12, 34) + \iint K_{\downarrow\uparrow}(12, 56)W(5^+6)R_{\downarrow\uparrow}^{(4)}(56, 34)d5\,d6\,, \tag{26}$$

from which we deduce

$$R_{\downarrow\uparrow}^{(4)}(12, 33) = \mathrm{i}\frac{\delta G_{\downarrow\uparrow}(12)}{\delta B^+(3)} \tag{27}$$

$$R^{+-}(12) = -2R_{\downarrow\uparrow}^{(4)}(11, 22)\,. \tag{28}$$

The magnetic response function can, furthermore, be written as the sum of two terms

$$R^{+-}(12) = -2K_{\downarrow\uparrow}(11, 22) - 2\iiiint K_{\downarrow\uparrow}(11, 34)T_{\downarrow\uparrow}(34, 56)$$
$$K_{\downarrow\uparrow}(56, 22)d3\,d4\,d5\,d6\,, \tag{29}$$

where the $T$ matrix, which can be interpreted as a reducible interaction kernel, fulfills the equation

$$T_{\downarrow\uparrow}(12, 34) = W(1^+2)\delta(13)\delta(24) + \iint W(1^+2)K_{\downarrow\uparrow}(12, 56)T_{\downarrow\uparrow}(56, 34)d5\,d6\,. \tag{30}$$

If we approximate the renormalized Green function in Eq. (25) by the Kohn-Sham Green function, then the first term of Eq. (29) contains single-particle excitations between Kohn-Sham levels from one spin channel into the other. The second term describes the correlated motion of an electron-hole pair with opposite spins through the $T$ matrix Fig. 2; each ladder diagram stands for a series of scattering events. This correlated motion is responsible for the occurrence of collective spin excitations. The second term also renormalizes the Stoner excitations.

TDDFT (Runge and Gross 1984) is another method that allows one to calculate the magnetic response function from first principles. In this theory, Eq. (3) is written in terms of the Kohn-Sham Green function $G_{\alpha\beta}^{\mathrm{KS}}(12)$ instead of $G_{\alpha\beta}(12)$. This

**Fig. 2** Diagrammatic representation of the $T_{\downarrow\uparrow}(12, 34)$ matrix consisting of an infinite series of ladder diagrams, each wiggly line (screened interaction $W$) representing a "rung" of the ladder. The indices 5 and 6 denote integration variables

is not an approximation since the Kohn-Sham system (Kohn and Sham 1965) is constructed to yield the *exact* electronic spin density of the interacting system (provided that the exact exchange-correlation functional is employed). A derivation, similar to the one above with $\Sigma$ in Eq. (10) replaced by the exchange-correlation potential $v_{\alpha\beta}^{\text{xc}}(1)$, then yields an expression for the magnetic response function with the interaction kernel

$$I_{\alpha\beta,\gamma\delta}^{\text{KS}}(12,34) = -\mathrm{i}\left[v(13)\delta_{\alpha\beta}\delta_{\gamma\delta} + f_{\alpha\beta,\gamma\delta}^{\text{xc}}(13)\right]\delta(12)\delta(3^+4)\,, \qquad (31)$$

where $f_{\alpha\beta,\gamma\delta}^{\text{xc}}(12) = \delta v_{\alpha\beta}^{\text{xc}}(1)/\delta\sigma_{\gamma\delta}(2)$ is the exchange-correlation kernel of TDDFT. This interaction kernel is effectively just a two-point function. Equation (26), hence, turns into a two-point matrix equation, which makes the implementation of the TDDFT approach much simpler and computationally less demanding. However, there are only few approximations available for $f_{\alpha\beta,\gamma\delta}^{\text{xc}}(12)$ to date, which, at that, cannot be systematically improved in contrast to the electronic self-energy. The most common approximation, the adiabatic local-density approximation, neglects time dependence and nonlocality altogether (and also requires the spin indices to be pairwise identical) so that $f_{\alpha\beta,\beta\alpha}^{\text{xc}}(1)$ becomes a local function. Still, several publications (Savrasov 1998; Buczek et al. 2009, 2010, 2011; Lounis et al. 2010, 2011) have demonstrated that the spin excitation spectra calculated within TDDFT are often in good agreement to results from MBPT and to experiment.

## 3   Implementation

In this section, we present the basics of a numerical implementation in the SPEX code (Friedrich et al. 2010). For more details, we refer the reader to Friedrich et al. (2014). The four-point quantities derived in the previous section are represented in a basis of Wannier functions. In Sect. 4, we will discuss and compare several mean-field systems as the reference noninteracting system. In the present section, we assume the Kohn-Sham solution (Kohn and Sham 1965) of density functional theory (DFT) (Hohenberg and Kohn 1964) be used. The corresponding Kohn-Sham equations are solved within the all-electron FLAPW method as implemented in the FLEUR code (http://www.flapw.de), which allows an accurate representation of the single-particle states $\varphi_{\mathbf{k}m}^{\alpha}(\mathbf{r})$, where $\mathbf{k}$ is the Bloch vector and $m$ the band index.

For a practical implementation, Eq. (26) is too complex because it contains quantities that, in general, depend on four points in space and on four time (or frequency) arguments (three if the Hamiltonian is time independent). A first simplification uses the fact that the spin-wave excitations are usually of low frequency, which motivates to replace the screened interaction by its static limit, i.e., $W(\mathbf{r}_1, \mathbf{r}_2; \omega) \rightarrow W(\mathbf{r}_1, \mathbf{r}_2; 0) = W(\mathbf{r}_1, \mathbf{r}_2)$, implying an instantaneous interaction in time, $W(\mathbf{r}_1 t_1, \mathbf{r}_2 t_2) = W(\mathbf{r}_1, \mathbf{r}_2)\delta(t_1 - t_2)$. For example, the two-particle propagator Eq. (25) then only depends on a single time (or frequency) argument because the delta function in the previous expression (and the contraction of

Eq. (28)) requires the argument pairs 12 and 34 to have the same time argument, i.e., $K_{\downarrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_3, \mathbf{r}_4; \tau = t_1 - t_3)$ with $t_1 = t_2$ and $t_3 = t_4$. Equation (26) then simplifies to

$$R_{\downarrow\uparrow}^{(4)}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_3, \mathbf{r}_4; \omega) = K_{\downarrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_3, \mathbf{r}_4; \omega) + \iint K_{\downarrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_5, \mathbf{r}_6; \omega)$$

$$W(\mathbf{r}_5, \mathbf{r}_6) R_{\downarrow\uparrow}^{(4)}(\mathbf{r}_5, \mathbf{r}_6; \mathbf{r}_3, \mathbf{r}_4; \omega) \, d^3 r_5 \, d^3 r_6 \qquad (32)$$

in the frequency domain. We employ another approximation in that we allow electrons (and holes) to interact with each other only when they are located on the same atomic site, thus making use of the fact that the screened interaction is short range in metallic systems. This on-site approximation is not strictly necessary, but it greatly simplifies the implementation and enables fast calculations. Besides, it is a very good approximation for the systems studied here (Müller et al. 2016).

Wannier functions (Marzari and Vanderbilt 1997) are localized functions defined by linear combinations of the single-particle wave functions

$$w_{\mathbf{R}n}^{\alpha}(\mathbf{r}) = \frac{1}{N} \sum_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{R}} \sum_{m} U_{\mathbf{k}m,n}^{\alpha} \varphi_{\mathbf{k}m}^{\alpha}(\mathbf{r}) \,, \qquad (33)$$

where $n$ is an index counting the Wannier functions at the atomic site $\mathbf{R}$ and $N$ is the number of $\mathbf{k}$ points of an $N_x \times N_y \times N_z$ Monkhorst-Pack set (Monkhorst and Pack 1976) including $\mathbf{k} = \mathbf{0}$. The transformation matrix $U_{\mathbf{k}m,n}^{\alpha}$ is determined by minimizing the spread of the Wannier functions (Souza et al. 2001; Marzari and Vanderbilt 1997; Freimuth et al. 2008), under the condition that the Wannier functions are orthonormal with respect to integrations over the $N_x \times N_y \times N_z$ supercell (whereas the $\varphi_{\mathbf{k}m}^{\alpha}(\mathbf{r})$ are orthonormalized with respect to the unit cell). The sum over $m$ runs over a limited number of electronic bands (at least as many as the number of Wannier functions).

In the frequency domain, Eq. (25) becomes

$$K_{\downarrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_3, \mathbf{r}_4; \omega) = \frac{i}{2\pi} \int_{-\infty}^{\infty} G_{\downarrow}(\mathbf{r}_1, \mathbf{r}_3; \omega') G_{\uparrow}(\mathbf{r}_4, \mathbf{r}_2; \omega' - \omega) d\omega'$$

$$= \frac{1}{N^2} \sum_{\mathbf{k}} \sum_{\mathbf{k}'} \sum_{m}^{\text{occ.}} \sum_{m'}^{\text{unocc.}} \left\{ \frac{\varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}_1) \varphi_{\mathbf{k}m}^{\downarrow*}(\mathbf{r}_3) \varphi_{\mathbf{k}'m'}^{\uparrow*}(\mathbf{r}_2) \varphi_{\mathbf{k}'m'}^{\uparrow}(\mathbf{r}_4)}{\omega + \varepsilon_{\mathbf{k}'m'}^{\uparrow} - \varepsilon_{\mathbf{k}m}^{\downarrow} - i\eta} \right.$$

$$\left. - \frac{\varphi_{\mathbf{k}'m'}^{\downarrow}(\mathbf{r}_1) \varphi_{\mathbf{k}'m'}^{\downarrow*}(\mathbf{r}_3) \varphi_{\mathbf{k}m}^{\uparrow*}(\mathbf{r}_2) \varphi_{\mathbf{k}m}^{\uparrow}(\mathbf{r}_4)}{\omega + \varepsilon_{\mathbf{k}m}^{\uparrow} - \varepsilon_{\mathbf{k}'m'}^{\downarrow} + i\eta} \right\} \qquad (34)$$

with a positive infinitesimal $\eta$, where we have used the Lehmann representation of the noninteracting Kohn-Sham Green function

$$G_\alpha(\mathbf{r}, \mathbf{r}'; \omega) = \frac{1}{N} \sum_\mathbf{k} \sum_m \frac{\varphi_{\mathbf{k}m}^\alpha(\mathbf{r})\varphi_{\mathbf{k}m}^{\alpha*}(\mathbf{r}')}{\omega - \varepsilon_{\mathbf{k}m}^\alpha + i\eta \operatorname{sgn}(\varepsilon_{\mathbf{k}m}^\alpha - \varepsilon_F)} \tag{35}$$

with the Fermi energy $\varepsilon_F$.

Each of the four vertices of $K_{\downarrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_3, \mathbf{r}_4; \omega)$ is now projected onto the Wannier basis defined by Eq. (33), which gives

$$
\begin{aligned}
K_{\mathbf{R}n_1\mathbf{R}n_2, \mathbf{R}'n_3\mathbf{R}'n_4}^{\downarrow\uparrow}(\omega) = \frac{1}{N^2} \sum_{\mathbf{k}m}^{\text{occ.}} \sum_{\mathbf{k}'m'}^{\text{unocc.}} \Bigg\{ & \frac{U_{\mathbf{k}m,n_1}^{\downarrow*} U_{\mathbf{k}m,n_3}^{\downarrow} U_{\mathbf{k}'m',n_2}^{\uparrow} U_{\mathbf{k}'m',n_4}^{\uparrow*}}{\omega + \varepsilon_{\mathbf{k}'m'}^{\uparrow} - \varepsilon_{\mathbf{k}m}^{\downarrow} - i\eta} e^{-i(\mathbf{k}'-\mathbf{k})(\mathbf{R}-\mathbf{R}')} \\
& - \frac{U_{\mathbf{k}'m',n_1}^{\downarrow*} U_{\mathbf{k}'m',n_3}^{\downarrow} U_{\mathbf{k}m,n_2}^{\uparrow} U_{\mathbf{k}m,n_4}^{\uparrow*}}{\omega + \varepsilon_{\mathbf{k}m}^{\uparrow} - \varepsilon_{\mathbf{k}'m'}^{\downarrow} + i\eta} e^{i(\mathbf{k}'-\mathbf{k})(\mathbf{R}-\mathbf{R}')} \Bigg\},
\end{aligned}
\tag{36}
$$

where the on-site approximation has been used to set $\mathbf{R}_1 = \mathbf{R}_2 = \mathbf{R}$ and $\mathbf{R}_3 = \mathbf{R}_4 = \mathbf{R}'$. This expression only depends on $\Delta\mathbf{R} = \mathbf{R} - \mathbf{R}'$, and a lattice Fourier transformation yields

$$
\begin{aligned}
K_{n_1n_2, n_3n_4}^{\downarrow\uparrow}(\mathbf{q}, \omega) &= \sum_{\Delta\mathbf{R}} K_{\mathbf{R}n_1\mathbf{R}n_2, \mathbf{R}-\Delta\mathbf{R}n_3\mathbf{R}-\Delta\mathbf{R}n_4}^{\downarrow\uparrow}(\omega) e^{-i\mathbf{q}\cdot\Delta\mathbf{R}} \\
&= \frac{1}{N} \sum_\mathbf{k} \sum_m^{\text{occ.}} \sum_{m'}^{\text{unocc.}} \Bigg\{ \frac{U_{\mathbf{q}+\mathbf{k}m,n_1}^{\downarrow*} U_{\mathbf{q}+\mathbf{k}m,n_3}^{\downarrow} U_{\mathbf{k}m',n_2}^{\uparrow} U_{\mathbf{k}m',n_4}^{\uparrow*}}{\omega + \varepsilon_{\mathbf{k}m'}^{\uparrow} - \varepsilon_{\mathbf{q}+\mathbf{k}m}^{\downarrow} - i\eta} \\
&\qquad - \frac{U_{\mathbf{q}+\mathbf{k}m',n_1}^{\downarrow*} U_{\mathbf{q}+\mathbf{k}m',n_3}^{\downarrow} U_{\mathbf{k}m,n_2}^{\uparrow} U_{\mathbf{k}m,n_4}^{\uparrow*}}{\omega + \varepsilon_{\mathbf{k}m}^{\uparrow} - \varepsilon_{\mathbf{q}+\mathbf{k}m'}^{\downarrow} + i\eta} \Bigg\}.
\end{aligned}
\tag{37}
$$

We use the tetrahedron method (Rath and Freeman 1975) for the $\mathbf{k}$ summation.

From this equation, it is clear that if $\mathbf{q}$ and $\mathbf{k}$ are elements of the $\mathbf{k}$-point set, then $\mathbf{q} + \mathbf{k}$ must be an element of the set, too. The Monkhorst-Pack grid fulfills this condition. On the other hand, this condition limits the number of $\mathbf{q}$ points at which a spin excitation spectrum can be calculated to the relatively few points of the $\mathbf{k}$-point set. In order to evaluate $K$ (and $R$) at an arbitrary Bloch vector $\mathbf{q}$, which would enable the calculation of smooth spin-wave dispersion curves, we have to introduce an auxiliary set of Wannier functions with a suitable Bloch character

$$\tilde{w}_{\mathbf{R}n}^\alpha(\mathbf{r}) = \frac{1}{N} \sum_\mathbf{k} e^{-i(\mathbf{k}+\mathbf{q})\cdot\mathbf{R}} \sum_m U_{\mathbf{k}+\mathbf{q}m,n}^\alpha \varphi_{\mathbf{k}+\mathbf{q}m}^\alpha(\mathbf{r}), \tag{38}$$

where the transformation matrices are distinguished from the ones used in Eq. (33) by the Bloch vectors $\mathbf{k} + \mathbf{q}$, which are generally not elements of the original $\mathbf{k}$-point set. With this definition, Eq. (37) remains valid, but it has to be taken into account

that the transformation matrices $U^\alpha_{\mathbf{q}+\mathbf{k}m,n}$ and $U^\alpha_{\mathbf{k}m,n}$ now belong to two different sets of Wannier functions.

The second quantity that we need for solving Eq. (26) is the screened interaction. We define its Wannier representation by

$$W^{\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}n_3\mathbf{R}n_4}(\omega) = \frac{N}{\mathcal{N}}\iint w^{\downarrow*}_{\mathbf{R}n_1}(\mathbf{r})w^{\downarrow}_{\mathbf{R}n_3}(\mathbf{r})W(\mathbf{r},\mathbf{r}';\omega)w^{\uparrow}_{\mathbf{R}n_2}(\mathbf{r}')w^{\uparrow*}_{\mathbf{R}n_4}(\mathbf{r}')d^3r\,d^3r'\,,$$
(39)

where $\mathcal{N}(\mathcal{N}/N)$ is the infinite number of unit cells (supercells). The prefactor is required to avoid double counting because the integrations extend over the whole infinite space. Inserting Eq. (33) gives

$$W^{\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}n_3\mathbf{R}n_4}(\omega) = \frac{1}{N^3}\sum_{\mathbf{k},\mathbf{k}',m_1,m_2,m_3,m_4}U^{\downarrow*}_{\mathbf{k}+\mathbf{k}''m_1,n_1}U^{\downarrow}_{\mathbf{k}m_3,n_3}U^{\uparrow}_{\mathbf{k}'+\mathbf{k}''m_2,n_2}U^{\uparrow*}_{\mathbf{k}'m_4,n_4}$$

$$\times\frac{1}{\mathcal{N}}\iint\varphi^{\downarrow*}_{\mathbf{k}+\mathbf{k}''m_1}(\mathbf{r})\varphi^{\downarrow}_{\mathbf{k}m_3}(\mathbf{r})W(\mathbf{r},\mathbf{r}';\omega)\varphi^{\uparrow}_{\mathbf{k}'+\mathbf{k}''m_2}(\mathbf{r}')$$

$$\varphi^{\uparrow*}_{\mathbf{k}'m_4}(\mathbf{r}')d^3r\,d^3r'\,,$$
(40)

where it has been used that $W(\mathbf{r},\mathbf{r}';\omega)$ is diagonal in $\mathbf{k}$. The evaluation of the double integral, which, together with the prefactor $1/\mathcal{N}$, is finite, is discussed elsewhere (Friedrich et al. 2009). Since Eq. (40) is independent of $\mathbf{R}$, we may write $W^{\downarrow\uparrow}_{n_1n_2,n_3n_4}(\omega)$.

We are now in the position to formulate the Bethe-Salpeter equation (Eq. (32)) in the Wannier basis

$$R^{(4)\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}'n_3\mathbf{R}'n_4}(\omega) = K^{\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}'n_3\mathbf{R}'n_4}(\omega) + \sum_{\mathbf{R}''}\sum_{n_5,n_6,n_7,n_8}K^{\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}''n_5\mathbf{R}''n_6}(\omega)$$

$$\times W^{\downarrow\uparrow}_{n_5n_6,n_7n_8}(0)R^{(4)\downarrow\uparrow}_{\mathbf{R}''n_7\mathbf{R}''n_8,\mathbf{R}'n_3\mathbf{R}'n_4}(\omega)\,.$$
(41)

As $K$ (and hence also $R$) depends only on the difference $\Delta\mathbf{R} = \mathbf{R} - \mathbf{R}'$, we can insert the lattice Fourier transformations

$$K^{\downarrow\uparrow}_{\mathbf{R}n_1\mathbf{R}n_2,\mathbf{R}'n_3\mathbf{R}'n_4}(\omega) = \frac{1}{N}\sum_{\mathbf{q}}e^{i\mathbf{q}\cdot(\mathbf{R}-\mathbf{R}')}K^{\downarrow\uparrow}_{n_1n_2,n_3n_4}(\mathbf{q},\omega)\,,$$
(42)

analogously for $R^{(4)}$, and obtain

$$R^{(4)\downarrow\uparrow}_{n_1n_2,n_3n_4}(\mathbf{q},\omega) = K^{\downarrow\uparrow}_{n_1n_2,n_3n_4}(\mathbf{q},\omega) + \sum_{n_5,n_6,n_7,n_8}K^{\downarrow\uparrow}_{n_1n_2,n_5n_6}(\mathbf{q},\omega)$$

$$\times W^{\downarrow\uparrow}_{n_5n_6,n_7n_8}(0)R^{(4)\downarrow\uparrow}_{n_7n_8,n_3n_4}(\mathbf{q},\omega)\,.$$
(43)

This is a matrix equation in pairs of Wannier indices. Since Wannier functions are orthonormal, their pairs are orthonormal, too. The summations on the right-hand side are mere matrix multiplications, and we can formally solve Eq. (43) for $R^{(4)}$

$$R^{(4)\downarrow\uparrow}(\mathbf{q}, \omega) = [\mathbb{1} - K^{\downarrow\uparrow}(\mathbf{q}, \omega)W^{\downarrow\uparrow}(0)]^{-1}K^{\downarrow\uparrow}(\mathbf{q}, \omega). \tag{44}$$

Using Eq. (28), we obtain the physically relevant magnetic response function from the matrix elements of $R^{(4)\downarrow\uparrow}(\mathbf{q}, \omega)$ by

$$R^{+-}(\mathbf{r}, \mathbf{r}'; \omega) = -\frac{2}{N} \sum_{\mathbf{q}} \sum_{n_1, n_2, n_3, n_4} R^{(4)\downarrow\uparrow}_{n_1 n_2, n_3 n_4}(\mathbf{q}, \omega)\Omega^{\downarrow\uparrow}_{\mathbf{q}n_1 n_2}(\mathbf{r})\Omega^{\downarrow\uparrow*}_{\mathbf{q}n_3 n_4}(\mathbf{r}'). \tag{45}$$

where $\Omega^{\downarrow\uparrow}_{\mathbf{q}n_1 n_2}(\mathbf{r})$ are the lattice Fourier transforms of the Wannier products $\Omega^{\alpha\beta}_{\mathbf{R}, n_1 n_2}(\mathbf{r}) = w^{\alpha}_{\mathbf{R}n_1}(\mathbf{r})w^{\beta*}_{\mathbf{R}n_2}(\mathbf{r})$, i.e.,

$$\Omega^{\alpha\beta}_{\mathbf{q}n_1 n_2}(\mathbf{r}) = \sum_{\mathbf{R}} \Omega^{\alpha\beta}_{\mathbf{R}n_1 n_2}(\mathbf{r})e^{i\mathbf{q}\cdot\mathbf{R}} = \frac{1}{N} \sum_{\mathbf{k}} w^{\alpha}_{\mathbf{q}+\mathbf{k}n_1}(\mathbf{r})w^{\beta*}_{\mathbf{k}n_2}(\mathbf{r}) \tag{46}$$

with the Wannier Bloch functions $w^{\alpha}_{\mathbf{k}n}(\mathbf{r}) = \sum_m U^{\alpha}_{\mathbf{k}m, n}\varphi^{\alpha}_{\mathbf{k}m}(\mathbf{r})$. If we use the matrix representation of $K^{\downarrow\uparrow}(\mathbf{q}, \omega)$ in Eq. (45), we obtain the bare susceptibility, i.e., the fictitious magnetic response function of the noninteracting reference system:

$$K^{+-}(\mathbf{r}, \mathbf{r}'; \omega) = -2K^{\downarrow\uparrow}(\mathbf{r}, \mathbf{r}; \mathbf{r}', \mathbf{r}'; \omega) \tag{47}$$

$$= -\frac{2}{N} \sum_{\mathbf{q}} \sum_{n_1, n_2, n_3, n_4} K^{\downarrow\uparrow}_{n_1 n_2, n_3 n_4}(\mathbf{q}, \omega)\Omega^{\downarrow\uparrow}_{\mathbf{q}n_1 n_2}(\mathbf{r})\Omega^{\downarrow\uparrow*}_{\mathbf{q}n_3 n_4}(\mathbf{r}'). \tag{48}$$

Of course, $R^{+-}(\mathbf{r}, \mathbf{r}'; \omega)$ is still a very complex quantity: it is nonlocal in space, it shows a frequency dependence, and it has a real and an imaginary part. The spectrum measured in neutron scattering experiments, for example, can be extracted from $R^{+-}(\mathbf{r}, \mathbf{r}'; \omega)$ by projecting its imaginary part from left and right to a plane wave $e^{i\mathbf{q}\cdot\mathbf{r}}$ giving Im $R^{+-}(\mathbf{q}, \omega)$ (Lowde et al. 1983). Sharp peaks in this function correspond to collective spin excitations, the spin waves, with wavevector $\mathbf{q}$ and frequency $\omega$. Plotting the respective $\omega$ values against $\mathbf{q}$ yields the dispersion relation of the spin-wave mode. We note that another possibility is to perform a normal mode analysis of the imaginary part of $R^{+-}$, in matrix notation Im $R^{+-} = (R^{+-} - R^{+-\dagger})/(2i)$.

## 4    Goldstone Condition

The Goldstone theorem states that the spontaneously broken spin-rotation symmetry in ferromagnetic materials leads to the appearance of a gapless magnon dispersion curve, i.e., the excitation energy vanishes in the limit $\mathbf{q} \to \mathbf{0}$. This has a very simple

physical explanation. The generating field is a magnetic field perpendicular to the ferromagnetic spin alignment, and it is commensurate with the unit cell in the limit $\mathbf{q} \rightarrow \mathbf{0}$. If the $\mathbf{B}$ field has a suitable shape in real space, it can act to rotate all electron spins collectively toward the field direction, i.e., the electron spins point in the same direction at all times. In the absence of spin-orbit coupling, this rigid rotation takes place without a cost of energy; hence $\omega = 0$. The pole at $\omega = 0$ corresponds to the long-wavelength limit of the acoustic magnon branch (Moriya 1985), identified as the *Goldstone mode*.

A rigid rotation of all spins does not change any relative spin alignment. The total energy calculated from the Heisenberg model is therefore invariant with respect to such a rotation, and the Goldstone condition is fulfilled identically. However, in the advanced methods based on TDDFT or MBPT, where the excitation energies define the pole structure of a two-particle propagator, the situation is much less transparent. We already know that the collective excitations arise from the nodes of the denominator of Eq. (44). (There is a very similar equation in TDDFT (Buczek et al. 2009; Lounis et al. 2010).) So, to be fulfilled, the Goldstone condition requires $KW$ to have an eigenvector with eigenvalue 1 in the limits $\mathbf{q} \rightarrow \mathbf{0}$ and $\omega \rightarrow 0$. (We omit the indices in this section for simplicity.) Any numerical inaccuracy will lead to a slight deviation of the respective eigenvalue from 1 and, as a consequence, to a violation of the Goldstone condition. Often, this problem is circumvented by using the Goldstone criterion to fix a free parameter of the numerical scheme, thus, making a virtue of necessity. This free parameter has been chosen to be the effective interaction (Kotani and van Schilfgaarde 2008; Karlsson and Aryasetiawan 2000), the exchange-correlation kernel (Lounis et al. 2010, 2011), the bare susceptibility (Rousseau et al. 2012), or a scaling factor for the screened Coulomb interaction (Şaşıoğlu et al. 2010; Friedrich et al. 2014). Another possibility is an a posteriori correction of the resulting susceptibility (Buczek 2009; Buczek et al. 2009, 2011). However, in our case, such a pragmatic approach seems inappropriate. There is no mistaking that $W$ is the RPA screened interaction Eqs. (13) and (14) and $K$ is the two-particle propagator Eq. (25). So, strictly speaking, there is no room or justification for introducing a free parameter. Therefore, we analyzed the problem in more detail in Müller et al. (2016). We argued that there is an inconsistency between the free propagator $G$ (and, hence, $K$) and the screened interaction $W$, and it is this inconsistency that is responsible for the Goldstone violation. In this chapter, we go a step further and present a mathematical proof that constructing the single-particle propagator from a self-consistent Coulomb-hole screened-exchange (COHSEX) self-energy (Hedin 1965, 1999) should revoke the inconsistency provided that a complete basis is used for the solution of the Bethe-Salpeter equation (Eq. (32)). However, the Wannier basis and, in particular, the on-site approximation do not fulfill the latter criterion so that a finite gap error must still be expected in our approach. Nevertheless, numerical results for the bulk $3d$ transition metals iron, cobalt, and nickel show that the Goldstone violation is substantially reduced if the propagator is self-consistently renormalized with the COHSEX self-energy. In practice, the application of the COHSEX self-energy is considerably more time-consuming than standard LSDA calculations. Therefore, we discuss a correction
**Fig. 3** Spin-wave spectra for Fe, Co, and Ni obtained with the LSDA (blue triangles), corrected LSDA (black circles), and COHSEX (red crosses) Green functions as starting point. (Müller et al. (2016) Copyright 2016 American Physical Society)

scheme for the LSDA Green function of ferromagnetic materials, ultimately introducing a free parameter as a pragmatic and efficient solution. We show that the corrected LSDA magnon spectra for the $3d$ transition metals iron, cobalt, and nickel are close to the results obtained from the much more expensive COHSEX approach.

In the following, we discuss the spin-wave spectra for the elementary bulk ferromagnets Fe, Co, and Ni with regard to the starting-point dependence of MBPT. We refer here to the Green function used in Eqs. (14) and (25). Since a set of single-particle states is already available from the ground-state calculation, a convenient choice is the LSDA Green function calculated from the corresponding Kohn-Sham wave functions and energies. We have used Wannier functions of $s$, $p$, and $d$ character constructed from the 18 lowest Kohn-Sham bands. The resulting spin-wave dispersions for all three materials are shown as the blue symbols in Fig. 3, correctly showing a quadratic behavior around the $\Gamma$ point. However, they also clearly exhibit a violation of the Goldstone theorem: the spin-wave excitation energy does not vanish in the center of the BZ as it should.

There are a number of approximations used in our numerical approach, which might be responsible for this violation, e.g., the on-site approximation, the incompleteness of the Wannier basis, convergence issues (**k**-point set, basis sets, empty-state summations), and so on. Apart from these, there is another more fundamental inconsistency in the chosen approach, which we will investigate in the following. This inconsistency concerns the choice of the starting point, i.e., the LSDA Green-function propagator. Equation (44) is derived under the assumption that the Green function be self-consistently renormalized with the $GW$ self-energy. Only if this condition is fulfilled do we obtain the infinite series of ladder diagrams shown in Fig. 1. The two quantities, $G$ and $W$, are thus related, and one must be chosen in accordance with the other.

Unfortunately, fully self-consistent $GW$ calculations for transition-metal bulk systems are nowadays still a major challenge due to the dense **k**-point sets that are needed. On a second thought, however, we should also remember the static approximation that we have applied to $W$. For this reason, the proper self-energy to be used in the framework of our theoretical approach would have to be constructed

with the static screened interaction. An obvious choice would be the Coulomb-hole screened-exchange (COHSEX) self-energy (Hedin 1965, 1999), in which the dynamical $W$ is replaced by the static $W(\mathbf{r}, \mathbf{r}') = W(\mathbf{r}, \mathbf{r}'; \omega = 0)$. It consists of two terms, the screened exchange (SEX) and the Coulomb-hole (COH) term. The former corresponds to Hartree-Fock theory with the bare Coulomb interaction replaced by $W(\mathbf{r}, \mathbf{r}')$

$$\Sigma_{\text{SEX}}^{\sigma}(\mathbf{r}, \mathbf{r}') = -n^{\sigma}(\mathbf{r}, \mathbf{r}')W(\mathbf{r}, \mathbf{r}') \tag{49}$$

with the density matrix $n^{\sigma}(\mathbf{r}, \mathbf{r}') = \sum_{\mathbf{k}}^{\text{BZ}} \sum_{n}^{\text{occ}} \varphi_{\mathbf{k}n}^{\sigma}(\mathbf{r})\varphi_{\mathbf{k}n}^{\sigma*}(\mathbf{r}')$. The latter is given by

$$\Sigma_{\text{COH}}(\mathbf{r}, \mathbf{r}') = \frac{1}{2}\delta(\mathbf{r} - \mathbf{r}')[W(\mathbf{r}, \mathbf{r}') - v(\mathbf{r}, \mathbf{r}')], \tag{50}$$

which acts as a local and spin-independent potential. It accounts for the interaction energy of a quasiparticle with its induced (static) polarization cloud. Therefore, this term only couples charge degrees of freedom (if spin-orbit coupling is set aside) and does not affect the linear response of transversal spin fluctuations. Only Eq. (49), corresponding to Eq. (12) with $W(\mathbf{r}, \mathbf{r}'; \tau + \eta)$ replaced by $W(\mathbf{r}, \mathbf{r}')$, contributes to the right-hand side of Eq. (16) with $\delta \Sigma / \delta G = iW(0)$. Obviously, this leads to the same form of the Bethe-Salpeter equation as before.

Up to now, our argumentation was based on "theoretical consistency." In the following, we analyze the Goldstone criterion in a mathematical way starting from Eq. (44) (or the more general Eq. (32)), in which all quantities are four-point functions, and $-2R^{(4)}$ and $-2K$ must be understood in the general sense that they give the response of the magnetic density matrix $m^{+}(\mathbf{r}, \mathbf{r}'; \omega)$ with respect to changes of a nonlocal magnetic field $B^{+}(\mathbf{r}, \mathbf{r}'; \omega)$ in the interacting and noninteracting system, respectively. Conversely, the expression $(-2R^{(4)})^{-1}\Delta m^{+}$ gives the perturbing field $\Delta B^{+}(\mathbf{r}, \mathbf{r}'; \omega)$ that would generate the change of the magnetization $\Delta m^{+}(\mathbf{r}, \mathbf{r}; \omega)$. For the Goldstone mode in the limit $\omega \to 0$, we know that a rigid rotation of the electron spins, i.e., $\Delta m^{+} \propto m$, can take place even without a perturbing field. So, we have $(-2R^{(4)})^{-1}m = 0$, and with Eq. (44) we can write $KWm = m$. The eigenfunction of $KW$ with eigenvalue 1 is, thus, revealed to be the magnetization density (matrix). We claim that this condition is fulfilled if COHSEX is taken for the starting point. When separating off the spin-independent part of Eq. (49), the remaining spin-dependent part can formally be interpreted as a nonlocal magnetic field

$$B(\mathbf{r}, \mathbf{r}') = -\frac{1}{2}W(\mathbf{r}, \mathbf{r}')[n^{\uparrow}(\mathbf{r}, \mathbf{r}') - n^{\downarrow}(\mathbf{r}, \mathbf{r}')] = -\frac{1}{2}W(\mathbf{r}, \mathbf{r}')m(\mathbf{r}, \mathbf{r}'). \tag{51}$$

Now we use the simple fact that rigidly rotating the $\mathbf{B}$ field that creates the magnetization in a noninteracting system will rotate the magnetization in the same way, which can be expressed as

$$m(\mathbf{r}, \mathbf{r}') = -2 \iint K(\mathbf{r}, \mathbf{r}'; \mathbf{r}'', \mathbf{r}''') B(\mathbf{r}'', \mathbf{r}''') d\mathbf{r}'' d\mathbf{r}''' . \tag{52}$$

(For the rotation to be rigid, $\Delta B^+ \propto B$, and the corotation of $B$ field and magnetization requires $\Delta B^+/B = \Delta m^+/m$.) The assertion then follows from inserting Eq. (51) into Eq. (52).

The proof is already complete, but it is helpful to show $KWm = m$ more explicitly. In the limit $\omega \to 0$, the imaginary part of the two-particle propagator Eq. (34) is zero, and we can write

$$K(\mathbf{r}, \mathbf{r}'; \mathbf{r}'', \mathbf{r}''') = \frac{1}{N^2} \sum_{\mathbf{k}, \mathbf{k}'} \sum_{m, m'} (f_{\mathbf{k}m}^{\downarrow} - f_{\mathbf{k}'m'}^{\uparrow}) \frac{\varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}) \varphi_{\mathbf{k}m}^{\downarrow *}(\mathbf{r}'') \varphi_{\mathbf{k}'m'}^{\uparrow *}(\mathbf{r}') \varphi_{\mathbf{k}'m'}^{\uparrow}(\mathbf{r}''')}{\varepsilon_{\mathbf{k}'m'}^{\uparrow} - \varepsilon_{\mathbf{k}m}^{\downarrow}} \tag{53}$$

with the occupation numbers $f_{\mathbf{k}m}^{\sigma}$. [We have used $\sum_m^{\mathrm{occ}} \sum_{m'}^{\mathrm{unocc}} \ldots = \sum_{m, m'} f_{\mathbf{k}m}^{\sigma} (1 - f_{\mathbf{k}'m'}^{\sigma}) \ldots = \sum_{m, m'} f_{\mathbf{k}m}^{\sigma} \ldots$ .] Because of Eq. (51) the COHSEX single-particle Hamiltonian fulfills $H^{\downarrow} - H^{\uparrow} = Wm$, which gives

$$\iint KWm = \frac{1}{N^2} \sum_{\mathbf{k}, \mathbf{k}'} \sum_{m, m'} (f_{\mathbf{k}m}^{\downarrow} - f_{\mathbf{k}'m'}^{\uparrow}) \frac{\varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}) \langle \varphi_{\mathbf{k}m}^{\downarrow} | H^{\downarrow} - H^{\uparrow} | \varphi_{\mathbf{k}'m'}^{\uparrow} \rangle \varphi_{\mathbf{k}'m'}^{\uparrow *}(\mathbf{r}')}{\varepsilon_{\mathbf{k}'m'}^{\uparrow} - \varepsilon_{\mathbf{k}m}^{\downarrow}}$$

$$= \frac{1}{N} \sum_{\mathbf{k}} \sum_{m, m'} (f_{\mathbf{k}m'}^{\uparrow} - f_{\mathbf{k}m}^{\downarrow}) \varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}) \langle \varphi_{\mathbf{k}m}^{\downarrow} | \varphi_{\mathbf{k}m'}^{\uparrow} \rangle \varphi_{\mathbf{k}m'}^{\uparrow *}(\mathbf{r}') = m(\mathbf{r}, \mathbf{r}') . \tag{54}$$

That the last expression is really the spin density matrix is seen by expanding $\varphi_{\mathbf{k}m'}^{\uparrow}(\mathbf{r})$ and $\varphi_{\mathbf{k}m}^{\downarrow *}(\mathbf{r})$ in terms of the functions of the other spin channel

$$m(\mathbf{r}, \mathbf{r}') = \frac{1}{N} \sum_{\mathbf{k}} \sum_{m'} f_{\mathbf{k}m'}^{\uparrow} \varphi_{\mathbf{k}m'}^{\uparrow}(\mathbf{r}) \varphi_{\mathbf{k}m'}^{\uparrow *}(\mathbf{r}') - \frac{1}{N} \sum_{\mathbf{k}} \sum_{m} f_{\mathbf{k}m}^{\downarrow} \varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}) \varphi_{\mathbf{k}m}^{\downarrow *}(\mathbf{r}')$$

$$= \frac{1}{N} \sum_{\mathbf{k}} \sum_{m, m'} (f_{\mathbf{k}m'}^{\uparrow} - f_{\mathbf{k}m}^{\downarrow}) \varphi_{\mathbf{k}m}^{\downarrow}(\mathbf{r}) \varphi_{\mathbf{k}m'}^{\uparrow *}(\mathbf{r}') \langle \varphi_{\mathbf{k}m}^{\downarrow} | \varphi_{\mathbf{k}m'}^{\uparrow} \rangle . \tag{55}$$

In Müller et al. (2016), we reported on spin-wave calculations based on the COHSEX Green function. Technically, we start from the mean-field LSDA solution and construct the LSDA Green function, the corresponding polarization function Eq. (14), and the static screened interaction Eq. (13), from which the COHSEX self-energy Eqs. (49) and (50) is evaluated. The latter is a Hermitian operator defining a new mean-field system. This allows the respective single-particle equations of motion to be solved in a similar way as the Kohn-Sham equations of DFT. To be more precise, the single-particle equations are iteratively solved until the density is converged. This process updates the density and, consequently, the Hartree potential in each iteration, while the COHSEX self-energy matrix remains fixed. This
**Fig. 4** DOS spectra for bulk Fe, Co, and Ni. The Fermi level is set to zero. (Müller et al. (2016) Copyright 2016 American Physical Society)

produces a new set of wave functions and energies that are then used to construct a new Green function and, ultimately, a new COHSEX self-energy matrix. The whole procedure is repeated until self-consistency is achieved. We have employed a $14 \times 14 \times 14$ **k**-point set for these calculations.

The mean-field solution of the $3d$ ferromagnets bcc iron, fcc cobalt, and fcc nickel based on the COHSEX self-energy is interesting in its own right. Figure 4 shows their densities of states (DOS) for both LSDA and COHSEX. At a first glance, the two DOS spectra look very similar for all materials. The COHSEX self-energy yields thus qualitatively the same correct result as LSDA: all three materials are ferromagnetic metals. There are however small quantitative differences. The occupied bandwidth shrinks, in particular for Co and Ni, and the spin-up and spin-down states show a relative energetic shift toward each other. This observation is confirmed by the exchange splittings of selected single-particle states listed in Table 1. The COHSEX values are systematically smaller than the LSDA ones, to the effect that the slight overestimation of the magnetic moment found in LSDA is

**Table 1** Spin magnetic moments (obtained from a projection onto Wannier orbitals) and exchange splittings for selected states of Fe, Co, and Ni from LSDA, corrected LSDA, COHSEX, and experiment. (Müller et al. (2016) Copyright 2016 American Physical Society)

corrected to smaller values in COHSEX, albeit somewhat too strongly in the case of Co and Ni. With the exception of iron, the exchange splittings are improved by the self-consistent COHSEX calculation, most notably for Ni, whose exchange splitting is known to be overestimated in LSDA.

Figure 3 shows the spin-wave dispersion calculated from the COHSEX Green function as red symbols. Employing the self-consistent COHSEX mean-field solution as starting point, in fact, decreases the gap error systematically compared to the corresponding LSDA values. In case of bcc iron, fcc cobalt, and fcc nickel, the error is reduced by 85%, 69%, and 79%, respectively.

The ansatz presented so far is computationally very demanding. It requires the self-consistent calculation of the COHSEX self-energy on a fine **k**-point set. On the other hand, aside from the gap error, the magnon dispersions obtained from LSDA are very similar to the corresponding COHSEX results. This raises the question if it is possible to correct the LSDA Green function in a simple way that respects the Goldstone condition. In fact, this is possible.

Our approach is motivated by studying spin-wave solutions (Moriya 1985) of the one-band Hubbard model. When solved in the Hartree-Fock approximation, we obtain the magnetic susceptibility as a simple algebraic expression in the same form as Eq. (44) with the $W$ matrix replaced by the Hubbard interaction parameter $U$. In the Goldstone limit, the two-particle propagator simplifies to $K = m/E_{ex}$ with the site magnetization $m$ and the exchange splitting $E_{ex}$, and the Goldstone

condition can be phrased in the form of the simple relation $Um/E_{ex} = 1$. To remain consistent, we have to evaluate $K$ in the Hartree-Fock mean-field system, in which case $E_{ex} = Um$, and the Goldstone condition is identically fulfilled. The simple form of the relation invites one to use one of the constituent quantities as an adjustable parameter. The $U$ parameter plays the role of the screened interaction $W$, which is a matrix and thus cannot be corrected easily by a single parameter. Besides, we obtain $W$ from a many-body treatment of screening, and it does not seem appropriate to correct it in such an ad hoc way. Second, the magnetization $m$ results from the self-consistent LSDA calculation and cannot be varied straightforwardly. At last, $E_{ex}$ can be regarded as the energy difference between the spin-up and spin-down electron bands, which can easily be varied once a self-consistent LSDA solution has been found. Moreover, this correction will specifically modify the LSDA Green function, which was our intention, while leaving the screened interaction unchanged. The correction can be hoped to mimic to some extent the missing renormalization in the Green function. Therefore, we choose $E_{ex}$ as an adjustable parameter. To be more precise, we rigidly shift the spin-up and spin-down states relative to each other $\varepsilon_{\mathbf{k}m}^{\uparrow/\downarrow} \rightarrow \varepsilon_{\mathbf{k}m}^{\uparrow/\downarrow} \pm \Delta E_{ex}/2$ until the Goldstone condition is fulfilled. The LSDA Green function corrected in this way is then used to construct the two-particle propagator $K$. This procedure yields magnon dispersions, which respect the Goldstone condition and are close to the COHSEX results for the three materials as shown in Fig. 3. The relative shift in the band energies is such that the exchange splittings decrease. For Fe, Co, and Ni, we find $\Delta E_{ex} = 0.10$ eV, $\Delta E_{ex} = 0.39$ eV, and $\Delta E_{ex} = 0.21$ eV. The Fermi energy is adjusted accordingly so that the correction affects the ground-state magnetic properties as well. Interestingly, the resulting magnetic moments and exchange splittings turn out to be close to the corresponding COHSEX values listed in Table 1. They also compare well with experiment. The proximity of COHSEX and corrected LSDA values can be regarded as an a posteriori justification of the correction. Among the three materials, fcc cobalt appears as a problematic case. The gap error is largest and the COHSEX spin-wave dispersion shows an unusually flat behavior at the $\Gamma$ point. In fact, the curvature there is very small, being between results from LSDA (small positive curvature) and PBE (small negative curvature, not shown), indicative of a magnetic instability. This is in accordance with previous DFT results. Janak (1978) found that there are two competing magnetic ground states with low and high magnetic moment, and Moruzzi et al. (1986) report an unusually strong dependence of the magnetic properties on the lattice constant.

The findings can be interpreted in a more fundamental way. Formally, the Hamiltonian which describes the magnetic system is invariant with respect to spin rotations, while the ferromagnetic ground state is not. This implies the existence of a gapless excitation due to a homogeneous magnetic perturbation perpendicular to the magnetization axis. Baym and Kadanoff (1961) and Baym (1962) formulated a conserving and self-consistent scheme for correlation functions. The scheme was extended by Brandt et al. (Brandt et al. 1970, 1971; Brandt 1971) to the magnetic case. They showed that for a spin-conserving formulation of the magnetic susceptibility, which fulfills the Goldstone theorem automatically, several conditions

have to be fulfilled. The chosen self-energy approximation is to be calculated self-consistently with the Green function. This ensures that the single-particle states which form the basis for the electron-hole propagator are consistent with the applied self-energy approximation. In addition, the spin-independent interaction that is responsible for the correlation among the electron-hole pairs with opposite spins is required to be consistent with the self-energy as these properties are connected via $\delta\Sigma/\delta G = iW$. If both conditions are fulfilled, the magnetic response function will fulfill the Goldstone theorem. Then, the electron-hole pair propagator and the screened interaction are compatible with the Ward identity ensuring spin conservation. In particular, the correct limit $\mathbf{q} \to \mathbf{0}$ is attained.

# 5    Spin Excitation Spectra

In this section, we present detailed results of first-principles calculations for the three bulk transition metals Fe, Co, and Ni. The properties of these materials are strongly governed by the presence of the localized $3d$ states. It is the exchange interaction among the $3d$ electrons that drives the systems into the ferromagnetic ground state. On the other hand, the materials are metallic. The $3d$ states of neighboring atoms overlap, and there is a partly filled itinerant $4s$ band which spans the entire valence region and mixes with the $d$ bands. As a consequence, Fe, Co, and Ni show signatures of itinerant magnetism. For example, they fulfill the Stoner criterion of ferromagnetism, and there is no order-disorder phase transition at the Curie temperature as would be described by the Heisenberg model.

So, one would expect these bulk transition metals to show both localized and itinerant magnetic behavior. The present formalism using MBPT is capable of describing both types of magnetism on the same footing. The spectrum of spin excitations in this theory is given by the imaginary part of the magnetic response function as calculated from Eqs. (28) and (44). The poles of this function lie infinitesimally below (above) the positive (negative) real-frequency axis, and they come from both the two-particle propagator (bare susceptibility) in the numerator and the roots of the denominator. In the former case, the spin excitations have a single-particle character. These Stoner excitations can be described as excitations of single electrons across the Fermi surface with an accompanying spin flip of the electrons. In the latter case, the excitations are collective in nature, again with a total spin flip of 1, and arise from superpositions of infinitely many electron-hole pairs (single-particle excitations) coupled to each other by the exchange interaction. These electron-hole pairs describe changes in the spin density, in which all electrons take part collectively and which can, for example, have the form of spin waves. The two types of excitations are just limiting cases. In general, the spin excitations have a mixed character of single-particle and collective excitations: spin waves acquire a finite lifetime through a coupling to Stoner excitations, and Stoner excitations lose or gain spectral weight by a coupling to spin waves.

It is instructive to consider the model of a homogeneous electron gas with spin polarization. The spin-up and spin-down bands have the form of free-electron bands,

but they are shifted with respect to each other by the exchange splitting $E_{ex}$, i.e., $\varepsilon_{\mathbf{k}}^{\sigma} = k^2 - \sigma E_{ex}/2$. Energies and momenta are in units of the Fermi wavevector $k_0$ and Fermi energy $\varepsilon_0 = k_0^2/2$ of the paramagnetic system, respectively. The bare susceptibility of this system can be calculated from Eqs. (34) and (47) in a pure plane-wave representation. To simplify the evaluation of $K^{\downarrow\uparrow}$, we replace $-i\eta$ in the first term by $+i\eta$, which amounts to using the corresponding retarded quantity. This enables a straightforward integration over the occupied spin-up and spin-down band (Moriya 1985) yielding

$$
K^{+-}(q, \omega) = \frac{-1}{4\pi^2 q} \sum_{\sigma=-1}^{1}
$$

$$
\sigma \left[ \frac{1}{2}(p_\sigma^2 - k_\sigma^2) \left( \ln \left| \frac{p_\sigma + k_\sigma}{p_\sigma - k_\sigma} \right| + i\pi \, \mathrm{sgn}(\omega)\theta(k_\sigma - |p_\sigma|) \right) - p_\sigma k_\sigma \right]
\tag{56}
$$

with $p_\sigma = (\omega - \sigma q^2 - E_{ex})/(2q)$, the spin-dependent Fermi wavevector $k_\sigma = (1+\sigma\zeta)^{1/3}$, the exchange splitting $E_{ex} = (1+\zeta)^{2/3} - (1-\zeta)^{2/3}$, the spin polarization $\zeta = M/N = (k_\uparrow^3 - k_\downarrow^3)/(k_\uparrow^3 + k_\downarrow^3)$, and the Heaviside function $\theta(x) = 1$ for $x > 0$ and $0$ for $x < 0$. The factor $\mathrm{sgn}(\omega)$ has been introduced to undo the sign change $-i\eta \to +i\eta$, which recovers the time-ordered two-particle propagator. All quantities can be written in terms of a single parameter, the spin polarization $\zeta \in [0, 1]$.

   The area where the imaginary part of $K^{+-}(q, \omega)$ is nonzero defines the Stoner continuum, which, by using the definition of $\theta$, can be shown to be bounded by the functions $2qk_\sigma + \sigma q^2 + E_{ex}$ from above and $-2qk_\sigma + \sigma q^2 + E_{ex}$ from below. Figure 5 presents a plot of $-\mathrm{Im}\, K^{+-}(\mathbf{q}, \omega)$ together with the boundary lines for a spin-polarized electron gas with $\zeta = 0.9$. The imaginary part diverges for $\omega = E_{ex} = 1.32$ and $q \to 0$, because the real part of the denominator of Eq. (34) vanishes in this limit. We also see that the Stoner continuum extends toward negative energies. This is because, as long as $\zeta < 1$, there can be transitions from occupied minority to unoccupied majority bands. At $\omega = 0$, the imaginary part of $K^{+-}$ is zero for all momenta because the phase space of single-particle excitations vanishes in this limit.

   Of course, the homogeneous electron gas is a relatively crude model. The absence of the crystal field and of atomic wave functions makes one wonder whether this model could be just too simple. Therefore, it is interesting to compare Fig. 5a to corresponding plots calculated with realistic wave functions and energies from a self-consistent Kohn-Sham solution. In particular, we have calculated the bare susceptibility from Eq. (48) and projected it onto the plane wave $e^{i\mathbf{q}\cdot\mathbf{r}}$ from both sides giving $K^{+-}(\mathbf{q}, \omega)$. A fine $20 \times 20 \times 20$ $\mathbf{k}$-point grid was employed, and the Wannier basis was the same as in Sect. 4. We have also applied the $E_{ex}$ correction. The plots for bcc Fe, fcc Co, and fcc Ni are presented in Fig. 6a–c. It is surprising that they share a number of similarities with the plot for the homogeneous electron gas. First, the maximum of $-\mathrm{Im}\, K^{+-}(\mathbf{q}, \omega)$ is seen for $\omega \approx E_{ex}$ and $\mathbf{q} = \mathbf{0}$. In
**Fig. 5** Imaginary part of (**a**) the bare $[-\operatorname{Im} K^{+-}(\mathbf{q}, \omega)]$ and (**b**) the renormalized susceptibility $[-\operatorname{Im} R^{+-}(\mathbf{q}, \omega)]$ for the homogeneous electron gas with spin polarization $\zeta = 0.9$; (**c**) is a magnification of (**b**). The green solid lines show the boundaries of the Stoner continuum. In (**b**) and (**c**), a finite imaginary frequency of, respectively, $i\eta = i10^{-5}$ and $i\eta = i10^{-7}$ has been employed in order to make the magnon branch visible, which would have a vanishing (delta-like) width in this system otherwise

contrast to before, there is no divergence because spin-up and spin-down bands have different dispersions in a real material, and the majority bands shifted up by $E_{ex}$ thus cannot coincide exactly with the minority bands, in particular, since $E_{ex}$ is not a unique quantity but $\mathbf{k}$ dependent. Consequently, the maximum at $\mathbf{q} = \mathbf{0}$ has a certain width in energy. Furthermore, as before, we observe a weak intensity of Stoner excitations for negative $\omega$. As a qualitative difference to Fig. 5, the spectra of Co and Ni exhibit a horizontal, nearly dispersion-less band of high intensity that emanates from the maximum at $\Gamma$ and stretches toward the X point. This feature can be directly related to the localized nature of the single-particle states. The densities of $d$ states of Co and Ni show particularly sharp peaks in the majority valence and minority conduction regions separated by 1.3 and 0.5 eV, respectively, revealing the feature to originate from single-particle $d \rightarrow d$ transitions.

There are no clear boundary lines as for the homogeneous electron gas beyond which the imaginary part of $K^{+-}$ would vanish. In fact, there can be Stoner excitations for all $\mathbf{q}$ and $\omega$ (except for $\omega = 0$). However, the form of $-\operatorname{Im} K^{+-}(\mathbf{q}, \omega)$ is
**Fig. 6** Imaginary part of the bare susceptibility $[-\operatorname{Im} K^{+-}(\mathbf{q}, \omega)$ in units of $(\Omega \mathrm{eV})^{-1}; \Omega = $ unit-cell volume] for (**a**) bcc Fe, (**b**) fcc Co, and (**c**) fcc Ni as a function of $\mathbf{q}$ and $\omega$

definitely similar. In particular, the characteristic V-shaped regions with (nearly) no excitations above and below the maximum are present, and, instead of the boundaries, one observes *stripes* of increased intensity seemingly extending from the maximum. A pronounced one is seen in the spectrum of Ni. These stripes will play an important role in the renormalized spectra later on. They can be understood by realizing that the function $-\operatorname{Im} K^{+-}(q, \omega)$ can roughly be thought of as giving the intersection of the valence majority states shifted upward by $\omega$ and sideways by $-\mathbf{q}$ with the conduction minority states. This is illustrated in Fig. 7 where the electronic bands are assumed to show a linear dispersion at finite $q$. Starting from the (near) coincidence of the bands at $q = 0$ and $\omega = E_{\mathrm{ex}}$, relatively large intensities are still expected when the majority band is shifted from there in such a way that the regions of linear dispersion remain overlapping, giving rise to the condition of proportionality $\omega \propto q$ and, hence, to the stripes. Here, we have assumed that the spin-up band is filled, while the spin-down band is empty and that they exhibit similar dispersions as is often the case in ferromagnets. Even in the case of the highly symmetric homogeneous electron gas, whose bands exhibit a constant curvature and no linear dispersions as in Fig. 7, the onset of the Stoner continuum at the boundaries is quite abrupt. So, it is not surprising that real materials show more structure there.

**Fig. 7** Illustration of the "band overlap" leading to the striped Stoner continuum of Fig. 6. The red arrow denotes the proportionality $\omega \propto q$
Up to now, we have discussed the spin excitation spectrum of the fictitious noninteracting reference system. The spectrum changes profoundly when one introduces a finite interaction among the electrons. In the case of the homogeneous electron gas, one would have to solve the Bethe-Salpeter equation $R^{+-}(q,\omega) = K^{+-}(q,\omega)/[1 - WK^{\downarrow\uparrow}(q,\omega)]$ with $K^{\downarrow\uparrow}(q,\omega) = -K^{+-}(q,\omega)/2$ (cmp. Eq. (47)) and a so-far unknown effective interaction $W$. The latter is a single parameter in this case and can be obtained conveniently from the Goldstone condition, giving $W = 1/K^{\downarrow\uparrow}(0,0) = -2/K^{+-}(0,0) = 3\pi^2 E_{ex}/\zeta$. The spin excitation spectrum is then given by $-\mathrm{Im}\,R^{+-}(\mathbf{q},\omega)$ shown in Fig. 5b for the homogeneous electron gas. Together with the spectrum, we have plotted the boundary lines of the Stoner continuum as solid green lines. Still, these lines separate the regions of finite intensity from the regions of no intensity, except for the spin-wave branch, which starts at the origin $q = \omega = 0$ and disperses quadratically for small $q$ according to $\omega \propto Dq^2$ with $D = [1 - 0.4(k_\uparrow^5 - k_\downarrow^5)/(k_\uparrow^2 - k_\downarrow^2)]/\zeta$ (Moriya 1985). For larger $q$, the magnon branch deviates from the parabolic dispersion and finally enters the Stoner continuum, where it couples to the Stoner excitations forming a broad maximum. The magnon energies are much smaller than $E_{ex}$, even for small $E_{ex}$ because $D \sim E_{ex}/12$ in this limit. Therefore, we show an enlarged picture of the magnon branch in Fig. 5c. We note that a finite (instead of infinitesimal) parameter $\eta = 10^{-5}$ and $\eta = 10^{-7}$ has been employed in (b) and (c), respectively, which leads to a corresponding finite linewidth of the magnon branch outside the Stoner continuum.

When comparing with Fig. 5a, we observe a strong redistribution of quasiparticle weight after solving the Bethe-Salpeter equation. In particular, the region of maximal intensity around $q = 0$ now appears very shallow, and a new maximum is found where the spin-wave branch enters the Stoner continuum. The former is a feedback effect: the transfer of spin-up electrons into the spin-down channel leads to a strong change in the exchange field of the interacting system, which acts against the transfer of electrons, an effect similar to the electronic screening effect. The new maximum comes from a resonance effect between the collective magnon and the Stoner excitations. The amplifying effect of the resonance extends into the Stoner excitations of negative energy ($\omega < 0$), which now appear more intense than in Fig. 5a. It is interesting to note that the maximum in Fig. 5a transforms continuously into the one of (b) if one smoothly varies the parameter $W$ from 0 to $3\pi^2 E_{ex}/\zeta$.

The spin-wave branch starts to appear for $W \gtrsim 0$ slightly below the maximum at $\omega = E_{ex}$, and as $W$ increases, it shifts down, first with a maximum at $q = 0$, then developing a minimum, until, for $W = 3\pi^2 E_{ex}/\zeta$, it finally has the form of Fig. 5c. Further increasing $W$ would shift the minimum of the magnon branch to negative energies. This again demonstrates how sensitive the Goldstone condition is and explains the difficulty of its fulfillment in first-principles calculations.

In Fig. 8a–c, we show the renormalized susceptibility for Fe, Co, and Ni, again projected onto $e^{i\mathbf{q}\cdot\mathbf{r}}$. We have used the same scales as before to make a direct comparison possible. Obviously, the regions around the spin-wave branch have values exceeding the maximum of the color scale (black area). Therefore, Fig. 8d–f presents a magnified picture with a different color scale. As with the bare susceptibility, there are a number of similarities to Fig. 5b: a spin-wave branch is formed by the renormalization; this branch acquires a finite lifetime broadening by a coupling to Stoner excitations; the former intensity maximum around $\omega = E_{ex}$ and $\mathbf{q} = \mathbf{0}$ has lost much of its intensity; there is a resonant enhancement of the Stoner intensity for $\omega < 0$. However, there are also some important differences to the case of the homogeneous electron gas. First, the coupling to Stoner excitations sets in much earlier, because the Stoner excitations are present at all energies. Nevertheless, the spin-wave dispersion remains discernible to quite large momenta and energies compared to the case of the homogeneous electron gas, indicating a localized nature of magnetism in these materials. Especially in Ni, the magnon branch seems to couple resonantly with the horizontal Stoner band toward the X point. While the spin-wave branches still have an overall parabolic shape, they show a rather irregular behavior, which can be attributed to the coupling to the Stoner continuum. In particular, in all cases the magnon branch is affected, sometimes interrupted, by the interaction with the *striped* Stoner spectrum we have discussed before. In fact, if we magnify the corresponding region of the spectrum for Ni (see inset in Fig. 8f), we observe that the coupling between the magnon branch and a line of strong Stoner intensity – we could call it a *Stoner band* – leads to a feature that looks like an "avoided crossing." In fact, this feature has a similar origin as an avoided crossing of single-particle bands, with the difference that the two states that interact here are not single-particle but many-body states, the collective spin-wave excited state and a superposition of Stoner excitations, which mix and exchange character.

Despite the multiple interactions with the Stoner background, we find that the dispersion of the spin-wave branches is mostly isotropic in $\mathbf{q}$ space. The numerical data for iron are in qualitative and also quantitative agreement with the neutron scattering experiments of Collins et al. (1969), Mook and Nicklow (1973), and Lynn (1975), where spin-wave energies up to 70, 118, and 110 meV were reported, respectively; see Friedrich et al. (2014) for a comparison. In Loong et al. (1984), spin-wave resonances up to an energy of 160 meV could be measured. However, the latter experimental results partly disagree with the values of Mook and Nicklow (1973), especially at the high end of the spectrum. We also find good agreement in the case of nickel (Minkiewicz et al. 1969; Mook and Tocchetti 1979; Mook and Paul 1985), while neutron scattering data for cobalt is scarce and limited to small momentum transfers (Frikkee 1966; Glinka et al. 1977).
**Fig. 8** Same as Fig. 6 for the renormalized susceptibility $[-\operatorname{Im} R^{+-}(\mathbf{q}, \omega)$ in units of $(\Omega\, eV)^{-1}]$; (**d**)–(**f**) are magnifications of (**a**)–(**c**) with different scales. The inset of (**f**) shows a magnified view of the region where the magnon branch couples to the increased Stoner intensity

A feature that has been discussed extensively in the literature (Cooke 1976; Mook and Tocchetti 1979; Cooke et al. 1980, 1985; Callaway et al. 1983; Mook and Paul 1985; Savrasov 1998; Karlsson and Aryasetiawan 2000; Şaşıoğlu et al. 2010; Friedrich et al. 2010) is the appearance of an "optical" spin-wave branch, in addition to the acoustic one, for example, in fcc Ni along $\Gamma - X$. The terminology is, however, a little bit misleading, as the acoustic branch just seems to exhibit a gap at around 130 meV. The lower-energy end flattens and eventually disappears toward larger momenta (or persists out to the zone boundary (Cooke et al. 1985; Blackman et al. 1985)), and the higher-energy end then continues to form the acoustic magnon branch. The two ends coexist in a certain region of the reciprocal space giving a double-peak structure in the spectra there. This indicates the existence of an optical branch that crosses the acoustic branch and splits it into two pieces. The optical branch has yet to be observed directly, however. (In some publications, the higher-energy branch is denoted as the optical branch, although it does not extend to zero momentum and finite energy as in the case of optical phonon branches.) After its theoretical prediction (Cooke 1976), the optical branch was detected in the form of a double peak in constant $\mathbf{q}$ scans in neutron scattering experiments (Mook and Tocchetti 1979; Mook and Paul 1985). However, this feature seems to be an elusive phenomenon, which is observed in some studies (Cooke et al. 1985; Blackman et al. 1985) but not in others (Callaway et al. 1983).

In Fig. 8f, we clearly see a gap in the acoustic branch at around 30 meV, which arises from the coupling to Stoner excitations as we have seen before. But this gap is located at a too low energy and too close to the $\Gamma$ point to be identified as the optical branch discussed in the literature. On the other hand, there is no gap to be seen in Fig. 8f at around 130 meV. However, if we analyze this part of the excitation spectrum more closely, we are able to identify two peaks, but these peaks do not appear as separate peaks in our calculation. They form a broad peak, and only a peak fit with Lorentzian functions reveals the existence of a lower-energy and a high-energy branch in the respective region of momentum (Şaşıoğlu et al. 2010). In the direction of increasing momentum, the higher-energy peak grows at the expense of the lower-energy peak, which eventually disappears, and the higher-energy peak then forms the magnon branch. It should be noted, however, that the double-peak structure was observed as two separate peaks in a TDDFT study (Savrasov 1998) and also in a calculation based on a Green-function formulation (Karlsson and Aryasetiawan 2000). The latter study also reported a gapped magnon branch along $\Gamma - L$ in fcc Ni and a gap around halfway on the line $\Gamma - N$ in bcc Fe. In fact, there is a gap in this direction in Fig. 8d, albeit at a smaller momentum and energy than in Karlsson and Aryasetiawan (2000). This gap can be attributed to the coupling of the spin-wave branch with a line of increased Stoner intensity. The gapped magnon branch has already been discussed by Blackman et al. (1985) and was observed experimentally (Paul et al. 1988). In conclusion, it remains an open question why the optical branch in fcc Ni appears as a well-defined feature in some calculations, whereas, in others, it is so close to the acoustic branch that the two branches coalesce into a broad peak.

# 6     Conclusions

We have presented a theoretical method to determine the electronic spin excitations of an interacting many-electron system from first principles. The scheme is based on many-body perturbation theory, in which the spin excitations form the pole structure of the magnetic response function or transverse spin susceptibility. The poles are close to the real-frequency axis, so the imaginary part of the response function yields the corresponding spin excitation spectrum, comprising both single-particle Stoner and collective spin-wave excitations as well as combinations thereof. The latter gives rise to lifetime effects and a redistribution of spectral weight. We have described a very general theoretical derivation, in which the density response function, which is central in describing optical absorption and excitonic effects, appears as a special case.

With the $GW$ approximation for the electronic self-energy, the magnetic response function has been shown to fulfill a Bethe-Salpeter equation, which can be solved in the basis of Wannier product functions. We have sketched a practical implementation in the SPEX code that relies on the full-potential linearized augmented plane-wave method. The screened interaction $W$ is calculated within the RPA. In metallic systems, $W$ falls off very quickly so that we can afford to employ an on-site approximation, i.e., an electron-hole pair is assumed to be on the same site when interacting. In addition, we use the static limit of $W$ for all frequencies, so the screened interaction acts instantaneously. Our implementation allows the magnetic response function to be calculated for arbitrary momenta, which can be used to map the magnetic excitation spectra in very fine detail.

We have studied the long-wavelength limit of the spin-wave spectra for the bulk $3d$ transition metals Fe, Co, and Ni. The long-wavelength limit is of special interest as the Goldstone theorem demands the existence of a gapless excitation in ferromagnetic materials (neglecting spin anisotropy). Often, this *Goldstone condition* is numerically violated in practical calculations from first principles. We can attribute a large part of this gap error to the approximation of the single-particle Green function. For example, a natural and convenient choice would be the LSDA Green function, which, however, introduces an inconsistency with regard to the theoretical derivation of the Bethe-Salpeter equation. We have proved mathematically that a gapless magnon branch requires the Green function to be self-consistently renormalized with a suitable self-energy, e.g., the COHSEX self-energy, the static limit of the $GW$ approximation. It was shown numerically that the gap error is substantially reduced when using the COHSEX Green function instead of the LSDA one. Furthermore, the self-consistent COHSEX calculations give rise to an overall reduction of the exchange splitting compared to LSDA, often leading to better agreement with experiment. The spin-wave solution of the one-band Hubbard model employing the Hartree-Fock approximation motivates a correction scheme for the LSDA Green function, where the exchange splitting of the Kohn-Sham system is adjusted so as to enforce the Goldstone condition. The resulting spin-wave dispersions are closer to the corresponding COHSEX than to the original

LSDA results. The same can be said about the magnetic moments and exchange splittings obtained from the COHSEX and the corrected LSDA Green function, which are found to be very similar, while the original LSDA values are a bit off. As a result, the corrected LSDA Green function mimics that of the self-consistent COHSEX calculation and is made to fulfill the Goldstone condition exactly, while the numerical cost is identical to a treatment within LSDA. This opens up the possibility of efficient first-principles MBPT calculations of spin excitations that respect the Ward identity of spin conservation.

Spin excitation spectra of the three elementary ferromagnets bcc Fe, fcc Co, and fcc Ni have been calculated and compared to results of model calculations using a spin-polarized homogeneous electron gas. By this comparison, we have shown that the bulk ferromagnets exhibit many features of itinerant-electron magnets that cannot be described by a simple atomic arrangement of magnetic moments, such as in the Heisenberg model. High-energy magnons are strongly damped due to the coupling to single-particle Stoner excitations, and the spin-wave dispersion possesses gaps along certain directions in the Brillouin zone, which can be attributed to a coupling of the spin-wave branch with *Stoner bands*, lines of increased intensity of Stoner excitations.

This coupling effect can be made responsible for the appearance of an *optical branch*, in addition to the acoustic one, in bcc iron. On the other hand, we cannot unambiguously identify an optical branch in fcc nickel along $\Gamma - X$, which has been much discussed in the literature. While a peak fit of the calculated spin excitation spectrum does reveal two spin-wave peaks at about the right momentum and energy, this appears as a very subtle effect compared to the gaps discussed before. Overall, we find a good agreement of the spin-wave dispersions to neutron scattering experiments.

The present treatment of spin excitations within many-body perturbation theory explicitly describes the correlated motion of an electron-hole pair. This formulation can be straightforwardly extended to yield the dynamical longitudinal spin susceptibility, including its coupling to the charge susceptibility (density response function). Furthermore, it opens up the way for constructing a diagrammatic electronic self-energy that describes the scattering of electrons and holes with magnons, in a similar way as the $GW$ approximation describes the scattering with plasmons. Such a self-energy can be defined by the product of the Green function with the $T$ matrix, yielding the $GT$ self-energy (Hertz and Edwards 1973; Edwards and Hertz 1973). A numerical implementation (Müller 2016; Müller et al. 2019) would be a formidable task given that the $T$ matrix depends on four points in space. It may be possible to combine this self-energy with $GW$ yielding $GW\Gamma$, a self-energy with vertex corrections. Such a self-energy could be able to describe the quasiparticle renormalization (kinks) of electronic bands in magnetic materials due to the scattering with spin fluctuations. It might even shed light on the coupling mechanism in high-temperature superconductors, as it is believed that this coupling arises from the exchange of magnons, through which the effective electron-electron interaction can become attractive.

# Non-equilibrium Green's Function Methods for Spin Transport and Dynamics

Ivan Rungger, Andrea Droghetti, and Maria Stamenova

## Contents

### Abstract

The modeling of spintronic devices is a theoretical challenge, since one has to describe accurately both the electronic structure of the constituent materials and their charge- and spin-transport properties. In this chapter we present the state-of-the-art quantum transport theory appropriate for this task. The theory is based on the so-called non-equilibrium Green's function formalism, which is

combined with density functional theory in order to provide a first principles description of materials properties. This allows for the evaluation of the steady-state charge and spin current through a quantum system at a finite applied bias voltage between the electrodes. It also describes the spin-transfer torque that flowing spins exert on localized magnetic moments, which is able to switch the magnetization of a magnetic system. In this chapter the detailed discussion about the principal methodological aspects is accompanied by the review of a number of technologically relevant applications.

# 1 Introduction

In the last decades, the continuous emergence of novel functionalities and related technologies has been a major boost for the advancement of spintronics. The current applications in hard disk drives and magnetic random access memories rely mostly on thin film heterostructures and exploit the magnetoresistance effect for the readout of the magnetic state and the spin-transfer torque for switching it. The key components that determine the functionality are typically only a few nanometers thick, so that the electron transport properties do not obey standard Ohm-Kirchhoff's laws, and a quantum mechanical description is ultimately required. Furthermore, since the device dimensions are often smaller than the electrons' mean free path and phase relaxation length, the coherent, phase-conserving carrier propagation governs the charge and spin transport. As a result, the conductance is determined by the transmission probability across a quantum mechanical scattering region as described in the Landauer-Büttiker framework (Landauer 1957; Büttiker et al. 1985). This requires the calculation of the wave function of the electrons, although the most convenient way to perform simulations of realistic device setups is based on the non-equilibrium Green's function (NEGF) formalism.

In this chapter we describe in detail the NEGF formalism (Stefanucci and van Leeuwen 2013; Datta 1995, 2005; Ghosh 2017), focusing on its application in spintronics. To begin with, we present the general properties of Green's functions for systems at equilibrium. We then discuss open systems and the implementation of NEGF in combination with density functional theory (DFT). This allows to present a number of representative results for first principles NEGF+DFT calculations of conductance, magnetoresistance, and spin-filter properties of nanoscale systems. We then discuss the inclusion of many-electron effects in the formalism and its application to calculate spin-transfer torques and dynamics of nanoscale devices.

# 2 Green's Functions at Equilibrium

A closed quantum system with noninteracting particles is described by the real-space one-particle Hamiltonian operator, $\hat{H}^\sigma(\mathbf{r})$, where the superscript $\sigma = \pm 1/2$ indicates the spin index, and the vector $\mathbf{r}$ is the real space position. Here we assume that the spins are collinear and that $\hat{H}^\sigma(\mathbf{r})$ does not include any spin-mixing term,

which couples up ($\sigma = +1/2$, also denoted by $\uparrow$) and down ($\sigma = -1/2$, also denoted by $\downarrow$) spins. Non-collinear spin systems, necessary also to include the effects of spin-orbit interactions, will be introduced in Sect. 6. The solution of the time-independent Schrödinger equation

$$\hat{H}^\sigma(\mathbf{r})\,\Psi_n^\sigma(\mathbf{r}) = E_n^\sigma\,\Psi_n^\sigma(\mathbf{r}) \tag{1}$$

yields the set of wave functions, $\{\Psi_n^\sigma(\mathbf{r})\}$, and eigenvalues $\{E_n^\sigma\}$ of the system, with the integer $n$ indexing the different eigenstates. Note that this single-particle Hamiltonian can also include electron-electron interactions at a mean-field level, as is the case in semi-local DFT calculations, where the Kohn-Sham (KS) Hamiltonian is used.

The electron density, $\rho(\mathbf{r})$, is obtained as $\rho(\mathbf{r}) = \sum_{n,\sigma} f_n^\sigma |\Psi_n^\sigma(\mathbf{r})|^2$. The sum runs over all eigenstates of $\hat{H}^\sigma$, whose occupation probabilities, $f_n^\sigma = f(E_n^\sigma)$, are given by the Fermi-Dirac distribution:

$$f(E) = \frac{1}{1 + e^{\frac{E - E_{\rm F}}{k_{\rm B}\theta}}}. \tag{2}$$

Here $k_{\rm B}$ is the Boltzmann constant, $\theta$ is the electronic temperature, and $E_{\rm F}$ is the Fermi energy.

In standard quantum transport calculations, $\Psi^\sigma(\mathbf{r})$ is expanded over a local orbitals basis set, $\{\Phi_\beta(\mathbf{r})\}$, as $\Psi^\sigma(\mathbf{r}) = \sum_\beta \psi_\beta^\sigma \Phi_\beta(\mathbf{r})$, where the integer $\beta$ indexes all the orbitals in the basis set, for a total of $N_\beta$ basis orbitals. Typically atomic-like orbitals are used as basis orbitals, where each integer $\beta$ is a collective index for the atom index, the principal quantum number, the angular momentum quantum number, and the magnetic quantum number. In what follows we further assume that each $\Phi_\beta^\sigma(\mathbf{r})$ is non-zero only over a confined region of space. We define the corresponding Hamiltonian matrix, $H^\sigma$, as $H_{\alpha\beta}^\sigma = \langle\Phi_\alpha|\hat{H}^\sigma|\Phi_\beta\rangle = \int \Phi_\alpha^*(\mathbf{r})\hat{H}^\sigma(\mathbf{r})\Phi_\beta(\mathbf{r})d\mathbf{r}$ and the overlap matrix, $\Omega$, as $\Omega_{\alpha\beta} = \langle\Phi_\alpha|\Phi_\beta\rangle = \int \Phi_\alpha^*(\mathbf{r})\Phi_\beta(\mathbf{r})d\mathbf{r}$. With these definitions we can rewrite the Schrödinger equation as $\sum_\beta H_{\alpha\beta}^\sigma \psi_{\beta,n}^\sigma = E_n^\sigma \sum_\beta \Omega_{\alpha\beta} \psi_{\beta,n}^\sigma$, or in the shorter matrix notation $H^\sigma \psi_n^\sigma = E_n^\sigma \Omega \psi_n^\sigma$. Here $\psi_n^\sigma$ is a vector of dimension $N_\beta$, normalized as $\psi_n^{\sigma\dagger}\Omega\psi_n^\sigma = 1$, and $H^\sigma$ and $\Omega$ are Hermitian matrices of dimension $N_\beta \times N_\beta$. The electron density can be expressed as $\rho(\mathbf{r}) = \sum_{\alpha\beta,\sigma} \rho_{\alpha\beta}^\sigma \Phi_\beta^*(\mathbf{r})\Phi_\alpha(\mathbf{r})$, where we have introduced the density matrix, defined as $\rho_{\alpha\beta}^\sigma = \sum_n f_n^\sigma \psi_{\alpha,n}^\sigma \psi_{\beta,n}^{\sigma\,*}$. It can be written equivalently in the shorter matrix notation as $\rho^\sigma = \sum_n f_n^\sigma \psi_n^\sigma \psi_n^{\sigma\dagger}$. The total number of electrons, $N_e = N_e^\uparrow + N_e^\downarrow$, is then obtained from $N_e^\sigma = \int \rho^\sigma(\mathbf{r})d\mathbf{r} = \sum_{\alpha\beta} \rho_{\alpha\beta}^\sigma \Omega_{\beta\alpha} = \text{Tr}[\rho^\sigma \Omega] = \sum_n f_n^\sigma$. For a given $N_e$ this relation implicitly determines $E_{\rm F}$.

The energy-dependent single-particle retarded Green's function (GF), $G^\sigma(E)$, is defined as

$$G^\sigma(E) = [(E + i\delta)\Omega - H^\sigma]^{-1}, \tag{3}$$

where $\delta \rightarrow 0^+$. If the eigenstates of $H^\sigma$ are known, then it can be written in its spectral form as $G^\sigma(E) = \sum_{n=1}^{N_\beta} \frac{1}{E+i\delta-E_n^\sigma} \psi_n^\sigma \psi_n^{\sigma\,\dagger}$. We note that if $H^\sigma$ and $\Omega$ are both real, then also the $\psi_n^\sigma$ can be made real, so that $G^\sigma(E)$ is symmetric. We now define the spectral function, $A^\sigma(E)$, as

$$A^\sigma(E) = i\left[G^\sigma(E) - G^{\sigma\,\dagger}(E)\right]. \tag{4}$$

By expanding $G^\sigma(E)$ in its spectral form, $A^\sigma(E)$ can be rewritten as

$$A^\sigma(E) = \lim_{\delta\rightarrow 0^+} 2\sum_{n=1}^{N_\beta} \frac{\delta}{(E-E_n^\sigma)^2+\delta^2} \psi_n^\sigma \psi_n^{\sigma\,\dagger} = 2\pi \sum_{n=1}^{N_\beta} \delta(E-E_n^\sigma)\,\psi_n^\sigma \psi_n^{\sigma\,\dagger}, \tag{5}$$

which shows that $A^\sigma(E)$ has a peak at each eigenstate of $H^\sigma$ and therefore corresponds to a generalized density of states (DOS). With above relation the spin-dependent density matrix, $\rho^\sigma = \sum_n f_n^\sigma \psi_n^\sigma \psi_n^{\sigma\,\dagger}$, can be written as

$$\rho^\sigma = \frac{1}{2\pi} \int dE\, f(E)\, A^\sigma(E), \tag{6}$$

where the energy integral goes from $-\infty$ to $+\infty$. If one defines the lesser Green's function, $G^{\sigma\,<}(E)$, for systems in equilibrium as

$$G^{\sigma\,<}(E) = if(E)\,A^\sigma(E), \tag{7}$$

then $\rho^\sigma$ can be rewritten as

$$\rho^\sigma = \frac{1}{2\pi i} \int dE\, G^{\sigma\,<}(E). \tag{8}$$

In Green's function-based numerical calculations, one therefore needs to calculate $G^{\sigma\,<}(E)$ and integrate this quantity over energies in order to then obtain the electron density.

In this chapter the Green's function method is combined with the KS equations of DFT, unless explicitly stated otherwise. Therefore, following a standard practice, we identify the single-particle Hamiltonian $\hat{H}^\sigma$ with the KS Hamiltonian, $\hat{H}_{KS}^\sigma$, and the corresponding eigenstates with the KS states. $\hat{H}_{KS}^\sigma$ includes a single-particle kinetic energy term, external classical potentials (such as the electron-nuclei interaction), the Hartree term describing the classical Coulomb interaction between electrons, and the exchange-correlation potential, which accounts for all remaining quantum many-body contributions. Spin-transport calculations are generally performed by using a semi-local approximation to the exchange-correlation density functional, such as the local spin density approximation (LSDA) (von Barth and Hedin 1972). DFT is a variational many-body theory that enables the calculation of the ground

state observables of a system, in particular the total energy, from the charge density, but the KS eigenvalues do not correspond to the true excitation energies. In exact DFT the only exception is the eigenenergy of the highest occupied state, which is equal to minus the ionization energy (Perdew and Levy 1997), although within LSDA-DFT this relation is only approximately valid. Nevertheless, for many systems the KS states provide a good approximate description of the electronic structure. Typically the physical nature of the studied system, e.g., whether it is metallic or insulating, as well as the orbital character of the valence and conduction states, is correctly predicted, although the calculated energy gaps or bandwidths deviate from experiments.

The quantitative shortcomings of KS-LSDA are often related to the self-interaction error (Perdew and Zunger 1981), which tends to favor charge delocalization and shifts localized states to higher energies. A number of exchange-correlation functionals to correct this error have been proposed. In quantum transport calculations, an efficient correction is given by the so-called atomic self-interaction correction (ASIC) (Pemmaraju et al. 2007) and by the LSDA+U method (Himmetoglu et al. 2014). ASIC corrects the self-interaction error in an approximate way for all occupied states, while it does not affect empty states, which have no self-interaction. In LSDA+U a Hubbard-like $U$ potential is applied to a chosen subset of either atomic orbitals, typically the $3d$ and $4f$ states, or molecular orbitals, which are expected to be localized due to strong correlation effects. This potential discourages fractional occupations and acts differently on occupied and unoccupied orbitals, leading to a bandgap of the order of $U$. The $U$ parameter, which describes the screened rather than the bare Coulomb interaction, is typically fitted so to achieve a satisfactory agreement with the experimental results, although different methods to calculate it from first principles have been proposed (for a review see Himmetoglu et al. 2014). In case of molecules or other spacers between metal electrodes, the effect of screening can be accounted for by using an image-charge model (Souza et al. 2014; Pertsova et al. 2015), while for $d$ or $f$ orbitals in solids several schemes based either on constrained DFT (Anisimov and Gunnarsson 1991), constrained random phase approximation (Miyake et al. 2009), and linear response (Himmetoglu et al. 2014) have been proposed.

## 3 Non-equilibrium Green's Function for Quantum Transport

The GF method described in the previous section can be naturally extended to describe out-of-equilibrium open systems at steady state. The typical system that we consider represents two-terminal devices at an applied bias voltage. It is subdivided in three parts: a central scattering region, also called extended molecule (EM), and left and right electrodes, from which electrons flow in and out (Fig. 1). We use the convention that the $z$-axis is the transport direction, and we assume that each electrode is semi-infinite and periodic away from the EM along $z$. The EM and the left (right) electrodes are described by the Hamiltonian matrices $H_{\text{EM}}^{\sigma}$ and
**Fig. 1** Schematic representation of the two-terminal setup used in typical quantum transport calculations. A central scattering region, also denoted as extended molecule (EM), is joined to the left and right leads, also denoted as electrodes. In practical quantum transport calculations, the EM typically includes at least one unit cell of the semi-infinite periodic electrodes at each of its ends, although in general this condition is not strictly necessary

$H_{L(R)}^\sigma$, respectively. The coupling between the left (right) electrode and the EM is accounted for by $H_{LM(MR)}^\sigma$, while there is no direct coupling between the two electrodes (Fig. 1). Due to its infinitely large size, each electrode is in local thermal equilibrium at its own chemical potential, $\mu_L$ for the left electrode and $\mu_R$ for the right electrode. The applied bias voltage is then defined as $V_b = \mu_L - \mu_R$. Note that the units of $V_b$ are in eV, and the corresponding voltage in volt, $V = V_b/e$, is obtained by dividing $V_b$ by the electron charge, $e$ ($e = -|e|$). The values of $\mu_{L(R)}$ are defined up to an arbitrary constant shift of the whole energy spectrum, and here we implicitly define this constant by setting $\mu_L = E_F + V_b/2$ and $\mu_R = E_F - V_b/2$.

A crucial advantage of solving the transport problem by using the Green's function method is that the EM can be separated out from the semi-infinite leads. Their effect on the EM is then captured via the energy-dependent retarded self-energies of the leads, denoted as $\Sigma_L^\sigma(E, V_b)$ ($\Sigma_R^\sigma(E, V_b)$) for the left (right) electrode. In analogy to Eq. (3), this allows to write the retarded GF of the EM at an applied bias voltage as

$$G_{EM}^\sigma(E, V_b) = \left[ (E + i\delta)\Omega_{EM} - H_{EM}^\sigma - \Sigma_L^\sigma(E, V_b) - \Sigma_R^\sigma(E, V_b) \right]^{-1}, \quad (9)$$

where $\Omega_{EM}$ is the overlap matrix of the EM. The detailed procedure to evaluate $\Sigma_L^\sigma(E, V_b) = \Sigma_L^\sigma(E - V_b/2, 0)$ and $\Sigma_R^\sigma(E, V_b) = \Sigma_R^\sigma(E + V_b/2, 0)$ goes beyond the scope of this chapter; the established methods for their calculation are based on either a semi-analytical expression (Rungger and Sanvito 2008) or on iterative procedures (López Sancho et al. 1984). The leads' self-energies, $H_{EM}$, $\Omega_{EM}$, and $G_{EM}^\sigma$, are all matrices of dimension $N_{EM} \times N_{EM}$, where $N_{EM}$ is the number of basis orbitals in the EM. Importantly, the self-energies are not Hermitian, and their antihermitian parts describe the flow of electrons between EM and the leads. To quantify these antihermitian components, one introduces the matrices

$\Gamma^\sigma_{L(R)} = i \left( \Sigma^\sigma_{L(R)} - \Sigma^\sigma_{L(R)}{}^\dagger \right)$, which are positive semi-definite and represent the energy-dependent strength of the electronic coupling of the EM to each of the electrodes. This can be seen by writing the spectral function from Eq. (4) as $A^\sigma = A^\sigma_L + A^\sigma_R$, with $A^\sigma_{L(R)} = G^\sigma_{EM} \Gamma^\sigma_{L(R)} G^\sigma_{EM}{}^\dagger$, which can be verified using Eq. (9), and assuming that there are no fully localized states in the EM, so that one can take $\delta$ to 0. The states of the system are therefore the sum of those coupled to the left electrode, which determine $A^\sigma_L$, and those coupled to the right electrode, which determine $A^\sigma_R$. In the out-of-equilibrium situation, the states coupled to the left (right) electrode are therefore at the chemical potential $\mu_L$ ($\mu_R$). This allows us to generalize the lesser GF from Eq. (7) to the non-equilibrium situation as $G^{\sigma <} = i f_L A^\sigma_L + i f_R A^\sigma_R$, where $f_{L(R)}(E, V_b) = f(E - \mu_{L(R)})$. If one defines the lesser lead self-energies, $\Sigma^\sigma_{L(R)}{}^<(E, V_b)$, as

$$\Sigma^\sigma_{L(R)}{}^<(E, V_b) = i f_{L(R)}(E, V_b) \Gamma^\sigma_{L(R)}(E, V_b), \tag{10}$$

this lesser GF is equivalently given by

$$G^\sigma{}^<_{EM}(E, V_b) = G^\sigma_{EM}(E, V_b) \left[ \Sigma^\sigma_L{}^<(E, V_b) + \Sigma^\sigma_R{}^<(E, V_b) \right] G^\sigma_{EM}{}^\dagger(E, V_b). \tag{11}$$

The density matrix of the EM, $\rho^\sigma_{EM}$, can then be evaluated at each bias by using Eq. (8):

$$\rho^\sigma_{EM}(V_b) = \frac{1}{2\pi i} \int dE \, G^\sigma{}^<_{EM}(E, V_b), \tag{12}$$

where we have explicitly introduced the energy and voltage dependence of all quantities. Furthermore, we also define the energy density matrix, $W^\sigma$, which is required for the calculation of forces and spin currents (see Sect. 6) and which is given by

$$W^\sigma(V_b) = \frac{1}{2\pi i} \int dE \, E \, G^\sigma{}^<(E, V_b). \tag{13}$$

We note that for computational efficiency the integral in the last two equations is usually split in a part running over real energies and a part evaluated over complex energies (Rocha et al. 2006).

When we use the DFT KS Hamiltonian for $H^\sigma_{EM}$, this becomes a functional of the density, i.e., $H^\sigma_{EM}(V_b) = H^\sigma_{EM}[\rho^\uparrow(V_b), \rho^\downarrow(V_b)]$. In this case $\rho^\sigma(V_b)$ and $H^\sigma_{EM}(V_b)$ need to be solved self-consistently, in analogy to standard ground state DFT calculations. This is typically achieved in an iterative procedure, where at each iteration for a given input $\rho^\sigma(V_b)$, one computes $H^\sigma_{EM}(V_b)$, which is then used to evaluate $G^\sigma_{EM}$ and with it to obtain a new output $\rho^\sigma(V_b)$. Self-consistency is achieved once the difference between the input and output density matrices is below

a given tolerance. Note that at finite $V_b$ we do not have a variational principle for the energy, so that at self-consistency instead of the ground state we obtain a steady state, where the inflow of electrons equals the outflow.

Once $\rho^\sigma(V_b)$ is calculated self-consistently, one can obtain the current across the EM, $I = I^\uparrow + I^\downarrow$, as

$$I^\sigma = \frac{G_0}{2e} \int T^\sigma(E, V_b) \left[ f_L(E, V_b) - f_R(E, V_b) \right] dE, \tag{14}$$

where $G_0 = 2e^2/h$ is the quantum of conductance, $h$ is the Planck constant, and $T^\sigma(E, V_b)$ is the spin-dependent transmission coefficient. This is given by

$$T^\sigma(E, V_b) = \mathrm{Tr} \left[ \Gamma_L^\sigma(E, V_b) G_{EM}^{\sigma}{}^\dagger(E, V_b) \Gamma_R^\sigma(E, V_b) G_{EM}^\sigma(E, V_b) \right], \tag{15}$$

where "Tr" denotes the matrix trace operation. The integrand in Eq. (14) is large only in an energy range of about $\pm V_b/2$ around $E_F$, which is called the bias window. The current is therefore mainly determined by the transmission integrated across this bias window.

If periodic boundary conditions are used in the $x - y$ plane perpendicular to the transport direction $z$, then $H_{EM}^\sigma$, $\Omega_{EM}$, $G_{EM}^\sigma$, $G_{EM}^\sigma{}^<$, $\Sigma_{L/R}^\sigma$, and $\Gamma_{L/R}^\sigma$ acquire a $\mathbf{k} = (k_x, k_y)$ index, so that we now have $H_{\mathbf{k},EM}^\sigma$, $\Omega_{\mathbf{k},EM}^\sigma$, $G_{\mathbf{k},EM}^\sigma(E, V_b)$, $G_{\mathbf{k},EM}^\sigma{}^<(E, V_b)$, $\Sigma_{\mathbf{k},L/R}^\sigma(E, V_b)$, and $\Gamma_{\mathbf{k},L/R}^\sigma(E, V_b)$. The equations outlined above are then valid for each $\mathbf{k}$-point, and the total density matrix and transmission are given by an integral over the Brillouin zone (BZ) perpendicular to the transport direction as

$$\rho_{EM}^\sigma(E, V_b) = \frac{1}{\Omega_{BZ}} \int_{\Omega_{BZ}} \rho_{\mathbf{k},EM}^\sigma(E, V_b) dk_x dk_y \tag{16}$$

and

$$T^\sigma(E, V_b) = \frac{1}{\Omega_{BZ}} \int_{\Omega_{BZ}} T_{\mathbf{k}}^\sigma(E, V_b) dk_x dk_y \tag{17}$$

where $\Omega_{BZ}$ is the area of the BZ.

The method described in this section is referred to as the NEGF formalism. When one uses the DFT KS Hamiltonian in the calculation, it is usually referred to as the NEGF+DFT method. In the following section, we will show how NEGF+DFT allows for the description of spin-dependent transport properties in nanoscale devices from first principles. All results are obtained by using the *Smeagol* quantum transport code (Rocha et al. 2006; Rungger and Sanvito 2008), which gets as input the DFT Hamiltonian from the *Siesta* DFT code (Soler et al. 2002).

# 4       Magnetoresistance and Spin Filtering

Thin film heterostructures combining magnetic and nonmagnetic materials are the most widely used spintronic devices to date. The typical setup, called spin valve, consists of two magnetic metals separated by one or more nonmagnetic spacer layers, which can be insulating, semiconducting, or metallic (Fig. 2a, b, d). For such systems the key quantity that determines the device performance is the magnetoresistance (MR), which is defined as

$$\text{MR} = \frac{I^{\text{P}} - I^{\text{AP}}}{I^{\text{small}}}, \tag{18}$$

where $I^{\text{P}}$ is the current for parallel (P) alignment of the magnetizations of the electrodes, $I^{\text{AP}}$ is the current for antiparallel (AP) alignment, and $I^{\text{small}}$ is the smaller of these two currents. The MR can be above tens of percent for metallic junctions, as first shown by A. Fert and P. Grünberg with their independent discovery of the giant magnetoresistance (GMR) effect (Baibich et al. 1988; Binasch et al. 1989). For insulating spacers the tunneling MR (TMR) can reach up to hundreds or thousands of percent, as is the case for the now widely used Fe/MgO/Fe(100) and related tunnel junctions. Notably, such huge TMR was first predicted by using NEGF+DFT (Butler et al. 2001) and subsequently confirmed experimentally (Parkin et al. 2004; Yuasa et al. 2004).

The general qualitative behavior of the MR for thin film stacks can be understood by modeling the left ferromagnet/spacer and right spacer/ferromagnet interfaces in

**Fig. 2** Prototypical spintronic device setups involving various combinations of magnetic and nonmagnetic layers, as well as metallic and insulating layers. The arrows indicate that a layer is magnetic, and the presence of a red down arrow indicates systems used for their magnetoresistance, obtained by reversing the magnetization direction of one of the layers. The unit cells shown underneath each general system setup indicate atomic structures of specific examples of its practical realization
**Fig. 3** (**a**) Fe band structure along the (100) direction, where the thick bands indicate states with $\Delta_1$ symmetry; spin-polarized transmission for P (**b**) and AP (**c**) alignment of the magnetization of the Fe electrodes in a Fe/MgO/Fe(100) junction with four MgO monolayers and resulting spin-dependent current for P (**d**) and AP (**e**) alignment; the resulting magnetoresistance as function of bias voltage is shown in (**f**). (Figure adapted from Rungger et al. 2009)

the devices of Fig. 2a, b, d as two independent scatters in series. If one assumes symmetric interfaces and neglects interference effects across interfaces, then one can indicate the majority (minority) spin transmission of each individual interface as $T^M(E)$ [$T^m(E)$]. Since spin-mixing is neglected, the P transmission can then be approximated as $T^P = (T^M)^2 + (T^m)^2$, while the AP transmission is $T^{AP} = 2T^m T^M$. For systems with $T^M \gg T^m$, indicating spin-filtering interfaces, one therefore has $T^P \gg T^{AP}$, which implies $I^P \gg I^{AP}$ and with it a very large MR. Even though this simple model does not apply to all systems (De Teresa et al. 1999), the general requirement for large MR is indeed that for the P alignment the current is highly spin-polarized.

In Fig. 3b we show a representative spin-polarized transmission curve of a Fe/MgO/Fe(100) junction as a function of the energy for the P alignment of the magnetic electrodes (Rungger et al. 2009). In the energy range from $-1$ to $+1\,\text{eV}$ around $E_F$ ones has $T^\uparrow \gg T^\downarrow$, and therefore this junction satisfies the requirement for large MR . Here the up (down) spin transmission is the majority (minority) transmission, so that $T^\uparrow = T^M$ and $T^\downarrow = T^m$. The AP transmission (Fig. 3c) lies between $T^\uparrow$ and $T^\downarrow$ calculated for the P alignment, in agreement to the qualitative model explained above. The origin of the spin-filtering property of this junction is the fact that MgO allows high transmission only for states with $\Delta_1$ symmetry (e.g., $s$-states, $p_z$-states, or $d_{z^2}$-states), and these states are only found in the up-spin spectrum of the Fe electrodes around $E_F$ (Fig. 3a). The current versus voltage characteristic curve ($I$-$V$) for P alignment therefore shows that $I^\uparrow \gg I^\downarrow$ at a moderate bias (Fig. 3d). In contrast, for the AP alignment, both $I^\uparrow$ and $I^\downarrow$ are very small at the same moderate bias, so that one has $I^P \gg I^{AP}$ (Fig. 3d, e) and a very high TMR (Fig. 3f). Note that $T^\downarrow$ for P alignment has a sharp peak very close to $E_F$ due to the formation of an interface state between Fe and MgO in the
**Fig. 4** Averages over the $(x, y)$ plane of the difference between finite-bias ($V_b = 0.5\,\text{eV}$) and zero-bias potential (**a**) and charge density (**b**) as function of the position along the transport direction $z$ in the Fe/MgO/Fe(100) junction. (Figure reproduced from Rungger et al. 2009)

down spins. With its high DOS, it leads to an increased $T^\downarrow$ in a small energy range around $E_F$, which does however become negligible compared to $T^\uparrow$ as the MgO thickness increases beyond the four monolayers considered here. Furthermore, the contribution of the interface states is drastically reduced when considering a small amount of disorder at the interface, which to a first approximation is achieved by applying a finite $\delta$ in the calculation of $G_{EM}$ (Eq. (9)). This leads to a further suppression of the low bias $I^{AP}$ and with it an increase of the TMR. For larger $V_b$ the TMR decreases progressively, since at about 1 eV $T^\downarrow$ becomes larger than $T^\uparrow$ (Fig. 3b). We note that the DFT bandgap of MgO is smaller than the experimental one (4.7 eV for the used LSDA vs. 7.8 eV in experiment). We can then correct the MgO DFT gap by using ASIC to achieve a quite good agreement with the experimental results. While ASIC changes the detailed quantitative values of the current and TMR, it leaves the qualitative picture obtained from LSDA unaffected. We also note that in these calculations the charge density and potential have been computed self-consistently at finite bias, and the typically resulting potential drop and charge polarization are shown in Fig. 4. One can see that the potential drop is approximately linear between the two metal electrodes, so that to a first approximation, one can also simulate the finite-bias potential non-self-consistently by rigidly shifting it inside the metal electrodes and by applying a linear potential ramp between them. The resulting transmission and current are similar to the ones obtained in the self-consistent calculation.

The key requirements in order to obtain high TMR are the good crystallinity of the interfaces and the large bandgap of the spacer. Both these requirements are met in Fe/MgO/Fe(100) junctions, which exhibit good epitaxial growth. In contrast, the smaller band gap of semiconducting spacers usually results in metal/semiconductor/metal junctions having a lower MR. For instance, in Fe/MoS$_2$/Fe junctions (Fig. 2b), multilayer MoS$_2$ has a gap of about 1–2 eV, and the epitaxy with Fe is less good. The MR is therefore reduced from thousands to a few hundred percent (Fig. 5a), which is nevertheless still sizeable (Dolui et al. 2014). Due to the smaller bandgap of MoS$_2$, the decay of MR with bias is also faster, and the MR approximately vanishes at a voltage of about 0.4 V (Fig. 5b). For metallic spacers the assumption used in the presented NEGF calculations of a fully coherent
**Fig. 5** (**a**) Magnetoresistance for a Fe/MoS$_2$/Fe(100) junction as function of the number of MoS$_2$ layers; (**b**) bias voltage dependence of the MR for a seven monolayer MoS$_2$ junction. (Figure adapted from Dolui et al. 2014)

current is not valid, since diffusive contributions to the electron transport become important even for thin spacers. The evaluation of the relative contribution of diffusive and coherent (also called ballistic) currents is an active area of theoretical and experimental research. Using ultrashort laser pulses on Fe/Au films (Fig. 2e), it is possible to estimate their relative contributions, and it is found that high-energy ballistic electrons can travel for tens of nanometers and that the NEGF transmission coefficient across the Fe/Au interface plays a determining role in the magnitude of the currents and of their spin polarization (Alekhin et al. 2017).

The example of the Fe/MgO/Fe(100) junction has demonstrated that the key factor to obtain a large MR is that each magnetic electrode in conjunction with the specific spacer acts as spin filter. Such spin filters can also be obtained by placing a ferromagnetic layer, either metallic or semiconducting, between nonmagnetic metallic electrodes (Fig. 2c, f). For common applications the main drawback of all known magnetic semiconductors is that they have rather low Curie temperatures far below room temperature. Despite that, ferromagnetic semiconductors can still be used in devices operating in cryogenic conditions. As typical example of ferromagnetic semiconductor we consider EuO. Here there are only spin-up states at the top of the valence band and at the bottom of the conduction band, which fix the bandgap. In contrast, the down-spin band structure shows a much larger gap. Consequently, in a prototypical Cu/EuO/Cu junction, the total transmission around $E_F$ is mostly determined by $T^\uparrow$ (Fig. 6), while $T^\downarrow$ is much smaller (Jutong et al. 2012). EuO therefore acts as an almost perfect spin filter, where the spin polarization of the current remains large up to high bias. Note that in these calculations the LSDA+U is used for the Eu $4f$ states, since the LSDA bandgap is found to be vanishingly small, in contrast to experimental observations (Pertsova et al. 2015).

Finally, we point out that spintronic devices can be realized also by using single molecules or molecular layers contacted between metal electrodes. For example, in the work by Rocha et al. (2005), a spin valve consisting of a 1,4-[3]-phenyl-dithiolate (tricene-dithiolate) molecule between Ni electrodes is investigated by using the NEGF method. The molecule corresponds to a nonmagnetic spacer,
**Fig. 6** Spin-resolved transmission for a Cu/EuO/Cu junction, for two different distances, $d$, between Cu and EuO. The transmission around $E_F$ is dominated by the majority (up) spins, and the precise alignment of the transmission spectrum with respect to $E_F$ depends on the distance between Cu and EuO. (Figure adapted from Jutong et al. 2012)

and the transmission function becomes spin-dependent as a result of the strong electronic coupling between the molecule and the spin-polarized Ni $d$ orbitals. The theoretical MR reaches about 600% for a bias voltage of 0.5 V.

## 5    Electron Correlations Beyond Kohn-Sham DFT

The successful application of DFT+NEGF to the nanodevices presented so far relies on the fact that the LSDA KS states return a reasonably accurate description of the electronic structure. As we have indicated for the Fe/MgO/Fe and Cu/EuO/Cu junctions, mean-field (MF) corrections such as the ASIC and LSDA+U can often bring DFT results in agreement with experiments. However, there are a number of effects, which are due to electron-electron correlations not captured by means of any static mean-field approach. In these cases, the KS Green's function can be used as zeroth-order approximation within a more accurate treatment based on advanced many-body techniques. The extension of the NEGF method to many-body systems is formally accomplished by adding to Eqs. (9) and (11) the retarded and lesser self-energies for the many-body (MB) electron-electron interaction, $\Sigma_{MB}^{\sigma}$ and $\Sigma_{MB}^{\sigma}{}^{<}$. Thus, one defines the MB Green's functions as

$$G_{MB}^{\sigma}(E, V_b) = \big[ (E + i\delta)\Omega_{EM} - H_{EM}^{\sigma} - \Sigma_L^{\sigma}(E, V_b) - \Sigma_R^{\sigma}(E, V_b) \\ - \Sigma_{MB}^{\sigma}(E, V_b) \big]^{-1}, \tag{19}$$

$$G_{MB}^{\sigma}{}^{<}(E, V_b) = G_{MB}^{\sigma}(E, V_b) \big[ \Sigma_L^{\sigma}{}^{<}(E, V_b) + \Sigma_R^{\sigma}{}^{<}(E, V_b) \\ + \Sigma_{MB}^{\sigma}{}^{<}(E, V_b) \big] G_{MB}^{\sigma}{}^{\dagger}(E, V_b). \tag{20}$$

We note that, if $H_{\rm EM}$ is the KS Hamiltonian, then the contribution to the electron correlation already accounted for at the KS level has to be subtracted out of $\Sigma_{\rm MB}$ and $\Sigma_{\rm MB}^<$. This so-called double counting correction is unfortunately unknown in general and has to be approximated (Kotliar et al. 2006). Also other interactions, such as the electron-phonon interaction, can be formally included by introducing into these equations the corresponding self-energies, which just add up to the leads' self-energies. However, we remark that a key assumption to guarantee the additive property of the interaction self-energies with the leads' self-energies is that these interactions are localized in the EM.

The formal introduction of the electron-electron interaction via self-energies in Eqs. (19) and (20) shows that the interaction effectively acts on the system as an additional electrode. Then one can define an effective "coupling matrix" for the interaction, $\Gamma_{\rm MB}^\sigma(E, V_{\rm b}) = i\left(\Sigma_{\rm MB}^\sigma(E, V_{\rm b}) - \Sigma_{\rm MB}^{\sigma \dagger}(E, V_{\rm b})\right)$, and express $\Sigma_{\rm MB}^{\sigma\,<}(E, V_{\rm b})$ in terms of $\Gamma_{\rm MB}^\sigma(E, V_{\rm b})$ through the relation (Droghetti and Rungger 2017; Ness et al. 2010):

$$\Sigma_{\rm MB}^{\sigma\,<}(E, V_{\rm b}) = i\, F_{\rm MB}^\sigma(E, V_{\rm b})\Gamma_{\rm MB}^\sigma(E, V_{\rm b}). \tag{21}$$

This has a similar structure to Eq. (10). However, we note that $F_{\rm MB}^\sigma$ is a $N_{\rm EM} \times N_{\rm EM}$ distribution matrix, which contains information about the interacting out-of-equilibrium in- and outflow of electrons from the EM. The calculation of $F_{\rm MB}^\sigma$ remains a challenge to date and is the topic of ongoing research. Only in equilibrium (i.e., for $V_{\rm b} = 0$) $F_{\rm MB}^\sigma$ becomes the Fermi-Dirac distribution.

The current can be expressed as (Droghetti and Rungger 2017; Ness et al. 2010)

$$I^\sigma = \frac{G_0}{2e}\int\left\{T^\sigma(E, V_{\rm b})\left[f_{\rm L}(E) - f_{\rm R}(E)\right] + {\rm Tr}\Big[[F_{\rm MB}^\sigma(E, V_{\rm b}) - f_{\rm R}(E)]\right.$$
$$\left.\Gamma_{\rm MB}^\sigma(E, V_{\rm b})G_{\rm MB}^{\sigma\,\dagger}(E, V_{\rm b})\Gamma_{\rm R}^\sigma(E, V_{\rm b})G_{\rm MB}^\sigma(E, V_{\rm b})\Big]\right\}dE. \tag{22}$$

$T^\sigma(E, V_{\rm b})$ is the transmission coefficient defined as in Eq. (15), but here it is computed by using the MB retarded Green's function in Eq. (19), i.e.:

$$T^\sigma(E, V_{\rm b}) = {\rm Tr}\left[\Gamma_{\rm L}^\sigma(E, V_{\rm b})G_{\rm MB}^{\sigma\,\dagger}(E, V_{\rm b})\Gamma_{\rm R}^\sigma(E, V_{\rm b})G_{\rm MB}^\sigma(E, V_{\rm b})\right]. \tag{23}$$

The last term on the right-hand side of Eq. (22) accounts for the effect of the "interaction electrode." It is similar to the first one, but $F_{\rm EM}^\sigma(E, V_{\rm b})$ cannot be brought outside the trace, and we cannot define a transmission coefficient related to the flow of electrons from the left lead into the interaction lead and then from this to the right lead. The first term of Eq. (22) accounts for the elastic contributions to the current, while the second term accounts for the inelastic ones, which are often not negligible. $\Gamma_{\rm MB}^\sigma$ is usually non-zero except for a few special cases such as the so-called irregular self-energies. These are instantaneous (local) in time self-energies, such as the Hartree-Fock one. $\Gamma_{\rm MB}^\sigma$ also vanishes for Fermi liquid systems at zero temperature, but only at the Fermi energy. Away from it there is always a non-zero contribution coming from the continuum of electron-hole excitations.

To date, studies including correlation effects for spin-dependent transport beyond NEGF+DFT are scarce and mostly limited to molecular devices and point contacts at zero-bias (see, e.g., Jacob (2015) and references therein) rather than to solid-state systems. In fact, although the discussion above provides the formal equations to solve the problem, in practice the calculation of the MB retarded and lesser self-energies within a treatable approximation is a challenging task. One possible approach is to use the GW approximation of the many-body perturbation theory to obtain a corresponding MB self-energy (Strange et al. 2011). A second approach is represented by the dynamical mean-field theory (DMFT) (Kotliar et al. 2006). In DMFT one starts by selecting a subspace of correlated orbitals in the very same way as in LSDA+U. The effective low-energy Hamiltonian of this subspace is projected out from the whole system and then solved by using DMFT to obtain the corresponding MB self-energy. Finally this is projected back from the correlated subspace to the original system. One of the strengths of DMFT is that it is not a perturbative approach, so that both weak and strong correlations are treated on an equal footing. However, DMFT neglects spatially nonlocal correlations.

As an example of application of NEGF+DFT+DMFT to a solid-state system, we present results for a Cu/monolayer-Co/Cu heterostructure (Chioncel et al. 2015) in Fig. 7. We note that to date no first principles study at finite bias has been reported and the transport properties have been assessed by calculating only the elastic transmission as defined in Eq. (23). DMFT significantly changes the DOS of the Co layer when compared to KS-LSDA. The most striking effect is the narrowing of the Co-3$d$ states and the reduced exchange splitting, and this is reflected in the transmission function. In fact, although its order of magnitude around $E_F$ is approximately unchanged, the spin polarization is significantly reduced in DMFT compared to LSDA results.

**Fig. 7** (**a**) Density of states of the Co layer between Cu electrodes and (**b**) up- and (**c**) down-spin transmission as function of energy. Black dashed curves (red solid lines) represent results without (with) DMFT corrections. (Figure adapted from Chioncel et al. 2015)

## 6 Finite-Bias Spin-Transfer Torque

If spin-mixing terms are present in the Hamiltonian, $H^\uparrow$ and $H^\downarrow$ are not anymore independent of each other. The Hamiltonian matrix then needs to be rewritten in a general non-collinear form as (Xie et al. 2016)

$$H = H_0 \otimes 1_2 + H_x \otimes \sigma_x + H_y \otimes \sigma_y + H_z \otimes \sigma_z \tag{24}$$

where $1_2$ is the $2 \times 2$ identity matrix, $\sigma_{x/y/z}$ are the three $2 \times 2$ Pauli spin matrices, and $H_{0/x/y/z}$ are matrices, which are of general dimension $N_\beta \times N_\beta$ (for an open system $N_\beta \to \infty$). For each pair of orbitals $\alpha$ and $\beta$ we have a $2 \times 2$ spin block matrix $H_{\alpha\beta} = H_{0,\alpha\beta} \, 1_2 + \mathbf{H}_{\alpha\beta} \cdot \boldsymbol{\sigma}$, with $\mathbf{H}_{\alpha\beta} = \left( H_{x,\alpha\beta}, H_{y,\alpha\beta}, H_{z,\alpha\beta} \right)$ a vector of three complex numbers, and $\boldsymbol{\sigma} = \left( \sigma_x, \sigma_y, \sigma_z \right)$ a vector of the three Pauli matrices. The self-energies, the $\Gamma$-matrices, the retarded and lesser Green's functions, and the density matrix are expanded in an analogous form. The equations derived in the foregoing part of this chapter are therefore also valid for the non-collinear case, but one needs to remove the spin index from each equation and replace the appearing matrices with their non-collinear counterparts given in Eq. (24).

We now present the relations that allow us to evaluate the NEGF spin-transfer torque (STT), which corresponds to the torque that the flowing electrons exert on the local magnetic moments and which leads to current-induced time-dependent spin dynamics. Using the Liouville equation for a general density matrix in a non-orthogonal basis, $\partial\rho/\partial t = \frac{1}{i\hbar} \left( \Omega^{-1} H\rho - \rho H \Omega^{-1} \right)$, we obtain the relation:

$$\frac{\partial\bar\rho}{\partial t} = \frac{1}{i\hbar} [H, \rho] + \frac{1}{i\hbar} [W, \Omega], \tag{25}$$

where we have introduced the symmetrized density matrix:

$$\bar\rho = \frac{1}{2} \left( \rho\Omega + \Omega\rho \right). \tag{26}$$

Here $W = \frac{1}{2} \left[ \Omega^{-1} H\rho + \rho H \Omega^{-1} \right]$, which for the steady state corresponds to Eq. (13). The total number of electrons, $N_{\text{e,tot}} = 2 \sum_{\alpha=1}^{N_\beta} \bar\rho_{0,\alpha\alpha}$, and the total spin, $\mathbf{S}_{\text{tot}} = \hbar \sum_{\alpha=1}^{N_\beta} \bar{\boldsymbol{\rho}}_{\alpha\alpha}$, depend only on the diagonal elements of $\bar\rho$. We introduce the Mülliken-partitioned local charge in orbital $\alpha$ as $q_\alpha = 2e \, \bar\rho_{0,\alpha\alpha}$ and the local spin as $\mathbf{s}_\alpha = \hbar\bar{\boldsymbol{\rho}}_{\alpha\alpha}$, so that $\bar\rho_{\alpha\alpha} = \frac{1}{2e} q_\alpha \, 1_2 + \frac{1}{\hbar} \mathbf{s}_\alpha \cdot \boldsymbol{\sigma}$. Note that $q_\alpha$ and $\mathbf{s}_\alpha$ are always real. Thus, from Eq. (25) we derive two equations of motion:

$$\frac{\partial q_\alpha}{\partial t} = I_{0,\alpha}, \tag{27}$$

$$\frac{\partial \mathbf{s}_\alpha}{\partial t} = \mathbf{T}_{\mathbf{H},\alpha} + \frac{\hbar}{2e} \mathbf{I}_\alpha. \tag{28}$$

Here we have introduced the field-induced orbital torque

$$\mathbf{T}_{\mathbf{H},\alpha} = 2 \sum_{\beta=1}^{N_\beta} \text{Re} \left[ \mathbf{H}_{\alpha\beta} \times \boldsymbol{\rho}_{\beta\alpha} \right]; \tag{29}$$

the orbital charge current, $I_{0,\alpha} = \sum_{\beta=1}^{N_\beta} I_{0,\alpha\beta}$; and the orbital spin current, $\mathbf{I}_\alpha = \sum_{\beta=1}^{N_\beta} \mathbf{I}_{\alpha\beta}$. These include the bond current between any two pairs of orbitals $\alpha$ and $\beta$, $\mathbf{I}_{\alpha\beta} = I_{0\alpha\beta} \, 1_2 + \mathbf{I}_{\alpha\beta} \cdot \boldsymbol{\sigma}$, for which using Eq. (25) the charge-current component results to:

$$I_{0,\alpha\beta} = \frac{4e}{\hbar} \text{Im} \left[ H_{0,\alpha\beta} \rho_{0,\beta\alpha} - \Omega_{\alpha\beta} W_{0,\beta\alpha} + \mathbf{H}_{\alpha\beta} \cdot \boldsymbol{\rho}_{\beta\alpha} \right], \tag{30}$$

and the spin-current component results to:

$$\mathbf{I}_{\alpha\beta} = \frac{4e}{\hbar} \text{Im} \left[ \mathbf{H}_{\alpha\beta} \rho_{0,\beta\alpha} + H_{0,\alpha\beta} \boldsymbol{\rho}_{\beta\alpha} - \Omega_{\alpha\beta} \mathbf{W}_{\beta\alpha} \right]. \tag{31}$$

Note that the orbitals $\alpha$ and $\beta$ can be located both inside and outside of the EM, and that $\mathbf{I}_{\alpha\beta} = -\mathbf{I}_{\beta\alpha}$ and $I_{0,\alpha\beta} = -I_{0,\beta\alpha}$. We can interpret Eq. (27) as the change of local charge due to in- and outflow of electrons from the orbital $\alpha$, the first term in Eq. (28) as torque leading to a spin precession around the effective field originating from the Hamiltonian matrix and the second term as change of spin on orbital $\alpha$ due to inflow and outflow of spins. In the steady state $I_{0,\alpha} = 0$ and $\mathbf{T}_{\mathbf{H},\alpha} = -\frac{\hbar}{2e} \mathbf{I}_\alpha$, so that the term in Eq. (28) proportional to $\mathbf{I}_\alpha$ can be interpreted as a spin-transfer torque from the flowing electrons to the local magnetization. We denote this STT as $\mathbf{T}_{\text{STT},\alpha} = \frac{\hbar}{2e} \mathbf{I}_\alpha$. In the non-steady state, $\mathbf{I}_\alpha$ can also lead to a change of magnitude of the spin.

If we denote with $A$ an arbitrary interface to the current flow, then the total current across this interface, $I_A$, is obtained by summing up the bond currents between all the orbitals $\alpha_L$ on the left side of this interface and the ones on the right of this interface, $\alpha_R$:

$$I_A = \sum_{\alpha_L, \alpha_R} I_{\alpha_L \alpha_R}. \tag{32}$$

Charge conservation at the steady state implies that the charge current, $I_{A,0}$, across any interface $A$ perpendicular to the transport direction must give the same value. In fact it can be shown that the current obtained in this way is equivalent to the NEGF current in Eq. (14). In contrast, the spin currents $\mathbf{I}_A$ can vary for two different interfaces $A$ and $A'$, and the difference between $\mathbf{I}_A$ and $\mathbf{I}_{A'}$ satisfies the relation:

$$\sum_{\alpha \in (A, A')} \mathbf{T}_{\mathrm{STT}, \alpha} = \frac{\hbar}{2e} \left( \mathbf{I}_{A'} - \mathbf{I}_A \right), \tag{33}$$

where the sum on the left side of the equation runs over all orbitals enclosed between the interfaces $A$ and $A'$, so that it is equal to the total STT in the region between $A$ and $A'$. In typical MR heterostructures shown in Fig. 2a, b, d, one is interested in the torque acting on the right magnetic electrode, $\mathbf{T}_R$, since it is the one that can reverse the magnetization, while the magnetization of the left electrode is usually pinned to one direction. $\mathbf{T}_R$ is then proportional to the difference in the spin current deep inside the right electrode, $\mathbf{I}_R$, and the one in the middle of the spacer, $\mathbf{I}_M$, and the value is given by

$$\mathbf{T}_R = \frac{\hbar}{2e} \left( \mathbf{I}_R - \mathbf{I}_M \right). \tag{34}$$

Note that $\mathbf{I}_R$ needs to be evaluated at a distance from the interface that is larger than the transverse spin relaxation length (Slonczewski 2005).

We can also compute the local torque on each atom, where the Mülliken-partitioned local atomic spin at an atom with integer index $a$ is $\mathbf{S}_a = \sum_{\alpha \in a} \mathbf{s}_\alpha$. Here the sum over $\alpha$ runs over all orbitals that belong to atom $a$, and $\mathbf{S}_{\mathrm{tot}} = \sum_a \mathbf{S}_a$. In the steady state the STT acting on the atom, $\mathbf{T}_a$, is then given by

$$\mathbf{T}_a = \sum_{\alpha \in a} \mathbf{T}_{\mathrm{STT}, \alpha} = \frac{\hbar}{2e} \sum_{\alpha \in a} \mathbf{I}_\alpha. \tag{35}$$

To obtain $\mathbf{T}_a$ we can therefore calculate directly $\mathbf{T}_{\mathrm{STT}, \alpha} = \frac{\hbar}{2e} \mathbf{I}_\alpha$ through Eq. (31). Note that since the spin-current can be non-zero even without applied voltage, the torque defined in this way can be finite even at 0 bias voltage. If one wants to calculate only the torque induced by the application of a bias voltage, one can simply take the difference $\mathbf{T}_a(V_b) - \mathbf{T}_a(V_b = 0)$.

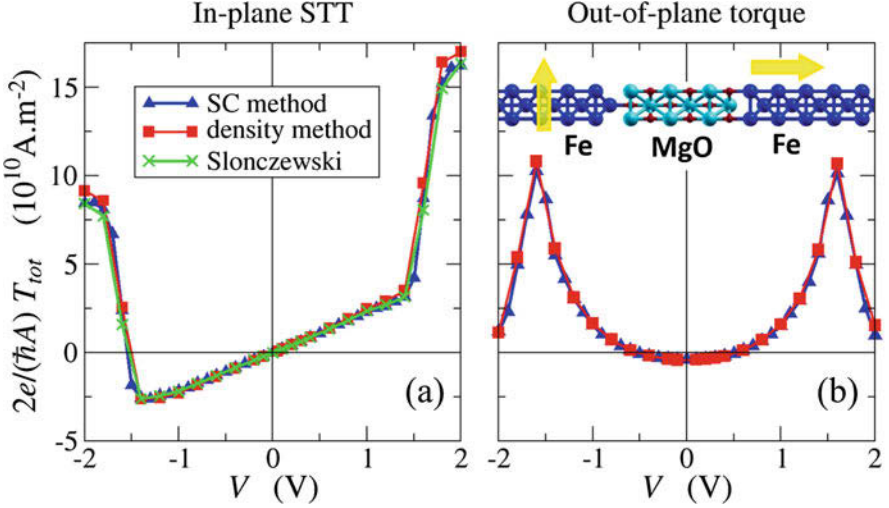
In Haney et al. (2007) an alternative approximate procedure for the calculation of $\mathbf{T}_{H, \alpha}$ is outlined, where one subdivides the full non-equilibrium electron density into a *condensate* part, $\rho_{\mathrm{cond}}$, which gives rise to the local moments at equilibrium, and a *transport* part due to the current flow, $\rho_{\mathrm{tr}}$, so that $\rho = \rho_{\mathrm{cond}} + \rho_{\mathrm{tr}}$. We note that the exact way of splitting $\rho$ into a condensate and a transport part is rather arbitrary, and the results can depend sensitively on this splitting, as shown in Xie et al. (2016). In a steady-state current-carrying condition, we choose the definition $\rho_{\mathrm{cond}} = \rho_{\mathrm{EM}}(V_b = 0)$, so that $\rho_{\mathrm{tr}}(V_b) = \rho_{\mathrm{EM}}(V_b) - \rho_{\mathrm{EM}}(V_b = 0)$. Within the LSDA, and in absence of spin-orbit interactions, we also have $\mathbf{H}[\rho]_{\alpha\beta} \propto \boldsymbol{\rho}_{\alpha\beta}$, where $\mathbf{H}[\rho]_{\alpha\beta}$ denotes the spin Hamiltonian obtained for the density matrix $\rho$. Assuming $\rho_{\mathrm{cond}} \gg \rho_{\mathrm{tr}}$ we have $\partial \rho_{\mathrm{cond}}/\partial t \gg \partial \rho_{\mathrm{tr}}/\partial t \approx 0$ and therefore $\partial \mathbf{s}_{\mathrm{tr}}/\partial t \approx 0$, and furthermore $\mathbf{H}[\rho_{\mathrm{cond}} + \rho_{\mathrm{tr}}]_{\alpha\beta} \approx \mathbf{H}[\rho_{\mathrm{cond}}]_{\alpha\beta} + \mathbf{H}[\rho_{\mathrm{tr}}]_{\alpha\beta}$. With Eqs. (28) and (35), this gives the following approximation for the STT:


**Fig. 8** Comparison of the two non-collinear STT methods (density method and spin-current method) for the in-plane and out-of-plane torques in the right lead of an Fe/MgO/Fe(100) stack with magnetizations set at 90° (see inset), as function of the applied voltage. For the in-plane case, also the STT calculated using collinear-state transmissions, based on the equivalent-circuit magnetic tunnel junction model of Slonczewski (2005) developed for STT by Theodonis et al. (2006), is shown. Note that all finite-bias calculations here are not fully self-consistent, but are instead based on a non-self-consistent finite-bias calculation, where the potential drop across the barrier is assumed to be linear, which is a good approximation of the self-consistent potential (see Fig. 4)

$$\mathbf{T}_a \approx \frac{\partial \mathbf{s}_{a,\text{cond}}}{\partial t} \approx 2 \sum_{\alpha \in a} \sum_{\beta=1}^{N_\beta} \text{Re} \left[ \boldsymbol{\rho}_{\text{tr},\beta\alpha} \times \mathbf{H}[\rho_{\text{cond}}]_{\alpha\beta} \right]. \tag{36}$$

With Eq. (36) $\mathbf{T}_a$ can be evaluated by first performing a zero-bias calculation to obtain $\rho_{\text{EM}}(V_\text{b} = 0)$ and $\mathbf{H}[\rho_{\text{EM}}(V_\text{b} = 0)]_{\alpha\beta}$ and then a finite-bias calculation to obtain $\rho_{\text{EM}}(V_\text{b})$.

In Fig. 8 we show an example for the bias dependence of the total STT on the right lead of an Fe/MgO/Fe(100) magnetic tunnel junction (MTJ) calculated by the two methods above, namely, what we call the spin-current (SC) method based on Eq. (34) and what we denote as the density method (DM) of Eq. (36). We see a linear bias dependence of the in-plane (damping-like) STT for $|V| < 1.5$ V, above which a sharp increase is observed. The latter is due to the band edge of the $\Delta_1$ band for the minority spin in bcc Fe at about 1.5 eV above $E_\text{F}$ and the consequent sharp increase of the current in the AP alignment of the junction at these rather high bias voltages (see Fig. 3). The out-of-plane (field-like) torque is quadratic in this bias range, becoming larger than the in-plane STT at high bias voltages and then decaying sharply at around ±1.5 V. Importantly, we find an excellent agreement of the two presented methods over the considered wide range of bias voltages. The

results of these methods agree also very well with the Slonczewski's equivalent-circuit result for a symmetric MTJ, which is based on an approximate collinear spin-current model (Theodonis et al. 2006).

# 7 Linear-Response Spin-Transfer Torque

If we consider the linear-response regime, where only a small bias voltage, $\delta V_b$, is applied across the junction, then the transport part of the density matrix induced by $\delta V_b$ is

$$\rho_{tr}(\delta V_b) \approx \left. \frac{\partial \rho(V_b)}{\partial V_b} \right|_{V_b=0} \delta V_b. \tag{37}$$

Based on this relation, and using Eq. (36), we can evaluate the so-called spin-transfer torkance on a site $a$, $\boldsymbol{\tau}_a$, as

$$\boldsymbol{\tau}_a = \frac{\delta \mathbf{T}_a}{\delta V_b} \approx 2 \sum_{\alpha \in a} \sum_{\beta=1}^{N_\beta} \text{Re} \left[ \frac{\partial \boldsymbol{\rho}_{tr,\beta\alpha}}{\partial V_b} \times \mathbf{H}[\rho_{cond}]_{\alpha\beta} \right]. \tag{38}$$

Assuming that $G_{EM}(E)$ and $\Gamma_{L/R}(E)$ are slowly varying functions around $E_F$ and that the junction is approximately left-right symmetric (the two electrodes and the interfaces), resulting in a symmetric bias drop ($\pm V_b/2$), the derivative in above equation takes the form (in accordance with Mahfouzi and Nikolic (2013) for this special case):

$$\left. \frac{\partial \rho(V_b)}{\partial V_b} \right|_{V_b=0} = \frac{1}{4\pi} G_{EM}(E_F) \left[ \Gamma_L(E_F) - \Gamma_R(E_F) \right] G_{EM}^\dagger(E_F) \Big|_{V_b=0}. \tag{39}$$

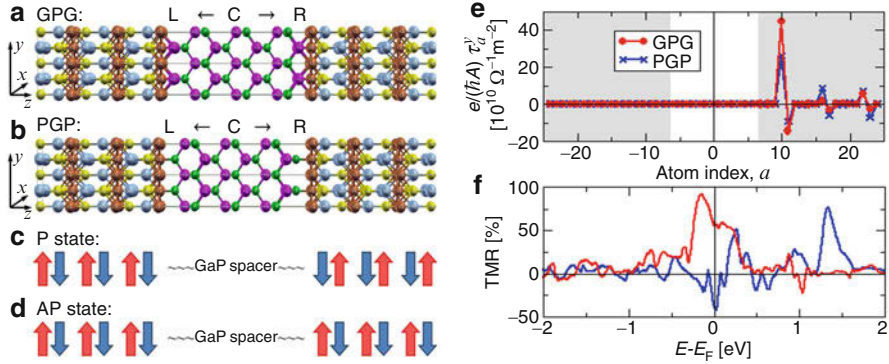
In Fig. 9 an example calculation of a linear-response torkance is shown. In this case the electrodes are made of CuMnAs, an antiferromagnetic (AFM) material recently proposed for spintronic applications (Wadley et al. 2013, 2016). In its tetragonal phase, CuMnAs is a metallic AFM ($T_N \approx 480$ K) and can be grown epitaxially on GaP. The general advantages of AFMs are that they are immune to stray magnetic fields and that they are expected to have much faster switching times compared to ferromagnets. For CuMnAs grown on GaP, the magnetization is uniformly aligned within the individual Mn layers parallel to the interface and alternates antiferromagnetically from layer to layer as one moves away from the GaP interface (Fig. 9c, d). Since the spin-transport properties are dominated by the interface magnetization, reversal of the magnetization of the right electrode leads to a significant MR in this system (Fig. 9f). This particular equilibrium interface spin polarization is then found to give rise to staggered spin-transfer torkance in the AFM (Fig. 9e) (Stamenova et al. 2017), and the total torkance in the right electrode is non-zero despite the zero total magnetic moment. The magnetic state


**Fig. 9** (**a,b**) Atomic structure of the CuMnAs/GaP/CuMnAs junctions; two possible terminations of the GaP spacer are considered: GPG ending with Ga layers and PGP ending with P; (**c,d**) definition of the P and AP spin states of the junction, arrows represent the spin of the corresponding Mn layer as per diagram above; (**e**) the in-plane spin torkance for a 90° spin misalignment, i.e., left lead polarized along $y$ and right lead along $x$; (**f**) energy-dependent linear-response TMR coefficient, which here is defined as $\text{TMR}(E) \equiv (T_{\text{P}}(E) - T_{\text{AP}}(E)) / (T_{\text{P}}(E) + T_{\text{AP}}(E))$. (Figure adapted from Stamenova et al. 2017)

of such heterostructures can therefore be read using the MR and switched using the torkance. We also note that, as shown in Fig. 9, the spin-transport properties are found to depend sensitively on the CuMnAs termination on GaP, but the staggered spin-transfer torkance is less sensitive to the details of the interface.

# 8 Time-Dependent Spin Dynamics: Current-Driven Domain Wall Motion

So far we have considered the charge and spin transport in the steady state. Time-dependent (TD) dynamical processes with non-collinear spin textures are typically evaluated in a multi-scale approach, where the NEGF+DFT STT steady-state results are used as parameters in a Landau-Lifshitz micromagnetic model (Xie et al. 2016; Ellis et al. 2017). The time evolution can in principle also be evaluated directly within NEGF+DFT; these calculations are however computationally highly demanding. Computations become significantly faster if instead of DFT one uses a simplified tight-binding (TB) model, where the Hamiltonian is based on a set of parameters instead of the fully first principles approach used in DFT. In Stamenova et al. (2005) a so-called $s - d$ model tight-binding Hamiltonian is used to describe a point contact, where the spatially varying localized spins, $\{\mathbf{S}_a\}$, are assumed to lie in a plane and are described by a one-dimensional set of classical angular coordinates $\boldsymbol{\phi} = \{\phi_a\}$, one for each site $a$. The corresponding Hamiltonian operator is written as

$$\hat{H}(\boldsymbol{\phi}) = \sum_{a,b} \left[ (H_{el})_{ab} + (V_{sd}(\boldsymbol{\phi}))_{ab} \right] \hat{c}_a^\dagger \hat{c}_b + V_{dd}(\boldsymbol{\phi}) \,, \tag{40}$$

where $a, b$ indicate the sites in the junction; $H_{el}$ is a single-band TB Hamiltonian matrix; $(V_{sd}(\boldsymbol{\phi}))_{ab} = -J_{sd}\mathbf{s}_a \cdot \mathbf{S}_b(\phi_b)\delta_{ab}$ corresponds to an on-site repulsion term; $\mathbf{S}_a(\phi_a) = (\sin(\phi_a), 0, \cos(\phi_a))$ are unit vectors representing the local atomic spins of uniform magnitude, $S$; and $\mathbf{s}_a = (0, 0, s_a) = (0, 0, \rho_{aa}^\uparrow - \rho_{aa}^\downarrow)/2$ is the expectation value of the on-site itinerant spin in the case of a two-spin-channel model (for ease of notation here and in the following, we define the spins as dimensionless). The equation includes an inter-site classical Heisenberg spin-spin interaction $V_{dd}(\{\phi_a\}) = -(J_{dd}/2)\sum_{a,b}\mathbf{S}_a(\phi_a)\cdot\mathbf{S}_b(\phi_b)$ with only nearest neighbor coupling. In this case the torques acting on the classical $d$-spins, defined through the Hellman-Feynman theorem, have an explicit form in the direction perpendicular to $\mathbf{S}_a$, allowing for spin-rotations energetics to be calculated, including transition barriers between different spin states in the junction. Within a NEGF steady-state spin-transport approach, this model has provided a valuable unequivocal numerical demonstration that the current-induced torques, which represent a special case of current-induced forces (CIFs), are nonconservative (Stamenova et al. 2005). The question of whether or not CIFs are conservative had been an open question in the field of electromigration and a subject of debate in the early 2000s (see, e.g., Di Ventra et al. 2004).

This model has been further extended beyond the two-spin channel model to fully non-collinear spins to investigate two almost reciprocal phenomena involving the dynamical interaction of electron transport and the underlying spin/magnetization texture in the time domain, i.e., the spin-motive force as a result of a domain wall (DW) rotation (Stamenova et al. 2008) on one hand and the current-induced DW motion (Stamenova and Sanvito 2010) on the other hand. The system of choice in the two cases was similar – a 1D chain of a few hundred localized spins forming a Néel-type DW. We will consider here in more detail the second case, where time-dependent steady-state transport is achieved by a single-parameter construction of an "ever-discharging" capacitor attached to the chain, analogous to the method of Sánchez et al. (2006). There it is also demonstrated that the steady state obtained in this method is equivalent to the NEGF steady state in the case where atomistic details of the coupling to the leads are neglected ($\Gamma_L(E) = \Gamma_R(E) = \Gamma$). An example of a possible TD transport scheme based on the NEGF is presented in McEniry et al. (2007). The $s-d$ spin Hamiltonian is now fully non-collinear, and the equation of motion for the localized spins reads (Stamenova and Sanvito 2010):

$$\dot{\mathbf{S}}_a = \frac{\mathbf{S}_a}{S} \times \left( J_{sd}\,\mathbf{s}_a + \gamma\,S\,\mathbf{B}(t) + J_{dd}\sum_b \mathbf{S}_b + 2J_{\text{ani}}\left(\mathbf{S}_a \cdot \hat{\mathbf{z}}\right)\hat{\mathbf{z}} \right) \,, \tag{41}$$

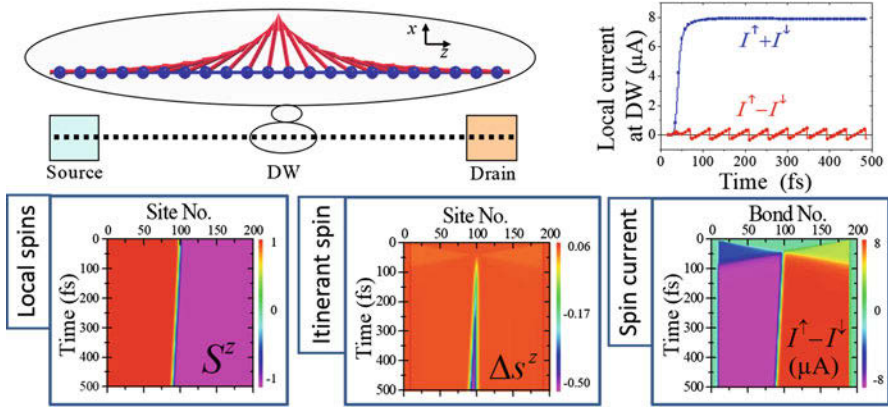
where $\mathbf{s}_a = \text{Tr}[\rho_{aa}\boldsymbol{\sigma}]/2$ is the instantaneous expectation value of the on-site itinerant spin and the electron density matrix is propagated according to a Liouville equation, including a "bias-maintaining" empirical damping term $\Gamma_b$ at the chain


**Fig. 10** Top panels: a schematic of the DW-containing 1D conducting chain with open boundary conditions and the dynamic establishment of steady-state regime (showing charge and spin bond currents at the DW center). Bottom panels: 2D contour plots (as function of time and position along the chain) of spin-related observables as indicated. (Figure adapted from Stamenova and Sanvito 2010)

boundaries, which effectively generates a source and a drain, as illustrated in Fig. 10. Note that the STT component of this equation, corresponding to the STT presented in Eq. (36), is the first term in the brackets, STT = $J_{sd} \mathbf{S}_a \times \mathbf{s}_a/S$. For a suitable choice of $\Gamma_b$, a steady current-carrying state is established after a short transient time of a few tens of fs (Fig. 10b). It is found that during the steady state, the DM in the chain is moving at a practically constant velocity. This is only gently perturbed by the emission of spin waves (see Fig. 11). Under the steady current flow, the DW is developing some deformation, and two comparative cases have been examined – a very narrow and a very wide wall (on the length scale of the chain). Although the two walls develop similar velocities for a given current flow (the wider DW being somewhat faster) that scale linearly with the current, they undergo different levels of deformations (Fig. 11). This can be interpreted as a result of the different balance of current-induced torque contributions: the adiabatic STT (ASTT) and nonadiabatic torque (NAT). The ASTT is due to the adiabatic alignment of the itinerant electron spin to the local spin texture, and the NAT is a result of the lag in that spin alignment, which is expected to be more pronounced in the case of abrupt spin texture variation (e.g., a sharp DW). These are closely related to the driving mechanisms for the in-plane STT and the out-of-plane field-like torque in the MTJs (Brataas et al. 2012).

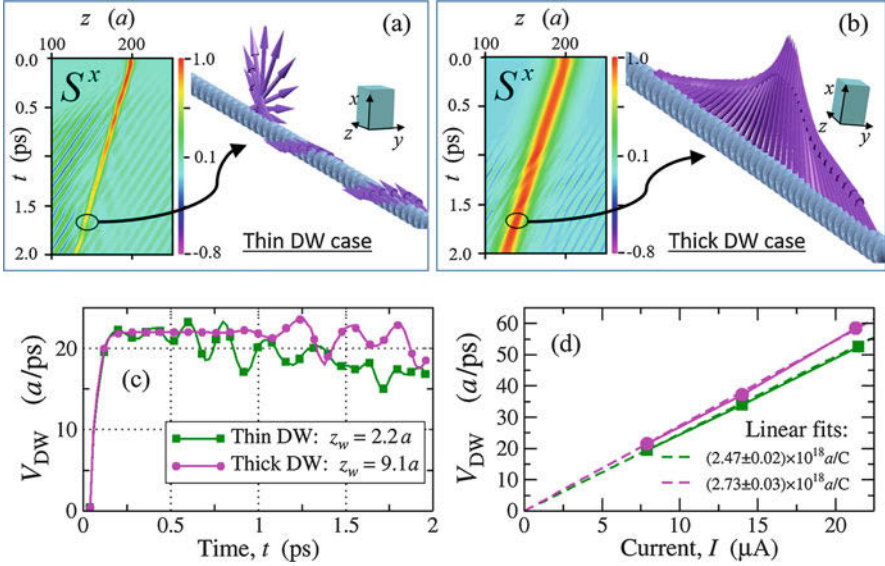
Alternatively, the current-driven DW motion can be studied by micromagnetic simulations based on the extended LLG equation incorporating STT terms, which have been shown to arise from the $s - d$ interaction by Zhang and Li (2004) in a diffusive semiclassical spin-transport model. An analogous to Eq. (41) fully classical atom-resolved LLG-like equation of motion, including the current-induced torques on the spin texture derived by Zhang and Li (2004), can be considered in the form:


**Fig. 11** (**a,b**) Current-driven evolution of the $x$-components of the local spins is shown in contour plots and a snapshot of the domain wall (DW) spin structure at a late stage of the simulation, comparing two DWs with different thicknesses. (**c**) DW velocities of the two different walls are presented as function of time from the beginning of the simulation, and it can be seen that they are nearly constant once steady state is established after about 0.2 ps. (**d**) The average velocity of the two DWs as a function of the average steady-state current. Here $a$ is the lattice constant of the one-dimensional chain of atoms, $z_w$ is the width of the DW and C is the SI unit Coulomb. (Figure adapted from Stamenova and Sanvito 2010)

$$\dot{\mathbf{S}}_a = \mathbf{S}_a \times \left[ \frac{J_{dd}}{S} \sum_b \mathbf{S}_b + \frac{2J_{\text{ani}}}{S} \left( \mathbf{S}_a \cdot \hat{\mathbf{z}} \right) \hat{\mathbf{z}} + \alpha \, \partial_t \mathbf{S}_a - b_J \, \mathbf{S}_a \times \partial_z \mathbf{S}_a - c_J \, \partial_z \mathbf{S}_a \right],$$

(42)

where $b_J$ is the strength of the ASTT in units of velocity, $c_J$ is the strength of the NAT, and $\alpha$ is the Gilbert damping parameter. Restricting the degrees of freedom within the wall to two time-dependent parameters: the center and the width of the wall, Zhang and Li (2004) show that the ASTT drives a DW widening deformation and that the NAT is responsible for the terminal velocity. The atomistic simulations using Eq. (42) by Stamenova and Sanvito (2010) agree qualitatively in general, for example, the wall does not start moving with the NAT alone. Relaxing the DW shape rigidity condition however reveals additional features of the current-driven DW evolution. For instance, the NAT tends to give rise to the out-of-plane DW deformation and DW precession, similarly to what has been found by the quantum-classical steady-state simulations, comparing the thick and the thin walls (Fig. 11). Atomistic spin dynamics combined with first principles STTs from NEGF+DFT calculations have also recently been used to study the switching process of a free layer in an MTJ and investigate the effects of heating on the switching times (Ellis et al. 2017).

# 9 Conclusions

The NEGF+DFT formalism is a powerful tool to extract spin-dependent transport properties of nanoscale devices. It allows for quantitative and predictive calculations of spin currents, magnetoresistance, and spin-transfer torque, and in particular to evaluate the dependence of the device properties on atomic-scale features in the structure, which are often not directly accessible in experiment. As such it is now a well-established state-of-the-art tool for nanoscale device design. Despite the success so far, methodological developments are ongoing, in particular for the inclusion of strong correlation effects, of spin-phonon and spin-photon interactions, and for the time-dependent dynamic evolution.

## Abstract

The micromagnetic model has proven to be a reliable tool for the description of a variety of magnetic materials and systems. Classical micromagnetics describes the equilibrium and dynamics of magnetization configuration under the influence of magnetic fields and other material-specific energy contributions such as the exchange interaction. With the rise of spintronics, the interaction of

spin-polarized currents with the magnetization has gained a lot of interest. This chapter aims to give an overview over extensions of the micromagnetic model for the description of spintronics effects.

# 1 Introduction

The micromagnetic model was originally developed as an analytical tool for the description of domain walls in ferromagnetic material (Brown 1963). In contrast to atomistic or ab initio descriptions of magnetic systems, it follows a mean-field-like approach where the discrete magnetic moments are approximated by a continuous magnetization field $\mathbf{M}(\mathbf{x})$. However, in contrast to Maxwell's equations, the magnetization field in micromagnetics is assumed to have a constant modulus $|\mathbf{M}| = M_s \mathbf{m}$ with $\mathbf{m}$ being a unit vector field and $M_s$ being a material constant called the saturation magnetization. This fundamental assumption is based on the fact that the strong exchange interaction in ferromagnetic materials results in a near-parallel orientation of neighboring spins. Assuming a constant spin density thus yields a saturated field when averaging over small spin ensembles. In contrast to the macroscopic description of the magnetization in Maxwell's equations where the magnetization is averaged over multiple domains, the magnetization field in micro-magnetics spatially resolves not only domains but also the structure of domain walls.

Besides extrinsic energy contributions like the Zeeman energy due to external fields, the micromagnetic model accounts for a number of intrinsic energy contributions like the exchange energy which is the root of ferromagnetism. Since some of the intrinsic energy contributions have a quantum mechanical origin, micromagnetism is often referred to as semiclassical theory.

The accurate description of magnetic domains makes the micromagnetic theory a valuable tool for the investigation of magnetic hysteresis. Since the response time of a magnetic system is much shorter than the field evolution in typical hard-magnetic applications, hysteretic properties are usually computed by direct energy minimization; see, e.g., Fischbacher et al. (2017). For other purposes, the magnetization dynamics need to be resolved, e.g., in order to investigate the switching times in storage applications; see, e.g., Lee and Dieny (2006). The micromagnetic model, both static and dynamic, is defined in terms of partial differential equations and can be solved analytically only for simple limiting cases. With the rise of high-performance computing, the numerical solution of the micro-magnetic model has become an invaluable tool for the investigation of magnetic systems. However, classical micromagnetics as introduced in Brown (1963) does not describe the interaction of spin-polarized currents. These interactions that are usually summarized as spintronics effects have recently gained a lot of interest in the magnetic community.

This chapter is supposed to give an overview over existing extensions to the micromagnetic model for the description of spintronics effects. It summarizes the review article (Abert 2019) which the interested reader is referred to for a more detailed introduction to micromagnetics, spintronics, and numerical methods.

## 2 Energetics of a Ferromagnet

The total free energy of a system with respect to its magnetization is key to static and dynamic micromagnetics. Depending on the material of the magnetic system, the total energy is composed of multiple contributions. According to classical electrodynamics, every magnetic body $\Omega_m$ has a Zeeman energy given by

$$E^{\text{zee}} = -\mu_0 \int_{\Omega_m} M_s \mathbf{m} \cdot \mathbf{H}^{\text{zee}} \, d\mathbf{x} \tag{1}$$

with $\mathbf{H}^{\text{zee}}$ being the Zeeman field and $\mu_0$ being the vacuum permeability. An essential energy contribution for micromagnetics is the exchange energy which is responsible for ferromagnetism. As mentioned in the preceding section, the micromagnetic assumption of a saturated magnetization field is valid only for systems with strong local ordering forces. This requirement is met by the exchange interaction that penalizes nonparallel alignment of neighboring spins. The exchange energy can be derived as the continuum limit of a Heisenberg Hamiltonian $H = \mathbf{s}_1 \cdot \mathbf{s}_2$ assuming a symmetric lattice structure and is given by

$$E^{\text{ex}} = \int_{\Omega_m} A \sum_{i,j} \left( \frac{\partial m_i}{\partial x_j} \right)^2 d\mathbf{x} = \int_{\Omega_m} A(\nabla \mathbf{m})^2 \, d\mathbf{x} \tag{2}$$

where $A$ is called the exchange constant and $(\nabla \mathbf{m})^2 = \sum_{i,j} (\partial m_i / \partial x_j)^2$ is to be understood as a Frobenius inner product. Although usually derived from the Heisenberg model, this energy expression accurately describes the exchange energy in various materials including band magnets; see Hubert and Schäfer (1998).

Another important intrinsic energy contribution is the demagnetization energy, also referred to as magnetostatic energy. It describes the energy of the magnetization in its self-generated dipolar field. According to classical electrodynamics, the demagnetization field can be expressed as negative gradient of a scalar potential $\mathbf{H}^{\text{dem}} = -\nabla u$ with the potential $u$ being the solution to the partial differential equation

$$\nabla \cdot (-\nabla u + \mathbf{M}) = 0 \quad \text{in} \quad \mathbb{R}^3 \tag{3}$$

with open boundary conditions

$$u(\mathbf{x}) = \mathcal{O}(1/|\mathbf{x}|) \text{ for } |\mathbf{x}| \to \infty, \tag{4}$$

i.e., the potential decays to zero at infinite distance from the magnetic region $\Omega_m$. The solution to this problem can be stated in terms of the integral equation

$$u(\mathbf{x}) = -\frac{1}{4\pi} \left[ \int_{\Omega_m} \frac{\nabla' \cdot \mathbf{M}(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} \, d\mathbf{x}' - \int_{\partial \Omega_m} \frac{\mathbf{M}(\mathbf{x}') \cdot \mathbf{n}}{|\mathbf{x} - \mathbf{x}'|} \, d\mathbf{s}' \right], \tag{5}$$

see Jackson (1999). The energy connected to the demagnetization field is given by

$$E^{\text{dem}} = -\frac{\mu_0}{2} \int_{\Omega_t} \mathbf{M} \cdot \mathbf{H}^{\text{dem}} \, d\mathbf{x} \qquad (6)$$

where the factor $1/2$ accounts for the quadratic dependence of the energy on the magnetization $\mathbf{M}$.

Depending on the material, the magnetization preferably aligns to certain axes in a magnetic body called easy axes. This effect originates from anisotropic spin-orbit coupling either due to an anisotropic crystal structure or due to lattice deformation at material interfaces; see Hubert and Schäfer (1998). In the case of a single easy axis, this anisotropy energy is given by

$$E^{\text{aniu}} = -\int_{\Omega_m} [K_{u1}(\mathbf{m} \cdot \mathbf{e}_u)^2 + K_{u2}(\mathbf{m} \cdot \mathbf{e}_u)^4] \, d\mathbf{x} \qquad (7)$$

where $\mathbf{e}_u$ is a unit vector parallel to the easy axis and $K_{u1}$ and $K_{u2}$ are the scalar anisotropy constants. The expression for this uniaxial anisotropy is derived in a phenomenological fashion by considering all terms that comply with the twofold symmetry up to fourth order in $\mathbf{m}$ (Brown 1963). Materials with cubic lattice symmetry such as iron or nickel exhibit three easy axes $\mathbf{e}_i$ which are pairwise orthogonal $\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}$. Like for the uniaxial anisotropy, the expression for the cubic anisotropy energy is developed as series in magnetization components along the easy axes up to sixth order

$$E^{\text{anic}} = \int_{\Omega} [K_{c1}(m_1^2 m_2^2 + m_2^2 m_3^2 + m_3^2 m_1^2) + K_{c2} m_1^2 m_2^2 m_3^2] \, d\mathbf{x} \qquad (8)$$

where $m_i = \mathbf{e}_i \cdot \mathbf{m}$ is the projection of the magnetization $\mathbf{m}$ on the anisotropy axis $\mathbf{e}_i$. Only contributions compatible with the cubic symmetry are considered.

Both, Eqs. (7) and (8) hold for magnetic anisotropies in bulk material. If magnetic anisotropy is caused by lattice deformation at material interfaces, the energy depends on the magnetization configuration $\mathbf{m}$ at this interface only. The energy for such a surface anisotropy is obtained by similar expressions as (7) and (8). However, instead of integrating over the magnetic volume $\Omega_m$, the integration in this case has to be carried out over the respective interface $\partial \Omega_m$ only.

While the presented energy contributions form the basis for the description of various system, several additional energy contributions may be required for specific systems. Recently, antisymmetric exchange interaction has been extensively studied, since materials with antisymmetric exchange enable the formation of stable magnetic skyrmions (Bogdanov and Rößler 2001). Other energy contributions arise from the existence of eddy currents (see Torres et al. 2003 and Hrkac et al. 2005), Oersted fields (see Hertel 2001), or magnetostriction (see Fabian and Heider 1996 and Shu et al. 2004).

## 3 Static Micromagnetics

Static micromagnetics deals with the investigation of stable magnetization configurations. An important application area of this theory is the computation of hysteresis loops of permanent magnets (Schrefl et al. 1994). The prerequisite for a stable configuration is that it minimizes the energy while complying with the micromagnetic unit-sphere constraint

$$\min E(\mathbf{m}) \quad \text{subject to} \quad |\mathbf{m}(\mathbf{x})| = 1. \tag{9}$$

Using a Lagrange-multiplier ansatz, this problem can be solved by minimizing

$$E_\lambda(\mathbf{m}, \lambda) = E(\mathbf{m}) + \int_{\Omega_m} \lambda(\mathbf{x})\big(|\mathbf{m}|^2 - 1\big)\, \mathrm{d}\mathbf{x}, \tag{10}$$

with respect to the magnetization $\mathbf{m}$ and the Lagrange-multiplier field $\lambda$. Variation of the magnetization yields

$$\delta E_\lambda(\{\mathbf{m}, \lambda\}, \mathbf{v}_m) == \int_{\Omega_m} \frac{\delta E}{\delta \mathbf{m}} \cdot \mathbf{v}_m\, \mathrm{d}\mathbf{x} + \int_{\partial\Omega_m} \mathbf{B}(\mathbf{m}) \cdot \mathbf{v}_m\, \mathrm{d}\mathbf{s} + 2\int_{\Omega_m} \lambda \mathbf{m} \cdot \mathbf{v}_m\, \mathrm{d}\mathbf{x}. \tag{11}$$

where the boundary condition $\mathbf{B}$ depends on the choice of energy contributions (Abert 2019). Since this condition has to hold for arbitrary $\mathbf{v}_m$, the minimum-energy magnetization has to fulfill $\delta E / \delta \mathbf{m} = -2\lambda \mathbf{m}$ which is equivalent to Brown's condition

$$\frac{\delta E}{\delta \mathbf{m}} \times \mathbf{m} = 0; \tag{12}$$

see Brown (1963).

Testing (11) with functions that are defined on the boundary only $\mathbf{v}(\Omega_m \setminus \partial\Omega_m) = 0$ yields the additional boundary condition

$$\mathbf{B}(\mathbf{m}) = 0. \tag{13}$$

Variation of (10) with respect to the Lagrange-multiplier field $\lambda$ accounts for the micromagnetic unit-sphere constraint.

Depending on the energy contribution, the variational derivative $\delta E / \delta \mathbf{m}$ gives rise to different boundary conditions $\mathbf{B}$. The derivative of the Zeeman energy is given by

$$\frac{\delta E^{\text{zee}}}{\delta \mathbf{m}} = -\mu_0 M_s \mathbf{H}^{\text{zee}} \tag{14}$$

while no boundary condition **B** is introduced. The derivative of the exchange energy is given by

$$\frac{\delta E^{\text{ex}}}{\delta \mathbf{m}} = -2 \boldsymbol{\nabla} \cdot (A \boldsymbol{\nabla} \mathbf{m}) \tag{15}$$

with the additional Neumann boundary condition $\mathbf{B} = 2A \partial \mathbf{m}/\partial \mathbf{n} = 0$ that arises through integration by parts which is necessary to transform the variational differential to the variational derivative. Similar to the Zeeman energy, the derivative of the demagnetization energy reads

$$\frac{\delta E^{\text{dem}}}{\delta \mathbf{m}} = -\mu_0 M_s \mathbf{H}^{\text{dem}} \tag{16}$$

with no additional boundary condition. The derivative of the uniaxial and cubic anisotropy is defined by

$$\frac{\delta E^{\text{aniu}}}{\delta \mathbf{m}} = -2K_{\text{u}1} \mathbf{e}_u (\mathbf{e}_u \cdot \mathbf{m}) - 4K_{\text{u}2} \mathbf{e}_u (\mathbf{e}_u \cdot \mathbf{m})^3 \tag{17}$$

and

$$\frac{\delta E^{\text{anic}}}{\delta \mathbf{m}} = 2K_{\text{c}1} \begin{pmatrix} m_1 m_2^2 + m_1 m_3^2 \\ m_2 m_3^2 + m_2 m_1^2 \\ m_3 m_1^2 + m_3 m_2^2 \end{pmatrix} + 2K_{\text{c}2} \begin{pmatrix} m_1 m_2^2 m_3^2 \\ m_1^2 m_2 m_3^2 \\ m_1^2 m_2^2 m_3 \end{pmatrix} \tag{18}$$

respectively.

## 4 Dynamic Micromagnetics

The micromagnetic theory provides models not only for the investigation of stable magnetization configurations but also for the investigation of time- and space-resolved magnetization dynamics. The central equation for the magnetization dynamics is the Landau-Lifshitz equation originally introduced in Landau and Lifshitz (1935) and reformulated as Landau-Lifshitz-Gilbert equation in Gilbert (1955)

$$\partial_t \mathbf{m} = -\gamma \mathbf{m} \times \mathbf{H}^{\text{eff}} + \alpha \mathbf{m} \times \partial_t \mathbf{m} \tag{19}$$

where $\gamma = \mu_0 \gamma_e \approx 2.2128 \times 10^5$ m/As is the reduced gyromagnetic ratio and $\alpha > 0$ is the dimensionless Gilbert damping constant. The so-called effective field $\mathbf{H}^{\text{eff}}$ accounts for all energy contributions of the magnetic system and reads

$$\mathbf{H}^{\text{eff}} = -\frac{1}{\mu_0 M_s} \frac{\delta E}{\delta \mathbf{m}}. \tag{20}$$
**Fig. 1** Magnetization dynamics as described by the Landau-Lifshitz-Gilbert (LLG) equation. (**a**) Precessional term. (**b**) Dissipative term. (**c**) Combined motion with precessional and damping contribution

With the choice of an appropriate Lagrangian, the LLG can be derived by variational calculus (see Wegrowe and Ciornei 2012), which explains the variational definition of the effective field. As for static micromagnetics, depending on the considered energy contributions, an addition boundary condition $\mathbf{B} = 0$ applies (see Sect. 3).

The semi-implicit formulation (19) introduced by Gilbert can be transformed into an explicit form by inserting the complete right-hand side of (19) into $\partial_t \mathbf{m}$ on the right-hand side of (19) and applying basic vector algebra

$$\partial_t \mathbf{m} = -\frac{\gamma}{1 + \alpha^2} \mathbf{m} \times \mathbf{H}^{\text{eff}} - \frac{\alpha\gamma}{1 + \alpha^2} \mathbf{m} \times (\mathbf{m} \times \mathbf{H}^{\text{eff}}). \tag{21}$$

This form is similar to the original formulation of the LLG proposed in Landau and Lifshitz (1935). Both in the implicit Gilbert form (19) and in the explicit form (21), the right-hand side of the LLG is composed of two terms. The first one is responsible for a precessional motion, and the second one, called damping term, accounts for energy dissipation due to eddy currents, lattice excitations, and other mechanisms (see Fig. 1).

## 5    Spintronics in Micromagnetics

The term spintronics was coined in the 1980s with the discovery of the giant magnetoresistance (GMR) by Fert and Grünberg and denotes spin-dependent interactions of conducting electrons with solid-state devices. In contrast to electronics which exploits the electron's charge, spintronics adds extra degrees of freedom and is believed to enable a variety of novel devices particularly in the area of storage and sensing.

In the continuous micromagnetic theory, the spin polarization of the conducting electrons is described by a vector field $\mathbf{p}$ that is bidirectionally coupled to both the magnetization $\mathbf{m}$ and the charge current $\mathbf{j}_e$. When passing magnetized regions, the conducting electrons gain polarization depending on the charge current and magnetization configuration. Reversely, the spin polarization affects the charge current by introducing a magnetization-dependent resistance, e.g., GMR. Moreover,

a spin-polarized current is able to manipulate a magnetization configuration by exerting a torque. Depending on the origin of the spin polarization, this torque is either referred to as spin-transfer torque or spin-orbit torque.

## 5.1    Spin-Transfer Torque in Multilayers

A possible device that generates and exploits spin-polarized currents is a magnetic multilayer. Depending on the magnetization configuration in the different magnetic layers, scattering processes produce spin-polarized currents which results in spin-transfer torque. A typical spin-transfer torque device has two magnetic layers, separated either with a nonmagnetic conducting layer or a tunnel junction and contacted via nonmagnetic leads. Figure 2 illustrates the dominating scattering processes in such a device for parallel and antiparallel magnetization configurations.

Following the electron flow, the first scattering process for any magnetization configuration occurs at the first nonmagnetic-magnetic interface where the minority electrons are scattered with a higher probability than the majority electrons. Consequently the electrons entering the second magnetic layer carry the polarization of the first magnetic layer FM1, i.e., FM1 acts as a spin filter. For the antiparallel magnetization configuration, this means that the majority of electrons entering FM2 are polarized antiparallel to the FM2 magnetization although some of these electrons are scattered at the interface of FM2 (see Fig. 2a). As a result, spin torque occurs in FM2 and leads to magnetization switching if a critical current is exceeded. The polarized electrons scattered at the FM2 interface reenter FM1 and stabilize its magnetization.

For the parallel configuration, the situation is depicted in Fig. 2b. As for the antiparallel configuration, FM1 acts as a spin filter which leads to a stabilization of FM2. The minority electrons scattered at the FM2 interface reenter FM1 and exert a torque that can switch the FM1 magnetization if a critical current is exceeded.

This torque mechanism was first predicted in Slonczewski (1996), Berkov et al. (1993), and Waintal et al. (2000). Possible applications for this effect include

**Fig. 2** Dominating scattering processes in multilayer structures subject to a perpendicular charge current. FM1 and FM2 are ferromagnetic layers, while NM are nonmagnetic conducting layers. (**a**) FM2 is destabilized by polarized electrons coming from FM1. FM1 is stabilized by polarized electronics scattered back from FM2. (**b**) FM2 is stabilized by polarized electrons coming from FM1. FM1 is destabilized by polarized electrons scattered back from FM2

spin-transfer torque magnetic random-access memory (STT MRAM) as described in Huai (2008) and Worledge et al. (2011) and spin-torque oscillators (STO) as described in Houssameddine et al. (2007) and Kim (2012). A comprehensive theoretical overview over spin-transfer torque is given in Ralph and Stiles (2008).

In the context of micromagnetics, the model introduced in Slonczewski (2002) is widely used for the description of spin-transfer torque. The original model applies to a macrospin description of the magnetic layers, i.e., every layer is described by a single spin. One of the two magnetic layers is assumed to have a fixed magnetization denoted as $\mathbf{p}$ and is called polarizing layer since it acts as a spin polarizer. The other layer is referred to as free layer, and its magnetization $\mathbf{m}$ is subject to the spin torque generated by the polarizing layer. According to the Slonczewski model, the motion of the free-layer magnetization $\mathbf{m}$ is described by an extended LLG

$$\partial_t \mathbf{m} = -\gamma \mathbf{m} \times \mathbf{H}^{\text{eff}} + \alpha \mathbf{m} \times \partial_t \mathbf{m} + \mathbf{T} \tag{22}$$

with the torque $\mathbf{T} = \mathbf{T}_{\text{damp}} + \mathbf{T}_{\text{field}}$ being the sum of a so-called damping-like torque $\mathbf{T}_{\text{damp}}$ and a field-like torque $\mathbf{T}_{\text{field}}$. The model of Slonczewski defines these contributions as

$$\mathbf{T}_{\text{damp}} = \eta_{\text{damp}}(\vartheta) \frac{j_e \gamma \hbar}{2e\mu_0 M_s} \mathbf{m} \times (\mathbf{m} \times \mathbf{p}) \tag{23}$$

$$\mathbf{T}_{\text{field}} = \eta_{\text{field}}(\vartheta) \frac{j_e \gamma \hbar}{2e\mu_0 M_s} \mathbf{m} \times \mathbf{p} \tag{24}$$

where $\eta_{\text{damp}}$ and $\eta_{\text{field}}$ are dimensionless functions describing the angular dependence of the spin-torque efficiency with $\vartheta$ being the angle between the polarization $\mathbf{p}$ and the free-layer magnetization $\mathbf{m}$.

The field-like torque (24) is similar to the torque generated by an external field. It causes a damped precessional motion of the free-layer magnetization with $\alpha$ being the scaling of the damping. The damping-like torque also causes a damped precessional motion. However, in contrast to the field-like torque, the precessional motion scales with $\alpha$, whereas the dissipative motion is independent from $\alpha$. This fact becomes apparent when considering a system with vanishing damping constant $\alpha = 0$. In this case the extended LLG reads

$$\partial_t \mathbf{m} = -\gamma \mathbf{m} \times \left[ \mathbf{H}^{\text{eff}} - \frac{j_e \hbar}{2e\mu_0 M_s} \eta_{\text{field}}\, \mathbf{p} \right] - \gamma \mathbf{m} \times \left( \mathbf{m} \times \left[ \frac{j_e \hbar}{2e\mu_0 M_s} \eta_{\text{damp}}\, \mathbf{p} \right] \right). \tag{25}$$

For this limiting case, the precessional motion is exclusively generated by the field-like torque, while the damping-like motion is exclusively generated by the damping-like torque, which shows the unique features of spin-transfer torque.

In the original work by Slonczewski, the angular dependence $\eta(\vartheta)$ was derived for a symmetric device, namely, a device with identical polarizing layer and free layer, and reads

$$\eta(\vartheta) = \frac{P\Gamma}{(\Gamma + 1) + (\Gamma - 1)\cos(\vartheta)} \tag{26}$$

where the dimensionless $P$ is a measure for the polarization of the electrons and $\Gamma$ is a dimensionless parameters depending on geometry and material composition of the complete device. Expression (26) is used for the damping-like torque as well as for the field-like torque but requires individual parameters $P$ and $\Gamma$ for the different torques. For the accurate description of nonsymmetric devices, a generalized model was introduced in Xiao et al. (2005) which reads

$$\eta(\vartheta) = \frac{q^+}{A + B\cos(\vartheta)} + \frac{q^-}{A - B\cos(\vartheta)}. \tag{27}$$

As for the symmetric case, the expression is used for both the damping-like torque and the field-like torque with a different set of dimensionless parameters $q^+$, $q^-$, $A$, and $B$ that depend on geometry and materials in a nontrivial fashion.

While the polarizing layer in the model of Slonczewski is generally considered to have a fixed magnetization, the model can also be used to describe the bidirectional coupling of two magnetic layers. This can be achieved by a second set of model parameters and considering a second torque term with polarizing layer and free layer interchanged (see, e.g., Rowlands and Krivorotov 2012).

Since the original model of Slonczewski uses the macrospin approach, another generalization is required in order to account for spatially varying magnetization configurations. Magnetic layers with small sizes below the single-domain limit are dominated by the exchange coupling and hence are almost homogeneously magnetized. While the macrospin approach is a valid assumption for these layers, it fails for larger layers that exhibit magnetic domains and hence cannot be represented by a single spin. For lateral magnetization inhomogeneities, the macrospin approach can be generalized as depicted in Fig. 3. Instead of describing the magnetization in both magnetic layers with a single spin, they are described with fields as usual in micromagnetics. The Slonczewski model is then applied pointwise to nearest sites across the interface. Perpendicular inhomogeneities are handled by considering the spin-transfer to be a pure surface effect. That means that both the

**Fig. 3** Application of the Slonczewski model for laterally varying magnetization configurations. The model is applied pointwise by considering the angle $\vartheta$ between the projected magnetization **p** of the polarizing layer FM1 and the magnetization **m** in the free layer

generation of spin polarization and the action of the spin torque are restricted to the magnetic-nonmagnetic interfaces. While this approach provides reasonable results for a number of applications, it neglect various diffusion processes which leads to inaccuracies. A comprehensive overview over Slonczewski-like spin-torque models is given in Berkov and Miltat (2008).

## 5.2    Spin-Transfer Torque in Continuous Media

The mechanism of spin-transfer torque is not restricted to magnetic multilayer structures but also appears in continuous magnetization configurations. In this case, magnetic domains take the place of distinct magnetic layers in the generation of spin-transfer torque. This process is depicted in a simplified fashion in Fig. 4. The electrons passing a magnetic domain are polarized parallel to its magnetization. When entering a region of magnetization gradient, namely, a domain wall, they carry this polarization in regions of nonparallel magnetization which leads to a spin torque. This process facilitates the current driven motion of domain walls in the direction of the electron flow. In contrast to field-driven domain wall motion, this process allows in theory for the coherent motion of complete domain structures. This characteristic is aimed to be exploited in the magnetic racetrack memory that was proposed in Parkin et al. (2008).

The model of Slonczewski is obviously not suited for the description of this spin-torque effect since it requires the existence of two distinct magnetization layers. For the description of spin torque in continuous magnetization configurations, a micromagnetic model was proposed in Zhang and Li (2004). This Zhang-Li model introduces a torque term given by

$$\mathbf{T} = -b\,\mathbf{m} \times [\mathbf{m} \times (\mathbf{j}_{\mathrm{e}} \cdot \nabla)\mathbf{m}] - b\xi\mathbf{m} \times (\mathbf{j}_{\mathrm{e}} \cdot \nabla)\mathbf{m} \qquad (28)$$

**Fig. 4** Spin-torque mechanism in a magnetic domain wall according to the model of Zhang and Li. The polarization of the magnetization is carried by the conducting electrons in their direction of motion. By neglecting diffusion, the Zhang-Li models consider this spin transport only in a local sense, i.e., depending on the local gradient of the magnetization. While the top row illustrates an electron flow from the left to the right, the bottom row illustrates the inverse direction. The magnetization is depicted by desaturated spins

where the dimensionless $\xi$ is called the degree of nonadiabacity and $b$ is defined as

$$b = \frac{\beta \mu_{\mathrm{B}}}{e M_{\mathrm{s}} (1 + \xi^2)} \tag{29}$$

with $\beta$ being a dimensionless polarization rate, $\mu_{\mathrm{B}}$ being the Bohr magneton, and $e$ being the elementary charge.

The Zhang-Li model describes spin-transfer torque purely in terms of local magnetization gradients, hence neglecting any diffusion processes which would lead to nonlocal effects. While this assumption is reasonable for materials with small characteristic diffusion lengths, it leads to inaccurate results for other materials, especially in the case of strongly inhomogeneous magnetization configurations. Moreover, the Zhang-Li model is not able to describe the nonlocal effect of spin torque in multilayers.

## 5.3    Spin-Diffusion

Neither the model of Slonczewski introduced in Sect. 5.1 nor the model of Zhang and Li introduced in Sect. 5.2 provide a comprehensive description of spin torque. Both models are restricted to certain material systems, and both models neglect diffusion effects to a certain extent. A more general spin-torque model is the three-dimensional generalization of the spin-diffusion model introduced in Zhang et al. (2002). In the spin-diffusion model, the polarization of the charge current is described by the so-called spin accumulation $\mathbf{s}$. The spin accumulation describes the deviation of a charge current's spin polarization from the equilibrium polarization at vanishing current. In nonmagnetic materials, the spin accumulation $\mathbf{s}$ equals the polarization $\mathbf{p}$. However, in magnetic materials, conducting electrons may contribute to the total magnetization and hence have polarization $\mathbf{p}^0$ even at vanishing current $\mathbf{j}_{\mathrm{e}} = 0$. The spin accumulation is then defined as $\mathbf{s} = \mathbf{p} - \mathbf{p}^0$.

Since the equilibrium spin polarization does not induce any torque on the magnetization, the spin torque in the spin-diffusion model can be defined in terms of the spin accumulation and reads

$$\mathbf{T} = -\frac{J}{\hbar M_{\mathrm{s}}} \mathbf{m} \times \mathbf{s} \tag{30}$$

where $J$ denotes the coupling strength of the spin accumulation $\mathbf{s}$ and the magnetization $\mathbf{m}$. The spin accumulation itself is subject to the equation of motion

$$\partial_t \mathbf{s} = -\boldsymbol{\nabla} \cdot \tilde{\mathbf{j}}_{\mathrm{s}} - \frac{\mathbf{s}}{\tau_{\mathrm{sf}}} - J \frac{\mathbf{s} \times \mathbf{m}}{\hbar} \tag{31}$$

where $\tau_{\mathrm{sf}}$ is a material constant and denotes the spin-flip relaxation time. Moreover, the spin-diffusion model defines a matrix-valued spin current $\tilde{\mathbf{j}}_{\mathrm{s}}$ and a vector-valued charge current $\mathbf{j}_{\mathrm{e}}$ as

$$\tilde{\mathbf{j}}_s = 2C_0\beta\frac{\mu_B}{e}\mathbf{m}\otimes\nabla u - 2D_0\nabla\mathbf{s} \tag{32}$$

$$\mathbf{j}_e = -2C_0\nabla u + 2D_0\beta'\frac{e}{\mu_B}(\nabla\mathbf{s})^T\mathbf{m} \tag{33}$$

where $u$ is the electric potential, $\mu_B$ is the Bohr magneton, and $e$ is the elementary charge. The remaining variables are the diffusion constant $D_0$, the dimensionless polarization parameter $\beta$ that is a measure for the polarization properties of magnetic materials, and $C_0$ which is connected to the electric conductivity $\sigma$ by the relation $\sigma = 2C_0$. It is important to note, that the spin accumulation is usually not only solved in the magnetic region $\Omega_m$ like the LLG, but in the complete device region $\Omega$ which might include nonmagnetic regions. That said, all material parameters might vary spatially and are hence described by scalar fields rather than constants.

In order to compute the spin accumulation, the spin current needs to be computed according to (32). However, the distribution of the electric potential $u$ is usually not known for a given system, and hence the definition of the electric current $\mathbf{j}_e$ needs to be taken into account, too. If $\mathbf{j}_e$ is given, the spin current $\tilde{\mathbf{j}}_s$ can be determined by inserting (33) into (32) via the potential $u$ which yields

$$\tilde{\mathbf{j}}_s = -\frac{\beta\mu_B}{e}\mathbf{m}\otimes\mathbf{j}_e - 2D_0\left(\nabla\mathbf{s} - \beta\beta'\mathbf{m}\otimes\left[(\nabla\mathbf{s})^T\mathbf{m}\right]\right). \tag{34}$$

Inserting into (31) yields the dynamics of the spin accumulation. The resulting magnetization dynamics can be obtained by coupling the solution of (31) to the solution of the extended LLG (22).

The problem with this approach, however, is the different time scales of spin-accumulation dynamics and magnetization dynamics. In most systems the spin accumulation relaxes two orders of magnitude faster than the magnetization (see Zhang and Li 2004). In order to determine the magnetization dynamics, it is hence sufficient to consider the spin accumulation $\mathbf{s}$ to instantaneously relax on magnetization changes, i.e., $\partial_t\mathbf{s} = 0$, which simplifies (31) to

$$\nabla\cdot\tilde{\mathbf{j}}_s + \frac{\mathbf{s}}{\tau_{sf}} + J\frac{\mathbf{s}\times\mathbf{m}}{\hbar} = 0 \quad\text{in}\quad \Omega. \tag{35}$$

In this quasistatic approach, the spin accumulation is obtained by the solution of a linear partial differential equation of second order in $\mathbf{s}$. Typical solutions of $\mathbf{s}$ for magnetic multilayers as well as domain walls are depicted in Fig. 5. The treatment of $\mathbf{s}$ in this approach becomes similar to the treatment of effective-field contributions that exclusively depend on the magnetization rather than the time.

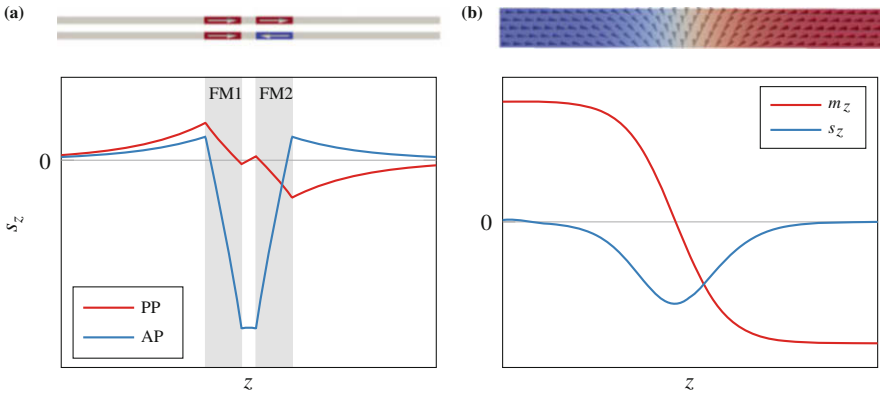
So far, the computation of the spin accumulation $\mathbf{s}$ requires the knowledge of the charge current $\mathbf{j}_e$. However, the charge current itself is subject to spintronics effects, e.g., the giant magnetoresistance (GMR) effect predicts that the resistance of a spintronics device depends on its magnetization configuration. In order to solve


**Fig. 5** Spatially resolved spin accumulation **s** for typical magnetization configurations. Only the dominated component in shown. (**a**) Spin accumulation $s_z$ for magnetic multilayer with parallel and antiparallel magnetization configuration, respectively. (**b**) Magnetic domain wall. The magnetization $m_z$ is plotted against the spin accumulation $s_z$

the spin-diffusion model in a self-consistent fashion, the source equation for the spin current (36) needs to be complemented by a source equation for the charge current $\mathbf{j}_e$. Since magnetic devices usually do not contain sources of charge currents, the source equation for $\mathbf{j}_e$ is naturally given by the continuity equation

$$\nabla \cdot \mathbf{j}_e = 0 \quad \text{in} \quad \Omega. \tag{36}$$

The source Eqs. (36) and (35) together with the current definitions (33) and (32) yield a coupled system of partial differential equations with the solution variables being both the spin accumulation **s** and the electric potential $u$. For this self-consistent approach, applying potentials and currents to a magnetic system is implemented by boundary conditions.

## 5.4   Boundary Conditions for the Spin-Diffusion Model

The self-consistent spin-diffusion model is a second-order partial-differential equation in both the electric potential $u$ and as the spin accumulation **s**. Hence, boundary conditions are required in order to retrieve a unique solution. A typical multilayer system for the application of the spin-diffusion model is depicted in Fig. 6. In order to account for an electric current flowing perpendicular through the layer system, appropriate boundary conditions for the electric potential $u$ have to be defined on the contact interfaces $\Gamma_1$ and $\Gamma_2$. While a Dirichlet boundary condition, e.g., $u = u_0$ on $\Gamma_1$, prescribes a defined potential on the respective contact interface, a Neumann condition can be applied in order to account for a defined current

**Fig. 6** Typical circular
magnetic multilayer
consisting of two magnetic
layers FM1 and FM2,
separated by a nonmagnetic
layer NM and sandwiched by
two nonmagnetic leads with
top and bottom contacts on
the surfaces $\Gamma_1$ and $\Gamma_2$

inflow. For instance, setting a constant current inflow $j_0$ on the second contact $\Gamma_2$ is
achieved by requiring

$$\mathbf{j}_e \cdot \mathbf{n} = -2 \left[ C_0 \nabla u + D_0 \beta' \frac{e}{\mu_B} \left[ (\nabla \mathbf{s})^T \mathbf{m} \right] \right] \cdot \mathbf{n} = j_0 \quad \text{on} \quad \Gamma_2 \qquad (37)$$

where $\mathbf{n}$ denotes the outward pointing normal to $\Gamma_2$. The boundary conditions for $u$
are completed by requiring vanishing current inflow on all boundaries that do not
act as contacts.

The spin accumulation $\mathbf{s}$, as the second solution variable, is solved with homoge-
neous Neumann boundary conditions on the complete boundary

$$\nabla \mathbf{s} \cdot \mathbf{n} = 0 \quad \text{on} \quad \partial \Omega. \qquad (38)$$

Inserting this condition into the definition of the spin current (34) and multiplying
with the boundary normal $\mathbf{n}$ yields

$$\tilde{\mathbf{j}}_s \cdot \mathbf{n} = \beta \frac{\mu_B}{e} \mathbf{m}(\mathbf{j}_e \cdot \mathbf{n}) \qquad (39)$$

which is equivalent to a noflux condition on the spin current $\tilde{\mathbf{j}}_s \cdot \mathbf{n} = 0$ if the charge
current $\mathbf{j}_e$ enters the system $\Omega$ in nonmagnetic regions only. This noflux condition
itself is assumed physically reasonable for all parts of the boundary with no charge-
current flux. For the contact region on the boundary $\Gamma_1$ and $\Gamma_2$, the noflux condition
is considered a reasonable assumption if the thickness of the nonmagnetic lead
regions exceeds the spin-diffusion length. If this is not the case, the homogeneous
Neumann condition should be replaced by the Robin condition

$$\nabla \mathbf{s} \cdot \mathbf{n} + \frac{1}{\sqrt{2D_0 \tau_{sf}}} \mathbf{s} = 0 \qquad (40)$$

which takes the exponential decay of $\mathbf{s}$ in nonmagnetic regions into account.

## 5.5    Extension to the Spin-Diffusion Model

The spin-diffusion model, introduced in the preceding sections, describes the generation of spin currents and spin accumulation due to polarizing magnetic materials. However, it was predicted in Dyakonov and Perel (1971) that spin currents can also be generated in nonmagnetic materials subject to charge currents due to spin-orbit coupling. This effect, referred to as spin-Hall effect, has its origin in the polarization-dependent deflection of the conducting electrons either due to material impurities as described in Hirsch (1999) or due to intrinsic asymmetries in the material as described in Murakami et al. (2003) and Sinova et al. (2004). While the spin-Hall effect enables the conversion from charge current into spin currents, the spin-orbit coupling also causes the inverse spin-Hall effect that enables the conversions of spin currents into charge currents. Both effects are schematically visualized in Fig. 7.

The integration of these effects with the spin-diffusion model is achieved by extending the original current definition (33) and (32) according to

$$j'_{e,i} = j_{e,i} + \varepsilon_{ijk}\theta_{SH}\frac{e}{\mu_B}j_{s,jk} \tag{41}$$

$$j'_{s,ij} = j_{s,ij} - \varepsilon_{ijk}\theta_{SH}\frac{\mu_B}{e}j_{e,k} \tag{42}$$

where index notation is used and $\varepsilon_{ijk}$ is the Levi-Civita tensor. Here, $\mathbf{j}_e$ and $\tilde{\mathbf{j}}_s$ are the original current definitions, and $\mathbf{j}'_e$ and $\tilde{\mathbf{j}}'_s$ are the current definitions including the spin-orbit couplings. Inserting $\mathbf{j}'_e$ and $\tilde{\mathbf{j}}'_s$ into the source Eqs. (36) and (35) instead of $\mathbf{j}_e$ and $\tilde{\mathbf{j}}_s$ then yields the spin-diffusion model including spin-orbit interactions. The dimensionless material constant $\theta_{SH}$ is called spin-Hall angle and describes the efficiency of the current conversion.

**Fig. 7** Spin current-charge current conversion due to spin-orbit torque-induced spin-dependent deflection processes. (**a**) Spin-Hall effect: A nonpolarized charge current $\mathbf{j}_e$ is converted to a pure spin current $\tilde{\mathbf{j}}_s$. (**b**) Inverse spin-Hall effect: A pure spin current $\tilde{\mathbf{j}}_s$ is converted to a charge current $\mathbf{j}_e$

Another extension of the spin-diffusion model is the addition of a spin-dephasing term, which was proposed in Akosa et al. (2015) and Haney et al. (2013). With this term the source equation for the spin current is extended to

$$\partial_t \mathbf{s} = -\boldsymbol{\nabla} \cdot \tilde{\mathbf{j}}_\mathrm{s} - \frac{\mathbf{s}}{\tau_\mathrm{sf}} - J \frac{\mathbf{s} \times \mathbf{m}}{\hbar} - \frac{\mathbf{m} \times (\mathbf{s} \times \mathbf{m})}{\tau_\phi} \tag{43}$$

where $\tau_\phi$ is the spin-dephasing time.

## 5.6    Valet-Fert Model

A related model to the spin-diffusion model introduced in the preceding sections is the Valet-Fert diffusion model introduced in Valet and Fert (1993). While the original model only accounts for magnetic multilayers with collinear magnetization, a three-dimensional generalization to noncollinear configurations is provided in Niimi et al. (2012). Like the spin-diffusion model from Sect. 5.3, the Valet-Fert model introduces a spin accumulation $\mathbf{s}$ and a spin current $\tilde{\mathbf{j}}_\mathrm{s}$. However, in contrast to the spin-diffusion model, both the spin accumulation and the spin current in magnetic materials are assumed to be collinear to the magnetization

$$\mathbf{s} = s\,\mathbf{m} \tag{44}$$

$$\tilde{\mathbf{j}}_\mathrm{s} = \mathbf{m} \otimes \mathbf{j}_\mathrm{s}. \tag{45}$$

According to (30), this definition of $\mathbf{s}$ would lead to vanishing spin torque. However, in contrast to the spin-diffusion model, the Valet-Fert model allows for discontinuities of the electric potential $u$ and the spin accumulation $\mathbf{s}$ across nonmagnetic-magnetic interfaces. These discontinuities are described by jump conditions that explicitly depend on distinct interface properties like the spin-mixing conductance $g_{\uparrow\downarrow}$. Hence, a noncollinear spin accumulation can occur at interfaces allowing for an interface-based description of spin torque. A detailed discussion of the generalized Valet-Fert model can be found in Niimi et al. (2012).

## 5.7    Connecting the Spintronics Models

The preceding sections discuss several models for the description of spintronics effects. While the Slonczewski model and the Zhang-Li model focus on spin torque in specific systems (see Sects. 5.1 and 5.2), other models like the spin-diffusion model introduced in Sect. 5.3 cover a variety of effects. In the following the connections of the different models will be discussed in detail.

### 5.7.1 Slonczewski Model

The Slonczewski model is a spin-torque model specifically designed for the description of magnetic multilayer structures. While the existence of a damping-like and a field-like torque is a rather generic assumption, the angular dependence $\eta$ introduced by Slonczewski is specific to the model. The angular dependence (26) proposed in the original paper is derived for symmetric structures with two similar magnetic layers, while the more general expression (27) removes this restriction. Since the model of Slonczewski is well established for the description of magnetic multilayers, a more general model like the spin-diffusion model is expected to reproduce its results. In order to compare both models, two simple multilayer systems with homogeneous magnetization configurations in the magnetic layers are investigated with the spin-diffusion model. The first system is a symmetric multilayer with two similar 3 nm thick magnetic layers, separated with a 2 nm metallic spacer, with typical material parameters as given in Abert et al. (2018). The spin accumulation **s** and the resulting torque for various angles between free-layer magnetization and polarizing-layer magnetization are computed with the spin-diffusion model. Projection of the total torque yields the angular dependence $\eta$ of the damping-like torque that is depicted in Fig. 8a. Along with the spin-diffusion results, Fig. 8a shows a fit to the original Slonczewski-formula (26) which exhibits perfect agreement.

The second system under consideration is an asymmetric multilayer which differs from the symmetric system by a higher polarizing layer thickness of 5 nm. As shown in Fig. 8b, the angular dependence of this asymmetric system is insufficiently fitted by the original Slonczewski formula but shows excellent agreement with the general expression (27). By reproducing the angular dependence of the spin torque, the spin-diffusion model proves to incorporate the Slonczewski model while

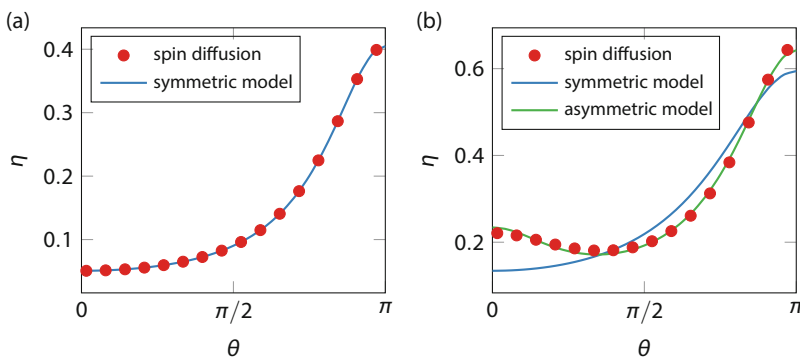

**Fig. 8** Spin-torque angular dependence $\eta$ as computed with the spin-diffusion model for homogeneous magnetization configurations in a magnetic multilayer with tilting angle $\vartheta$. The results are fitted with the Slonczewski formulas for symmetric and asymmetric structures, respectively. (**a**) Angular dependence $\eta$ for a symmetric multilayer with similar ferromagnetic layer thicknesses. (**b**) Angular dependence $\eta$ for an asymmetric multilayer

having a much broader application range including further spintronics effects. Moreover, the free parameters in the spin-diffusion model are material parameters with physical meaning in contrast to the free parameters of the Slonczewski-model that depend on the system as a whole in a nontrivial fashion.

### 5.7.2 Zhang-Li Model

Like the Slonczewski model, the Zhang-Li model discussed in Sect. 5.2 is a specialized model that describes the effect of spin torque in specific systems. It can be derived from the more general spin-diffusion model by neglecting diffusive effects, i.e., by setting $D_0 = 0$. Considering the definition of the spin current (34) and the source equation (35), this simplification yields

$$-\nabla \left( \frac{\beta \mu_B}{e} \mathbf{m} \otimes \mathbf{j}_e \right) + \frac{\mathbf{s}}{\tau_{sf}} + \frac{J}{\hbar} \mathbf{s} \times \mathbf{m} = \tag{46}$$

$$-\frac{\beta \mu_B}{e} (\mathbf{j}_e \cdot \nabla) \mathbf{m} + \frac{\mathbf{s}}{\tau_{sf}} - \frac{J}{\hbar} \mathbf{m} \times \mathbf{s} = 0. \tag{47}$$

Multiplication with $\mathbf{m}$ and $\mathbf{m} \times \mathbf{m}$, respectively, and inserting via $\mathbf{m} \times (\mathbf{m} \times \mathbf{s})$ result in the torque

$$\mathbf{T} = -\frac{J}{\hbar M_s} \mathbf{m} \times \mathbf{s} \tag{48}$$

$$= \frac{\beta \mu_B}{e M_s} \frac{1}{1 + \left( \frac{\hbar}{J \tau_{sf}} \right)^2} \left( \mathbf{m} \times [\mathbf{m} \times (\mathbf{j}_e \cdot \nabla) \mathbf{m}] + \frac{\hbar}{J \tau_{sf}} \mathbf{m} \times (\mathbf{j}_e \cdot \nabla) \mathbf{m} \right) \tag{49}$$

which exactly reproduces the spin torque of the Zhang-Li model (28) with the degree of nonadiabacity being defined as

$$\xi = \frac{\hbar}{J \tau_{sf}}. \tag{50}$$

While the calculation of the spin torque requires the solution of a linear system in the case of the spin-diffusion model, the same calculation reduces to the evaluation of expression (49) for the Zhang-Li model. However, this simplification restricts the application of the Zhang-Li model to systems with neglectable diffusive effects.

### 5.7.3 Valet-Fert Model

As discussed in Sect. 5.6, the Valet-Fert model is very similar to the spin-diffusion model introduced in Sect. 5.3. However, while the spin-diffusion model exclusively considers bulk material parameters for spin-transport properties, the Valet-Fert model introduces additional interface properties. These interface properties can be modelled in the spin-diffusion model by introducing thin effective interface layers. The respective material parameter mappings are discussed in detail in Abert (2019).

## 5.8 Beyond the Spin-Diffusion Model

The spin-diffusion model introduced in Sect. 5.3 accounts for various spintronics effects. However, it is certainly not a complete model for spintronics. While some spintronics effects like spin pumping, anomalous Hall effect, and inplane GMR are in principle compatible to the spin-diffusion model and could be introduced by suitable extensions, the main restriction of this model is its focus on diffusive transport. An important class of spintronics devices comprises magnetic tunnel junctions that are not well described by diffusive transport models. Various ab initio models for the description of magnetic tunnel junctions have been proposed; see, e.g., Mathon and Umerski (2001), Caffrey et al. (2011), and Butler et al. (2001). Integration of ab initio models with micromagnetics has been done (see Ellis et al. 2017) but is still a subject of ongoing research, partly due to the high computational complexity that is usually introduced by ab initio calculations.

## 6 Discretization

As a continuum theory, the micromagnetic model is defined in terms of partial differential equations. While analytical solutions to these equations can be derived for simple problem, the micromagnetic model is usually solved numerical. Suitable numerical algorithms have to account for various challenges that are particular to micromagnetic problems. Micromagnetic problems are multiscale problems. The demagnetization field is a global interaction which usually implies a computational complexity of $\mathcal{O}(n^2)$ when implemented naively. Various efficient methods for the demagnetization-field computation have been proposed in order to reduce the complexity to $\mathcal{O}(n \log n)$ or even $\mathcal{O}(n)$. The exchange field on the other hand is a short-range interaction that competes with the demagnetization field. While the computation of short-range fields is computationally cheap, the exchange field adds a high stiffness to the problem due to its second order in space. This high stiffness calls for stable time-integration schemes in order to solve the LLG. Another challenge of the micromagnetic model is its high degree of nonlinearity which leads to a complex energy landscape. This complexity leads to a high risk of missing local energy minima when computing hysteresis properties.

Among the existing discretization strategies, the most established methods used in micromagnetics are the finite-difference method and the finite-element method. A major difference of these approaches is the spatial discretization which is required to be a regular cuboid grid in the case of finite differences and may be an irregular, usually tetrahedral, mesh in the case of finite elements (see Fig. 9).

A detailed description of classical finite-difference micromagnetics is presented in Miltat and Donahue (2007). Several software packages implementing the finite-difference method were developed. One of the most popular packages is the open-source package OOMMF (see Donahue 1999), a multi-platform code running on central processing units (CPUs). Other CPU packages include the open-source
**Fig. 9** Spatial discretization of a sphere for different numerical methods. (**a**) Regular cuboid grid with 8217 cells as required for finite-difference micromagnetics. (**b**) Tetrahedral mesh with 7149 vertices as required for finite-element micromagnetics

software Fidimag (see Cortés-Ortuño et al. 2016) and the commercial software MicroMagus (see Berkov and Gorn 2007). A very basic finite-difference code written in Python was published in Abert et al. (2015).

The advent of multipurpose graphics processing units (GPGPUs) gave rise to a new class of simulation packages that take advantage of this highly parallel hardware. A very popular GPGPU package is MuMax3 (see Vansteenkiste et al. 2014). Alternatives are magnum.fd (see Selke et al. 2014) and the GPGPU extension to OOMMf (see Fu et al. 2016).

On overview over classical finite-element micromagnetics is given in Schrefl et al. (2007). Open-source finite-element packages include FinMag (see Bisotti et al. 2018) and Magpar (see Scholz 2010). Closed-source implementations include FEMME (see Suess and Schrefl 2018), FEELLGOOD (see Sturma et al. 2015), and magnum.fe (see Abert et al. 2013). GPGPU implementations include Tetramag (see Kakay et al. 2010) and Fastmag (see Chang et al. 2011).

Several of these simulation packages implement the spin-torque models of Slonczewski as well as of Zhang and Li. However, to the knowledge of the author, only the finite-element packages FEELLGOOD and magnum.fe implement the spin-diffusion model introduced in Sect. 5.3. A finite-difference implementation of this model, however, is described in García-Cervera and Wang (2007).

## 7    Conclusion

With the rise of high-performance computing, numerical micromagnetics has become an important tool for the development of magnetic devices. Micromagnetic simulations help to understand experimental measurements and guide the design of novel devices.

While classical micromagnetics relies on a well-approved theory that accurately describes numerous applications, the simulation of spintronics devices still poses challenges on the modelling procedure since various additional effects have to be considered. Simplified models like the spin-torque models of Slonczewski or Zhang and Li are computationally cheap and sufficiently accurate for a number of applications. However, the more general spin-diffusion model incorporates the simplified models and furthermore accounts for several additional spintronics effects. The accurate description of tunnel barriers in the context of micromagnetic simulations is still an active and important area of research.

# Quantum Monte Carlo for Electronic Systems Containing *d* and *f* Electrons

# 46

Lucas K. Wagner

## Contents

### Abstract

This article briefly summarizes how to use standard fixed-node diffusion Monte Carlo to obtain accurate results for materials containing *d* and *f* electrons.

## 1  Introduction

Quantum Monte Carlo (QMC) techniques treat electron correlation directly and to reasonably high accuracy. Systems containing *d* and *f* electrons tend to have strong electron correlation effects, so one might expect that QMC techniques could be helpful to treating these systems. For the purposes of this article, we will mainly

L. K. Wagner (✉)
Department of Physics, University of Illinois at Urbana-Champaign, Urbana, IL, USA
e-mail: lkwagner@illinois.edu

consider diffusion Monte Carlo (DMC), since most applications to $d$ and $f$ electron systems have used that technique. For clarity, we will also focus on standard techniques that have seen wide use. There are many variations on QMC methods that can sometimes offer higher accuracy but are less well-explored. For details on the methods, see the handbook article on QMC methods. The field is rather quickly moving, so this article will focus on basic considerations when performing calculations on these materials and some expectation for what can be achieved with standard approaches. It is not meant to be a comprehensive summary of the literature on this subject.

## 2 Technical Considerations for High Accuracy

Here we will list the current state of the art in performing these calculations to the highest accuracy and efficiency. Some of the guidelines here are rules of thumb that have been empirically found to work, while others are more rigorous. We will try to be as clear as possible on the difference between these two situations.

### 2.1 Effective Core Potentials/Pseudopotentials

Using effective core potentials based on density functional theory is particularly problematic for systems containing $d$ and $f$ electrons. Instead, high accuracy effective potentials so far seem to be based mainly on Hartree-Fock and quantum chemistry results. A reasonable justification for this is that the core electrons are described reasonably well in Hartree-Fock. This is because in the core, the electrons are at high density, in which case the terms covered exactly in Hartree-Fock dominate (see Ceperley and Alder 1980). Ultimately, one should show that the effective potentials reproduce high accuracy solutions of the all-electron atom and molecules to have confidence in the effective potentials. There are several repositories of high-quality effective core potentials designed for quantum Monte Carlo calculations available to date, which are based on the preceding principles. For some examples, see Burkatzki et al. (2007) and Trail and Needs (2015).

### 2.2 Effective Core Potentials/Pseudopotential Projection Error

In DMC, non-local potentials lead to an additional sign problem. The projection onto a low-energy state must then be performed approximately, leading to an additional dependence on the trial wave function beyond the fixed-node approximation. In recent years, this error has been investigated, and it can at times be a sizable fraction of the total error of the methods. In most cases, the projection error can be minimized by using high-quality Jastrow factors and energy optimization of the parameters.

## 2.3    Nodal Error/Orbitals

DMC requires a trial function to determine the nodal surface. Given a Hamiltonian, this nodal surface is one of the main approximations in the calculation. While it is possible to use complex trial wave functions to obtain high accuracy for small systems, for larger systems, typically a single Slater determinant is used as a trial wave function. For systems containing *d* and *f* electrons, the electron interactions are strong enough that they can affect the degree of hybridization in the one-particle orbitals. For that reason, orbitals based on Hartree-Fock methods or local density approximation are not typically optimal (see Wagner and Mitas 2007).

While direct orbital optimization is possible, it is often computationally prohibitive for large systems. It has been found that orbitals from hybrid density functionals are close to optimal (see Busemeyer et al. 2016) when compared to direct orbital optimization. In this technique, the amount of hybridization is varied, and a sequence of DMC calculations is performed. The orbitals that produce the lowest DMC energies give the lowest upper bound. Some authors also perform DFT+U calculations, but to the knowledge of this author, the relative performance of hybrid functionals versus a +U calculation has not been systematically assessed. Figure 1 contains the density difference between PBE0 (hybrid) and PBE orbitals for $La_2CuO_4$. A major theme is that the total charge on the Cu atom is larger in the PBE functional, which leads to worse nodes for the QMC calculation and significantly higher fixed-node energy.

## 2.4    Finite Size Effects

As with any many-body technique, we must extrapolate to infinite size to simulate a bulk material. There are a number of detailed papers on finite size scaling in DMC, for example Chiesa et al. (2006).

**Fig. 1** Density difference between a Slater determinant of hybrid PBE0 orbitals and PBE orbitals for $LaCu_2O_4$. The slice is through the copper oxide plane. Red regions indicate that PBE orbitals have higher density in the region, while blue means that PBE0 has higher density
# 3    What Can Be Calculated Using DMC

- Ground state properties: magnetic/nonmagnetic ground state
- Spin properties: constrain to different spin states + model fitting

## 3.1    Ground State Energy as a Function of Atomic Position

FN-DMC offers very high accuracy on ground state properties, including those of $d$ and $f$ materials. As one can see in Fig. 2, it offers similar accuracy on those sorts of materials as for $s$ and $p$ systems, with errors of a few percent on many ground state properties.

## 3.2    Electronic Gap Calculation

One can consider two possible electronic gaps in interacting electronic systems. The first is called the *quasiparticle* or sometimes *transport* gap. This is computed using three ground state calculations of varying number of electrons:

$$\Delta_{QP} = E(N+1) + E(N-1) - 2E(N), \tag{1}$$

where $N$ is the number of electrons in a neutral unit cell and $E$ is the estimated ground state energy with that number. This quantity has the advantage that it involves only ground state calculations, so the variational principle obviously holds, but it can have large finite size effects.

The second gap is often called the *optical* gap. This is computed by promoting an electron from an unoccupied orbital to an occupied orbital. The fixed-node condition

**Fig. 2** Performance of FN-DMC on several ground state properties for a variety of materials. (Data from Kolorenč and Mitas 2008, 2011, Santana et al. 2015, 2016, Mitra et al. 2015, Lee et al. 2004, Foyevtsova et al. 2014, Wagner and Abbamonte 2014, Zheng and Wagner 2015, Schiller et al. 2015, Yu et al. 2015, Hood et al. 2012, Pozzo and Alfè 2008, Shin et al. 2014, and Esler et al. 2010)

**Fig. 3** Electronic gap estimation for a variety of correlated electron materials
is used to prevent the system from falling into the ground state, so this can be viewed as an approximate computation of the excited state energy of the fixed $N$ system. This quantity approximates the lowest energy electronic optical transition that a material might have. It typically has smaller finite size effects and is easier to compute than the quasiparticle gap.

Figure 3 shows gaps computed for a number of correlated electron systems. Density functional theory calculations (DFT) in the most common PBE approximation are shown for reference. Most of these gaps were computed using the optical excitations, which match the transport gap typically to the accuracy of the calculation. The optical and the quasiparticle gap are not guaranteed to be the same value in general; however, they represent different physical quantities.

## 3.3    Nature of the Ground State

Since FN-DMC obtains tight upper bounds to the ground state energy, it can offer higher certainty estimates of the nature of the ground state than less accurate methods. To see why, suppose that one is interested in determining whether the ground state has double occupancy on a given atom in the ground state or not. If it has no double occupancy, then one might say that there are local spin moments and some sort of magnetic behavior would be expected, while in the contrary case, there are no local spin moments. Exactly this question has been asked about the metallic state of $VO_2$, which was addressed using fixed-node quantum Monte Carlo in Zheng and Wagner (2015).

To answer this question, consider a Hamiltonian $\hat{H}$. Divide all wave functions (which may or may not be eigenstates) into three classes:

$A$: double occupancy on the transition metal atom,
$B$: no double occupancy on the transition metal atom, and
$C$: superposition of $A$ and $B$.

**Fig. 4** Assignment of the
ground state class as a
function of the errors $\varepsilon$ in the
states. In this, $\Delta$ is the correct
difference between the actual
minima of the different
classes: $\Delta = E_{min}(B) -
E_{min}(A)$ for an $A$ ground
state

Define the function $E_{min}(X)$ as the minimum energy expectation value across all wave functions in class $X$.

In a fixed-node diffusion Monte Carlo calculation, one can typically control which class of wave function is produced using the trial function. Often several trial wave functions from each class are tested; let the minimum fixed-node energy for each class be $E_{FN}(A)$, $E_{FN}(B)$. One should be careful to evaluate the class after the diffusion Monte Carlo process. If the nodal optimization is perfect, then $E_{FN}(X) = E_{min}(X)$ for class $X$; however, in general $E_{FN}(X) \geq E_{min}(X)$. The error of a class $X$ is $\varepsilon_{FN}(X) = E_{FN}(X) - E_{min}(X)$.

Assume without loss of generality that $E_{min}(A) < E_{min}(C) < E_{min}B$. In that case, the ground state is of class $A$. To decide between $A$ and $B$, one evaluates

$$E_{FN}(B) - E_{FN}(A) = E_{min}(B) - E_{min}(A) + \varepsilon_{FN}(A) - \varepsilon_{FN}(B). \tag{2}$$

As one can easily see that the smaller the $\varepsilon$ values (more accurate calculations), the less likely a misidentification of the ground state (Fig. 4).

## 4      Summary

Fixed-node quantum Monte Carlo calculations offer highly accurate results for materials containing $d$ and $f$ elements. Since they treat the electron correlation explicitly and accurately, they can predict many properties of materials, some of which are summarized in this article.

**Abstract**

Finite temperature magnetic fluctuations determine a variety of properties of magnetic materials, including their phase stability, their thermodynamic properties, and even the structure of defects formed under irradiation. A fundamental feature of microscopic magnetic fluctuations is the directional non-collinearity of fluctuating atomic magnetic moments, which stems from the rotational invariance of an atomic magnetic Hamiltonian. To model the dynamics of magnetic moments of atoms that move themselves, a fast and computationally efficient simulation approach is required. Spin-lattice dynamics simulates atomic movements as well as rotational and longitudinal fluctuations of atomic magnetic moments within a unified framework, generalizing molecular dynamics

to magnetic materials. Collective magnetic and atomic excitations can now be investigated on the microscopic scale, similarly to how transformations of atomic structures can be investigated using molecular dynamics simulations. This chapter outlines theoretical foundations and numerical algorithms of spin-lattice dynamics and describes applications of the method.

# 1    Introduction

Magnetic materials play a pivotal part in modern technology; their applications include long-term information storage, fast access memory devices, and even quantum computing. Magnetic and mechanical properties of magnetic materials are intimately related, in particular this applies to steels and iron alloys. For example, ferromagnetic iron is the only element in Group 8 of the Periodic Table that adopts the bcc crystal structure. All the other elements in the same group have hcp crystal structure, and bcc Fe owes its stability to magnetism (Pettifor 1995). A self-interstitial atom defect in bcc iron adopts a ⟨110⟩ dumbbell configuration (Fu et al. 2004), whereas in all the nonmagnetic bcc metals, a single self-interstitial defect has the ⟨111⟩ symmetry (Nguyen-Manh et al. 2006; Derlet et al. 2007). At high temperatures, bcc-fcc-bcc phase transitions in iron occur as a result of competition between magnetic excitations and atomic vibrations (Lavrentiev et al. 2010; Ma et al. 2017).

Neither molecular dynamics nor spin dynamics on their own can capture *both* magnetic and atomic excitations. A broader mathematical simulation framework is required to describe the dynamics of spin and lattice subsystems and their coupling. Omelyan et al. (2001a, b, 2002) and Tsai et al. (2004, 2005) proposed models unifying spin dynamics and molecular dynamics. We have developed their ideas further, arriving at an algorithm suitable for simulating real materials.

Spin-lattice dynamics follows the time evolution of coupled spin and lattice subsystems. Precession of spins and atomic motion are coupled through spin-dependent forces and coordinate-dependent effective exchange fields. Figure 1 shows snapshots of magnetic order in iron at 0 and 300 K. The figure illustrates an important aspect of finite temperature magnetic simulations. Magnetic moments (which sometimes are also called atomic spins) become non-collinear due to thermal excitation. The fact that interaction between magnetic moments depends on the position of atoms, generates additional, spin direction dependent, forces acting between the atoms in the material. This is how magnetic excitations affect the dynamics and stability of atomic lattice.

In what follows, we first discuss the spin equations of motion and the notion of spin temperature. Then, we outline theoretical foundations of spin-lattice dynamics. We also describe a numerical integration algorithm that does not normally receive much attention in the context of molecular dynamics but proves essential in the framework of spin-lattice dynamics. Finally, we highlight the still outstanding scientific challenges, particularly those associated with magnetic many-body interatomic interaction potentials.
**Fig. 1** Snapshots of magnetic configurations generated using spin-lattice dynamics simulations of iron at 0 and 300 K. Simulations were performed using spin-lattice dynamics simulation program SPILADY (Ma et al. 2016)

## 2     The Quantum Origin of Spin Dynamics

The localized nature of $d$ and $f$ electrons justifies the notion of an atomic magnetic moment **M** or atomic spin **S**, where $\mathbf{M} = -g\mu_B\mathbf{S}$, $g$ is the electron $g$-factor, and $\mu_B$ is the Bohr magneton. Atomic magnetic moments form due to intra-atomic exchange interaction between the localized electrons. Interaction between magnetic moments associated with different atoms can be understood as resulting from the interplay between intra-atomic exchange and interatomic quantum hopping of electrons. The quantum nature of atomic spins gives rise to their unusual properties, for example, an atomic spin has no mass and hence has no conjugate variable. The classical equation of motion for a spin vector is in fact the mean-field analog of the quantum equation of motion for the spin operator, which can be derived using the Poisson brackets approach (Ma and Dudarev 2012).

Consider an arbitrary quantum-mechanical spin Hamiltonian $\hat{\mathscr{H}}$. It can be expressed as a Taylor series in the spin vector operator $\hat{\mathbf{S}}$ as

$$\hat{\mathscr{H}} = \sum_{n=0}^{\infty} \mathbf{a}_n \hat{\mathbf{S}}^n, \tag{1}$$

where tensor quantities $\mathbf{a}_n$ are the Taylor series expansion coefficients. The $n^{th}$ order of operator $\hat{\mathbf{S}}$ can be written as

$$\begin{aligned}
\hat{\mathbf{S}}^n &= (\hat{\mathbf{I}}\mathbf{S} + \delta\hat{\mathbf{S}})^n, \\
&= \hat{\mathbf{I}}\mathbf{S}^n + n\mathbf{S}^{n-1}\delta\hat{\mathbf{S}} + \cdots,
\end{aligned} \tag{2}$$

where $\mathbf{S}$ is the expectation value of $\hat{\mathbf{S}}$, $\hat{\mathbf{I}}$ is the identity operator, and $\delta\hat{\mathbf{S}} = \hat{\mathbf{S}} - \hat{\mathbf{I}}\mathbf{S}$ is what can be called the deviation of the operator from its expectation value. Substituting Eq. (2) into Eq. (1), we find

$$\hat{\mathscr{H}} = \hat{\mathbf{I}} \sum_{n=0}^{\infty} \mathbf{a}_n \mathbf{S}^n + \sum_{n=1}^{\infty} \mathbf{a}_n n \mathbf{S}^{n-1} \delta\hat{\mathbf{S}} + \cdots ,$$

$$= \hat{\mathbf{I}}\mathscr{H} + \frac{\partial\mathscr{H}}{\partial\mathbf{S}} \cdot \delta\hat{\mathbf{S}} + \cdots . \tag{3}$$

The first term in (3) is the Hamiltonian *function* $\mathscr{H}$, which is equivalent to a classical Hamiltonian, where the spin operator $\hat{\mathbf{S}}$ is replaced by its expectation value $\mathbf{S}$. Ignoring higher-order terms in Eq. (3), the equation of motion for a spin operator can be derived using the Poisson brackets commutator

$$\frac{d\hat{\mathbf{S}}}{dt} = \frac{i}{\hbar}\left[\hat{\mathscr{H}}, \hat{\mathbf{S}}\right] = \frac{1}{\hbar}\left[\hat{\mathbf{S}} \times \left(-\frac{\partial\mathscr{H}}{\partial\mathbf{S}}\right)\right],$$

$$= \frac{1}{\hbar}\left[\hat{\mathbf{S}} \times \mathbf{H}\right], \tag{4}$$

where $\mathbf{H} = -\partial\mathscr{H}/\partial\mathbf{S}$ is the effective field acting on spin $\hat{\mathbf{S}}$. Since the first term in Eq. (3) commutes with $\hat{\mathbf{S}}$, it gives no contribution to the equation of motion. The first non-vanishing contribution to the right-hand side of (4) comes from the second term in Eq. (3).

The above derivation remains valid for any spin Hamiltonian. We note that the form of Eq. (4) is the same as that of the equation of motion for a classical spin vector. This can be proven by evaluating expectation values of both sides of the equation.

## 3    Spin Temperature Monitoring and Control

If a statistical and dynamically evolving system is in contact with another statistical, and also dynamically evolving, system, energy flows from the hotter to the cooler one, until they reach thermal equilibrium. There is an established procedure for thermalizing an atomic system in a molecular dynamics simulation, which involves putting the system in contact with a heat reservoir, represented by certain fluctuation and dissipation terms in the classical equations of motion for the atoms. This thermalization method is known as Langevin dynamics. The treatment of Brownian motion is probably one of the best known examples of application of the method (Chandrasekhar 1943; Kubo 1966). The use of Langevin dynamics for equilibrating and thermalizing large systems of interacting atoms is a well-established part of the molecular dynamics simulation toolkit.

In the preceding section, we derived equations of motion for a closed system of interacting spins. To thermalize a spin system, one can also use a special form of Langevin dynamics, the implementation of which requires suitably modified spin equations of motion. Langevin dynamics approach to spin dynamics was proposed by Brown (1963). For an arbitrary Hamiltonian $\mathscr{H}(\{\mathbf{S}_i\})$ describing $N$ atomic spins, the Langevin equation of motion for an atomic spin vector $i$ can be written as

$$\frac{d\mathbf{S}_i}{dt} = \frac{1}{\hbar}\left[\mathbf{S}_i \times (\mathbf{H}_i + \mathbf{h}_i) - \gamma\mathbf{S}_i \times (\mathbf{S}_i \times \mathbf{H}_i)\right] \tag{5}$$

where $\mathbf{H}_i = -\partial\mathscr{H}/\partial\mathbf{S}_i$ is the effective magnetic field acting on atomic spin $i$, $\gamma$ is a dissipation constant, and $\mathbf{h}_i$ is a delta-correlated fluctuating vector satisfying conditions $\langle\mathbf{h}_i(t)\rangle = 0$ and $\langle h_{i\alpha}(t)h_{j\beta}(t')\rangle = \mu\delta_{ij}\delta_{\alpha\beta}\delta(t - t')$. Subscripts $\alpha$ and $\beta$ refer to the Cartesian components of a vector, and parameter $\mu$ characterizes the magnitude of thermal magnetic fluctuations.

Stochastic and dissipative forces acting together drive a dynamic system to thermal equilibrium. Fluctuation and dissipation terms are related through the fluctuation-dissipation theorem (Chandrasekhar 1943; Kubo 1966). The fluctuation-dissipation relation (FDR) between the fluctuating and dissipative terms can be obtained by mapping the Langevin equation of motion to a Fokker-Planck equation (Zwanzig 2001; Van Kampen 2011) and identifying the asymptotic stationary solution of that equation with the Gibbs distribution (Brown 1963; Ma and Dudarev 2011). The FDR for Eq. (5) reads $\mu = 2\gamma\hbar k_B T$, where $T$ is the temperature of the heat reservoir. Without the fluctuating term, Eq. (5) reduces to the Landau-Lifshitz equation (Landau and Lifshitz 1935; Gilbert 2004), which contains only the dissipative term. In the asymptotic limit $t \to \infty$, solutions of the Landau-Lifshitz equation describe stationary spin configurations, where $d\mathbf{S}_i/dt = 0$. Directions of vectors $\mathbf{S}_i$ in a stationary spin configuration can be found by solving equations $\mathbf{S}_i \times \mathbf{H}_i = 0$, where $i = 1, 2 \ldots N$ (see Lavrentiev et al. 2011). The latter condition has a simple meaning, namely, that in the lowest energy configuration every spin vector $\mathbf{S}_i$ is collinear with the exchange field $\mathbf{H}_i$ acting on it.

A notable feature of Eq. (5) is that the magnitude of the spin vector $|\mathbf{S}_i(t)|$, where $\mathbf{S}_i(t)$ is a solution of the equation, remains constant. This can be easily proven by multiplying both sides of the equation by $\mathbf{S}_i$ and noting that a vector product, involving an arbitrary vector, is orthogonal to it. As a result, the magnitude of the spin vector is conserved $d\mathbf{S}_i^2(t)/dt = 0$.

Due to the simultaneously localized and itinerant nature of electrons in a solid, both the magnitude and direction of atomic spins are variable quantities. A revision of Langevin spin dynamics is required to relax the constraint that the magnitude of an evolving spin vector is a constant. Bearing in mind the Langevin treatment of atomic dynamics, we find that longitudinal fluctuations of an atomic magnetic moment, i.e., fluctuations of the magnitude of a spin vector, can indeed be treated using some suitably chosen fluctuation and dissipation terms (Ma and Dudarev 2012). We write

$$\frac{d\mathbf{S}_i}{dt} = \frac{1}{\hbar}\left[\mathbf{S}_i \times \left(-\frac{\partial \mathscr{H}}{\partial \mathbf{S}_i}\right)\right] - \gamma\frac{\partial \mathscr{H}}{\partial \mathbf{S}_i} + \boldsymbol{\xi}_i, \tag{6}$$

$$= \frac{1}{\hbar}\left[\mathbf{S}_i \times \mathbf{H}_i\right] + \gamma\mathbf{H}_i + \boldsymbol{\xi}_i, \tag{7}$$

where $\boldsymbol{\xi}_i$ is a delta-correlated fluctuating vector satisfying conditions $\langle\boldsymbol{\xi}_i(t)\rangle = 0$ and $\langle\xi_{i\alpha}(t)\xi_{j\beta}(t')\rangle = \mu\delta_{ij}\delta_{\alpha\beta}\delta(t-t')$. The FDR can now be obtained by mapping Eq. (6) onto a Fokker-Planck equation (Zwanzig 2001; Van Kampen 2011):

$$\frac{\partial W}{\partial t} = -\sum_{i\alpha}\frac{\partial}{\partial S_{i\alpha}}(A_{i\alpha}W) + \frac{1}{2}\sum_{ij\alpha\beta}\frac{\partial^2}{\partial S_{i\alpha}\partial S_{j\beta}}(B_{i\alpha j\beta}W). \tag{8}$$

In the above equation, $A_{i\alpha} = \lim_{\Delta t \to 0}\frac{1}{\Delta t}\langle S_{i\alpha}\rangle$ is an effective drift coefficient, and $B_{i\alpha j\beta} = \lim_{\Delta t \to 0}\frac{1}{\Delta t}\langle S_{i\alpha}S_{j\beta}\rangle$ is an effective diffusion coefficient. According to Eq. (6), the drift and diffusion coefficients have the form (Zwanzig 2001; Van Kampen 2011):

$$\mathbf{A}_i = \frac{1}{\hbar}\left[\mathbf{S}_i \times \left(-\frac{\partial \mathscr{H}}{\partial \mathbf{S}_i}\right)\right] - \gamma\frac{\partial \mathscr{H}}{\partial \mathbf{S}_i}, \tag{9}$$

$$B_{i\alpha j\beta} = \mu\delta_{ij}\delta_{\alpha\beta}. \tag{10}$$

In thermal equilibrium, the energy distribution asymptotically approaches the Gibbs distribution $W = W_0\exp(-\mathscr{H}/k_BT)$, where $W_0$ is a normalization constant. Substituting Eqs. (9) and (10), and the Gibbs distribution, into Eq. (8), one finds that

$$\frac{\partial W}{\partial t} = \left(\gamma - \frac{\mu}{2k_BT}\right)\left[\sum_{i,\alpha}\left(\frac{\partial^2 \mathscr{H}}{\partial S_{i\alpha}^2} - \frac{1}{k_BT}\left(\frac{\partial \mathscr{H}}{\partial S_{i\alpha}}\right)^2\right)\right]W. \tag{11}$$

Stationary solutions of this equation corresponding to $\partial W/\partial t = 0$ describe thermal equilibrium. From Eq. (11) we see that the right-hand side of Eq. (11) vanishes if

$$\mu = 2\gamma k_BT. \tag{12}$$

Surprisingly, the form of this FDR is exactly the same as that of the lattice Langevin dynamics. The right-hand side of Eq. (11) also vanishes if

$$k_BT = \sum_{i,\alpha}\left(\frac{\partial \mathscr{H}}{\partial S_{i\alpha}}\right)^2 \bigg/ \sum_{i,\alpha}\frac{\partial^2 \mathscr{H}}{\partial S_{i\alpha}^2}. \tag{13}$$

Equation (13) defines the dynamic spin temperature at equilibrium as a function of microscopic dynamic variables. This resembles the well-known equipartition principle for atoms where the lattice temperature can be estimated using the relation $3Nk_BT/2 = \sum_i\mathbf{P}_i^2/2m$, where $\mathbf{P}_i$ is the momentum of atom $i$. Equation (13)

has similar functionality, and it can also be used for estimating the local spin temperature of an arbitrary spin configuration, which potentially may be very far from equilibrium. Applying a similar procedure to Eq. (5), we find an alternative formula for the spin temperature, which applies if the longitudinal fluctuations of magnetic moments can be neglected (Ma et al. 2010).

$$k_B T = \frac{\sum_i |\mathbf{S}_i \times \mathbf{H}_i|^2}{2 \sum_i \mathbf{S}_i \cdot \mathbf{H}_i}. \tag{14}$$

Here we note an alternative way of deriving Eqs. (13) and (14). If a system is in thermal equilibrium, there is no net energy exchange with the heat reservoir, resulting in $d\langle E \rangle/dt = 0$. Since $dE/dt = \sum_i (\partial E/\partial \mathbf{S}_i)(d\mathbf{S}_i/dt)$, by using either of the two forms of Langevin equations of motion for the spins, taking the ensemble average, and applying the FDR, we arrive at the above formulae for the spin temperature expressed in terms of dynamic spin variables. Condition $T = 0$ corresponds to the lowest energy spin configuration that, according to Eq. (14), is defined by a set of algebraic equations noted earlier in this section, namely, $\mathbf{S}_i \times \mathbf{H}_i = 0$ for $i = 1, 2 \ldots, N$.

## 4    Spin-Lattice Dynamics

Interaction between atoms in a magnetic material is determined by its spin-dependent electronic structure. A suitable mathematical framework is required to describe the many-body phonon and magnon excitations at elevated temperature. Conventional molecular dynamics provides a convenient starting point for the incorporation of spin degrees of freedom in an atomistic simulation. It is possible to reformulate molecular dynamics and spin dynamics and combine them within a unified simulation framework. This also makes it possible to treat interaction between the lattice and magnetic subsystems, where interatomic forces and effective exchange fields acting on magnetic moments are related and dynamically coupled with each other.

Consider an arbitrary coordinate and spin-dependent Hamiltonian $\mathcal{H}(\mathbf{R}, \mathbf{P}, \mathbf{S})$, where $\mathbf{R} = \{\mathbf{R}_i\}$ are the atomic coordinates, $\mathbf{P} = \{\mathbf{P}_i\}$ are the atomic momenta, and $\mathbf{S} = \{\mathbf{S}_i\}$ are the atomic spin vectors. The Hamilton equations of motion for a closed system have the form (Ma et al. 2008, 2016):

$$\begin{aligned}
\frac{d\mathbf{R}_i}{dt} &= \frac{\partial \mathcal{H}}{\partial \mathbf{P}_i}, \\
\frac{d\mathbf{P}_i}{dt} &= -\frac{\partial \mathcal{H}}{\partial \mathbf{R}_i}, \\
\frac{d\mathbf{S}_i}{dt} &= \frac{1}{\hbar} \left[ \mathbf{S}_i \times \left( -\frac{\partial \mathcal{H}}{\partial \mathbf{S}_i} \right) \right].
\end{aligned} \tag{15}$$

From their appearance, these equations formally amount to no more than a combination of molecular dynamics and spin dynamics, and the only quantity that formally unifies them is the Hamiltonian. However, there is a subtle difference between spin-lattice dynamics defined by Eqs. (15) above and molecular dynamics or spin dynamics treated as separate simulation methods. The force $\mathbf{F}_i = -\partial \mathscr{H}/\partial \mathbf{R}_i$ acting on atom $i$ and the effective magnetic field $\mathbf{H}_i = -\partial \mathscr{H}/\partial \mathbf{S}_i$ acting on spin vector $i$ are coordinate *and* spin-dependent. The direction and magnitude of atomic spin vectors $\mathbf{S}_i$ affect the direction and magnitude of forces acting between the atoms in a magnetic material, whereas the effective exchange field acting on spin $\mathbf{S}_i$ depends on atomic positions. The lattice and spin subsystems are now coupled through the spin-orientation-dependent interatomic forces and coordinate-dependent effective exchange fields.

Generalizing Eqs. (15) to Langevin dynamics, we write the Langevin equations of motion for the spins and atomic coordinates and momenta as

$$\frac{d\mathbf{R}_i}{dt} = \frac{\partial \mathscr{H}}{\partial \mathbf{P}_i},$$

$$\frac{d\mathbf{P}_i}{dt} = -\frac{\partial \mathscr{H}}{\partial \mathbf{R}_i} - \gamma_l \frac{\partial \mathscr{H}}{\partial \mathbf{P}_i} + \mathbf{f}_i,$$

$$\frac{d\mathbf{S}_i}{dt} = \frac{1}{\hbar} \left[ \mathbf{S}_i \times \left( -\frac{\partial \mathscr{H}}{\partial \mathbf{S}_i} \right) \right] - \gamma_s \frac{\partial \mathscr{H}}{\partial \mathbf{S}_i} + \boldsymbol{\xi}_i, \tag{16}$$

where $\mathbf{f}_i$ and $\boldsymbol{\xi}_i$ are the fluctuating components of interatomic forces and exchange fields, respectively. They satisfy the Langevin equations conditions $\langle \mathbf{f}_i(t) \rangle = 0$ and $\langle f_{i\alpha}(t) f_{j\beta}(t') \rangle = \mu_l \delta_{ij} \delta_{\alpha\beta} \delta(t - t')$ for the fluctuating components of interatomic forces and $\langle \boldsymbol{\xi}_i(t) \rangle = 0$ and $\langle \xi_{i\alpha}(t) \xi_{j\beta}(t') \rangle = \mu_s \delta_{ij} \delta_{\alpha\beta} \delta(t - t')$ for the fluctuating exchange fields. The FDR relations for the lattice and spin subsystems read $\mu_l = 2\gamma_l k_B T$ and $\mu_s = 2\gamma_s k_B T$, where $T$ is the temperature of the heat reservoir. The dissipative constants $\gamma_l$ and $\gamma_s$ determine the thermalization rates, which can be derived from experimental observations. An example of thermalization process is given in Fig. 2. The figure shows how the spin and lattice temperatures vary in an interacting spin-lattice dynamic system. The simulation involves 16,000 magnetic atoms of iron. The reservoir temperature is set to 300 K. We used the values of parameters describing ferromagnetic iron that were derived by Ma and Dudarev (2012) and Ma et al. (2012). The different thermalization rates characterizing spin and lattice subsystems are primarily due to the difference between the values of dissipation constants $\gamma_l$ and $\gamma_s$.

The spin-lattice dynamics simulation model can be extended to include the treatment of conduction electrons, if we assume that there is a significant amount of heat dissipated to the electrons. This is often the case in metals. For example, in applications, the heat reservoir is nothing but the time-dependent evolving electron subsystem. Its dynamic behavior is described by the heat transfer equation

$$C_e \frac{dT_e}{dt} = \nabla(\kappa_e \nabla T_e) + G_{el}(T_l - T_e) + G_{es}(T_s - T_e), \tag{17}$$

**Fig. 2** Spin and lattice temperatures in magnetic iron during thermalization, predicted by spin-lattice dynamics simulations. The temperature of the reservoir is 300 K. Initial temperatures of atoms and spins are $T = 0$ K. The simulation follows the evolution of 16,000 magnetic iron atoms, initially forming a perfect bcc lattice configuration
where $C_e$ is the electronic specific heat and $\kappa_e$ is the coefficient of thermal conductivity. The coupling constants describing interaction between electron and lattice subsystems $G_{el}$ and between electron and spin subsystems $G_{es}$ are

$$G_{el} = \frac{3k_B \gamma_l}{m\Omega} \tag{18}$$

$$G_{es} = \frac{k_B \gamma_s}{\Omega} \langle \sum_\alpha \frac{\partial^2 \mathcal{H}}{\partial S_{i\alpha}^2} \rangle \tag{19}$$

where $\Omega$ is the atomic volume. Detailed derivations of $G_{el}$ and $G_{es}$ are given in Ma et al. (2012, 2016) and references therein. Equations (16) and (17) constitute a fully self-consistent atomistic spin-lattice-electron model. In the ultrafast laser experiments, where over a relatively short period of time only a small amount of heat is exchanged with the environment, the spin-lattice-electron model can be successfully applied to modelling transient processes of thermalization and heat exchange between the three subsystems, as well as to the treatment of fast demagnetization (Ma et al. 2016).

## 5 The Suzuki-Trotter Decomposition

In a dynamic simulation of the evolution of a system of atoms, a numerical algorithm advances the state of the system as a function of time by propagating a configuration through a sequence of finite time steps. This generates numerical errors, for example, biased errors and truncation errors, resulting from analytical or numerical approximations. An integration algorithm based on the Suzuki-Trotter decomposition (STD) (Hatano and Suzuki 2005) can minimize numerical errors over a relatively long interval of computation time due to its symplectic nature,

which means that the algorithm conserves the phase space volume of the system during evolution. The STD involves breaking up an evolution operator, which consists of several noncommutative operations, into simpler sub-evolution steps. The second-order STD has the form

$$e^{(\hat{A}+\hat{B})\Delta t} = e^{\hat{A}\Delta t/2}e^{\hat{B}\Delta t}e^{\hat{A}\Delta t/2} + O(\Delta t^3) \tag{20}$$

where $\hat{A}$ and $\hat{B}$ are arbitrary operators and $\Delta t$ is the time step. The above formula describes how to decompose an operator that evolves the system over a time step, into several simpler evolution steps, each involving the evolution of only a subset of variables describing the microscopic configuration of the system.

Omelyan et al. (2001a, b, 2002) and Tsai et al. (2004, 2005) explored applications of the STD to spin-lattice dynamics, and in what follows we adopt a similar approach. Equations of motion for a spin-lattice system can be rewritten as

$$\frac{d\mathbf{x}}{dt} = (\mathcal{R} + \mathcal{P} + \mathcal{S})\mathbf{x}, \tag{21}$$

where $\mathbf{x} = \{\mathbf{R}, \mathbf{P}, \mathbf{S}\}$ is a generalized coordinate and $\mathcal{R}$, $\mathcal{P}$, $\mathcal{S}$ are the evolution operators acting on $\mathbf{R}$, $\mathbf{P}$, and $\mathbf{S}$, respectively. The formal solution of Eq. (21) can be written as

$$\mathbf{x}(t + \Delta t) = e^{(\mathcal{R}+\mathcal{P}+\mathcal{S})\Delta t}\mathbf{x}(t). \tag{22}$$

Using the STD decomposition given by Eq. (20), we write

$$e^{(\mathcal{R}+\mathcal{P}+\mathcal{S})\Delta t} = e^{\mathcal{P}\Delta t/2}e^{\mathcal{S}\Delta t/2}e^{\mathcal{R}\Delta t}e^{\mathcal{S}\Delta t/2}e^{\mathcal{P}\Delta t/2} + O(\Delta t^3). \tag{23}$$

Reading the right-hand side of this equation from right to left, we see that the STD decomposition rule requires that we would integrate equations for the momenta of particles over the time interval $\Delta t/2$, then integrate equations for the spins over the time interval $\Delta t/2$, and then integrate equations for atomic coordinates over the time interval $\Delta t$, followed by the integration of equations for the spins over $\Delta t/2$ and equations for the momenta over $\Delta t/2$. The order in which we integrate the equations minimizes the number of times where forces are evaluated and significantly reduces the time required to do a simulation. The main advantage offered by the STD (23) is that it circumvents the need to integrate the coupled equations for the coordinates, momenta, and spins all at the same time.

A particular subtlety associated with the presence of spin equations of motion in Eqs. (15) is that spin dynamics involve rotations, which, as opposed to translations, do not commute. Bearing this in mind, the evolution of the spin subsystem can be split into a series of operations involving evolution of individual spins, namely

$$e^{\mathcal{S}\Delta t} = e^{\mathcal{S}_1\Delta t/2}e^{\mathcal{S}_2\Delta t/2}\cdots e^{\mathcal{S}_N\Delta t}\cdots e^{\mathcal{S}_2\Delta t/2}e^{\mathcal{S}_1\Delta t/2} + O(\Delta t^3). \tag{24}$$

Each operation of evolution of an individual spin depends on all the previous operations, because the effective magnetic field $\mathbf{H}_i$ acting on spin $i$ depends on the entire configuration $\mathbf{S}$ of all the other spins. In serial programming, one only needs to integrate the equations of motion for individual spins in a certain order, determined by the STD decomposition (24), one equation at a time. However, Eq. (24) prohibits performing multiple spin operations at the same time, in effect prohibiting the parallelization of the integration algorithm.

Parallel integration of spin equations of motion is still possible if interaction between the spins has a finite spatial extent (Ma and Woo 2009). In this case the effective exchange field acting on a spin depends only on a finite number of neighboring spins. The simulation cell can then be subdivided into separate spatial regions, where spins belonging to different regions do not interact. Spins can then be separated into noninteracting groups, and the STD can then be applied to the groups. The integration algorithm can then be parallelized between the groups, rather than between individual spins. An intrinsic part of an MD simulation program is the linked cells algorithm. A linked cell is a local spatial region, ideally suited for the parallel implementation of the STD of evolving spin operators. The parallel implementation of spin-lattice dynamics, adopted here, relies on and benefits from the linked cells decomposition of the simulation cell (Ma and Woo 2009).

## 6      Interatomic Potentials

In the sections above, we derived equations of motion and integration algorithms for spin-lattice dynamics simulations. These simulation algorithms have now been implemented in the form of a computer program SPILADY (Ma et al. 2016). The outstanding scientific challenge in spin-lattice dynamics is the development of high-fidelity interatomic potentials, suitable for modelling the microscopic dynamics of atoms and spins in magnetic materials, composed of various chemical elements. Similarly to the interatomic potentials used in molecular dynamics (Finnis 2003), an interatomic potential can have any functional form and can be parameterized in an arbitrary way, provided that it describes the physical properties that are of interest to applications. In most cases, potentials are fitted to data derived from ab initio calculations as well as to the data derived from experimental observations. There is no universal potential yet available for any material that would be able to predict energies and forces acting between the atoms in an arbitrary atomic configuration in good agreement with ab initio calculations.

In our work, we have adopted a relatively simple functional form of the many-body non-collinear spin-lattice potential. The potential can be derived from the Hamiltonian of the form

$$\mathscr{H} = \sum_i \frac{\mathbf{P}_i^2}{2m} + U(\mathbf{R}, \mathbf{S}). \tag{25}$$

In the above Hamiltonian, the potential energy $U$ of a system with $N$ magnetic atoms is written as a function of atomic coordinates and spin vectors. One can write the energy in a Taylor series in spin variables $\mathbf{S}$. Retaining only the rotationally invariant terms, we write (Dudarev and Derlet 2007)

$$U(\mathbf{R}, \mathbf{S}) = U^{(0)}(\mathbf{R}) + \sum_i U_i^{(1)}(\mathbf{R})\mathbf{S}_i^2 + \sum_{ij} U_{ij}^{(2)}(\mathbf{R})\mathbf{S}_i \cdot \mathbf{S}_j + \sum_i U_i^{(3)}(\mathbf{R})\mathbf{S}_i^4 + \cdots .$$

(26)

This makes it possible to map Eq. (25) to a nonmagnetic many-body interatomic potential complemented with a Heisenberg-Landau Hamiltonian

$$U = U_l(\mathbf{R}) - \frac{1}{2} \sum_{ij} J_{ij}(\mathbf{R})\mathbf{S}_i \cdot \mathbf{S}_j + \sum_i A_i(\mathbf{R})\mathbf{S}_i^2 + \sum_i B_i(\mathbf{R})\mathbf{S}_i^4,$$

(27)

where $J_{ij}(\mathbf{R})$ is a coordinate-dependent exchange coupling function and $A_i(\mathbf{R})$ and $B_i(\mathbf{R})$ are the coordinate-dependent Landau coefficients. For the nonmagnetic "lattice" part $U_l(\mathbf{R})$ of the potential, we have adopted the embedded atom method (EAM) (Daw and Baskes 1984) functional form and assumed that the Landau coefficients $A_i$ and $B_i$ are functions of the effective electron density. This is by no means the only way of representing the non-collinear spin-lattice potential. However, this particular functional form has at least two advantages. Firstly, it has a clear physical meaning. The Heisenberg term describes spin-spin interactions, whereas the Landau terms describe longitudinal fluctuations of $\mathbf{S}_i$. Exchange coupling and the Landau coefficients depend on atomic coordinates, which couple the spin and lattice subsystems through forces and effective magnetic fields. Secondly, the spin and lattice equations of motion have a relatively simple form, which assists the numerical implementation of the algorithm.

A remarkable property of Eq. (27) is that in the nonmagnetic limit $\mathbf{S} = \mathbf{0}$, the spin-lattice interaction potential reduces to a conventional molecular dynamics many-body potential. This poses a question about the type of data required for fitting a spin-lattice interatomic interaction potential. The above argument shows that data on magnetic as well as on nonmagnetic atomic configurations are required, as in potential (27) one can switch on and off the magnetic spin-dependent part. Experimental observations do not always provide information about magnetic and nonmagnetic properties at the same time, making ab initio calculations an invaluable and irreplaceable source of data required for fitting spin-dependent potentials. Also, ab initio calculations allow greater freedom for preconditioning, for example, through the exploration of many non-collinear magnetic configurations in a variety of atomic environments.

The functional form of the potential given by Eq. (27) does not take into account spin-orbit coupling. Spin-orbit coupling allows the transfer of angular momentum and energy from the spin to the lattice subsystem and vice versa. Perera et al. (2016) proposed a phenomenological model for the magneto-crystalline anisotropy, which models the effect of spin-orbit coupling. They add an anisotropic term to the Hamiltonian

$$\mathscr{H}_{\mathrm{aniso}} = -C_1 \sum_i \mathbf{K}_i \cdot \mathbf{S}_i - C_2 \sum_i \mathbf{S}_i^T \cdot \mathbf{\Lambda}_i \cdot \mathbf{S}_i, \tag{28}$$

where $C_1$ and $C_2$ are adjustable parameters. $\mathbf{K}_i(\mathbf{R}) = \partial \rho_i(\mathbf{R})/\partial \mathbf{R}_i$ and $\Lambda_{i,\alpha\beta}(\mathbf{R}) = \partial^2 \rho_i(\mathbf{R})/\partial R_{i\alpha} \partial R_{i\beta}$ are the coordinate-dependent functions defining the character of the on-site magnetic anisotropy, where $\rho_i(\mathbf{R})$ describes the symmetry of local environment. This approach may help treat the effect of magneto-crystalline anisotropy, although the link between (28) and the microscopic quantum-mechanical spin-orbit coupling Hamiltonian requires further analysis.

In the study of bcc-fcc-bcc phase transitions in pure iron (Ma et al. 2017), we have fitted a new spin-lattice potential using ab initio data as input. The functional form of the spin-dependent potential was assumed to be given by Eq. (27). In the process of fitting the potential, we have generated large data sets using ab initio calculations. The data included bcc, fcc, bct, rhombohedral, amorphous, and various defect structures under the constraint that the system remained entirely nonmagnetic. Using the data, we have fitted an EAM potential, which is the first term in (27). Then, we fitted the magnetic terms, separately for bcc and fcc crystal structures. Applying the umbrella sampling and adiabatic switching thermodynamic integration to spin-lattice dynamics simulations, we have evaluated the difference between the free energies of bcc and fcc phases as a function of temperature. Each free energy difference calculation referred to a particular temperature, hence avoiding the need to perform integration from 0 K, otherwise required in other simulation approaches (Lavrentiev et al. 2010).

Figure 3 shows the calculated free energy difference between the fcc and bcc phases. When the difference is positive, bcc phase is more stable, for example, at low temperatures. Otherwise, fcc phase is more stable. The curve crosses the horizontal axis at two points, near 1130 K and then again near 1600 K. These points correspond to the bcc-fcc $\alpha - \gamma$ and fcc-bcc $\gamma - \delta$ phase transitions, respectively. The predicted transition temperatures are close to the experimentally observed transition temperatures $T_{\alpha-\gamma} = 1185$ K and $T_{\gamma-\delta} = 1667$ K. The minimum free energy difference between the fcc and bcc phases is only $-2$ meV per atom. Analysis given in Lavrentiev et al. (2010) and Ma et al. (2017) shows that $\alpha$-$\gamma$-$\delta$ phase transitions in magnetic iron stem from the interplay between magnetic excitations and lattice vibrations. The free energy contribution from non-collinear magnetic fluctuations reduces the free energy difference as temperature increases. When the temperature is higher than the Curie temperature $T_C$, the long-range magnetic order vanishes although the short-range order remains (see Ma et al. (2008) and Fig. 4).

At temperatures exceeding the Curie temperature, the contribution to entropy from magnetic excitations is superseded by the contribution from lattice vibrations, and it is the balance between entropy contributions to the free energy from spin and lattice dynamics that is ultimately responsible for the occurrence of the two, $\alpha$-$\gamma$ and $\gamma$-$\delta$, rather than one, phase transitions in iron. This also illustrates the significance of taking into account spin-lattice coupling when modelling magnetic phase transitions in any real material.
**Fig. 3** Difference between the free energies of fcc and bcc phases of magnetic iron plotted as a function of temperature. Calculations were performed using a spin-lattice potential, taken as a sum of a nonmagnetic EAM potential and a Heisenberg-Landau Hamiltonian, as detailed by Eq. (27). The minimum free energy difference between fcc and bcc phases is $-2$ meV per atom

**Fig. 4** Time average projection of an atomic spin on a magnetization axis and spin-spin short-range correlation functions evaluated for the first, second, . . ., fifth nearest-neighbor atoms and plotted as functions of absolute temperature. Long-range magnetic order vanishes at the Curie temperature $T_C$, whereas the magnetic short-range order does not vanish even at temperatures well above $T_C$

# 7    Outlook and Challenges

Applications of spin-lattice dynamics are still fairly sparse. The main difficulty associated with applications of spin-lattice dynamics is that, like molecular dynamics, spin-lattice dynamics requires a sufficiently accurate many-body spin-dependent potential. Although spin-lattice dynamics has been applied extensively to simulations of various microscopic dynamic effects in pure iron, including vacancy migration (Wen et al. 2013), and magnetic excitations in cobalt (Beaujouan et al. 2012), there is still no spin-lattice potential suitable for simulating mechanical deformations, magnetic fluctuations, and defect properties at the same time. There are two main reasons why this question remains outstanding.

First, the number of degrees of freedom in spin-lattice dynamics is twice that of molecular dynamics. In molecular dynamics, one needs to fit an interatomic interaction potential to input data based on atomic configurations in $3N$ dimensions, where $N$ is the number of atoms in a simulation cell. In the case of spin-lattice dynamics, the number of degrees of freedom is $6N$ because each atom is characterized by its position as well as by the orientation and magnitude of the atomic magnetic moment. This poses a major challenge in the context of the fitting procedure as well as data generation and selection, since a significantly greater amount of data is required to span the multidimensional coordinate and spin phase space.

On the other hand, pure spin dynamics on a static lattice, which is a subset of spin-lattice dynamics, can be run as efficiently as MD. If we assume that the exchange coupling parameters $J_{ij}$ are independent of atomic coordinates, the spin-dynamics part of the integration algorithm can be used for generating detailed information about magnetic phase transitions, as illustrated in Figs. 4 and 5.

**Fig. 5** Specific heat of bcc iron evaluated using purely rotational spin dynamics with no longitudinal fluctuations included, and Langevin spin dynamics taking longitudinal fluctuations of magnetic moments into account (Ma and Dudarev 2012). The peaks correspond to second-order magnetic phase transitions, where the long-range ferromagnetic order vanishes
**Fig. 6** Magnetic configuration of atoms in the vicinity of a mono-vacancy in ferromagnetic bcc iron, derived from ab initio calculations. The simulation cell contains 53 atoms. The magnitude of magnetic moments is greater in the first nearest-neighbor coordination shell of the vacancy, whereas magnetic moments are suppressed in the second nearest-neighbor coordination shell. Color refers to the magnitude of magnetic moments given by the scale bar, expressed in the Bohr magneton units

Second, a suitable functional form of the spin-lattice potential is yet to be firmly established. For example, if we adopt the form given by Eq. (27), we still do not know what functional form should be used for $J_{ij}(\mathbf{R})$, $A_i(\mathbf{R})$, and $B_i(\mathbf{R})$. In Figs. 6 and 7, we show a vacancy and a $\langle 110 \rangle$ self-interstitial dumbbell configurations in bcc ferromagnetic iron. These configurations were derived from ab initio calculations. We see that the magnitude and direction of magnetic moments depend on the local environment. Atoms near a defect have significantly different magnetic moments in comparison with moments of atoms in a perfect crystal. An often used pairwise form for $J_{ij}(\mathbf{R})$ does not fit the data for defects well, although it does fit reasonably well the data on magnetic moments in a nearly perfect lattice. A good spin-lattice potential should help model magnetic configurations associated with extended defects, such as line dislocations, dislocation loops, vacancy clusters, and voids, where ab initio calculations are still impossible or too computationally demanding.

In addition to defects, alloys present an even more challenging issue. Figure 8 shows the magnetic configuration of a FeCrNi ternary alloy. The data for the figure were taken from Wróbel et al. (2015). Even though the alloy adopts a nearly perfect fcc crystal structure, its magnetic configuration is fairly complex. This implies that a spin-lattice potential must contain information about the underlying spin-dependent electronic structure to be able to reproduce magnetic properties at a reasonable level of accuracy.

The functional form of a spin-lattice potential should reflect the many-body electron interactions. A recently derived tight-binding Hamiltonian (Coury et al. 2016) for non-collinear magnetic configurations is expected to provide a good starting point for a comprehensive treatment of this problem.
**Fig. 7** A ⟨110⟩ self-interstitial dumbbell configuration in ferromagnetic bcc iron, predicted by ab initio calculations. The supercell contains 129 iron atoms. The magnitude of magnetic moments of the two atoms forming the center of the dumbbell is significantly smaller than that of the neighboring atoms. Magnetic moments of atoms in the center of the dumbbell have antiferromagnetic orientation with respect to the ferromagnetically ordered neighboring atoms. Color represents the magnitude of an atomic magnetic moment, expressed in the Bohr magneton units

**Fig. 8** Magnetic configuration of a FeCrNi fcc alloy containing 108 atoms in the simulation cell. The alloy configuration consists of 58 Fe atoms (red), 16 Cr atoms (green), and 34 Ni atoms (blue). Color of arrows refers to the magnitude of atomic magnetic moments defined by the scale bar, expressed in the Bohr magneton units

# 8 Conclusion

Spin-lattice dynamics is a powerful simulation tool for studying magnetic materials on the atomic scale. In this chapter, we have outlined the fundamental theory of spin-lattice dynamics and algorithms suitable for its numerical implementation.

Although there are still significant challenging issues that remain to be resolved, the field is open for exploration. Spin-lattice dynamics can be applied to a broad range of topics from modelling high-frequency electronic and magnetic devices to mechanical properties of magnetic alloys.

## Contents

### Abstract

This introductory chapter presents a perspective on multiscale modeling that emphasizes the role and challenges of mesoscale methods and their impact on understanding and predicting material properties. The predictive power of the combined experimental, theoretical, and computational mesoscale approaches is illustrated by a brief discussion of the phase field method and its application to microstructure evolution. After summarizing the main ideas of each chapter in the section, the state of the art and the future of the field are examined by asking and answering four questions: Is the 3-D representation always necessary?, Do mesoscale computational methods capture nonequilibrium?, To what degree are mesoscale methods quantitative?, and Are mesoscale methods computationally efficient?

# 1 Introduction

There is a growing appreciation in recent years of the essential role that materials phenomena at the mesoscale play in controlling bulk properties and performance (BES 2012). This is especially true for structural materials in which microstructure evolution informs deformation mechanisms as well as damage and failure. Increasingly, advanced characterization techniques are revealing microstructural variability and heterogeneity in materials, and theory and simulation have a difficult time explaining these phenomena. Recent reviews of scientific opportunities at mesoscale propose that the evolution from reductionist atomistic approaches to constructionist mesoscale strategies is representative of a broader evolution and opportunity in materials research (Sarrao 2015). Complementing other sections and their emphasis on both finer and coarser length scales, this section of the *Handbook of Materials Modeling* explores mesoscale materials phenomena and microstructure, revealing novel behavior only present at the mesoscale and describing the state of the art in modeling and computational approaches the objective of which is to explain and predict these behaviors.

This introductory chapter starts with a perspective on multiscale modeling that emphasizes the importance of mesoscale methods and the impact on understanding and predicting material properties. As an example, the phase field method, which is not the subject of a standalone chapter, is discussed in the context of "atomistic to bulk" multiscale simulation studies. The introduction continues with brief descriptions of the chapters starting with the discussion of model frontiers spanning scales in ► Chaps. 49, "Mesoscale Modeling of Dislocation-Interactions in Multilayered Materials" by Shao, S., Zhou, C., Misra, A., ► 50, "Advances in Discrete Dislocation Dynamics Simulations" by LeSar, R. and Capolungo, L. ► 51, "Mesoscale, Microstructure-Sensitive Modeling for Interface-Dominated, Nanostructured Materials" by Beyerlein, IJ. Multi-Physics and adaptive physics refinement are central to ► Chap. 52, "Adaptive Physics Refinement at the Microstructure Scale" by Germann, T.C., while ► Chap. 53, "Synchrotron Capabilities to Understand Microstructure of Additively Manufactured Materials: Challenges and Opportunities for Modeling and Simulations" by Rollett, A.D. focuses on experimental validation at the mesoscale, with specific application to APS experiments. ► Chapter 54, "Computational Modeling of Morphology Evolution in Metal-Based Battery Electrodes" by Srinivasan et al. emphasizes the technological implications of mesoscale modeling using as an example the design of Li-ion battery materials. The introductory chapter ends with a brief summary of conclusions and ideas for future studies.

# 2 Perspective on Multiscale Modeling

To understand, predict, and ultimately control matter and energy at the electronic, atomic, molecular, microstructural, and continuum levels, scientists need to investigate materials at a combination of length and time scales that are characteristic to

relevant physical and chemical phenomena. Therefore, experimental, theoretical, and computational methods must cover a wide range of space and time scales, starting with the nucleus and the electronic structure of individual or clustered atoms (Å), to nano-/microstructural features, all the way to continuum properties of the sample (cm). Along the time scale, the investigation domain ranges from excitations (ps) to nucleation of new phases (ns), all the way to diffusion (minutes, hours) and aging characteristic times (months, years).

Figure 1 shows examples of applicability domains of several theoretical and computational methods that operate at various time and length scale (Stan 2009). Some applicability limits are rooted in the physics of the associated phenomena. For example, density functional theory (DFT) – a quantum mechanical method – is best suited for investigations at short times and in small volumes, where quantum effects are prominent. Other limitations result from computational aspects such as bandwidth (speed of communication) or available computer memory. For example, molecular dynamics (MD) simulations can account for all atoms in a *mole* of matter but the time necessary to converge to solution is unrealistic, at present time. It is likely that in the next decades some methods will expand their investigation domains while others will disappear. With the accelerated advancement of theoretical and computational methodologies and capabilities, it is conceivable that quantum mechanical calculations will soon predict properties of polycrystalline, multicomponent materials, at room and higher temperatures. In recent years, considerable progress has been made in bridging mesoscale to neighboring scales by either downscaling to atomistic simulation in materials science or upscaling to the finite element simulations in structural engineering (Geers et al. 2010; Li et al. 2004). For a detailed discussion of multiscale models and simulations for soft material characterization, see Praprotnik et al. (2008).

Mesoscale interactions yield complex architectures and phenomena that serve as the building blocks of macroscopic materials behavior. Science at the mesoscale builds on dramatic advances at the atomistic and nanoscale that the research community has produced in recent years and continues to produce. The mesoscale brings profound changes, replacing the atomic granularity of matter and the quantization of energy with continuous matter and energy thereby enabling the onset of collective behavior, the interaction of coupled and competing degrees of freedom, and the appearance of defects and fluctuations that alter the behavior of perfect structures. These emergent mesoscale phenomena represent a profound challenge for multiscale materials models. A series of articles exemplify the excitement and challenges that exist at the mesoscale (Jonusauskas 2018; Sarrao and Crabtree 2012, 2015; Short and Yip 2015; Bowden et al. 1997).

# 3    The Phase Field Method

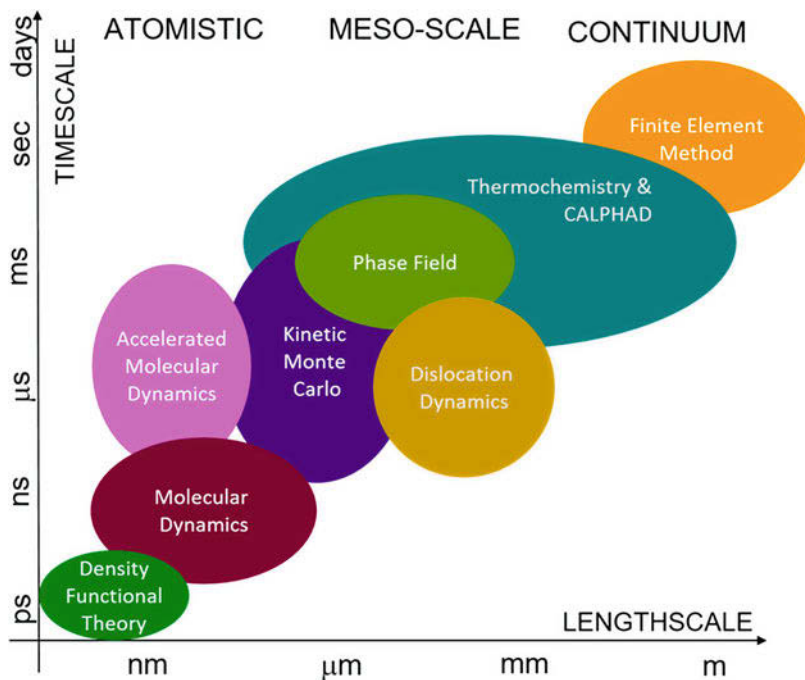
The phase field (PF) method is a powerful mesoscale simulation tool that can predict evolution of complex three-dimensional (3-D) microstructures. Applications include important materials processes such as solidification and melting,


**Fig. 1** Multiscale theoretical and computational methods (Stan 2009)

ferroelectric and ferromagnetic phase transitions, phase-separation and precipitation, martensitic transformation, and twinning. The PF method requires a good understanding of the thermodynamics and kinetics of the system under examination and presents several advantages over competing methods. For example, there is no prior assumption on microstructure morphology. Also, no explicit tracking of the location of interfaces is made, which presents computational advantages. The most powerful feature is the ability to predict the evolution of multidimensional (2-D, 3-D) inhomogeneous and anisotropic microstructures with high computational efficiency. First applications of the PF method revolved around melting/solidification and solid-state phase transformations (Chen 2002; Moelans et al. 2008; Steinbach 2009; Steinbach 2013; Hu 2009; Karma and Rappel 1998). Recently, phase field simulations successfully predicted microstructure evolution of irradiated materials, including radiation-induced segregation, second-phase nucleation, void migration, interstitial loop evolution, and grain growth (Millett and Tonks 2011a, b; Li et al. 2017; Tonks et al. 2018).

In the PF method, the evolution of the microstructure is captured using two sets of field variables. One is the *concentration field*, $c$, that describes the spatial distributions of conserved material components such as chemical species. The other field variable is the *order parameter field*, $\eta$, which describes nonconserved

**Fig. 2** Schematic representation of the phase field method phase variables. The diffuse (not sharp) interface between phase 1 and adjacent phases 2 and 3 is consistent with nanoscale observations and improves computational efficiency
microstructural features such as crystal structures and orientations, voids or gas bubbles, or ferromagnetic domains (Fig. 2).

In the PF method, all field variables change smoothly across the interface. Therefore, the interfaces are diffuse (have a certain width). This is a key characteristic of the PF method. By avoiding singularities (locations where some inverse parameters go to infinity), the PF algorithms avoid convergence issues that are common in sharp interface and level set approaches (Ratsch et al. 2002).

We summarize here the key components of the PF mathematical formalism. For a detailed description, see Chen (2002) and Li et al. (2017).

The location and time dependence of the constituents are represented by a concentration vector $c(x,t)$, while the phases are represented by an order parameter vector $\eta(x,t)$. Here $x$ is the spatial location vector and $t$ is the time. The total free energy of the system is given by:

$$F = \int_V' \left[ f_{chem}\left(c, \eta\right) + f_{grad}\left(c, \eta\right) + f_{lr}\left(c, \eta\right) \right] dV \tag{1}$$

where $V$ is the volume of the system, $f_{chem}$ the chemical free energy density, $f_{grad}$ is the gradient energy density (interfacial energy), and $f_{lr}$ is the long-range

interaction energy density that may include elastic energy, magneto-static energy, etc. The evolution of concentration $c$ is governed by the time-dependent Cahn-Hilliard equation (Cahn 1961):

$$\frac{\partial c_i}{\partial t} = \nabla \cdot \sum_j \left( M_{ij} \nabla \frac{\partial F}{\partial c_j} \right) + \xi_i \quad i=1,2...M \; (compositions) \tag{2}$$

The phase variable $\eta$ evolves based on the Allen-Cahn equation (Cahn and Allen 1977)

$$\frac{\partial \eta_k}{\partial t} = -L_k \frac{\partial F}{\partial \eta_k} + \xi_k \quad k=1,2...N \; (phases) \tag{3}$$

where $M_{ij}$ is the chemical mobility tensor, $L_k$ is the interface mobility, and $\xi_i$ and $\xi_k$ are thermal fluctuations. Equations (1, 2, and 3) represent a general description of the multicomponent, multiphase phase field model. Additional terms appear in the equations in PF formulations for specific applications.

Application of the PF approach to microstructure evolution has attracted growing interest because of its unique capability in predicting three-dimensional microstructure evolutions in a multicomponent and multiphase system. In the past decade, PF simulations predicted a number of important microstructure evolution phenomena and their subsequent impact on material thermo-mechanical properties of materials. In 2007, Stan *et al.* presented, for the first time, a PF model able to simulate the evolution of gas bubbles in an irradiated material (Stan et al. 2007). A more sophisticated PF model for gas bubble evolution in a polycrystalline was developed in subsequent studies (Hu et al. 2009, 2010). The approach relies on the coexistence of two phases: matrix and gas bubbles. The gas bubbles have a complex chemical composition that includes gas atoms and vacancies. In the initial approach, the grain boundaries (GBs) were fixed and did not evolve with time. Shortly after, Hu and Henager proposed a PF model that integrates elements of the kinetic Monte Carlo (kMC) method (Opplestrup et al. 2006) to simulate the evolution of void ensembles under irradiation (Hu 2009).

Besides predicting 3-D microstructure evolutions in a multicomponent and multiphase system, the PF models is able to evaluate the subsequent impact of microstructure evolution on mechanical, thermal, and magnetic properties (Klinsmann et al. 2015; Chakraborty et al. 2016).

PF simulations of polycrystalline structures with intra-granular and inter-granular pores or gas bubbles demonstrated the effect of inhomogeneous thermal conductivity on the overall thermal transport (Hu 2009; Millett et al. 2008; Millett and Tonks 2011a, b; Li et al. 2012; Chockalingam et al. 2012; Hu et al. 2015). In this case, the output microstructure resulting from PF calculations serves as input to calculations of thermal conductivity. Then, finite element simulations update the temperature field and provide feedback to new PF calculations. This iterative process can capture complex mesoscale effects and predict degradation of properties

in severe environments at very high temperatures, some close to melting (Welland et al. 2011].

## 4      Chapters in This Section

Fundamental understanding of mesoscale phenomena that influence microstructure evolution is crucial to the discovery of new materials and can accelerate material design. The chapters in this section summarize the status of a broad spectrum of mesoscale research topics and provide different perspectives regarding challenges and opportunities at mesoscale.

▶ Chapter 49, "Mesoscale Modeling of Dislocation-Interactions in Multilayered Materials" by Shao, S., Zhou, C., Misra, A. focuses on interface dislocation dynamics models for studies of ultrafine grain dynamics. The methodology relies on the atomistically informed interface dislocation dynamics (AIDD) model that is capable of bridging the mesoscale gap. The chapter includes a discussion of the fundamentals of interface deformation physics at atomic scale and the implementation into the AIDD model. To illustrate the capabilities of the AIDD model, the authors examine multilayer materials with extremely fine interface spacing exhibiting interface-dominated thermomechanical behaviors. Modeling and predicting properties of such materials on the micro and continuum scales has been challenging, with new insights recently becoming available from atomic-scale simulations.

Continuing the discussion, (▶ Chap. 50, "Advances in Discrete Dislocation Dynamics Simulations" by LeSar, R., Capolungo, L.) summarizes important, recent contributions in the field of discrete dislocation dynamics and the impact on dynamic loading/creep. The analysis goes from nanometers to tens of microns by bridging discrete dislocation dynamics simulations with harmonic transition state theory, which enables coarse graining. Advances in this methodology have taken the field closer to predicting the mechanical response of polycrystals such as textured crystalline aggregates with impurities.

▶ Chapter 51, "Mesoscale, Microstructure-Sensitive Modeling for Interface-Dominated, Nanostructured Materials" by Beyerlein, I.J. enhances the discussion of the mechanical response of polycrystalline metals and the importance of the underlying microstructure evolution and deformation mechanisms. The chapter covers recent advancements in modeling processing-microstructure-property relationships of polycrystalline metals. The model extensions highlighted in the chapter overcomes several limitations of similar approaches by incorporating nonhomogeneity. The chapter ends with recommendations for mesoscale modeling advancements as well as improvements in computational speed.

▶ Chapter 52, "Adaptive Physics Refinement at the Microstructure Scale" by Germann, T.C. focuses on long-sought goals of computational materials science and engineering: creating a simulation framework that spans all necessary length and time scales, providing the appropriate level of physics fidelity where needed, and enabling the user to trade off accuracy and computational time in an optimal manner.

After a brief review of heterogeneous multiscale methods and adaptive sampling, the authors discuss the computational workflow, data, and runtime requirements of these methods, as well as key enabling technologies such as task-based programming models, heterogeneous computer architectures, database, and machine learning algorithms.

▶ Chapter 53, "Synchrotron Capabilities to Understand Microstructure of Additively Manufactured Materials: Challenges and Opportunities for Modeling and Simulations" by Rollett, A.D. introduces the reader to techniques employed to characterize additively manufactured materials, with an emphasis on metals and ceramics. The techniques that are discussed include micro-tomography (CT), wide angle scattering (WAX), high energy diffraction microscopy (HEDM), residual stress (RS), and dynamic X-ray radiography (DXR). The chapter provides insights into both the required input for mesoscale modeling and the characterization information that can assist mesoscale model validation.

Continuing the discussion of the impact of mesoscale models on technology, ▶ Chapter 54, "Computational Modeling of Morphology Evolution in Metal-Based Battery Electrodes" by Srinivasan, V. et al. presents recent applications to lithium ion batteries. The main mesoscale challenges in developing lithium metal battery materials include dendritic growth, formation of dead lithium, and continuous decomposition of electrolyte at the solid-electrolyte interphase layer. Multiscale computational models (DFT, AIMD, kMC) capture several physical phenomena at the lithium-electrolyte interface, including mass transport, charge balance, heat transfer, and mechanical equilibrium. Successfully bridging these computational techniques is key to developing precise and accurate models.

All chapters emphasize the partnership between theory, experiment, and computation in understanding and predicting mesoscale phenomena. A new generation of supercomputers with higher computational power may also help bridge the gap between atomistic and continuum length scales by connecting with physical and chemical models of phenomena observed at the mesoscale.

## 5    Conclusions and Outlook

While acknowledging the successes of the mesoscale methods in predicting microstructure evolution and the impact on properties, a number of questions remain. For example, is the 3-D representation always necessary? There is no doubt that spatial distribution of mesoscale features is key to a number of phenomena, especially heterogeneous microstructure evolution. Furthermore, we expect that soon mesoscale computational methods will interface with 3-D material tomography to collect input data and validation information. Therefore, the answer is yes, multidimensionality is important.

Another question relates to the treatment of nonequilibrium processes that require the system to overcome energy barriers. Do mesoscale computational methods capture nonequilibrium? Of course, the laws of thermodynamics are universal and – when applied correctly – describe well both equilibrium and nonequilibrium

processes. However, the success of the mesoscale models depends upon their ability to account for nonequilibrium mechanisms of microstructure evolution, such as nucleation and growth of new phases. Capturing nucleation of secondary phases is challenging due to the small characteristic length and time scales. Often, mesoscale methods evolve the phases using as input critical nucleus information and nucleation rates from atomistic simulations such as DFT or MD. So again, coupling scales may provide the optimal path forward.

To what degree are mesoscale methods quantitative? We acknowledge that simulated microstructures are not replicas of experimentally observed microstructures but rather representations of reality. Similarly, experimental samples are not replicas but "experimental models" of real materials. Therefore, the qualitative aspect of mesoscale models is not negligible. In some instances, scientists qualitatively evaluate the dominant mechanisms behind complex phenomena as a preliminary step toward more rigorous, quantitative models and predictions. The long-term goal of mesoscale modeling is to attain a high level of precision and accuracy in quantitatively representing real materials.

The computational efficiency of mesoscale methods is also under debate. As with any computational method, going beyond the limits of applicability requires coupling with approaches that are valid at adjacent length or time scales. For example, the spatial and temporal correlations in phase field simulations require information exchange with atomistic and continuum methods. In addition, adaptive time and mesh refinement can improve the precision but decrease the numerical efficiency of solving PDF equations. Furthermore, the smallest time step and grid size are the limiting factors. All microstructure evolution simulations require highly scalable methods, as discussed in (▶ Chap. 52, "Adaptive Physics Refinement at the Microstructure Scale" by Germann, T.).

**Abstract**

Multilayer materials with extremely fine interface spacing exhibit interface-dominated thermomechanical behaviors. Modeling and predicting properties of such materials on the micro- and continuum scales have been challenging, however, despite recent elucidations of the unit mechanisms from atomistic modeling and in situ experiments. This chapter presents a mesoscale, atomistically informed interface dislocation dynamics (AIDD) model that is capable of bridging the meso length-scale gap. The fundamentals of interface deformation physics at atomic-scale, implementation into the AIDD model, and the capabilities of the model are demonstrated and discussed.

# 1    Introduction

Bulk ultrafine-grained (UFG) materials are single or multiphase polycrystals with nanoscale grain size (<1000 nm). In comparison with conventional polycrystalline materials, UFG materials may exhibit increased strength/hardness, improved toughness, reduced ductility, and enhanced diffusivity (Gleiter 1989; Suryanarayana 1995; Palumbo et al. 1990; Meyers et al. 2006). Differing from coarse-grained polycrystalline materials, the most important structural characteristic of UFG materials is a large volume fraction of boundaries which significantly alters physical, mechanical, and chemical properties of materials (Hall 1951; Petch 1953; Ashby 1970; Würschum et al. 2003). For example, the UFG materials virtually exhibit no strain hardening after an initial stage of rapid strain hardening (Koch et al. 1999; Koch 2003; Van Swygenhoven and Caro 1997; Suryanarayanan Iyer et al. 1999; Carsley et al. 1998), because the density of dislocations saturates due to dynamic recovery or due to the annihilation of dislocations into the grain boundaries (Valiev et al. 2000; Jia et al. 2001; Wang et al. 2002). Besides the boundary effects, grain size also plays a crucial role in changing the deformation mechanisms, evidenced by the breakdown of the classical Hall-Petch (H-P) relationship at grain sizes below approximately 100 nm (Suryanarayanan Iyer et al. 1999; Sanders et al. 1997; Chokshi et al. 1989).

The predominant deformation mechanisms in UFG materials change from dislocation pileups to boundary-mediated unit mechanisms with decreasing size (Yamakov et al. 2002; Was and Foecke 1996; Sproul 1996; Barnett 1993; Phillips et al. 2003; Tench and White 1984; Misra et al. 2008; Anderson and Li 1995). However, the current state-of-the-art modeling methods follow the "constituent-dominated paradigm" and neglect the defect phenomena at boundaries (Cuitiño and Ortiz 1993; Dawson and Marin 1997; Roters et al. 2010; Tomé et al. 2011).

This chapter introduces a mesoscale numerical approach incorporating interface physics, the atomistically informed interface dislocation dynamics (AIDD) method, to model and predict the deformation behavior and mechanical properties of UFG materials.

## 1.1 Microstructures of UFG Materials

Here we focus on *UFG materials* with laminated microstructure which can be processed in the form of thin films via bottom-up processes such as physical vapor deposition (PVD) (Was and Foecke 1996; Mahan 2000; Ross 1994) and electrode-position (Ross 1994) or in the form of bulk materials via top-down processes such as solid-state phase transformation (Lütjering et al. 2007; Callister and Rethwisch 2007), accumulative roll bonding (ARB) (Carpenter et al. 2012; Tsuji et al. 2003), heavily drawn in situ composites (Embury 1992), or solidification (Callister and Rethwisch 2007; Shen et al. 2005; Wang et al. 2011). Figure 1 shows typical microstructures via these fabrication paths. In epitaxial films, solid-state phase transformation, or eutectic solidification, energetically favorable crystallographic orientation relationships and interface habit planes develop naturally during synthesis (Was and Foecke 1996; Mahan 2000; Wang et al. 2011; Lutjering and Williams 2007). On the other hand, bulk materials via severe plastic deformation processes often contain mechanically driven interfaces with preferred orientation relationships in order to maintain the compatibility of plastic deformation between the adjacent layers (Carpenter et al. 2012). For example, in Cu-Nb with the Kurdjumov-Sachs orientation relationship, the interface habit planes are $\{111\}_{Cu}||\{110\}_{Nb}$ for PVD (Misra et al. 2005a; Li et al. 2012; Mara et al. 2008a; Lee et al. 2012) and $\{338\}_{Cu}||\{112\}_{Nb}$ or $\{112\}_{Cu}||\{112\}_{Nb}$ for ARB (Beyerlein et al. 2014; Carpenter et al. 2012; Lee et al. 2012).

## 1.2 Mechanical Behavior of Ultrafine Scale Materials

Unlike constituent-dominated deformation mechanisms in coarse-grained materials (Fig. 2a), interfaces in nanolaminated structures play multiple roles in determining mechanical properties: sources for nucleating plastic deformation carriers (dislocations, phase transformation bands, twins, and shear bands) (Shao et al. 2015; Wang et al. 2014a, 2009a; Van Swygenhoven et al. 2006; Mara et al. 2010), barriers for impeding the propagation of these carriers (Wang et al. 2011; Misra et al. 2005a; Li et al. 2012; Mara et al. 2008b), and preferred sites for storage, reassembly, and reaction (that may lead to recovery) of interface defects (Han et al. 2014; Zhang et al. 2014; Demkowicz et al. 2008a; Höchbauer et al. 2005).

Interface spacing, $\overline{d}$ (typically layer thickness, which is often smaller than grain size), is the key microstructural parameter in determining mechanical properties of
**Fig. 1** Transmission electron microscopy (TEM) and high-resolution TEM images of microstructures of various types of UFG materials. (**a**) PVD Al-Nb multilayers (Fu et al. 2008), (**b**) ARB Cu-Nb multilayers (Beyerlein et al. 2014), (**c**) wire drawn Cu-Nb nanocomposites (Sauvage et al. 2001), (**d**) rapid solidified Cu-Ag lamellar eutectic (Zheng et al. 2015)

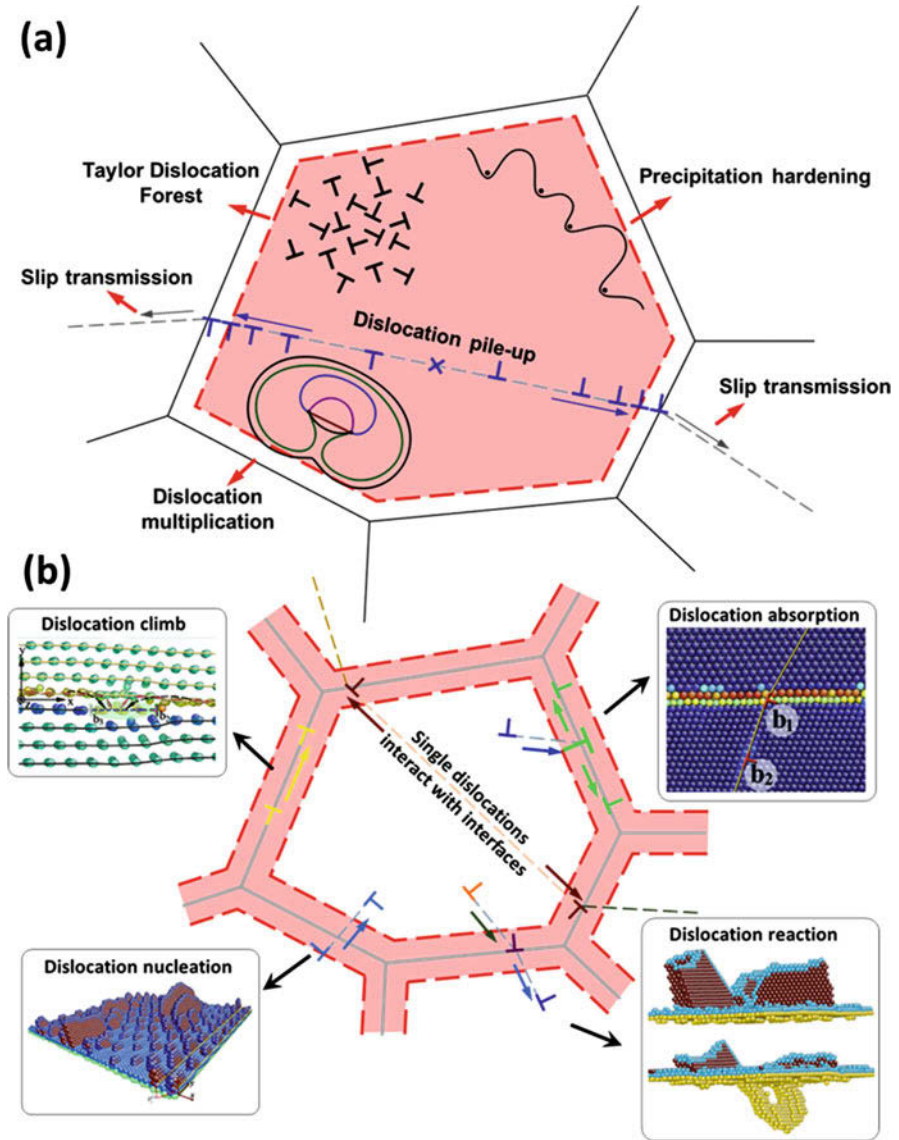
laminated composites (Misra et al. 2005a, 2008). Assuming that a certain interface acts as barrier for continuous motion of lattice dislocations, the development of plastic deformation requires high local stresses that act on the dislocation to overcome the barrier. Corresponding to this theoretical assumption, the dislocation pileup based on Hall-Petch scaling law (Anderson and Li 1995; Misra et al. 1998; Friedman and Chrzan 1998; Huang and Spaepen 2000) is applicable at $\bar{d}$ greater than ∼100 nm, varying with properties of constituent phases. For $\bar{d}$ in the range of approximately ∼10 to ∼100 nm, dislocation pileup on the same plane is unlikely due to the strong repulsion among like-sign coplanar dislocations. The dominant deformation mechanism is confined layer slip (CLS) (Phillips et al. 2003; Anderson et al. 2003; Misra et al. 2002; Embury and Hirth 1994; Anderson et al. 1999; Freund 1990; Nix 1989) that involves propagation of single dislocation loops parallel to the interfaces within layers. At $\bar{d}$ less than approximately 10 nm, experimental data on a variety of metallic nanolaminates indicate that the hardness or strength of laminated materials (Misra et al. 1998, 2002, 2005a, 2008) shows no significant increase in the flow strength with decreasing $\bar{d}$. This behavior has been interpreted as a change in dominant deformation mechanism from CLS to interface crossing of single dislocations. In this regime, interface defect contents and the structure of line defects within interfaces strongly impact mechanical properties of UFG materials. Therefore, in addition to the nucleation of lattice dislocations, the dynamics of interface dislocations include (Fig. 2b) the motion of the interface dislocations (including climb and glide), the reactions between lattice dislocation and interface dislocations, the absorption and core spreading of lattice dislocations by interfaces of relatively low shear strength, etc.


**Fig. 2** Schematic illustration of the transition in governing deformation mechanisms from constituent dominated (**a**) to interface dominated (**b**) as the characteristic length scale is decreased

## 1.3    Multiscale Perspective of Modeling Interface-Dominated Mechanical Behaviors

For interface-dominated mechanical behaviors, predictive material models must incorporate interface physics, including interface structures, unit deformation mechanisms, and dislocation density evolution at interfaces. Such interface physics is multiscale in nature. Atomistic modeling (top-left inset, Fig. 3) is able to elucidate structure and properties of interfaces and the unit processes of defect-interface interactions (Hoagland et al. 2004; Van Swygenhoven et al. 2001; Derlet and Van Swygenhoven 2002; Yamakov et al. 2003; Shenoy et al. 1999), providing the insight into the deformation processes, such as GB sliding/shear/migration (Henager et al. 2004; Wang et al. 2008a, b; Demkowicz et al. 2008b; Derlet et al. 2009), slip transmission (Sansoz and Molinari 2004; Wang and Huang 2006; Zhu et al. 2007; Afanasyev and Sansoz 2007), dislocation nucleation (Wang et al. 2009c, d, 2010, 2012a; Wang and Beyerlein 2012; Zhang et al. 2011; Kang et al. 2012a), etc. (bottom inset, Fig. 3). Beyond the temporal scale of several nanoseconds, knowledge regarding interface dislocations such as climb and glide of interface dislocations, reaction rules of interface dislocation, and evolution of interface dislocation is necessary to predict the mechanical behavior of the UFG materials. In this regard, atomistic modeling techniques are inadequate due to

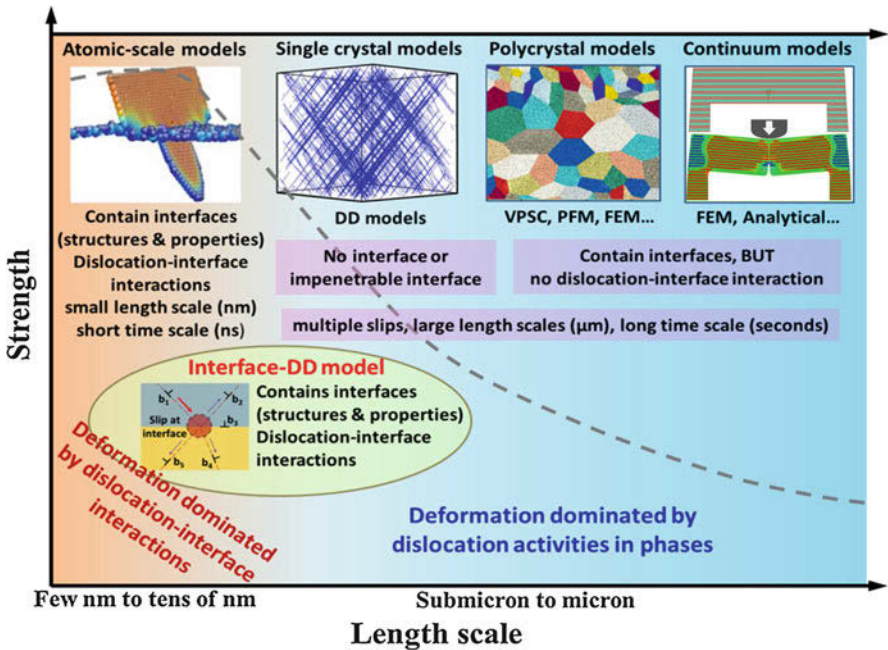

**Fig. 3** Commonly used modeling and simulation tools for studying mechanical behavior of materials at various length scales

their limitations in both length (nanometers) and temporal (nanoseconds) scales; there exists a demand for models that can close gap between atomic-scale and micro-/macroscale. Dislocation dynamics (DD) simulations (top, central-left inset, Fig. 3), in which dislocations are the simulated entities, offer a way to extend length and time scales beyond atomistic simulations and have the unique advantage of exploring dislocation activities in crystalline materials. The challenge is to describe the interactions between dislocations and interfaces. By exploiting the advantages of DD method and coupling with atomistic-level deformation mechanisms at boundaries, an atomistically informed interface dislocation dynamics (AIDD) model has been developed to link the atomistic-scale physics with macroscopic mechanical properties. The microscale grain-level crystal plasticity models (top, central-right inset of Fig. 3) can therefore benefit from the output of the AIDD model, including the constitutive relations, evolution rules of dislocations, etc. These microscale models can then inform the continuum-scale models, such as FEM and analytical constitutive models (top-right inset of Fig. 3).

This chapter reviews the fundamental aspects in developing the interface dislocation dynamics and the capabilities of the AIDD model. Conclusions and perspectives for future directions are presented.

## 2   Atomistic Information of Interface-Dominated Plasticity

Two important aspects of interface physics must be considered when describing the mechanical behavior of interface-dominated materials, namely, interfaces (structure and properties) and defect-interface interactions, both of which reside on the atomic level. Recent advances on the characterization of interface structure and properties (Kang et al. 2012a; Wang et al. 2012b, 2013, 2017; Hirth et al. 2013) as well as the elucidation of the unit interaction mechanisms between defects and interfaces (Wang et al. 2011; Shao et al. 2013; Demkowicz et al. 2012; Beyerlein et al. 2015) are achieved by combining atomistic simulations with high-resolution microscopy.

### 2.1   Atomic Structure and Thermodynamic Properties of Interfaces

In this section we categorize interfaces into four general types according to a geometrical interface classification (GIC) scheme (Wang et al. 2014a) and show that interfaces within each type share common structural as well as mechanical characteristics (Wang et al. 2014a). Within the context of the GIC scheme, we discuss these key interface-dominated plastic deformation mechanisms in detail.

The GIC scheme categorizes interfaces based on the atomic packing factors on the habit planes on the interface. For detailed discussion of the GIC scheme and information about its theoretical ground, readers are referred to ref. Wang et al. (2014a). In GIC scheme, interfaces between crystalline phases are classified into four mutually exclusive types according to the three geometric factors, namely,

compact planes (CP), compact directions (CD), and interface unit cells, which are detailed as follows:

*Type I:* the habit planes of both crystals coincide with the interface plane and the CP.

*Type II*: at least one of the two habit planes from each crystal is non-compact; however, the interface contains compact directions of the two crystals that are aligned.

*Type III*: the interface does not match the CPs or the CDs. The unit cells, however, are similar in that they have the same basic shape.

*Type IV*: the interface does not belong to Type I, Type II, or Type III.

Atomistic modeling combined with interface defect theory can be employed to determine the characteristics of all types of interfaces, such as their structures (Kang et al. 2012a, b; Wang et al. 2012b, 2014b; Misra et al. 2005b; Salehinia et al. 2015) and properties (Zheng et al. 2015; Zhu et al. 2010; Wang et al. 2009e; Liu et al. 2011; Kramer and Foecke 2002; Tian and Zhang 2012). As shown in Fig. 4, the four types of interfaces show distinct structural characteristics. In addition, interfaces that belong to the same type show strikingly similar structural features.

Two instances of *Type I* interfaces, namely, the Cu-Ni (111) interface, are shown in Fig. 4a. Indeed, the habit planes of Cu and Ni are all CPs at the interface planes;

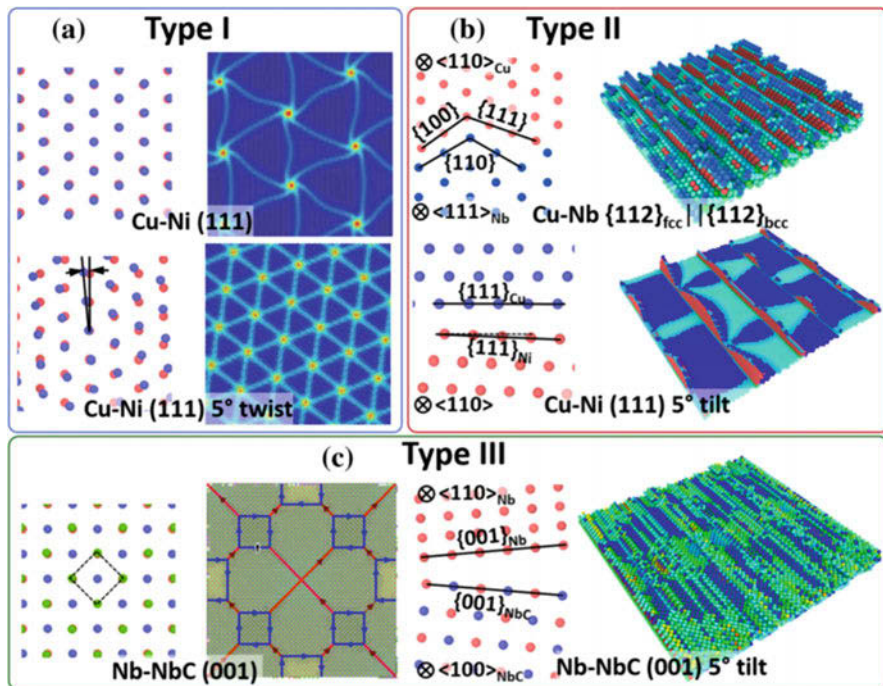

**Fig. 4** Typical examples of Type I, Type II, and Type III interfaces (Shao et al. 2018a)

the interfaces are therefore atomically flat. Networks of misfit dislocations are visible (light blue and red-colored atoms) and accommodate the transition of lattice constants, structures, and orientations (Wang et al. 2014a; Hirth et al. 2013). In general, the particular structure of the misfit dislocation network, i.e., dislocation character (edge, screw, or mixed), dislocation spacing, and number of dislocation sets, is dependent on the size and shape of the natural dichromatic patterns of the two joining crystals on the habit planes (Wang et al. 2013; Hirth et al. 2013) and the gamma surface at the interface (Salehinia et al. 2015; Chen et al. 2017; Shao et al. 2014a).

Figure 4b shows two examples of *Type II* interfaces, namely, the Cu-Nb $\{112\}_{fcc}||\{112\}_{bcc}$ and the Cu-Ni (111) interface with 5° tilt about the <110> direction. Since there is only an alignment of one CD, this type of interface is often faceted. These facets are in fact small patches of coherent regions where the respective habit planes of the joining crystals on the facet are CPs. The coherent facets are typically of relatively low excess energy. As a result, Type II interface, although comprising coherent facets separated by interfacial line defects (such as dislocations and disconnections), is still relatively low in specific energy. The Burgers vectors of the line defects can be parallel to and out-of-plane with respect to the facets as well as the interface plane.

Example of *Type III* interfaces, Nb-NbC interfaces with and without a tilt, are shown in Fig. 4c. Due to the presence of similar unit cells on the habit planes, this type of interfaces may still be preferred, even in the absence of aligning CD and CP. The non-compact habit planes are often either atomically flat (Nb-NbC interface) with relatively high atomic packing factor or faceted with patches of flat regions (Nb-NbC interface with tilt). In both scenarios, one or more sets of interface misfit dislocations/disconnections (the Burgers vectors of which can be parallel or out-of-plane with respect to the interface) separate these patches of coherent regions. Due to the strong Nb-C bonds, the *Type III* (001) interfaces are energetically preferred for Nb-NbC over other interface types.

*Type IV* interfaces typically constitute the general grain boundaries and are geometrically more complex. Characters in such interfaces can be approximately described by treating them as a superposition between small patches of interfaces of *Types I–III* and periodic interface dislocations, disconnections, and/or low-energy ledges.

One or more sets of interface line defects commonly exist on all types of interface described above (Hirth et al. 2013). Although the net defect content obeys the Frank-Bilby (F-B) theory, specific variations in the interface structures may be complex and must be resolved by atomistically informed Frank-Bilby theory and high-resolution microscopy (Wang et al. 2013; Hirth et al. 2013; Salehinia et al. 2015).

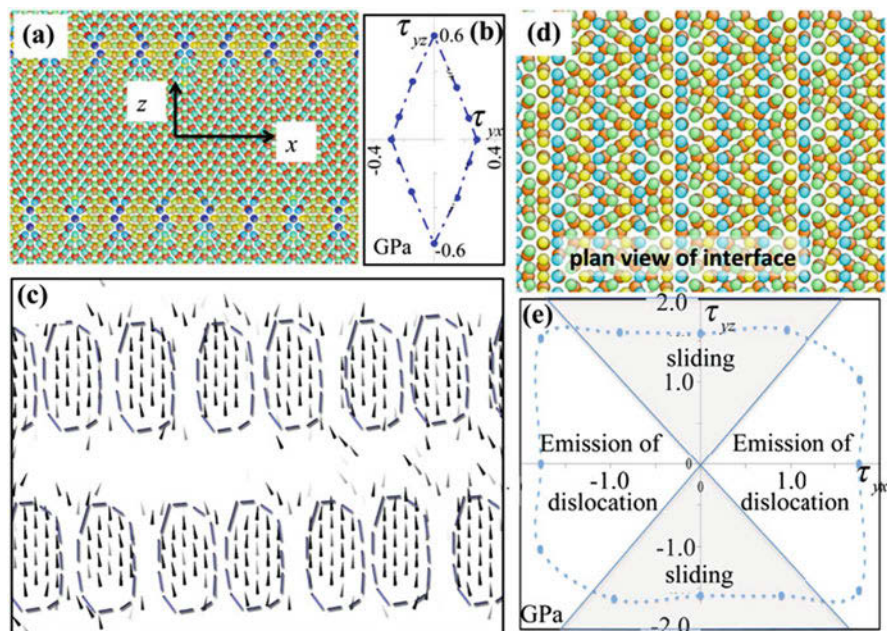
Mechanical responses (such as shear) of interfaces within each type also show similar behaviors. The shear responses of *Types I* and *II* interfaces are summarized in Fig. 5, using the *Type I* Cu-Nb Nishiyama-Wassermann (N-W, $\{111\}_{fcc}||\{110\}_{bcc}$) interface and the *Type II* Kurdjumov-Sachs (K-S, $\{112\}fcc||\{112\}bcc$) as examples. As shown, the shear strength of the *Type I* interface (Fig. 5b) is (i) significantly lower than the theoretical shear strengths in perfect crystals of Cu and Nb and (ii) is in-plane anisotropic. The shear mechanism for the Type I interface, as revealed


**Fig. 5** Structure, shear strengths, and shear mechanisms of Type I N-W Cu-Nb (**a–c**) interface and Type II K-S interface (**d**, **e**) (Wang et al. 2014a)

by interfacial disregistry analysis (Fig. 5c), is the easy nucleation and expansion of interface dislocations (loops) at the interface dislocation nodes or the glide of misfit dislocations if the habit planes for both joining phases are compact/near-compact. The in-plane, anisotropic shear resistance for the *Type II* interface is plotted in Fig. 5e. As shown, the shear strength along the compact directions is relatively low (Fig. 5d), and when shear deformation is applied along the non-compact directions, lattice dislocations may nucleate and emit from interfaces (Fig. 4b). Type III interfaces do not possess compact directions or compact planes; hence they typically do not slide in response to in-plane shear load. Instead, the shear loading is accommodated by nucleation and emission of lattice dislocations from interfacial intrinsic dislocations. The shear response of *Type IV* interfaces is more complicated due to the disordered atomic structure. At room temperature, they are typically associated with a high shear resistance (>2.0 GPa) in concomitant to either atomic reconstruction or the nucleation/emission of lattice dislocations.

## 2.2 Dislocation Nucleation at Interface

Lattice dislocations can be nucleated from interface via two distinct mechanisms, namely, (1) creation of a complete new loop due to stress concentration and (2) dissociation of a pre-existing misfit dislocation into a lattice dislocation half

loop and an interfacial residual dislocation. In the first mechanism, the interfacial dislocations typically retain their Burgers vector, unless the deposited portion of the nucleated loop reacts with the intrinsic interface dislocations. In the second mechanism, the Burgers vectors of the intrinsic interfacial dislocations are altered. For instance, on a pristine K-S $\{111\}_{fcc}||\{110\}_{bcc}$ interface, there are only misfit dislocations with in-plane Burgers vectors. Therefore, lattice dislocations with out-of-plane Burgers vectors can only be produced in full loops via stress concentration (Fig. 5a). On the other hand, the faceted K-S $\{112\}_{fcc}||\{112\}_{bcc}$ interfaces have lattice misfit with components both inside and out of the interface plane. Under a mechanical excitation, the intrinsic interface defects can therefore dissociate into a lattice dislocation and an interface residual.

The theoretical model and the atomistic simulations (Zhang et al. 2011, 2012; Wang et al. 2012b; Beyerlein et al. 2013a, b) indicated that only higher ranking slip systems can be nucleated from the interface. Nucleation of lattice dislocations with low-ranked or zero Schmid factors (also known as the non-Schmid effect) is not observed. The nucleation behavior of lattice dislocations from interface, similar to the interfaces' shear responses, can be classified by their types (Fig. 6). On a *Type*

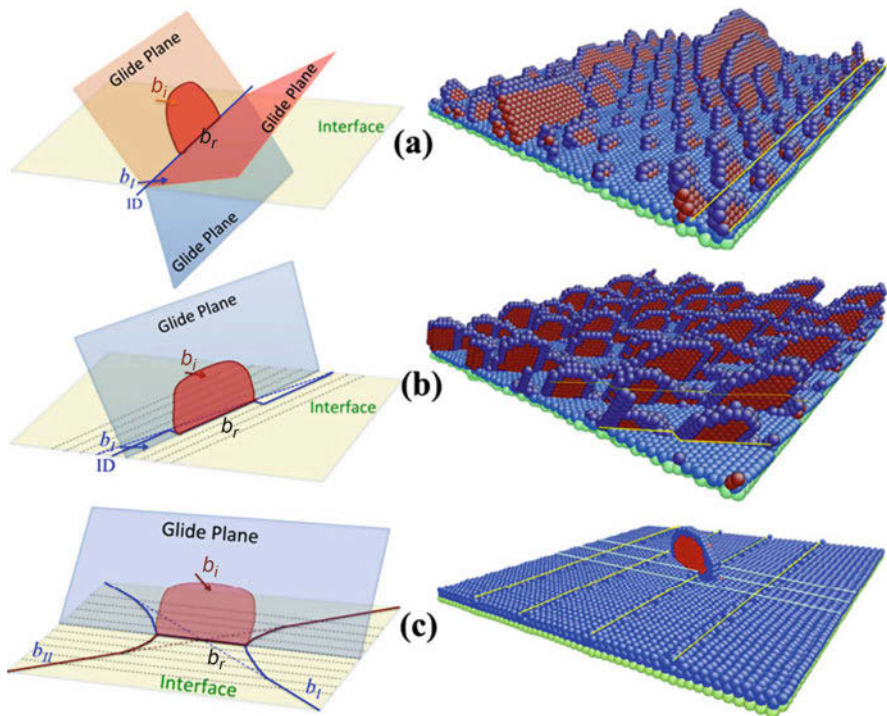

**Fig. 6** Schematic illustrations and snapshots of atomistic configurations demonstrating the mechanisms of lattice dislocation nucleation at interfaces. Three figures, respectively, show typical scenarios when interface dislocations lines are (**a**) parallel, (**b**) near-parallel, and (**c**) non-parallel to the trace of glide planes at interface (Wang et al. 2014a; Beyerlein et al. 2013b)

*I* interface (Zhang et al. 2011, 2012), there are commonly aligned traces of glide planes and the intrinsic interfacial dislocations. Due to the low shear resistance of interface, the local intensive shear results in the nucleation of lattice dislocations along the lines of interface dislocations (Fig. 6a). On *Type II* and *III* interfaces (Wang et al. 2012b, 2013), the interface dislocations may have Burgers vectors that are out of the interface plane. Their cores are typically non-planar even though they may have an in-plane Burgers vectors (Shao et al. 2018b). For these types of interfaces, dissociated-based nucleation is easier when interface dislocations are along or near-parallel (such as shown in Fig. 6a, b) to the interfacial traces of glide planes. When this parallelism cannot be established, nodes can serve as nucleation sites associated with the reassembly of interface dislocations around the node (Fig. 6c).

## 2.3    Dislocation Transmission Across Interface

Slip transmission for dislocation across interfaces takes place, to a large degree, depending on the structure of a given interface. For the investigation of slip transmission, two important criteria, both geometrical and energetic, have to be considered. Geometrically speaking, in order for transmission to happen, slip systems of the crystals on both sides of the interface have to be well aligned to provide an efficient slip path way. A good alignment between slip systems from both crystals requires that their Burgers vectors are aligned and their slip planes join at the interface. A geometrical factor, $\chi$, that describes the alignment of these slip system can therefore be expressed as (Werner and Prantl 1990)

$$\chi = \left\langle \cos\left(\frac{\pi}{2}\frac{\theta}{\theta_c}\right)\right\rangle\left\langle \cos\left(\frac{\pi}{2}\frac{\kappa}{\kappa_c}\right)\right\rangle, \tag{1}$$

where $\kappa$ is the minimum angle between their Burgers vector, $\theta$ is the minimum angle between the intersection lines that each plane makes with the interface (Roters et al. 2010), and $\theta_c$ and $\kappa_c$ are the limiting angles for $\kappa$ and $\theta$, respectively. The bracketed $<x>$ has value 0 when $x < 0$, and a value of $x$ otherwise. Apparently, an efficient transmission path across the interface would have $\chi = 1$ (Beyerlein et al. 2013b). Equation (1) also implies that when $\kappa > \kappa_c$ or $\theta > \theta_c$, $\chi = 0$, i.e., transmission is not possible. Note that $\chi$ is purely a geometrical measure and is independent of local stress. Since the Schmid factor of the outgoing slip system, $m_{\mathrm{OUT}}$, is also a limiting geometric factor (Lee et al. 1989), Eq. (1) can be modified: $\chi_\sigma = \chi m_{\mathrm{OUT}}$.

Energetically, easy transmission demands a low activation barrier. For instance, a glide lattice dislocation tends to spread within interfaces with low shear strengths (weak interfaces) and reduces its self-energy. Slip transmission would require the dislocation to re-constrict its core, leading to a relatively high energy barrier. Weak interfaces are therefore difficult for dislocations to pass. Conversely, stronger interfaces offer lower resistance for dislocation passing due to the significantly less pronounced core spreading.

Generally, since the phases joining at the interfaces can be of different crystal structure, orientation, elastic properties, chemistry, etc., dislocations are energetically favored to be trapped at interfaces rather than crossing it (Wang et al. 2008b). The complete transmission phenomenon is indeed an absorption-nucleation-emission process (Wang and Misra 2011).

## 2.4    Dynamic Recovery of Dislocations Within Interface

Remarkably, in multilayered materials fabricated via the ARB route, such as the roll-bonded Cu-Nb, the interfaces develop well-ordered atomic structures with preferred orientation relations, even under severe plastic strains (Beyerlein et al. 2014). In order to attain such extraordinary stability under such extreme conditions, mechanisms must be in place for interfaces to recover from the accumulation of damage due to the defect-interface interactions. For instance, interfacial defects can move, annihilate, or assemble then re-emit into the joining phases (Wang et al. 2011). Relative to their reaction rates, the mobility of these defects within interfaces are the limiting mechanism. Characteristics of an interface, such as its geometry, defect structure, and defect content, may all lead to different levels of difficulty for a defect to move. The interfaces with the right combinations of such attributes that facilitate motion of defects are less susceptible to accumulation of extrinsic interface defects, leading to a stable interface structure and orientation relation. These interfaces are therefore referred to as *kinetically stable interfaces*. Conversely, interfaces with poor defect mobility are referred to as *kinetically unstable interfaces*.

## 3    Fundamental Aspects of Interface Dislocation Dynamics

Interface-mediated plastic deformation mechanisms, as shown in Sect. 2, can be described by the motion/reaction of line defects at/near interfaces. By incorporating the interface physics in existing DD models, the AIDD model is developed (Wang et al. 2014a). The essential aspects are summarized as follows:

1. The interface is modeled as a piecewise flat "slip" plane, allowing the glide and climb motion of interface dislocations, depending on the relation between Burgers vector and the local interface plane normal.
2. Two distinct types of dislocations are modeled – interface dislocations and lattice dislocations. The interface dislocations include the intrinsic interface dislocations (misfit dislocations) as well as the extrinsic interface dislocations (deposited by lattice dislocations).
3. The evolution of dislocation aggregations inside the constitutive phases in the UFG and at the interfaces is dependent on the dislocation activities within phases, interfaces, and interchanges between the two. The mobility law and reaction rules of dislocations within the constitutive phases are identical to the conventional DD models (El-Awady et al. 2009; Ghoniem et al. 2000; Shao et al. 2014b; Hirth et al. 1998; Zbib and Diaz de la Rubia 2002). The laws for the motion/reaction

of the interface dislocations (e.g., drag coefficients and vacancy/interstitial migration energies) are different from that for the lattice dislocations and are, therefore, necessary to be calibrated using atomistic simulations/experimental observations.

4. Interchange between the lattice and interface dislocations can happen via the entrapment of lattice dislocation at interfaces and the nucleation/emission of lattice dislocations from interfaces.

In this section, the implementation of such interface physics, including intrinsic interface dislocation structure as well as the unit reaction mechanisms, in the AIDD model is discussed in detail.

## 3.1    Description of Interface Structures

Structure of the intrinsic interface dislocations (misfit dislocations) can be uniquely obtained via the atomistically informed Frank-Bilby (AIFB) theory (Wang et al. 2013; Hirth et al. 2013; Chen et al. 2017). Taking the Al-TiN interface as an example, the crystal structures of Al and TiN are FCC and zinc blende (in which both Ti and N atoms form FCC lattices), respectively. Experimental observations and ab initio calculations (Xie et al. 2009; Yadav et al. 2015) revealed that the adjoining Al and TiN have preferred orientation of $<110>_{Al}||<110>_{TiN}$ on $\{111\}_{Al}||\{111\}_{TiN}$ and form a *Type I* interface. The lattice constants of Al and TiN are $a_{Al} = 4.05$ Å and $a_{TiN} = 4.25$ Å, which corresponds to a 5% lattice mismatch. This mismatch results in a semi-coherent interface with the spacing between misfit dislocations of around 6 nm. Since zinc blende structure is similar to FCC, the (111) interface between Al-TiN is geometrically similar to a (111) Cu-Ni interface (Fig. 7a). Similarly, the Al-TiN interface is decorated with FCC and HCP coherent patches separated by a hexagonal/triangular network of Shockley partial dislocations (Yadav et al. 2015). The interface stacking fault energy on the Al-TiN interface, according to first principles calculations, is above 1 J/m$^2$ (Yadav et al. 2015); this energy is extremely high compared to that of the Cu-Ni (111) interface ($\sim$0.04 J/m$^2$). Atomistic simulations performed on (111) Cu-Ni interface reveals that high interface stacking fault energy results in the recombination of Shockley partial dislocations forming perfect dislocations (Fig. 7b) (Shao et al. 2013). Therefore, the misfit dislocation network of Al-TiN is modeled in AIDD as a combination of perfect and partial dislocations (Fig. 7c) (Yadav et al. 2015). In practice, to improve computational efficiency of AIDD, the spacing is enlarged while preserving the geometrical feature of the dislocation network.

## 3.2    Dislocation Nucleation at Interface

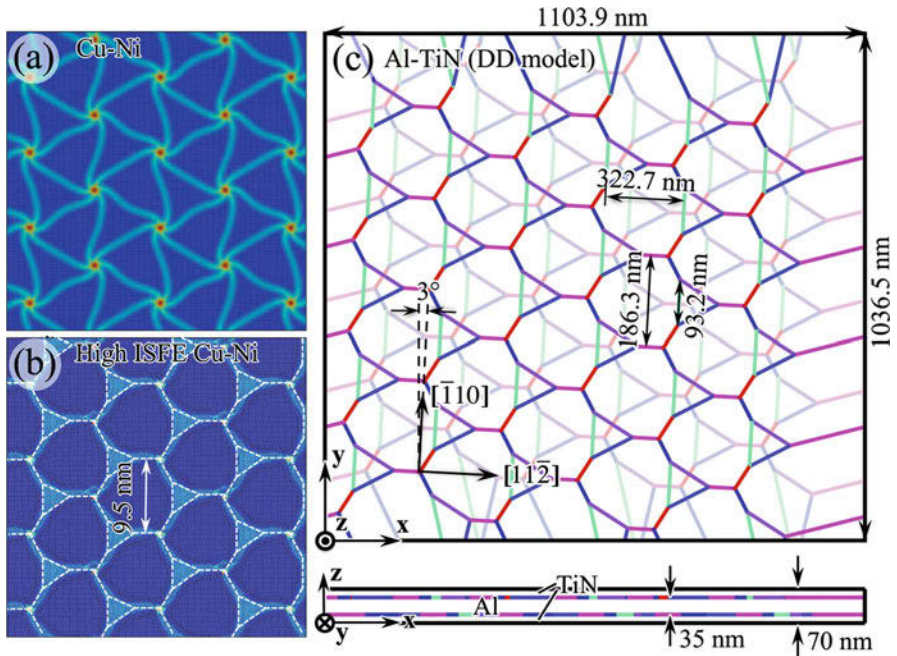
The treatment of lattice dislocation nucleation (Fig. 8a) from interfaces is carried out in several steps: (1) the dislocation lines are checked with respect to the traces of


**Fig. 7** Incorporating atomistic information of the Cu-Ni interface, the dislocation structure of the Al-TiN (111) interfaces is obtained. (**a**) Shows the structure of Cu-Ni (111) interface obtained from atomistic simulation, (**b**) shows structure of an Cu-Ni (111) interface with an augmented interface stacking fault energy, (**c**) shows the dislocation structure of the Al-TiN (111) interface as implemented in the AIDD (Shao et al. 2018a)

slip planes (faint dashed lines) for parallelism, (2) a dislocation segment of a finite length that is parallel or near-parallel to a trace is "pulled" on to the trace and is registered as potential dislocation nucleation sources, and (3) the nucleation is then commenced on a fraction of the selected sources according to a global nucleation rate shown below. The various situations in which a dislocation can be selected as a source are shown in Fig. 8a.

The global dislocation nucleation rate in a crystalline material under stress can be written as (Hirth and Lothe 1982):

$$J = V C_n \omega n_0 \exp \left( \frac{-\Delta E_{line} + \pi r^2 b \tau_a / 2}{kT} \right) \tag{2}$$

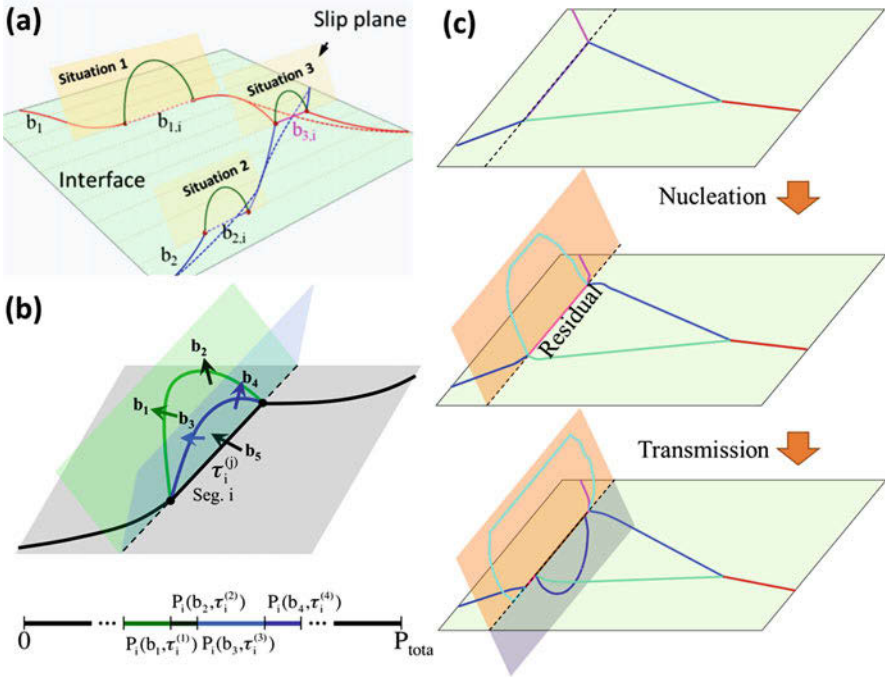
where $V$ is volume of the material, $\omega$ is the frequency that an atom on the periphery joins the critical nucleus, $n_0$ is the instantaneous concentration of the number of the nucleation sites for lattice dislocation identified by step (2), and $C_n$ is a numerical term to scale the global probability. The exponential term in Eq. 2 gives the probability of finding a particular nucleation site in critical condition, $\Delta E_{line}$


**Fig. 8** (**a**, **b**) Schematics of the implementation of nucleation mechanism in AIDD. (**c**) The realization of slip transmission across interface via a series of nucleation events, shown by actual snapshots of dislocation configurations from AIDD (Shao et al. 2018a)

is the change in dislocation line energy associated with the nucleation of a critical dislocation half loop, $r$ is the radius of a critical nucleus, and $\tau_a$ is the resolved shear stress on each of the slip systems due to the applied stress. The current version of the AIDD model does not explicitly compute contribution of stacking fault energy to nucleation. A nominal, uniform radius of critical nucleus is assumed. The actual size of the nucleus can be computed from experimental observations. This nucleation routine is performed periodically, namely, every $\Delta T = n\Delta t$ ($\Delta t$ is the numerical time step), a total of $J\Delta T$ sources are activated. The selection of the nucleation sites to be activated is achieved by a random Monte-Carlo process (Gillespie 1976) constrained by the relative nucleation probability per site (Fig. 8b).

Each of the potential nucleation sites can nucleate lattice dislocations with different Burgers vector, radius of the nucleus (half length of the interface dislocation segment) at different local resolved shear stress. Each combination of these factors is associated with a distinct probability, $P_i^{(j)}\left(b_i^{(j)}, \tau_i^{(j)}, r_i\right)$:

$$P_i^{(j)} = \exp\left(\frac{-\Delta E_i^{(j)} + \pi r_i^2 b_i^{(j)} \tau_i^{(j)}/2}{kT}\right). \tag{3}$$

Variables in Eq. 3 are similar to those in Eq. 2, but they represent local information at a particular source for a particular nucleation scenario. The Monte-Carlo selection process (Fig. 8b) is carried out by first constructing a grand probability interval according to $P_{\text{total}} = \sum_{i,j} P_i^{(j)}$ and generating a random number $\hat{r} \in [0, 1)$. A particular nucleation scenario at a nucleation source is selected if $\hat{r}P_{\text{total}}$ falls within the corresponding subinterval.

Kinematically, a lattice dislocation is nucleated by introducing a semielliptical half loop with a designated Burgers vector on to the selected slip plane. The two ends of the loop coincide with those of the interface dislocation source. Interface dislocation source is now the residual dislocation, $b_{res} = b_{\text{int.}} - b_i^{(j)}$. Under the drive of a sufficient resolved shear stress, the nucleated dislocation can propagate within the grain/phase until it reaches an adjacent interface. Slip transmission can be captured using the current nucleation scheme. Figure 8c shows the successive snapshots of dislocation structures for nucleation of a lattice dislocation and subsequent transmission of another lattice dislocation to the other side of the interface.

### 3.3   Reaction Kinematics of Dislocations Within Interface

Figure 9 lists typical reaction kinematics of interface dislocations that has been implemented into the AIDD model. An interface dislocation, depending on its Burgers vector, can glide or climb on the interface plane, i.e., when $\mathbf{b}_{inter} \cdot \hat{n}_{inter} = 0$, the dislocation is glissile; otherwise, it can only move by climb. If portions of two dislocations are in close proximity and have the same Burgers vector and opposite line sense, they annihilate (Fig. 9a). The reaction is expressed as $b_{react.\,1} - b_{react.\,2} = 0$. The reaction between two non-opposite dislocations is still permitted (Fig. 9b) if they are (1) critically close, (2) near-parallel line sense, and (3) if the resulting dislocation has lower line energy, i.e.

$$b_{react.1}^2 + b_{react.2}^2 > b_{product}^2.$$   (4)

As a result of this reaction, two new nodes form at both ends of the newly formed dislocation segment (junction). As discussed in Sect. 2.4, when the reactant dislocations are of climb type, these mechanism are responsible for the dynamic dislocation recovery at interfaces.

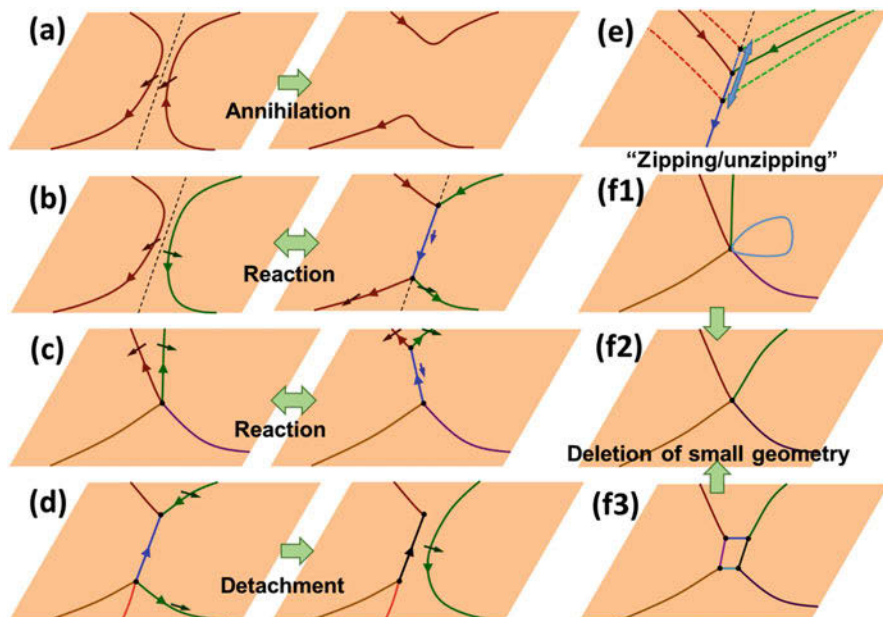
Near a dislocation node, more complex reactions are possible. If two dislocation "arms" branching out from a single condensed node are attracted to each other and satisfy Eq. (1), they react and result in an extended nodal structure comprising two nodes and a junction (Fig. 9c). A dislocation line (represented by the two dislocation arms colored in green in Fig. 9c) may detach from an extended node when it does not intersect other dislocation lines topologically (i.e., its arms lie adjacent to each other and on one side of the extended node). The result is an extended node with the number of arms in each condensed node reduced by one. Similar to the behavior


**Fig. 9** Schematic illustration of possible reaction kinematics implemented into the AIDD

of dislocation junctions in a grain/phase (El-Awady et al. 2009; Hirth et al. 1998; Zbib and Diaz de la Rubia 2002), the nodes can move via the zipping/unzipping mechanism (Fig. 9e).

The reactions among interface dislocations over an extended time and loading history may produce "debris," in the form of small dislocation geometries, such as dislocation loops and small extended nodes (Fig. 9f1, f3). Some small geometries do not have long range stress field and can be eliminated to improve computational efficiency (Fig. 9f2).

## 3.4 Dislocation-Interface Interactions

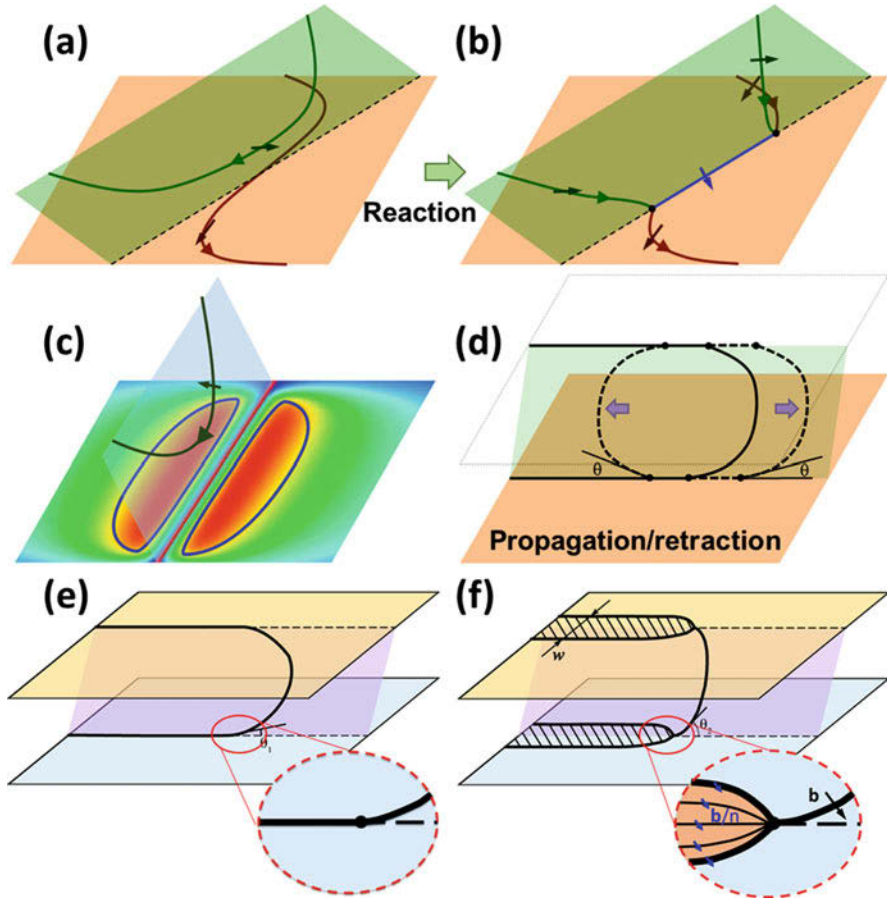
When lattice dislocations approach within a critical distance to a "strong" interface, they are captured by the interface and converted to interface dislocations; their Burgers vectors are conserved (Wang et al. 2014a; Shao et al. 2018a; Beyerlein et al. 2013a, b). If an interface dislocation with near-parallel line sense is present, the incoming lattice dislocation may react with it and form a new interface dislocation (Fig. 10a, b), once the reaction leads to a lower dislocation line energy, i.e., $b_{\text{lattice}}^2 + b_{\text{inter}}^2 > b_{\text{result}}^2$. On the other hand, when a "weak" interface with relatively low shear strength is considered, interface dislocation loop may nucleate associated with the localized shear in response to the stress field of the incoming lattice


**Fig. 10** Schematic illustration of lattice dislocation – interface interaction mechanisms as implemented in the AIDD model

dislocation (Fig. 10c, the interface plane is color coded by absolute magnitude of resolved shear stress).

When the interface spacing is below ∼100 nm, dislocation motion is confined between adjacent interfaces. The CLS mechanism is modeled in AIDD (Fig. 10d) such that if the angle between a dislocation segment and the interface is small ($\theta < \theta_c$), it will be continuously deposited on the interface, and the remaining dislocation will "thread" within the layer. Conversely, if the direction of the resolved shear stress and the bow-out direction of the threading dislocation reverse, the retraction of the deposited dislocations on the interfaces (extrinsic dislocations) can be achieved.

The extrinsic dislocations create strong back stress to the threading dislocations in their vicinity and give rise to a high strain hardening rate in the multilayered

materials (Wang and Misra 2014). However, the hardening rate is dependent on the localization of interfacial dislocations' cores. Core delocalization (core-spread) is expected to moderately relieve the back stress from the extrinsic interface dislocations. A spread dislocation core is modeled in the AIDD by treating a dislocation line as a set of $n$ parallel dislocation lines distributed across a width ($w$) with reduced Burgers vector ($\mathbf{b}/n$). This is shown in Fig. 10e, f.

## 4 Applications of Atomistically Informed Interface Dislocation Dynamics

The AIDD model has been applied to the deformation of the metallic multilayers (Cu-Nb) and metal-ceramic multilayers (Al-TiN) (Wang et al. 2014a; Shao et al. 2018a; Huang et al. 2015). In this section, we briefly review these applications and discuss the capabilities of the AIDD model.

### 4.1 Metallic Multilayers

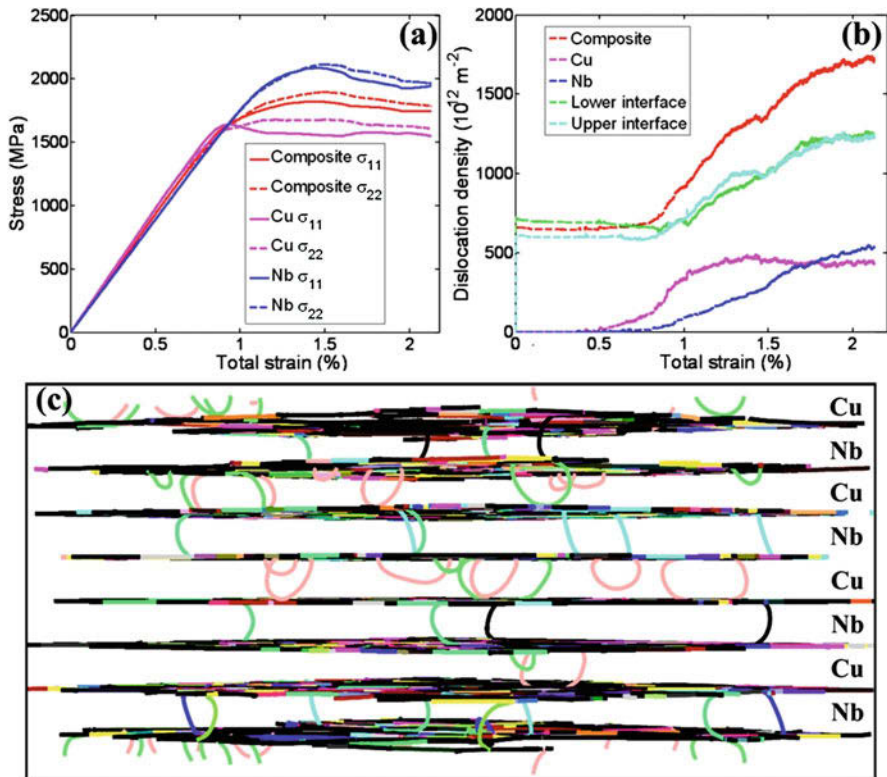
The mechanical response of Cu-Nb multilayers has been investigated by an AIDD simulation. In this simulation, the dimensions of the simulation box are $0.5 \times 0.5 \times 0.1$ µm. Equal thickness of 50 nm has been assigned to Cu and Nb layers. Full periodic boundary conditions are applied. As an initial condition, dislocation loops with random Burgers vectors (obeying crystallographic relations in Cu and Nb, respectively) were inserted in both interfaces corresponding to an initial dislocation density of $1.8 \times 10^{15}$ m$^{-2}$. An in-plane stretch loading is applied to the model by prescribing $\dot{\varepsilon}_{xx} = \dot{\varepsilon}_{yy} = \dot{\varepsilon}_{app}$ and $\sigma_{zz} = 0$, where the x and y are in-plane orthogonal directions and z is perpendicular to the interface plane. The stress-total strain curves for Cu and Nb individual layers and the multilayer are shown in Fig. 11a. Agreeing well with atomistic simulations (Abdolrahim et al. 2014), in AIDD, Cu layers yielded earlier than Nb layers, due to lower activation energy barrier in Cu. After nucleation of lattice dislocations, the lattice dislocations continued propagating similar to the Frank-Read mechanism. After continued propagation, the portion of the dislocation loop approaching the interface eventually was absorbed by the interface. Truncated by the absorption event, the remainders of the dislocation loop within the layers thread within the layers following the CLS mechanism. The gross behavior of dislocations is reflected in the evolution of dislocation densities in Fig. 11b. Corresponding to the stress-strain curves shown in Fig. 11a, an increase in dislocation density is first observed at a total strain of around 0.5% and 0.8%, corresponding to the strains at which dislocations in Cu and Nb were nucleated. The dislocation density in the two interfaces can be seen to constantly rise after nucleation. This is due to the operation of the CLS mechanism, where extrinsic interface dislocations are continuously deposited on to the interfaces as the threading dislocations propagate.


**Fig. 11** Results from the AIDD simulation of Cu-Nb multilayers, including (**a**) the stress-strain curves and (**b**) the dislocation densities for the individual layers and the composite, as well as a snapshot of dislocation configuration during simulation (Wang et al. 2014a)

## 4.2 Metal-Ceramics Multilayers

Two main sources contribute to the strain hardening of the metal-ceramic multilayers, namely, (1) the relative slip activity between the metal and ceramic layers and (2) the back stress imposed by the "deposited" (extrinsic) dislocations at interfaces (Wang and Misra 2014). The effect of the first source is demonstrated here (Shao et al. 2018a; Huang et al. 2015) using the Al-TiN as the materials of choice. The metal layers, contrasted with the ceramic layers, typically undergo much more extensive plastic deformation ascribed to factors including lower yield strength, easier nucleation of dislocations, and higher dislocation mobility. In Al layers, plastic deformation takes place following the CLS mechanism, i.e., threading dislocations propagate within the Al layer bound by the interfaces and deposit extrinsic interface dislocations. In experiments, the mechanical properties of the Al-TiN multilayers have been extensively evaluated using compressive tests normal to the interfaces. Under this loading condition, due to the aforementioned

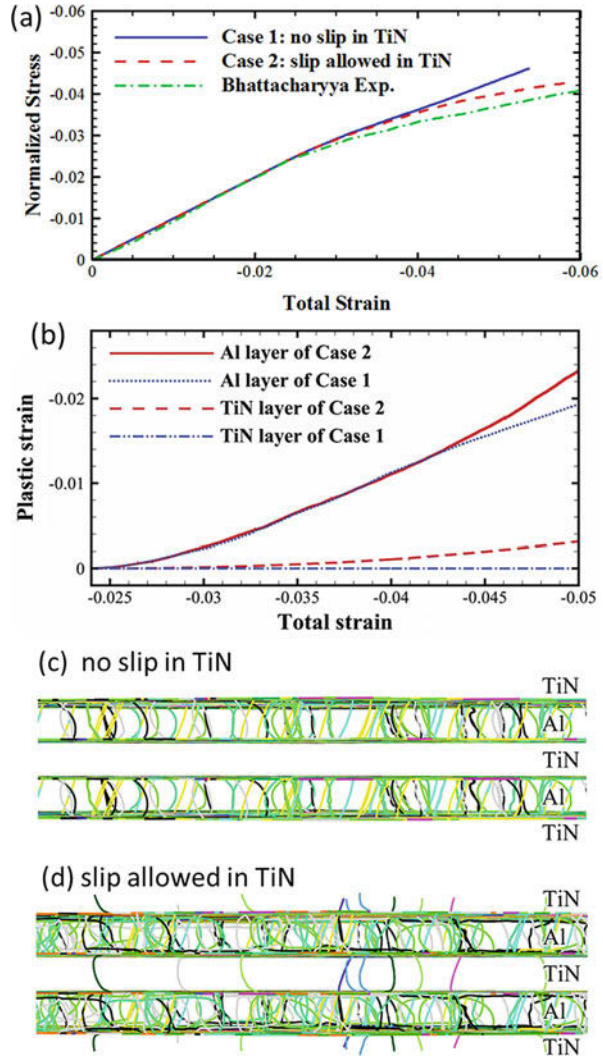
incompatibility in plasticity and elastic constants, a large compressive (tensile) stress exists in the Al (TiN) layer parallel to the interface. The strain hardening of Al-TiN owing to the first source is ascribed to this factor, which, in turn, is dependent on the relative slip activity between the metal and ceramic layers. Next we study the deformation of two cases of Al-TiN: (1) no slip is allowed in TiN layer, and (2) moderate slip activity is allowed in TiN. The elastic constants used in the simulations are $E_{Al} = 70.7$ GPa, $\mu_{Al} = 26.2$ GPa, and $\nu_{Al} = 0.35$ and $E_{TiN} = 251$ GPa, $\mu_{TiN} = 100.4$ GPa, and $\nu_{TiN} = 0.25$. The computational cell has periodic boundary conditions in all three directions. The dimensions in x and y are around 1 μm. In the computational cell, the Al layers have the same thickness of 35 nm.

For this demonstration, both Al and TiN layers are initially dislocation free; the plasticity therefore initiates via the interface nucleation of dislocations. For the cases considered, the nucleation rate for Case 1 is zero, while nucleation rate for Case 2 is non-zero but $J_{TiN} < <J_{Al}$. The mobility of dislocations in TiN is also much lower. The results of the simulations are shown in Fig. 12. Apparently no dislocations are present in TiN in Case 1, while a few dislocations are visible in Case 2. Dislocation activity is observed in Al in both cases. In Case 2, the plastic deformation in TiN layer at total strain of 5%, $\varepsilon_p^{TiN}$, is only about 13% of the plastic strain in Al, $\varepsilon_p^{Al}$. Although this is the case, it significantly reduces the strain hardening rate (red dashed curve in Fig. 12a). The AIDD model with the plasticity enabled in TiN layer shows good agreement with the experiments by Bhattacharyya et al. (2011). The stress-strain curves normalized by the measured compressive elastic moduli of the simulations compared with the experimental results are shown in Fig. 12a. Although the yield point shows a small difference (a parameter that can be easily adjusted in AIDD), the simulated strain hardening rate for Case 2 approaches the values observed in the experiments. The results also indicate that the plastic co-deformation between the Al and TiN layers is necessary for the observed strain hardening rate in the experiment.

## 5    Remarks and Perspectives

Bulk ultrafine-grained materials, notably the multilayered materials, can exhibit a remarkable combination of thermomechanical properties, such as high yield strength, good ductility, thermal stability, and mechanical stability at extreme strains. All of which are ascribed to a number of unique characteristics of these materials, namely, high density of internal surfaces (interfaces), intergrain/interphase/interlayer geometrical constraints, highly regulated layer thickness, and finely tuned interface properties (including orientation relation, atomic and defect structure, and in-plane shear strengths).

Specifically, these extraordinary properties stem from the ability of the nanolaminates in regulating the behavior of glide dislocations. The interfaces serve multiple roles to dislocations, including the sources, barriers, as well as sites for storage, reaction, and dynamic recovery. Deep understanding toward these interface physics

**Fig. 12** Results from the AIDD simulations of Al-TiN multilayers: (**a**) stress-strain curves with experimental result from Bhattacharyya et al. (2011) and (**b**) evolution of plastic strains as a function of the total strain. Snapshots of dislocation configurations of the two simulations are shown in (**c**) for Case 1 and (**d**) for Case 2 (Shao et al. 2018a)


in the recent year has been provided through an abundant collection of modeling efforts at various length scales combined with experimental observations. The fruition of these theoretical studies provided insights using different techniques, including atomistic simulations (Derlet et al. 2009; Wang et al. 2008b; Wang and Misra 2011; Hoagland et al. 2002), dislocation dynamics (Zbib et al. 1998; Shehadeh et al. 2006; Overman et al. 2009), and crystal plasticity (Marin and Dawson 1998; Groh et al. 2009) simulations. However, a challenge still remains in the integration of all the discovered interface physics into a unified multiscale model to realize predictive capability (Wang et al. 2014a, 2009b).

### Abstract

Over the past few decades, discrete dislocation dynamics, a modeling framework allowing for the simulation of the collective motion and interactions of dislocations in crystalline media, has been the subject of intense development worldwide. In recent years, a series of novel numerical algorithms, chemomechanical frameworks, and applications have been proposed. These advances have taken the field closer to enabling predictions of the mechanical response

of engineering polycrystals, e.g., textured crystalline aggregates with impurities. Further, interesting pathways have been proposed to bridge discrete dislocation dynamics simulations with harmonic transition state theory, thereby delineating potential routes for performing coarse graining from the viewpoint of thermodynamics. This chapter summarizes some of the important recent contributions in the field of discrete dislocation dynamics.

# 1    Introduction

Plastic deformation in crystalline metals is generally a consequence of the collective motion of large numbers of curvilinear defects called dislocations. The mobility of dislocations gives rise to plastic flow at relatively low stress levels compared to the theoretical strength. In a typical metal, dislocation densities, $\rho$, range from $10^{10}$ to $10^{15}$/m$^2$, i.e., $10^{10}$–$10^{15}$ m of dislocations per cubic meter of material, values that typically increase rapidly under applied stress (or strain). Further, dislocations form organized structures such as pile-ups, walls, and cells (typically referred to as dislocation substructures). The topological constraints arising from the crystallography greatly add to the complexity of describing dislocation evolution and dynamics. More information about dislocations can be found in many places, for example, in Bacon (1992), Hull and Bacon (2001), and Anderson et al. (2017).

The length scale of dislocation substructures is on the order of many microns, well beyond what can be studied with atomistic-based methods like molecular dynamics. To capture the complexity of correlated and collective dislocation motion and interactions requires a *mesoscale* approach, in which both the length and time scales are extended – in comparison to atomistic simulations – by using dislocations as the simulated entities. In discrete dislocation dynamics simulations (DDD), the elastic forces on dislocations are calculated, and the equations of motion are solved, yielding a quantification of plastic strain as a function of an applied load. While many interesting results have been found using simple two-dimensional models (e.g., Balint et al. 2008; Quek et al. 2014; Zheng et al. 2016), the focus of this paper will be on fully three-dimensional DDD simulations.

The purpose of this chapter is to discuss recent advances in DDD simulations, so in Sect. 2 we give only a brief overview of the basics of dislocation simulations while pointing out some of the limitations in the methods as usually employed. In Sect. 3, recent advances in algorithms will be discussed, including methods to extend the time scales (Sect. 3.1) and recent Green function methods, used to calculate the stresses arising from the dislocations, that are solved using fast Fourier transforms (FFT) in Sect. 3.2. Recent advances in applications of DDD are discussed in Sect. 4, with a specific focus on polycrystalline materials in Sect. 4.1 and the coupling of DDD with chemistry (Sect. 4.2). Improvements in models for sub-scale physics are discussed in Sect. 5, focusing on models for transmission across boundaries (Sect. 5.1) and kinetic models for activated processes (Sect. 5.2). A summary of the state of the field and a discussion of what new capabilities are needed are captured in Sect. 6.

## 2       Basics of Dislocation Dynamics Simulations

DDD simulations all follow the same general procedure, as shown schematically in Fig. 1, which indicates the types of calculations needed and the required information at each step. Here we present the basics of what happens at each time step, with more details available from many sources, such as (Fivel 2008a, b; Sills et al. 2016b; LeSar 2014), recent books (Bulatov et al. 2006; Kubin 2013), and another chapter in this Handbook ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry.

   Dislocations are generally represented as a series of nodes connected by straight lines (Kubin and Canova 1992; Devincre and Kubin 1997; Zbib et al. 2000) or spline-fitted curves (Ghoniem et al. 2000; Wang et al. 2006), as shown in Fig. 1a. As the dislocation network evolves, the nodes must be adjusted (referred to as remeshing). In Fig. 1a, the red segment (connecting nodes 3 and 4) is a *junction* between the dislocation connecting nodes {12345} and the dislocation connecting nodes {7346}. More details on junctions in dislocation dynamics simulations are described in another chapter in this Handbook ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry.

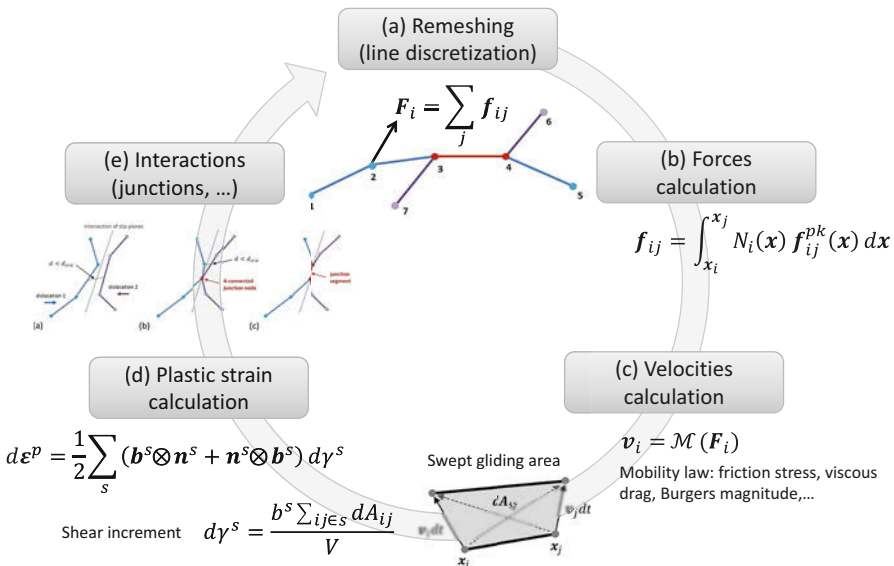

**Fig. 1** Diagram of the main stages composing the basic cycle performed at each time step in DDD simulations. (a) Dynamic discretization of dislocation lines: the topology of the dislocation network evolves at each time step requiring discretization to be performed dynamically. (b) Forces calculation: the stress driving dislocation motion is evaluated from the spatial configuration of the dislocation network. (c) Velocities calculation: once forces on dislocations have been computed, the motion of dislocation lines can be calculated through the mobility law. (d) Plastic strain calculation: the areas swept by dislocation motion allow for the determination of the plastic activity. (e) Interactions: collisions between dislocations during glide are treated via topological rules. The DDD cycle (a) to (e) is repeated until simulation is completed

Once the dislocation network is discretized, the forces on the dislocation segments must be calculated. These forces are determined by calculating the stress at each segment and then applying the usual Peach-Koehler force expression (described in Anderson et al. 2017). For each dislocation node $i$, the nodal force $\mathbf{F}_i$ is the sum of the contributions by each segment $ij$ connected to node $i$ (Fig. 1a):

$$\mathbf{F}_i = \sum_j \mathbf{f}_{ij} , \tag{1}$$

in which $\mathbf{f}_{ij}$ is the force on segment $ij$ acting at node $i$ and is found by integration of the effective force acting along the dislocation segment, as shown in Fig. 1b. More complete details of the calculation of forces on a node are given in Bulatov and Cai (2006).

The stresses from the dislocations are generally calculated by adding up analytical expressions that were derived assuming isotropic elasticity, e.g., as a sum over individual straight segments (e.g., as presented in Anderson et al. 2017) or, for curved segments, as an integral over the dislocation line (de Wit 1960; Ghoniem and Sun 1999). In another chapter of this Handbook ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry, recent advances for calculating stresses based on anisotropic elasticity are discussed.

A major challenge is that the stresses from a dislocation are long ranged and special methods are needed to sum those interactions efficiently. A particularly effective method is the fast multiple method, which has been used in both two-dimensional simulations (Wang and LeSar 1995) and, more recently, in three dimensions (Arsenlis et al. 2007). Another approach, called the box method (Verdier et al. 1998), is less accurate but easier to implement and has less computational overhead and thus likely to be more computationally efficient for small systems. Given that the stress calculation represents the major computational burden, much effort has been made to increase its efficiency through the use of highly parallel computational methods, as in, for example, Arsenlis et al. (2007) and Wang et al. (2006). An alternative approach, based on a direct fast Fourier transform (FFT)-based integration of the Green function to calculate the stress, is described in Sect. 3.2.

The equations of motion for the dislocations are then solved for a given time step. At high strain rates, the full damped dynamics equations of motion are required (Wang et al. 2007) for each node:

$$\frac{d\left(m_i^\star \mathbf{v}_i\right)}{dt} = \mathbf{F}_i - \gamma \mathbf{v}_i , \tag{2}$$

in which, for each node $i$, $m_i^\star$ is the effective mass (which depends on the velocity as described in Hirth et al. 1998), $\mathbf{v}_i$ is the velocity, $\mathbf{F}_i$ is the force on the node from Fig. 1a, and $\gamma$ is the damping coefficient. For strain rates in the range of $10^4 \, \mathrm{s}^{-1}$ and below, it is usually sufficient to assume that the time to reach terminal velocity is small relative to the time step used to solve Eq. (2) (Wang et al. 2007) and equations assuming overdamped dynamics can be employed, with the velocity of the ith node given by

$$\mathbf{v}_i = \mathbf{M} \cdot \mathbf{F}_i, \tag{3}$$

in which $\mathbf{M}$ is the mobility tensor. Mobility laws are discussed in ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry.

The simplest approach to solve for the new nodal position ($\mathbf{R}_i$) is to use a linear, forward, Euler integration based on Eq. (3) and a time step $\delta t$:

$$\mathbf{R}_i(t + \delta t) = \mathbf{R}_i(t) + \mathbf{v}_i(t)\delta t. \tag{4}$$

The choice of time step in Eq. (4) is critical, for if the nodal displacement ($\Delta\mathbf{R}_i(t) = \mathbf{v}_i(t)\delta t$) approaches the size of the segments to which node $i$ is connected, instabilities can arise. One way to minimize instabilities is to use a dynamic time step, which can be done in a number of ways. A particularly simple approach is to prescribe the maximum distance of a nodal displacement, $\delta R_{max}$, calculating the absolute value of the maximum force on a node $|F|_{max}$ at each time step and setting the time step by $\delta t = \delta R_{max}/|F|_{max}$. $\delta R_{max}$ can be varied to achieve stable integration of the nodal positions; however, the time steps can be very small (on the order of $10^{-13}$ s or less) for situations in which dislocations are close together (Wang et al. 2007).

A major issue with the simple integration scheme just described is that there is no way to set an accuracy of the time integration. One approach to improve the time integration and allow for longer time steps is by the use of "predictor-corrector" methods. Predictor-corrector methods use an iterative procedure to find the change in nodal positions. For example, the Heun's method (used in the commonly used DDD program ParaDiS) is a second-order accurate explicit method that uses a forward predictor (Sills et al. 2016a):

$$\mathbf{R}^0(t + \delta t) = \mathbf{R}^0(t) + \delta t\, \mathbf{v}(t), \tag{5}$$

coupled with a trapezoidal method corrector,

$$\mathbf{R}^{j+1}(t + \delta t) = \mathbf{R}^0(t) + \frac{\delta t}{2}\left(\mathbf{v}(t) + \mathbf{v}^j(t)\right), \tag{6}$$

in which $\mathbf{R}$ is the nodal position, $\mathbf{v}$ is the nodal velocity, and the superscript $j$ indicates the iteration number. The error is estimated as

$$E_{iter} = ||\mathbf{R}^{j+1}(t + \delta t) - \mathbf{R}^j(t + \delta t)||, \tag{7}$$

in which $||\cdot||$ is the $L_2$ norm. An iteration proceeds until $E_{iter}$ is less than a prescribed parameter. In Sills et al. (2016a), other, more complicated and more accurate, time integration algorithms are discussed. The time step is dynamically chosen to control the absolute error at each time step, with an error tolerance set by the user. Details are provided in Sills and Cai (2014).

Sills et al. (2016a) described the effectiveness of time integration schemes in simulations of strain hardening in samples with dislocation densities in the range of 0.5 to $3 \times 10^{12}$ m$^{-2}$. When using the Heun algorithm, the authors found that accurate integration of the equations of motion required a range in time steps between $10^{-14}$

and $10^{-11}$ s, with an average time step of $6.5 \times 10^{-13}$ s. Such small steps limit the utility of DDD simulations to relatively small total times, which in turn limits the use of DDD to achieve high levels of strain when using relevant strain rates. In Sect. 3.1, we will discuss recent progress on advanced algorithms for time integration.

In part (d) of Fig. 1 are shown the two stages for calculating the net plastic strain after having determined the dislocation motion. First the area swept by the dislocation is calculated, yielding the amount of shear on its slip plane, $d\gamma^s$ in Fig. 1. The total plastic strain increment $d\varepsilon^p$ is the projection of the shear summed over all slip systems $s$.

The final step of a simulation involves the inclusion of various models that describe sub-scale physics, i.e., physics that is inherently atomistic in nature, which includes the formation of junctions, annihilation, and dissociation. The computational challenges include the detection of possible events and the topological procedures needed to ensure that the correct physics is being modeled. Some aspects of these models are discussed elsewhere in this Handbook ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry.

All three-dimensional discrete dislocation dynamics calculations involve these basic steps. In the next section, we discuss new algorithmic developments that extend the capabilities of DDD simulations to longer times and more complex microstructures.

## 3    Recent Advances in Algorithms

The key computational challenges of discrete dislocation dynamics as usually employed are the time it takes to calculate the stresses, the use of equations for the stress based on isotropic elasticity, and the very small time steps needed to resolve motion when dislocations are close together (discussed in Sect. 3.1). As noted above, much effort has been spent developing ways to reduce the time needed for calculating the stresses by using ways to speed up the calculation of long-range stresses, the use of parallel computation, and, more recently, the use of GPUs.

As discussed elsewhere in this Handbook ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" by Sills and Aubry, the inclusion of anisotropic elasticity has been addressed by many researchers, with a number of methods having been developed. Most of these methods, however, are computationally intensive (over 200 times calculations based on isotropic elasticity) and thus have been rarely used (Yin et al. 2010). Recent work by Aubry and coworkers (Aubry and Arsenlis 2013) using a spherical harmonic expansion of the Green function has led to increased efficiencies of the anisotropic calculations. The computational expense of these methods is highly dependent on the anisotropy factor, ranging from a 50% increase for an anisotropy factor of about 2 (aluminum) to a factor of 60 increase for an anisotropy factor of 7.4 (iron). In Sect. 3.2, we will discuss a new approach that reduces the excess computational burden even further.

## 3.1   Extending Time Scale

The question of finding efficient time integration schemes is recognized as a key issue for discrete dislocation dynamics, as discussed in a series of recent papers (Gardner et al. 2015; Sills and Cai 2014; Sills et al. 2016a). In this section, we focus on recent work that extends the time scales to enable simulations of complex phenomena that require long times, for example, models of work hardening that achieve strains relevant to experiment.

As noted in Sect. 2, the time steps needed for accurate solutions to the equations of motion in discrete dislocation dynamics calculations are typically small enough to limit simulations to small plastic strains. The small time steps are the result of dislocations that are sufficiently close together so that the net forces between them are quite high and nonlinear. The motion of dislocations that are not close to other dislocations will generally have slowly varying interactions and can be accurately calculated with much larger time steps. The disparity of time steps suggests the need for a method that employs time step subcycling for those dislocations that have nearby dislocation and require small time steps.

Cai and coworkers (Sills et al. 2016a) present a specific approach for efficient time integration that is based on the use of the `ParaDiS` code. `ParaDiS` represents dislocations as a series of nodes connected by segments and employs the O(N) fast multipole method (FMM) to calculate the long-ranged stress fields. In the FMM, the net stress at a point is determined by direct sums of the pairwise stresses for nearby dislocations and a hierarchical multipole expansion for more distant dislocations. `ParaDiS` employs the Heun's method from Eqs. (5), (6), and (7) to do the time integration. In Sills et al. (2016a), they also examine the use of more advanced time integration schemes, but we will restrict the discussion to results with the Heun method.

The method of Sills et al. (2016a) is a force-based subcycling. The set of forces on the segments are divided into groups based on the minimum distance between the segments and their neighboring segments, as shown schematically in Fig. 2a. The forces between all segments that lie between zero and $r_2$ are assigned to group 2, forces for segments between $r_2$ and $r_3$ are in group 3, forces between segments with distances between $r_3$ and $r_4$ are in group 4, and all other forces are assigned to group 0, the global group.

Based on velocities of the segments (Eq. (3)), segments in the global group (0) are evolved using a standard time evolution algorithm (e.g., Heun), and the global time step is determined. For segments in other groups, a sequential splitting method (Geiser 2009) is employed, continuing until the time integration converges. Additional procedural and details are described in Sills et al. (2016a).

The subcycling time integration approach was tested (by comparing the calculations based on standard time integration Sills et al. 2016a) for the same simulations of strain hardening in samples with dislocation densities in the range of 0.5 to $3 \times 10^{12} \, \mathrm{m}^{-2}$ described above. For these studies, the groups were created using $r_{g2} = 100b$, $r_{g3} = 600b$, and $r_{g4} = 1600b$, where $b$ is the Burgers vector. As noted above, with the Heun algorithm and no subcycling, the average time step

**Fig. 2** (**a**) Schematic view of how interaction forces are assigned to subcycle groups based on the minimum distance between segments. The dashed ovals represent regions of constant minimum distance from the segment centers at distances of $r_{g2}$, $r_{g3}$, and $r_{g4}$. In their approach, $r_{g1} = 0$ so the segment's self-interaction is assigned to group 1. Colors and numbers indicate the group. (Adapted from Sills et al. 2016a)

was $6.6 \times 10^{-13}$ s. For the same system with time subcycling, the average global time step (with subcycling) was extended to $1.8 \times 10^{-10}$ s (Sills et al. 2016a). The consequence of the longer time step is clear: for the same clock time, the Heun algorithm without subcycling could calculate a total strain of about 0.13%, while with subcycling, the net strain was about 0.6%. Overall, the authors found that the global time step was approximately a factor of 100 larger than in simulations with no subcycling.

These advances in subcycled time integration offer new possibilities for achieving higher calculated strains in discrete dislocation dynamics simulations, which enhances the ability to study such important phenomena as strain hardening. It remains unproven, however, how much these methods will affect simulations at the high dislocation densities common in well-worked metals ($10^{15}$ m$^{-2}$). In Sills et al. (2016a), the reported dislocation densities ($10^{12}$ m$^{-2}$) were considerably smaller, and in dense networks, the fraction of dislocations in the "global group" may be negligible and the benefits of subcycling the time integration reduced.

## 3.2   Fast-Fourier Transform Methods

Stresses in a lattice can also be calculated by identifying the *eigenstrains* associated with the presence of defects. From Mura (1987), an eigenstrain is a nonelastic strain, arising from several potential effects, such as thermal expansion misfits, phase transformations, plastic strains, or misfit strains. Eigenstresses are the self-equilibrated internal stresses caused by the eigenstrains. Here we show how to

calculate the stresses from a set of dislocations such as to simulate their dynamic evolution (Bertin et al. 2015; Graham et al. 2016).

We decompose the total strain into elastic strains and eigenstrains, denoted by $\varepsilon_{ij}^e$ and $\varepsilon_{ij}^*$, respectively, i.e.:

$$\varepsilon_{ij}(\mathbf{r}) = \varepsilon_{ij}^e(\mathbf{r}) + \varepsilon_{ij}^*(\mathbf{r}) . \tag{8}$$

Let us denote the displacement field within the system with $u_i$. The total strain is given in terms of the distortions, which are the displacement gradients $u_{i,j} = \partial u_i / \partial x_j$, in which a subscript comma indicates a derivative. For example, the elastic strain is given by the usual expression:

$$\varepsilon_{ij}^e = \frac{1}{2} \left( u_{i,j}^e + u_{j,i}^e \right) \tag{9}$$

and the total distortion can be written as

$$u_{i,j}(\mathbf{x}) = u_{i,j}^e(\mathbf{r}) + u_{i,j}^*(\mathbf{r}) . \tag{10}$$

Starting with the equation for mechanical equilibrium, $\sigma_{ij,j} = 0$, it is straightforward to show that the elastic distortions are given by

$$u_{k,l}^e = u_{k,l} - u_{k,l}^* = -G_{ki,l} * (c_{ijmn} u_{m,nj}^*) - u_{k,l}^* , \tag{11}$$

in which $G_{km}$ is the elastic Green tensor (described in detail elsewhere de Wit 1960) and $g * f = \int g(\mathbf{x} - \mathbf{x}') f(\mathbf{x}') d\mathbf{x}'$ is the convolution integral. The Fourier transform of Eq. (11) is

$$\hat{u}_{k,l}^e(\mathbf{k}) = \hat{G}_{ki} c_{ijmn} k_j k_l \hat{u}_{m,n}^* - \hat{u}_{k,l}^* , \tag{12}$$

in which a Fourier transform of a function $f$ is denoted by $\hat{f}$, $k_i$ is a component of a wave vector, and $c_{ijkl}$ are elastic constants. $\hat{G}_{ki}$ is the Fourier transform of the elastic Green tensor, whose inverse is given by de Wit (1960)

$$\hat{G}_{ik}^{-1} = c_{ijkl} k_j k_l . \tag{13}$$

Given the Fourier transform of the distortion associated with the eigenstrain, $\hat{u}_{m,n}^*$, we have an algebraic expression for the elastic distortion, $\hat{u}_{k,l}^e(\mathbf{k})$, at each point in $k$-space.

A fast Fourier transform (FFT) method is used to calculate $\hat{u}_{i,j}^*(\mathbf{k})$ at each point of the FFT grid ($\mathbf{x}$). Equation (12) is used to evaluate $\hat{u}_{k,l}^e(\mathbf{k})$, from which $\hat{\varepsilon}_{kl}^e(\mathbf{k})$ is determined. We take the inverse transform to find $\varepsilon_{kl}^e(\mathbf{x})$ using Eq. (9). The stress at each FFT grid point is

$$\sigma_{ij}(\mathbf{x}) = c_{ijkl}\,\varepsilon_{kl}^e(\mathbf{x})\,. \tag{14}$$

Since there are no constraints on the values of $c_{ijkl}$, there is no extra penalty for using the full anisotropic elastic constants in computing the stress and strain fields.

These equations are applicable for any eigenstrain or combination of eigenstrains. The eigenstrain associated with a dislocation is the co-called *plastic distortion tensor*, which is denoted by $\beta_{ij}^p$ and is the distortion associated with the plastic strain:

$$\beta_{ij}^p = u_{i,j}^p\,. \tag{15}$$

$\beta_{ij}^p$ replaces $u_{i,j}^*$ in Eq. (12).

The plastic distortion tensor is a direct measure of the incompatible slip caused by a dislocation. Following Mura (1987), the distortion tensor for a straight edge dislocation located at $(x_1, x_2) = (0, 0)$ with Burgers vector along $\hat{x}_1$ and line direction along $\hat{x}_3$ has only the 21 component that is non-zero. The distortion tensor is

$$\beta_{21}^p = b\,\delta(x_2)\Theta(x_1)\,, \tag{16}$$

where $\Theta(x)$ is the Heaviside step function defined by $\Theta(x) = 1$ for $x < 0$ and 0 for $x > 0$ and $b$ is the magnitude of the Burgers vector. $\delta(x_2)$ is a Dirac delta function that restricts the slip to the plane defined by $x_2 = 0$. Thus, $\beta_{21}^p$ describes the slip (with magnitude $b$) introduced in the upper half plane by the dislocation. Similarly, for a circular loop in the $x_1 x_2$ plane with $\hat{b} = \hat{x}_1$, there is slip inside the loop but not outside the loop – the only non-zero component of the plastic distortion tensor is $\beta_{31}^p$. In all cases, a dislocation line can be identified by a discontinuous jump in $\beta_{ij}^p$.

Recent papers Bertin et al. (2015) and Graham et al. (2016) have implemented this general procedure for calculating the stresses needed for discrete dislocation dynamics simulations. Detailed comparisons in each paper show that the stresses arising from distributions of dislocations calculated with the FFT method agree with those determined from standard analytical expressions (Anderson et al. 2017) for isotropic elasticity. They also show, however, a standard problem that arises when using Fourier transform methods with discontinuous functions (e.g., $\beta^p$) – spurious oscillations and spiking in calculated quantities. Such oscillations, often referred to as Gibbs oscillations, occur frequently in signal processing and computer graphics applications, and many work-arounds have been proposed, mostly focused on smoothing the discontinuity over the Fourier grid. In Graham et al. (2016), for example, an antialiasing method from computer graphics coupled with a low-pass filter was shown to remove the oscillations with minimal effect on the final calculated stresses. Bertin et al. (2015) used an approach in which the dislocation density was spread in a three-dimensional triangular distribution over a $3 \times 3 \times 3$ set of voxels, again with minimal effect on the calculated stresses. This numerical

spreading is analogous to the spread of a dislocation near its core, though with a core width that is related to the mesh size. More recently, replacing the Fourier transform of the derivatives with a transform of discrete derivatives has also been successfully employed to attenuate the Gibbs oscillations (Graham et al. 2019).

Based on the above FFT stress calculations, two approaches for using those stresses in discrete dislocation dynamics calculations were proposed. In Graham et al. (2016), the size of the FFT grid was set such that only one dislocation segment was allowed in each voxel (the three-dimensional volume between grid points). This choice limits the simulations to relatively small sizes and densities of dislocations. The other approach assumes that many dislocations can lie in each voxel (Bertin et al. 2015), which has some complications but enables simulations of more relevant dislocation distributions, as will be summarized next.

The main components of the implementation of the FFT stress calculation within a discrete dislocation dynamics framework in Bertin et al. (2015) are the following: the distortions in Eq. (12) are replaced by the strain tensor $\varepsilon_{kl}$ (which can be shown to be equivalent), the plastic strain change at each time step is calculated by measuring the area swept by the dislocation movement, and by coupling the FFT-based approach to the discrete continuous model (DCM) (Lemarchand et al. 2001; Vattré et al. 2014a). By using the DCM, the FFT approach takes advantage of the high computational efficiency of the FFT algorithm for calculating the long-range forces while allowing for a discrete representation of local dislocation interactions. The computational time associated with the new DDD-FFT approach is significantly lower than that of other DDD approaches when large number of dislocation segments are involved (Bertin et al. 2015). Moreover, the use of anisotropic elasticity comes at a similar computational cost to that of an isotropic simulation. In Sect. 4.1, this approach forms the basis of a new approach for polycrystal plasticity based on discrete dislocation dynamics.

The promise of the FFT approach is that it scales essentially linearly with the number of dislocation segments and, with the use of GPUs to evaluate the stresses, is computationally very fast, such that the stress calculation no longer dominates the time to perform a calculation. This approach opens up the possibility of extending DDD to the high dislocation densities present in such important problems as well-worked metals and fatigue.

## 4   Recent Advances in Applications

Advances in algorithms have enabled the use of DDD for a number of new applications. One such example is the use of new time integration schemes to extend calculations of strain hardening to longer times and, thus, larger strains, as discussed in Sect. 3.1. Here we focus on two other examples, the first being the ability, based on the FFT method described above, to do simulations of the deformation of polycrystals with arbitrary grain sizes, shapes, and orientations. The second example is the linkage between dislocation dynamics and chemistry, an important advance for understanding the effects of chemical constituents on deformation.

## 4.1    Polycrystal Plasticity

A number of studies of dislocation dynamics in polycrystalline materials have been made using two- and three-dimensional models. For this chapter, we restrict the discussion to simulations in three dimensions. We also focus our discussion of calculations in three dimensions on those in which the deformation in all grains in a polycrystalline sample is calculated, rather than in just a single, representative, grain.

All of the studies to date using DDD to study deformation in polycrystalline have been on model systems that do not directly reflect the grain sizes, shapes, and orientations found in general polycrystalline materials. (For more details of prior applications on DDD in polycrystals, see Sect. 5.1.) For example, one study coupled finite element polycrystal plasticity with discrete dislocation dynamics using a system of nine uniform cuboidal grains located in a plane with periodic boundary conditions (Siška et al. 2009). Each grain was oriented along a few specific crystal directions. Others used the same system of nine grains to study the effects of grain size and aspect ratio on the plasticity of free-standing polycrystalline films; however in this work all the grains had the same orientation and the boundaries between the grains served only as stress-controlled barriers to transmission (Zhou and LeSar 2012). Recent simulations were done on pseudo bi-crystals with varying grain disorientation (Prasad Reddy et al. 2013) while other studies examined the role of twins in magnesium (Fan et al. 2015a, b, 2016) and laths in iron (Chaussidon et al. 2008). The most complete model of polycrystalline plasticity at the discrete dislocation dynamics level was in a recent calculation in which the system was represented with a set of equal-sized truncated-octahedral grains with random orientations (de Sansal et al. 2010). While the grain shapes were fixed (and uniform), the effects of the grain size and orientation on the deformation were studied. Overall, however, all of these studies approximated the grain distributions in some way.

Modeling the deformation in polycrystalline systems can be accomplished by coupling polycrystal plasticity calculations, in which the constraints placed on grain evolution by their neighboring grains are directly modeled in the calculation, with discrete dislocation dynamics simulations. The approach described here uses an FFT-based polycrystal plasticity model linked to the FFT-based DDD model described in Sect. 3.2.

Building on previous work (Moulinec and Suquet 1998; Michel et al. 1999), Lebensohn (2001) and Lebensohn et al. (2012) introduced a description of crystal plasticity based on the same basic fast Fourier transform (FFT) algorithm described above but modified to solve an eigenstrain description of the elasticity of heterogeneous media (Mura 1987). The FFT approach solves for the equilibrium stress and strains under the constraint of strain compatibility for systems with periodic microstructures. The plasticity of the polycrystal is described by a parametrized constitutive model, for example, an elasto-viscoplastic model in Lebensohn et al. (2012). The computational time can be several orders of magnitude shorter for the FFT than in the traditional finite element methods (FEM). The results of the FFT approach have been compared in detail with similar calculations based on FEM for a

periodic system of face-centered cubic grains (Liu et al. 2010). The final textures and strain distributions calculated with the two methods show some differences which are still under investigation, in which the FFT approach appears to be less dependent on the resolution of the grids than FEM and, indeed, predicts strain gradients very well at quite low resolution.

The challenge with polycrystalline materials is that the elastic tensor of a grain in the system frame is different depending on the orientation of the grain. To treat such heterogeneous elastic media, Lebensohn, following Moulinec and Suquet (1998) and Michel et al. (1999), introduced a reference stiffness tensor $C_{ijkl}^o$, with details given in Lebensohn et al. (2012). It is relatively straightforward to show that in this approach, the equations for the stress given in Eqs. (12) and (13) are replaced by

$$
\sigma_{ij}^{tot}(\mathbf{x}) = C_{ijkl}^o \varepsilon_{kl}(\mathbf{x}) + \tau_{ij}(\mathbf{x})
$$
$$
\tau_{ij}(\mathbf{x}) = \delta C_{ijkl}(\mathbf{x}) \varepsilon_{kl}(\mathbf{x}) - C_{ijkl}(\mathbf{x}) \varepsilon_{kl}^p(\mathbf{x}) \tag{17}
$$
$$
\delta C_{ijkl}(\mathbf{x}) = C_{ijkl}(\mathbf{x}) - C_{ijkl}^o ,
$$

in which $\mathbf{x}$ is an FFT grid point, $C_{ijkl}(\mathbf{x})$ is the stiffness tensor in the grain associated with $\mathbf{x}$, and $\delta C_{ijkl}(\mathbf{x})$ is a fourth-order tensor quantifying the deviation in the elastic properties associated with each material point $\mathbf{x}$ from that of the reference medium. Note that the solution to the equations in Eq. (17) must be solved in an iterative fashion (Lebensohn et al. 2012).

The FFT-based dislocation dynamics approach (Bertin et al. 2015) described in Sect. 3.2 has recently been implemented (Graham et al. 2019) within the polycrystal plasticity method of Lebensohn et al. (2012). A three-dimensional polycrystalline sample with random grain size shape can either be created through a Voronoi construction or from experimentally determined microstructures. The orientation of the grains is either set randomly or from experiment. An appropriate FFT grid is overlaid on the 3D sample, and periodic boundary conditions are employed. The grain in which each FFT grid point is located is determined, and the stiffness tensor in the system frame is determined from the grain orientation. Typical simulations are done by seeding an initial random distribution of dislocation loops on the slip systems within each grain. For example, in the example discussed below, dislocation loops were placed randomly on the 12 slip systems of a face-centered cubic system within each grain, and the initial plastic strain determined by a method equivalent to evaluating the plastic distortion tensor of Eq. (15). The DDD method described in Sect. 3.2 (Bertin et al. 2015) was then employed, tracking the total deformation of the system as well as the deformation in each grain. The outcome is a polycrystal plasticity simulation package in which a constitutive model of plasticity is replaced by the discrete dislocation dynamics approach described in Bertin et al. (2015).

An example calculation is shown in Fig. 3, in which a system of six grains of nickel with random size, shape, and orientation is included in a periodic cube 1.5 μm per side. The grains were created with a Voronoi construction and mapped onto the FFT grid. A time step of $10^{-13}$ s was used. After an initial relaxation sequence

**Fig. 3** Example calculation of a system of six grains of nickel with random size, shape, and orientation is included in a periodic cube 1.5 μm per side. Shown is the dislocation distribution after an initial relaxation sequence of 1000 time steps, followed by an additional 5000 time steps under stress. The dislocations are shown in the same color as the grain in which they are located

of 1000 time steps, an additional 5000 time steps were performed. At each time step, the iterative solution described in Eq. (17) was used to determine the stress at each FFT grid point. Figure 3 shows the final configuration of that run, with the dislocations shown in the same color as the grain in which they are located. In this model, the interactions between dislocations and the interfaces are approximated with a simple transmission model.

The combined FFT-based polycrystal plasticity/discrete dislocation dynamics (PP/DDD) approach is, to our knowledge, the only such method available for three-dimensional polycrystal plasticity of grains with arbitrary size, shape, and orientation based on the DD simulation of the motion of individual dislocations. Given the linear scaling of the FFT with the number of dislocation segments, there are many potential applications of the PP/DDD approach to important problems in the deformation of materials. There are, however, numerous advances in physics that are needed for accurate polycrystal plasticity calculations, the most important of which are the interactions of dislocations with grain boundaries, which are discussed in Sect. 5.1.

## 4.2 Coupling Dislocation Dynamics with Chemistry

With the intent to develop concurrent multiscale/multiphysics modeling schemes predicting microstructure evolution due to dislocation motion and interaction as well as point and defect cluster rearrangements, a series of studies have focused on coupling mean-field rate theory (MFRT) (Braislford and Bullough 1981), or one

of its derivatives such as cluster dynamics, and DDD. In the former, one establishes continuity equations for each chemical species considered. These essentially translate the effects of point defects and defect cluster generation, migration, and interactions (i.e., annihilation, absorption, emission) on the local concentration of the species of interest. As such, the treatment of dislocation/vacancy interactions has seen a significant gain in interest over the past decade. Fundamentally, this problem holds the key to developing predictive laws of the contribution of dislocation climb to plasticity. In a relatively large series of experimental studies focused on the creep response of metals, the discernment of the contribution of cross-slip and climb to the overall creep rate has been problematic (Kombaiah and Murty 2015; Morrow et al. 2013). More generally and as discussed in Keralavarma et al. (2012) and Keralavarma and Benzerga (2015), the hope is to be able to perform a virtual mapping of the prominence of specific dissipative processes (i.e., glide, cross-slip, climb), similar to that proposed by Frost and Ashby (1982), by means of a hybrid DDD/MFRT approach. Overall, two different types of challenges have to be addressed. First, from the numerical standpoint, the question of time integration is not trivial. The relative rates associated with both processes depend on stress and temperature. Second, one must be able to quantify the two-way coupling between the mechanical and "chemical" problem. Indeed, in the short range, the net current of vacancies toward the dislocation leads to a change in the dislocation geometry (i.e., creation of jogs). However, the long-range stress field inherent to the dislocation and to the point defects necessarily modifies the kinetics of point defect migration. Further, in the very short range, modeling of pipe diffusion requires extraneous considerations to be detailed later in this section. Focusing first on the physical aspects of the problem. Most proposed schemes rely on early analytical developments proposed by Hirth and Lothe summarized in Anderson et al. (2017). The net climb rate of a dislocation segment can be directly related to the vacancy current into the segment. One can relate the climb rate of a unit length segment, $v_{climb}$, to the net vacancy current (i.e., difference between the interstitial and vacancy currents into the segment) into said segment $I$ as follows:

$$v_{climb} = \frac{I.\Omega}{L_{seg}|\mathbf{b} \times \boldsymbol{\xi}|} \tag{18}$$

Here $\Omega$, $\mathbf{b}$, $\boldsymbol{\xi}$, and $L_{seg}$ denote the atomic volume, Burger's vector, the unit tangent vector to the line, and the length of the segment considered, respectively. To quantify the net vacancy current toward the dislocation segment, most DDD-based studies disregard the flux of interstitials toward the dislocation (despite the preferred attraction of those toward dislocations) and focus solely on vacancies. One then must solve the diffusion problem formally posed by

$$\frac{dC}{dt} = -\nabla \cdot \mathbf{J}, \tag{19}$$

in which $C$ denotes the spatially varying vacancy concentration. The dot product between operator Nabla and the vacancy flux, $\mathbf{J}$, denotes the divergence of the flux vector. The latter is formally expressed as

$$\mathbf{J} = -D\left(\nabla C + \beta C \nabla E\right), \tag{20}$$

in which $D$ denotes the vacancy diffusivity and $\beta = 1/kT$ with T the temperature in Kelvin and $k$ the Boltzmann constant. One notes that the flux depends on two distinct contributions. The first term is related to the gradient of the concentration and is purely chemical, while the second involves the interaction energy between the defect and the surrounding microstructure, $E$. It is typically expressed as the double dot product between the local elastic strain and an interaction dipole tensor $d$. With this, one has $E = \varepsilon_{ij}d_{ij}$. Unfortunately, even in the simplest case, an isolated dislocation interacting with a cloud of vacancies with equilibrium concentration at zero stress $C_{eq}$, there is no analytical solution to the aforementioned problem, owing to the non-radial flux induced by the $E$. Thus far, two solutions have been proposed. First, it has been suggested to simply neglect the elastic interactions between the point defect and the dislocation. Such simplification renders the problem entirely radial. The solution procedure then relies on determining the boundary conditions of the problem from which the flux toward the dislocation can be found in the steady state. The local concentration near the dislocation core is given as:

$$C_{core} = C_{eq}e^{\beta P \Delta V} = C_{eq}e^{\dfrac{F_{climb}\beta\Omega}{L_{seg}|\mathbf{b}\times\boldsymbol{\xi}|}}, \tag{21}$$

in which $P$ denotes the hydrostatic pressure within the medium and $\Delta V$ refers to the relaxation volume associated with the vacancy such that $P\Delta V$ denotes the work associated with the creation of a vacancy in the core of dislocation. As shown in the rightmost part of Eq. (21), this work is balanced by the work done by the dislocation as it climbs, in a fashion similar to that proposed by Hirth and Lothe (Anderson et al. 2017). With the steady-state vacancy concentration, the solution to Eq. (19) is as follows:

$$C(r) = C_{core} + (C_{eq} - C_{core})\dfrac{\ln\dfrac{r}{r_{\infty}}}{\ln\dfrac{r}{r_{core}}}. \tag{22}$$

Here $r$, $r_{core}$, and $r_{\infty}$ denote the distance from the dislocation core, the critical core radius, and the distance from the dislocation at which the equilibrium concentration is reached. The latter is often taken as the mean spacing between dislocations. One notes that in all such derivations, the interaction energy between the dislocation and the vacancy is disregarded. In any case, the current toward the dislocation is then simply written as the integral around the core of the dislocation of the vacancy flux. One has

$$I = -2\pi r_{core} L_{seg} \frac{D}{\Omega} \frac{\partial C(r)}{\partial r}\bigg|_{r=r_{core}} \tag{23}$$

This approach was used in a series of studies (Mordehai et al. 2008; Bako et al. 2011; Danas and Deshpande 2013; Gao et al. 2017), both two and three dimensional. Among others, a recent and particularly interesting application of this type of approach – albeit with an improved treatment of the dynamics of vacancy motion treated at an intermediate scale via the use of fast Fourier transform operators – concerns the predictions of the vacancy-assisted climb in $\gamma\gamma'$ Ni superalloy single crystals. The study shows that in regimes mimicking in-service conditions (e.g., uniaxial stress in the order of 180 MPa and temperatures in the order of 1100 K), dislocation climb can significantly affect the overall dissipation within the system by providing more energetically favorable paths for dislocation to glide. While these studies are up to now limited to relatively short time scale and idealized scenarios, they are likely to be the bedrock for the development of temperature-sensitive constitutive models in which the contribution of climb is not obtained by reverse engineering parameters from experimental data.

## 5 Advances in Sub-scale Physics

## 5.1 Dislocation/Interface Interactions

As stated in the above, DDD has only recently been applied to simulate plasticity in polycrystals (Balint et al. 2008; de Sansal et al. 2010). In these early attempts, grain boundaries have typically been treated as impenetrable barriers to dislocation motion. Clearly, these approaches will necessarily overpredict the generation of "backstresses" due to dislocation pile-ups, thereby not yielding quantitative predictions of well-known effects such as the correlation between the inverse of the square root of the grain size and the yield strength, as per the work of Hall and Petch (Balint et al. 2008), Bauschinger phenomenon, etc. As a dislocation interacts in the short range with a material interface, the number of potential outcomes is relatively limited. Indeed the incoming dislocation can either be stopped near the interface, transmitted through the interface, or absorbed. The outcome depends on the interface character, imposed stress state, temperature, and dislocation character itself (Froseth et al. 2004; Capolungo et al. 2007). For example, atomistic simulations applied to hexagonal close-packed magnesium have clearly revealed that a basal screw dislocation can transmit via cross-slip through a $\{10\bar{1}2\}$ twin interface without seeing any change in its core structure (Serra and Bacon 1995). This is not the case if the $\langle a \rangle$ dislocation interacts with a $\{10\bar{1}1\}$ twin boundary. Similarly edge dislocations will dissociate onto the $\{10\bar{1}2\}$ twin interface, leading to the generation of interface disconnections as well as generating new segments in the twin domain.

The development of predictive approaches describing both short- and long-range interactions between dislocations and materials interfaces is particularly challenging. It entails that (i) the stress field within each point in the medium fully

accounts for the effects of heterogeneous elasticity, manifesting itself through image forces, (ii) one can assess under which stress orientation and magnitude do slip transfer occur, (iii) a model can be developed to predict on which slip system would transfer occur, and (iv) a predictive capability can be developed to fully account for the dislocation core changes (i.e., dissociation, shearing, absorption) occurring within the material interface. Further, as stated in the above (v), a material interface can also act as a dislocation source. (iv) and (v) necessarily induce a change in the local interface character (i.e., local misorientation, excess volume, energy). Given the infinite number of material interfaces that can exist in polycrystals, it is unlikely that an exact physical rendition of all these processes can be derived. "Data mining" approaches might, however, allow for simulations of dislocation/interface interactions to be statistically representative. This has been done to some extent to understand grain boundary mobility (Olmsted et al. 2009) as well as to quantify the energy barrier for dislocation transmission (Sangid et al. 2011). Despite this, several advances have been proposed in recent years to address (i)–(iv). The intent is not to provide an exhaustive list but rather a perspective on such a vast topic.

To address (i), both the superposition method (Weygand et al. 2002) and discrete continuous method (DCM) have been used (Lemarchand et al. 2001; Vattré et al. 2014b). The use of the finite element method necessarily poses the question of the mesh resolution near the material interface (Sobie et al. 2014). Interestingly, numerical methods have been proposed to accurately compute the stress state at interface elements (Liu et al. 2016). The DCM is rigorously derived from a variational formulation – such that driving forces on dislocation are exactly related to the energy gradient – and is expected to be more accurate. Further, recent developments of the fast Fourier transform-based discrete continuous approach to the case of heterogenous elasticity should alleviate the issue of the computational burden associated with images forces (Bertin et al. 2015; Bertin and Capolungo 2018).

Challenges (ii)–(iv) have been addressed in the case of coherent interfaces, particularly twin boundaries in hexagonal close pack metals (Fan et al. 2015b). As detailed in what follows, the development of such models requires considerable input from either topological interface models (Hirth and Pond 1996) and/or atomistic simulations. For the sake of illustration, consider the case of a basal dislocation in hexagonal close-packed magnesium interacting in the short range with a twin boundary on the $\{10\bar{1}2\}$ plane. Seminal works (Serra and Bacon 1995; Serra et al. 1999) have allowed one to establish a catalog of potential reactions between glide dislocations and twin boundaries. One notes that such catalog is still evolving. Consider the case of basal $\langle a \rangle$ dislocations. Three such type of dislocations, with Burgers vector $a_1 = \frac{1}{3}[2\bar{1}\bar{1}0]$, $a_2 = \frac{1}{3}[\bar{1}2\bar{1}0]$, and $a_3 = \frac{1}{3}[\bar{1}\bar{1}20]$, can meet the $(0\bar{1}\bar{1}2)$ twin boundary. As stated previously, the interaction between a screw $a_1$ dislocation and the $(0\bar{1}\bar{1}2)$ twin boundary leads to a complete transmission into the twin domain. As such issues (iii) and (iv) do not require any treatment – the DDD framework can compute the driving force on each dislocation. However, (ii) is not trivially addressed as the dislocation could continue its path on either a basal or a prismatic system in the twin domain. To select the most likely outcome, a local maximum dissipation rule can be introduced. The idea is simply to compute

the product of the driving force and velocities for all nodes in contact with the interface for each potential transfer slip system and select the system that maximizes dissipation. In other cases, for example, $a_2$ intersecting the same twin boundary, one needs to further account for the dissociation of the incoming dislocation into the sum of a twinning partial dislocation and a residual dislocation with Burgers vector $b_r = \frac{[\bar{2}113]}{6}$. The residual dislocation can in turn be transferred into several potential slip systems into the twin domain (i.e., pyramidal type I and II), and the maximum dissipation criterion can be used to select the transferred slip system.

In Fan et al. (2015b), the authors used this approach to simulate the effects of twin volume fraction on both yield strength and hardening of a system subjected to monotonic compression. Figure 4 shows the hardening response as a function of twin volume fraction, $f_t$. The blue lines indicate the disconnections formed as a result of dislocation/twin interactions.

The previous example was concerned with fully coherent interfaces (e.g., twin boundaries) in which challenges (iii) and (iv) can be addressed relatively easily. To increase the level of complexity and in correlation with the recent growth in interest in nanolayered metallic composites (Misra et al. 2005), significant effort has been placed in simulating dislocation/hetero-interface interactions. In particular, Cu/Nb nanolayered composites, consisting of an alternating stack of Cu and Nb layers, have been a focal point of investigation. These heterointerfaces intrinsically contain a network of potentially mobile misfit dislocations rendering the interface relatively weak and capable of shearing the core of an incoming dislocation from either side of the interface (Hoagland et al. 2006). A first series of atomistically guided simulations have been proposed whereby the shearing of the core of the dislocation upon intersecting the hetero-interface is taken account (Sobie et al. 2014). Pragmatically, the numerical approach simply consists of removing segments upon arriving into the interface. It has been shown that these considerations best approximate results from atomistic simulations. Further complexity was latter added

**Fig. 4** Engineering stress strain curves of a twinned domain as a function of twin fraction (Reprinted from Fan et al. 2015b)
to predict dislocation nucleation from the hetero-interface (Wang et al. 2014). In summary, the authors proposed an original approach whereby both interfacial dislocations and bulk dislocations are modeled simultaneously. Further, interfacial dislocations are allowed to both glide and climb. The climb process, necessarily nonconservative, was further calibrated via atomistic simulations. Nucleation was modeled by essentially letting the interfacial dislocation evolve and simultaneously checking for the alignment of interfacial dislocation lines with potential slip systems, for the driving force acting on said segment and for an energy-based criterion (Frank's rule). These models do not, however, explicitly treat the network of misfit dislocations present at the interface such that substantial calibration against atomistic simulations is required. To circumvent these challenges, recent developments have expanded on the original work of Frank, Bilby, and Bollman in order to predict exactly, and in agreement with atomistic simulations, the network of misfit dislocations within the material interface as well as its dynamic relaxation process and interactions with bulk dislocations (Vattré 2017; Vattré and Pan 2017).

Finally, the case of general boundaries has also received attention. However, to date the solutions proposed do not reflect the complexity of the short-range dislocation/grain boundaries interaction process. To address the barrier for propagation across a boundary, Fan et al. (2015b) simply propose to compute the shear stress at each dislocation in contact with the grain boundary interface and let it transmit once a critical value is reached. The authors proposed to relate the barrier strength to the misorientation angle across the grain boundary $\tau_c = Gbsin^2(\theta_{mis})$, with $\theta_m$ denoting the misorientation angle. Clearly such a criterion does not capture the complexity of the process. In parallel to the aforementioned development and in the restricted case of two-dimensional models, it has been proposed to describe the process of grain boundary sliding by introducing interface dislocations along the grain boundaries as well as to introduce dislocation sources at grain boundaries and triple lines (Quek et al. 2016).

## 5.2    Kinetics

Over the past decade, DDD has been successfully used to, in essence, validate reduced-order models formally relating the change in zero temperature strength of a system to its defect content (e.g., voids, self-interstitial atom loops, precipitates, and other dislocations) (Madec et al. 2003; Greer et al. 2008; Sobie et al. 2015). Recently, however, focus has been placed on unraveling the linkage between both defect content and temperature with the kinetics of slip (e.g., strain rate sensitivity), dislocation nucleation, etc. (Geslin et al. 2017; Sobie et al. 2017a, b, c).

Fundamentally, the local activation of a dislocation-mediated dissipative process (e.g., cross-slip, slip, nucleation) depends both on the system geometry and on the local stress state within the activation volume associated with said process. In an engineering material (i.e., departing from model materials), the microstructure is formally described by the defect content (e.g., the number density of voids and precipitates, dislocation density on each slip system) as well as by the spatial

arrangements between defects. This complexity necessarily raises the question of homogenization, i.e., how to derive laws predicting both the effectiveness and the distributions of the activation of dissipative processes that are statistically representative of bulk behavior?

At the atomistic length scale, both in the context of harmonic transition state theory and of transition state theory in general, a series of algorithms have been proposed to quantify both the minimum energy pathways (MEP) and prefactors (associated with attempt frequencies and entropic contributions) for unit processes (e.g., migration of dumbbells Marinica et al. 2011). These methods include the nudged elastic band (NEB), Dimer, Free End NEB, activation-relaxation technique, umbrella sampling, etc. (Jonsson et al. 1998; Henkelman and Jonsson 2000; Mousseau and Barkema 1998; Saroukhani et al. 2016). Since their inception, MEP search methods have been extensively and successfully used to address point and defect cluster diffusion, dislocation nucleation from material interfaces, dislocation precipitate interactions, etc. (Saroukhani et al. 2016; Zhu et al. 2008). In the context of multiscale modeling and echoing the challenge stated above, the direct application of MEP search methods in the context of atomistic simulations to derive constitutive relationships – or at the very least to calibrate existing laws – will in most cases be inadequate. Indeed, the volumes and geometrical configurations accessible within atomistics do not necessarily satisfy the necessary requirements to render predictions of MEP statistically representative.

Over the past few years, several independent efforts have been made to jointly use DDD and MEP methods (Geslin et al. 2017; Sobie et al. 2017a, b, c). Clearly the significant reduction in degrees of freedom associated with the use of DDD allows one to probe MEPs in statistically representative volumes (in the order of several $\mu m^3$). Two distinct classes of problems have been addressed thus far. First, one can study or quantify the relationship between activation barriers and unit process as a function of geometry and imposed stresses. In this case, one can advantageously perform a direct comparison with atomistic simulations pertaining to smaller systems prior to using DDD to study large volumes. One notes that particularly interesting developments to the DDD framework have been proposed to capture core contributions to the energy landscape in accordance with atomistic simulations (Geslin et al. 2017). Second, the question of coarse graining can be addressed.

While several MEP approaches have been used thus far, here the focus is placed on the NEB method. In short, NEB determines the MEP between transition states following a steepest descent approach. To this end, starting from well-defined initial and final configurations, a set of images are created. These formally represent an initial guess of the trajectory of the system. One such guess can simply consist of a linear interpolation between the initial and final configurations. The NEB algorithm will search for the MEP by solving a modified equation of motion for each image until convergence is reached. As such, all images are simultaneously evolved to equilibrium under a modified force (Eq. (24)) toward a level curve on the energy landscape. The total force on each degree of freedom $i$ is written as (Jonsson et al. 1998)

$$F_i = F_i^s|_\parallel + F_i^R|_\perp, \tag{24}$$

with the true force being related to the gradient of the potential energy within the system,

$$F_i^R = -\nabla V(R_i) = F_i^{PK} . \tag{25}$$

$R$ is the $3N$-dimensional vector containing the coordinates of each dislocation node.

In isotropic elastic media, the force acting on a dislocation is known in closed form from the derivation proposed in Cai and Bulatov (2006). One notes that recent extensions have been proposed in the case of anisotropic media (Po et al. 2018). Finally, the discrete continuous approach – applied either in the context of finite elements or fast Fourier transform methods – provides a direct access to the energy and its gradient in a thermodynamically consistent fashion at any finite element node or voxel, such that a simple interpolation procedure provides access to the force acting on each node without need for the use of an analytically derived solution. Regardless of the numerical approach (i.e., discrete continuous or not), the force acting on a node is projected perpendicularly to the energy gradient:

$$F_i^R|_\perp = F^{PK}(R_i) - F^{PK}(R_i) \cdot \hat{\tau}_i . \tag{26}$$

A modified tangent that depends on local image energy is used (Henkelman and Jonsson 2000) and represents a tangent to the high-dimensional energy landscape. The spring force parallel to the tangent is defined as (Henkelman and Jonsson 2000)

$$F_i^s|_\parallel = k \left[ |R_{i+1} - R_i| - |R_i - R_{i-1}| \right] \hat{\tau}_i . \tag{27}$$

In practice, the NEB method can be coupled to an existing DDD implementation without an onerous numerical implementation. The DDD code naturally calculates the true force in Eq. (24). Each image is evolved similarly to a DDD simulation, except that forces have to be modified according to Eq. (24). The numerical procedure to converge to the MEP is nearly identical to simulating the time evolution of several DDD simulations simultaneously – each image influences its neighbors via the spring force but otherwise evolves independently. Consequently, the method can be readily parallelized with little communication overhead.

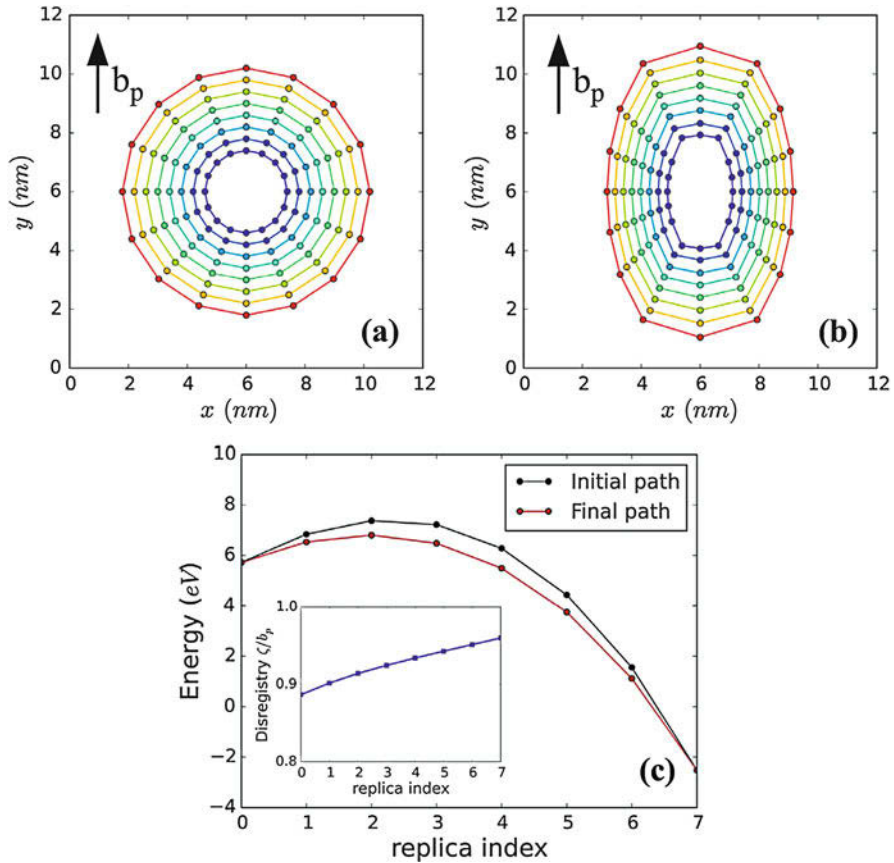
For the sake of illustration, consider the unit process associated with the homogeneous nucleation of a dislocation in aluminum. Note here that owing to the low stacking fault energy of the system, novel developments were proposed to fully predict the role of dislocation cores to the nucleation process. Figure 5 shows the initial path assumed with the nucleation of a shear loop (a) as well as the predicted MEP (b) and (c).


**Fig. 5** Initial configurations used to simulate the homogeneous nucleation of a partial dislocation in Al under an applied resolved shear stress of 1.6 GPA, (**b**) final configuration obtained, (**c**) predictions of the MEP associated with the nucleation process (Reprinted from Geslin et al. 2017)

### 5.2.1 Application to the Case of Dislocation Nucleation

The aforementioned case of homogeneous dislocation nucleation delineates a particularly interesting illustration of the degree to which DDD can be calibrated against atomistic simulations. Pragmatically, the authors (Geslin et al. 2017) proposed to use a discrete continuous method, in the context of the fast Fourier transform method of Bertin et al. (2015), allowing one to have a thermodynamically rigorous relationship between the free energy within the system and the force acting on a dislocation segment or node, depending on the approach chosen. With this, the free energy within the system, $E_{tot}$, can be written as

$$E_{tot} = E_{elastic} + E_{core} + E_{fault}, \tag{28}$$

in which the subscripts "elastic," "core," and "fault" refer to the contributions to the free energy of the system from the linear elastic strain field within the medium, to the core energy of dislocations (in which linear elasticity does not hold), and to the stacking faults within the medium, respectively. All quantities in the above are spatially resolved. With this and in perfect analogy with Eq. (25), the force acting on a dislocation node can be expressed as the negative of the derivative of the total energy within the medium:

$$F_n = -\frac{\partial E_{tot}}{\partial R_n}, \tag{29}$$

in which $F_n$ is the vector force acting on node $n$ and $R_n$ denotes the position vector of node $n$. The contribution to the total force acting on the dislocation due to the elastic strain energy within the medium can be computed either from a direct numerical derivative of $E_{elastic}$ with respect to the position of the node or as a line integral of the Peach-Koehler force over the segments on the left and right of node $n$. One notes that the former method is naturally more computationally involved, in that one typically uses a line integral formally expressed as

$$F_n^{elastic} = \int_{L^n} \frac{s}{L_n} \sigma.b^n \times \xi^n ds + \int_{L^{n+1}} \frac{s}{L_{n+1}} \sigma.b^{n+1} \times \xi^{n+1} ds . \tag{30}$$

Here $\xi^n$ denotes the unit vector tangent to the segment bound by nodes $n-1$ and $n$. Similarly, $L^n$ denotes the length of the segment bound between nodes $n$ and $n+1$.

Following the original proposal from Clouet et al. (2009), the core energy per unit length associated with a dislocation segment can be written as

$$e_{core} = c_0 + c_1\alpha^2 + c_2\alpha^2, \tag{31}$$

in which $\alpha$ introduces the character (i.e., line orientation) dependence of core energy of the dislocation, $\alpha = |b.\xi|/||b||$. With this, the core energy of segment bound by nodes $n-1$ and $n$, $E_n^{core}$, can be written as

$$E_n^{core} = \left(c_0 + c_1\alpha_n^2 + c_2\alpha_n^2\right) L^n, \tag{32}$$

such that the force acting on a dislocation arising from core contributions is simply written as the sum of the partial derivative of $E_n^{core}$ and $E_{n+1}^{core}$ with regard to the position of node $n$. Fortunately, in this case, one can trivially find a closed form expression for such contributions. Finally, in the case of loop nucleation, the contribution of the stacking fault energy due to dislocations can also be taken into account. An approach, similar to that delineated in the above to account for core contributions, is used to this end. The reader is referred to Geslin et al. (2017) for more details.

The approach summarized above shows that the core energy and stacking fault energy contributions can be rigorously calibrated against atomistic simulations, thereby enabling the method to quantitatively predict the activation barriers associated with unit processes. In Geslin et al. (2017), it has been demonstrated that the barrier associated to the nucleation of a shear loop can be predicted with similar accuracy with atomistic of DDD approaches provided that both core and stacking fault energy contributions are taken into account.

### 5.2.2   Connections to Multiscale Modeling

The connection between DDD and MEP search methods allows one to address the key question of homogenization/coarse graining, with particular insight found in seminal papers by McDowell (1997, 1999). Among other things, one can quantify the role of microstructure (i.e., the number density, type, and spatial distribution of defects) on the effective barrier associated with a unit process. Further, from such simulations, one can produce reduced-order models introducing a mathematical linkage between the imposed stress, microstructure, and probability distribution of barriers.

As an example, consider a body center cubic system in which one seeks to quantify the barrier associated with the bypassing of a distribution of $< 100 >$ sessile self-interstitial atom (SIA) loops, as described in Sobie et al. (2017c). Consider first a model that consists of placing an isolated SIA loop within a simulation volume and quantifying the effects of geometry on the predicted activation barriers, which we will refer to as "unit bypass." Periodic boundary conditions are used, creating an array of SIA loops with a mean spacing of 117 nm. (Note that in these simulations, neither the contributions of core energies nor those of the stacking faults are accounted for.) From these simulations, one can extract a distribution of potential barriers, which will be compared to a direct set of simulations in which a dislocation travels through a network of obstacles with similar density and mean spacing as in the unit bypass simulations. As will be detailed in what follows, these approaches, the latter corresponding to the configuration most resembling realistic microstructures, yield vastly different quantification of the barriers encountered by a moving dislocation.

The activation energy for unit bypass in a linear array of SIA loops with spacing of 117 nm was calculated as a function of interaction geometry $(z/L)$ (i.e., the relative position of the glide plane with respect to the loop center, in which $L$ denotes the size of the SIA loop) and an applied shear stress of 10 MPa. The configuration is shown in the left panel of Fig. 6. The activation barriers associated with these processes are shown in the left panel of Fig. 7. One sees a significant effect of the relative position between the glide loop and the SIA loop, showing the inadequacy in quantifying a unique barrier associated with a dislocation-mediated process. Further, the energy shown in the left panel of Fig. 7 can be integrated as a function of relative distance between the glide planes to generate a distribution of barriers akin to what a dislocation would be facing in a more realistic scenario. Assuming an equal likelihood for the relative distance $(z)$ between the glide plane and the SIA loops, the probability of activation barriers can be computed simply by integrating
**Fig. 6** (left) The minimum energy pathway taken by a $1/2 \langle 111 \rangle (1\bar{1}0)$ glide dislocation as it overcomes a $\langle 001 \rangle$ SIA loop of 4.3 nm size. Periodic boundary conditions are used such that the mean spacing between the SIA loop array is 117 nm. The red lines correspond to the dislocation configuration as it overcomes the SIA loop. (right) The minimum energy pathway taken by a dislocation as it overcomes an ensemble of SIA loops. The configurations in the left and right panels have similar SIA density and mean spacing. The resolved shear stress imposed in both cases is 10 MPa. (From Sobie et al. 2017b)

**Fig. 7** (left) Activation barrier corresponding to the bypass of a regular array of SIA loops as a function of the ratio of the distance between the glide plane and center of the SIA loop, $z$, and the SIA loop size is $L$. The energy obtained corresponds to configuration in the left panel of Fig. 6. (right) The black line corresponds to the probability distribution of the activation energy for an edge dislocation bypassing an ensemble of obstacles similar to that depicted in Fig. 6 (right). The red line is the probability distribution obtained by integrating the activation barriers on the left figure (corresponding to unit bypass) over $-1.5$ to $1.5 \, z/L$. (From Sobie et al. 2017c)

the results shown in Fig. 6 (left) for $z/L$ varying from $-1.5$ to $1.5$. The resulting distribution is shown in red in Fig. 7 (right).

The distribution of barriers from the unit bypass simulations can be compared to simulations corresponding to the scenario depicted in Fig. 6 (right). The distribution of barriers in Fig. 6 (right) was obtained by considering a volume containing six randomly positioned SIA loops with a mean separation distance equal to the linear spacing of the array of SIA loops in the previous calculation, 117 nm. The activation energy barriers for glide were calculated for 800 simulation repetitions. The resulting probability density function of activation barriers is shown in Fig. 7 (right panel, black line).

The activation energy probability distribution for an ensemble of loops has fewer defined features than the distribution obtained for unit bypass. The variation in the connected segment lengths and relative defect geometry acts to spread the well-defined peak seen for the unit bypass process. Furthermore, the mean activation energy is 43.4% lower for an ensemble of defects (6.56 vs. 11.6 eV). It is clear that the highly localized interaction between the defects and the dislocation does not entirely characterize the energetics of the process. The change in morphology of the extended dislocation segments neighboring the bypassed defect induces important changes in the activation energy that cannot be captured in unit bypass simulations.

# 6       Summary and Conclusion

In this short summary of recent advances in the field of discrete dislocation dynamics, a few promising developments have been presented. First, from the computational material science viewpoint, two distinct efforts have been proposed to limit the computational burden as well as to increase the effective time step used to solve the dynamics problem. To this end the subcycling method, allowing in essence the reduction of the number of force calculations to be performed within the subcycles, and the fast Fourier transform (FFT) algorithms have been proposed. As is often the case, these two approaches have different advantages. While the FFT method is expected to be far less efficient for smaller dislocation densities (e.g., on the order of $1 \times 10^{12} \, \mathrm{m}^{-2}$), the FFT-based approach, combined with the discrete continuous method, is relatively insensitive to dislocation content and should continue to be effective at the high dislocation densities associated with well-worked or fatigue metals. Moreover, the FFT approach is amenable to the treatment of plasticity in heterogeneous media (i.e., polycrystals, crystals containing precipitates, etc.). However, FFT methods will likely break down if large strains could be reached. Despite these key developments, state-of-the-art methods remain confined to the realm of dynamical loading or, in the case of creep-type simulations, to relatively limited simulation times.

A question that may arise lies in the potential of current modeling capabilities in performing virtual characterization of statistically representative microstructures. To this end, both finite element-based and FFT-based formalisms have been proposed to solve the boundary value problem. One notes that the use of the discrete continuous method advantageously yields thermodynamically consistent stress fields and driving forces acting on dislocations. Clearly, the problem of the treatment of short-range interactions between dislocations and materials interfaces, with varying degree of coherency, is now becoming central to future applications. In this regard, some strategies have been proposed to accurately depict dislocation transmission, core changes, etc. at coherent boundaries. While of great interest and appropriate in the case of coherent twin boundaries, one relies on the development of an atomistic simulation-based dictionary of potential reactions. Clearly, this approach is unlikely to be applicable to general grain boundaries for which a data informatics-driven approach is likely to yield more statistically meaningful simulations. In addition to

treating the effects of grain sizes and texture, a solid interest has been gained in addressing the problem of coupling with the materials chemistry. It is the authors opinion that such a path is likely to be particularly significant as it will allow one to depart from predictions limited to model material systems. While of interest, current approaches are limited to consideration of the vacancy flux toward dislocations, and a complete coupling between both the mechanical and diffusional problems has not yet been proposed.

Finally, in another recent, and promising, advance, DDD is used to extract activation barriers pertaining to unit processes or to sequences of unit processes. To this end, minimum energy pathway search algorithms, originally derived in the context of atomistic simulations, have been adapted to the DDD framework. It has been shown that the DDD formalism can be enhanced to account for the contribution of both dislocation cores and stacking faults enabling the reproduction of energy barriers computed by atomistic simulations. Further, taking the example of dislocation sweeping through a network of obstacles, the inadequacy of extracting activation barriers from non-statistically representative simulations was quantified. These methods open a path toward homogenization of the response of a material from the viewpoint of the energy landscape (or barriers) to be able to derive temperature-sensitive constitutive laws from discrete dislocation dynamics. It must be acknowledged, however, that most DDD simulations rely on the use of overdamped equations of motion, which calls into question the temperature sensitivity of the simulations and, in particular, the accuracy of the prediction of the rate of activation of cross-slip events. One could envisage the use of Langevin dynamics to capture statistical fluctuations in the system that control the activation of rare events.

outperform those in use today. In this chapter, recent advancements in modeling processing-microstructure-property relationships of nanocrystalline metals are covered. These developments include linking mesoscopic microstructure, such as grain (orientation, size, and shape), grain boundaries, twin boundaries, and interface properties with the development of local stress states and deformation mechanisms during mechanical processing or straining. Many recent examples of these techniques are discussed, particularly those demonstrating unanticipated couplings between size effects and texture development. The chapter concludes with a discussion of recommended directions and associated challenges to further advance mesoscale modeling efforts.

## 1 Introduction

Many future engineering systems will rely on high-performance metals that bear strengths and toughness values several times of those in use today. In several situations, these superior properties will be desired in harsh environments, such as elevated temperatures, at high rates, and under radiation. Nanolaminates, built from stacks of crystalline layers each with nanoscale individual thickness, are proving to exhibit many of these target properties. Examples span from nanotwinned materials, wherein individual nanolayers alternate in orientation according to the twin-matrix relationship and are divided by a twinned interface, to biphase nanolaminates, in which the nanolayers differ not only in orientation but also in chemistry and crystal structure (Dalla Torre et al. 2002; Ebrahimi et al. 1999; Hughes et al. 1986; Schuh et al. 2002; Schwaiger et al. 2003; El-Sherik et al. 1992; Xiao et al. 2001; Godon et al. 2010; Champion et al. 2001; Chen et al. 2006; Das et al. 2006; Khan et al. 2008; Shen et al. 1995; Youngdahl et al. 1997; Youssef et al. 2004; Nizolek et al. 2016). Nanotwinned materials have been shown to exhibit excellent strength and hardness, even harder than their nanocrystalline counterparts, while exhibiting reasonable ductility (Lu et al. 2004, 2009a; Beyerlein et al. 2014), outstanding thermal stability (Zhang et al. 2005; Anderoglu et al. 2008), electrical conductivity (Chen et al. 2007; Zhang et al. 2007), and fatigue resistance (Pan et al. 2013; Pan and Lu 2014). The number of superior structural properties biphase nanolaminates is equally large, including strengths that are over five to ten times higher and hardness values that are several orders of magnitude larger than values expected from volume averaged properties of their constituents (Beyerlein et al. 2013a; Mara et al. 2008; Mara and Beyerlein 2014; Han et al. 2013a; Misra et al. 2004, 2007). While the properties are clearly attractive, use of these materials in application relies on understanding and predicting these new properties based on

known and measureable variables, such as basic nanostructure dimensions, chemical composition, and loading conditions, including temperature and strain rate.

All structural metals are polycrystalline, or aggregates of grains, wherein each grain has a distinct crystallographic orientation with respect to all its nearest neighboring grains (Barrett and Massalski 1966). In conventional polycrystalline materials, the sizes of the individual grains have micron and submicron dimension. In the nanostructured materials, these grains have nanoscale dimension, and hence the density of internal boundaries, such as grain, twin, and biphase boundaries, is unconventionally large.

Many ways are being employed to make these nanostructured materials, from bottom-up deposition to top-down forming processes (Yasuna et al. 2000; Carpenter et al. 2015a, b; Kikuchi et al. 1997; Nizolek et al. 2015; Beyerlein et al. 2013b, c; Wang et al. 2013; Kang et al. 2012). As commonly expected of metals, their final nanostructure is sensitive to the how the material was made. Quantifying both the processing/nanostructure relationships and nanostructure-property relationships constitutes a multiscale modeling challenge. Multiscale models for conventional coarse-grained polycrystalline materials have been in development for several years, but analogous versions for nanostructured aggregates require extensions to explicitly account for the effect of internal boundaries on these relationships.

Many multiscale mechanics models for understanding and calculating the deformation of polycrystalline employ a combination of crystal plasticity (CP) theory and polycrystal modeling schemes for which there are many. CP theory relates the distortion of a strained crystal to slip on crystallographic slip systems (Kocks et al. 1998). Polycrystal plasticity models link individual grain response predicted by CP theory to the overall mechanical response of a polycrystalline aggregate.

These polycrystal plasticity models appear in various levels of sophistication and computational efficiency. Among the more popular are mean-field approaches, such as the full constraints Taylor model (1938), and self-consistent schemes such as viscoplastic self-consistent (VPSC) and elastoplastic self-consistent (EPSC) (Lebensohn and Tomé 1993, 1994; Lebensohn et al. 2007), which homogenize the grain neighborhood of an individual grain. Used less often are crystal plasticity models that spatially resolve the grain neighborhoods, which can be referred to as 3D full-field, spatially resolved mechanics techniques. In this class, there are two main types of mesoscale models differentiated by their solution technique: CP finite element (FE) models (Bronkhorst et al. 1991, 1992) and Green's function fast Fourier transform (FFT) models (Lebensohn et al. 2004, 2011; Lieberman et al. 2016; Liu et al. 2010).

Compared to mean-field approaches, 3D full-field, spatially resolved can yield additional information on the effects of grain-grain interactions, intragranular stress and strain evolution, and heterogeneous onset of localization, all of which are important for understanding and designing nanocrystalline materials, as will be demonstrated in this chapter. They also account for local neighborhoods and spatial resolution in the mechanical fields below the grain scale, such as stress concentrations at boundaries and intersections of many boundaries (e.g., triple points, twin/grain boundary intersections). These capabilities are important for modeling

the many boundary-driven mechanisms that are sensitive to a combination of inter-face morphology, character, and crystal orientation, as will be shown later as well.

This chapter will cover studies that have employed and extended mesoscale 3D, full-field spatial resolved computational models to investigate processing-microstructure relationships in boundary-dominant materials. These include examining the influence of bimetal interfaces on slip activity in adjoining grains and on texture evolution. Also presented and discussed here are advancements made to this type of models to include the effects of grain size and shape and layer and twin thickness on dislocation emission and propagation.

## 2    Part I: Methodology

### 2.1    Multiscale Overview

As mentioned, a 3D spatially resolved scheme used frequently in mechanical deformation modeling is the crystal plasticity finite element (CPFE) method. This technique can provide predictions of not only texture evolution but also evolution of intragrain and intergrain misorientations, grain shape, and grain boundary character distribution.

An abbreviated review of the formulation of CPFE is provided below. Regarding notation, vector and tensors are indicated by boldfaced characters and are not italicized. For a second-order tensor $\mathbf{A}$, the notation $\mathbf{A}^T$ denotes its transpose, i.e., $A_{ij}{}^T = A_{ji}$ for $i, j = 1 \dots 3$. The notation tr$\mathbf{A}$ means its trace, while det$\mathbf{A}$ signifies its determinant. The contracted product between two symmetric tensors, $\mathbf{A}$ and $\mathbf{B}$, is defined as: $\mathbf{A} \cdot \mathbf{B}$. The dyadic product of any two vectors, $\mathbf{a}$ and $\mathbf{b}$, is a second-order tensor given by $\mathbf{a} \otimes \mathbf{b} = a_i b_j$ Scalars and tensor components are italicized and not boldfaced.

Figure 1 displays a multiscale CPFE model and the submodel components that it links. Going from the left to right side (frames a–c), the material length increases, and each frame represents a specific instance at which the material response is being evaluated. At the coarsest level (frame a) is the material response of a polycrystal, which is in the form of a granular microstructural model, by the use of the finite element (FE) homogenization method. As a full-field model, this method fulfills both stress equilibrium and strain compatibility conditions making it a suitable modeling tool for capturing the interactions between the constituent grains. Each grain in the polycrystal is represented by an element set, which discretizes a given grain into finite elements (frame b). At this length scale, at each FE integration point, the material constitutive response is being estimated utilizing crystal plasticity (CP) theory. In application of CP, the model usually allows the strain to be accommodated by the simultaneous action of crystallographic slip and deformation twinning. In CPFE, the shear accommodated by the latter mechanism is most often modeled as slip and is referred to as the "pseudo slip" model for twinning (Van Houtte 1978; Kalidindi 1998).
**Fig. 1** A multiscale CPFE modeling framework for the plastic deformation of polycrystals (Taken with permission from Ardeljan et al. 2015a)

## 2.2 Meshing Microstructure, Grain Boundaries, and Interfaces

It is widely recognized that modeling both grain and grain boundary evolution during deformation is critical for understanding material response. Capturing important neighboring grain interactions on deformation is one of the primary reasons for choosing a full-field, spatially resolved over the less computationally expensive mean-field approaches. However, common methods for generating 3D microstructures have been limited in how well they can represent grain morphologies and grain boundaries. In most studies, the grains were blocks or polygons, such as cuboids, rhombic dodecahedrons, and truncated octahedrons. Such inaccurate representations of grain structure and grain boundaries can create numerical artifacts in mechanics calculations of stress and strain states near microstructural boundaries and interfaces (Ritz and Dawson 2008).

Since then, many techniques have been used to better represent microstructures than cuboid grains. One widely used technique for generating 3D microstructures for these codes is the Voronoi tessellation method. The technique does well in creating a set of near-equiaxed grains. The Voronoi tessellation starts with random grain seeds and creates polyhedral-shaped grains. This method, however, still has its limitations. Polyhedral-shaped nonuniform grain shapes created by the Voronoi tessellation methods are often unrealistic because rules for the organization and geometrical constraints of the grains produced are not unique. In addition, the grain boundaries appear as coarse disordered polygons. To produce say elongated grains, it is possible to place these seeds far apart from each other along one dimension in order to get elongated grains, but generally it is difficult to control

the grain aspect ratios. Furthermore, since the grain boundary between the two neighboring domains (grains) is created halfway between the seed points, it proves to be challenging to acquire neighboring grains of dissimilar sizes. Grains often do not look realistic and grain boundaries appear as very coarse polygons, and as a result, the grain boundaries are not continuous surfaces. Finally, a characteristic of Voronoi tessellation is perfectly planar grain boundaries, which generally are notably different from real boundaries inferred from microstructure characterization experiments.

In recent years, explicit meshing of the grain structure and grain boundary surfaces and capturing their evolution with plastic strain have notably advanced the predictive capabilities of these 3D full-field approaches. Creation of realistic grain structures has been largely addressed with the introduction of techniques for explicit grain structure. Gaining much use is DREAM.3D, a software that generates the 3D synthetic voxelized microstructure and the surface meshes for the grain boundaries (DREAM.3D Version 4.2 2013; Groeber and Jackson 2014). It overcomes many of the limitations with the commonly used Voronoi tessellation method. The digital microstructure generated in DREAM.3D appears far more realistic in terms of grain morphology and grain size distribution than that generated by Voronoi tessellation scheme in 3D.

The output from DREAM.3D can be used directly in the voxel-based CP-FFT codes, but since meshing of grain structures is not a capability of the DREAM.3D software, additional processing is needed so that the output can be used to create a 3D mesh for grains and grain boundaries in CPFE. Recent work by Knezevic et al. (2014) and Ardeljan et al. (2015a) developed an integrated tool set that takes a grain boundary surface mesh from DREAM.3D and provides a volume mesh for each 3D grain and its grain boundary surfaces. Before acquiring the triangular surface mesh for each grain, it is convenient to apply a Laplacian-based smoothing filter available in DREAM.3D. The filter smooths out and suppresses any jagged boundaries between grains to achieve better grain structure representation. The final polycrystalline aggregate is comprised of element sets representing individual grains (Fig. 2a, c) and grains with conformal grain boundaries between neighboring 3D grains (Fig. 2b, d). The conformal conditions between constituent grains mean that neighboring grains share triangular elements at grain boundaries.

## 2.3   Modeling Single Crystal Constitutive Response

In order to determine the single crystal response at each integration point, a User MATerial (UMAT) subroutine based on crystal plasticity constitutive formulation is used in Abaqus Standard. The framework facilitates various loading conditions from low to high level of complexity that can be applied in the form of suitable boundary conditions. This applied load is divided into time/strain increments, where for each one, a global stress equilibrium solution is found using a numerically
**Fig. 2** An explicit grain structure model consisting of 784 equiaxed grains generated synthetically using DREAM.3D: (**a**) voxel-based model with highlighted edges, (**b**) triangular surface mesh. The triangular surface mesh in (**b**) describes grain boundaries. (**c, d**) The midsection along half the x-axis shows the internal structure of the (**c**) finite element-based model and (**d**) triangular surface mesh. The edge length of the cube is 1000 μm, the average grain size is 135 μm, and the total number of tetrahedral elements (type C3D4 or C3D10 in ABAQUS) in (**c**) is approximately 1,000,000 (Taken with permission from Knezevic et al. 2014)

iterative procedure of the finite element method. This end is achieved by solving the nonlinear FE governing equation in its linearized form, which is given by:

$$\left( \int_V \mathbf{B}^T \mathbf{J} \mathbf{B} dV \right) \Delta \mathbf{U} = \mathbf{R} - \int_V \mathbf{B}^T \boldsymbol{\sigma} dV. \tag{1}$$

In this relation, the listed quantities are, respectively, $\mathbf{B}$, the quantities are, respectively,finite element strain-displacement matrix; $\mathbf{J}$, the material Jacobian matrix; $\mathbf{\Delta U}$, the displacement increment solution; $\mathbf{R}$, the applied force vector; and $\boldsymbol{\sigma}$, the Cauchy stress tensor.

An essential part of CPFE is the crystal plasticity constitutive law that relates the material stress to material distortion (stretch plus rotation) at each integration point within each finite element in the model.

The total velocity gradient tensor, $\mathbf{L}$, can be additively decomposed as the following:

$$\mathbf{L} = \mathbf{L}^e + \mathbf{L}^p, \tag{2}$$

where $\mathbf{L}^e$ and $\mathbf{L}^p$ represent elastic and plastic velocity gradients, respectively. The plastic part of the velocity gradient contains the contributions from both slip and twinning via

$$\mathbf{L}^p = \mathbf{L}^{sl} + \mathbf{L}^{tw}. \tag{3}$$

The corresponding contributions to the velocity gradients, due to slip and twinning, are further expressed as:

$$\begin{aligned} \mathbf{L}^{sl} &= \sum_{\alpha}^{N^{sl}} \dot{\gamma}^{\alpha} \mathbf{m}_o^{\alpha} = \sum_{\alpha}^{N^{sl}} \dot{\gamma}^{\alpha} \mathbf{b}_o^{\alpha} \otimes \mathbf{n}_o^{\alpha}, \\ \mathbf{L}^{tw} &= \sum_{\beta}^{N^{tw}} \dot{f}^{\beta} S^{\beta} \mathbf{m}_o^{\beta} = \sum_{\beta}^{N^{tw}} \dot{f}^{\beta} S^{\beta} \mathbf{b}_o^{\beta} \otimes \mathbf{n}_o^{\beta}, \end{aligned} \tag{4}$$

where $\dot{\gamma}^{\alpha}$ stands for the shearing rate on slip system $\alpha$; $\mathbf{m}_o^{\alpha}$ and $\mathbf{m}_o^{\beta}$ are the Schmid tensors associated with slip system $\alpha$ and twin system $\beta$, respectively; and $S^{\beta}$ is the characteristic twin shear for the twin system $\beta$. Finally, $N^{sl}$ and $N^{tw}$ represent the total number of available slip and twinning systems, respectively. The Schmid tensors represent the unit slip or twin system tensor, defined as the dyadic product ($\otimes$) between the unit Burgers direction ($\mathbf{b}_o$) and unit plane normal ($\mathbf{n}_o$) vectors of slip system $\alpha$ or twin system $\beta$, respectively, in the undeformed configuration indicated by subscript "$o$." The rate of change of the twin volume fraction per twin system $(\dot{f}^{\beta})$ is related to the shear rate on the twin system $(\dot{\gamma}^{\beta})$ according to

$$\dot{f}^{\beta} = \frac{\dot{\gamma}^{\beta}}{S^{\beta}}. \tag{5}$$

In the finite deformation formulation, an assumption is made that the deformation gradient ($\mathbf{F}$) can be multiplicatively decomposed into its elastic ($\mathbf{F}^e$) and plastic ($\mathbf{F}^p$) contributions according to

$$\mathbf{F} = \mathbf{F}^e \mathbf{F}^p, \tag{6}$$

where the elastic component contains contributions from both elastic stretching and lattice rotation, while the plastic component embodies contributions due to

plastic deformation. The constitutive relationship between $\mathbf{F}^e$ and stress in the crystal is obtained considering two expressions for the second Piola-Kirchhoff stress tensor $\mathbf{T}^e$,

$$\mathbf{T}^e = \mathbf{C}\mathbf{E}^e, \, \mathbf{T}^e = \mathbf{F}^{e^{-1}} \left\{ \left( \det \mathbf{F}^e \right) \boldsymbol{\sigma} \right\} \mathbf{F}^{e^{-T}}, \tag{7}$$

where $\mathbf{C}$ is the fourth-order elasticity tensor and $\boldsymbol{\sigma}$ is the Cauchy stress in the crystal. $\mathbf{E}^e$, the Lagrangian finite strain tensor is related to $\mathbf{F}^e$ via

$$\mathbf{E}^e = \frac{1}{2} \left\{ \mathbf{F}^{e^T} \mathbf{F}^e - \mathbf{I} \right\}, \tag{8}$$

Finally to compute stress, the evolution of $\mathbf{F}^p$ needs to be evaluated. It is determined by crystallographic slip and twinning (microshear rates), and it can be expressed in rate form using the following flow-rule relationship:

$$\dot{\mathbf{F}}^p = \mathbf{L}^p \mathbf{F}^p. \tag{9}$$

Integrating Eq. (9) from $t$ to $\tau = t + \Delta t$ yields

$$\mathbf{F}^p(\tau) = \exp\left(\mathbf{L}^p \Delta t\right) \mathbf{F}^p(t). \tag{10}$$

Furthermore, the exponential can be conveniently approximated and further expanded using Eq. (3) to give

$$\mathbf{F}^p(\tau) = \left\{ \mathbf{I} + \Delta t \mathbf{L}^p \right\} \mathbf{F}^p(t) = \left\{ \mathbf{I} + \Delta t \left( \mathbf{L}^{sl} + \mathbf{L}^{tw} \right) \right\} \mathbf{F}^p(t), \tag{11}$$

where again, $\mathbf{I}$ is the identity matrix.

Moreover, the previous equation can be rewritten as

$$\mathbf{F}^{p^{-1}}(\tau) = \mathbf{F}^{p^{-1}}(t) \left\{ \mathbf{I} - \Delta t \left( \mathbf{L}^{sl} + \mathbf{L}^{tw} \right) \right\}. \tag{12}$$

## 2.4    Subgrain Mechanisms: Slip Resistances

Predicting slip activity is fundamental to predicting the evolution of microstructure, textures (the reorientations of the crystals), and material flow stress with strain. Through Eq. (4), the theory of crystal plasticity can relate slip activity on crystallographic slip and twinning systems to the distortion of a crystal. It does not, however, include criteria for the threshold of slip. Nearly all crystal plasticity-based constitutive models, including the three methods presented above, polycrystal models, CPFE, and CP-FFT, require choosing a criterion for activating a slip system in order to predict slip activity.

According to the thermodynamics theory of slip, in the regime of strain rates, roughly from $10^{-5}$/s to $10^{5}$/s, dislocation motion is thermally activated, and dislocations must overcome energetic barriers in order to move. For this regime, the commonly used flow rule of viscoplasticity relating slip rate to resolved stress has a power-law form:

$$\dot{\gamma}^s = \dot{\gamma}_0 \left( \frac{|\tau^s|}{\tau_c^s} \right)^{\frac{1}{m}} \text{sign}\left( \tau^s \right), \ \dot{\gamma}^s = \begin{cases} \dot{\gamma}_0 \left( \frac{|\tau^s|}{\tau_c^s} \right)^{\frac{1}{m}} \text{sign}\left( \tau^s \right) \text{ if } \tau^s > 0 \\ \qquad\qquad 0 \qquad\qquad \text{ if } \tau^s < 0 \end{cases} \tag{13}$$

where $\dot{\gamma}^s$ is the shear strain rate for a slip system $s$. The resolved shear stress is given by $\tau^s = \boldsymbol{\sigma} \cdot \mathbf{m}_0^s$, which is the tensor product of the stress $\sigma$ and Schmid tensor $\mathbf{m}_0^s$, and where $\dot{\gamma}_0$ is a reference slip rate (arbitrarily taken here as 0.001 s$^{-1}$). In the exponent, $m$ denotes the strain rate sensitivity factor. This power-law form is desirable because it provides uniqueness of solution for the active slip systems that accommodate an imposed strain rate.

The flow rule introduces a threshold critical resolved shear stress $\tau_c^s$ in order to activate slip. It is commonly called the critical resolved shear stress (CRSS). Nearly all CRSS models introduced over the past several decades are phenomenological. The simplest model for the CRSS is a constant value, which does not evolve with strain. However, for calculations of deformation behavior beyond the elastic-plastic yield transition, it is desirable that the CRSS represent the resistance to move dislocations, consistent with changes in subcrystalline and granular microstructure. Most CRSS hardening models have been developed for coarse-grained polycrystals, where in the large grains, dislocations tend to accumulate in amounts that increase with strain and depend on strain rate and temperature (Beyerlein and Tomé 2008). CP models that employ these hardening laws are able to predict changes in constitutive response with temperature and strain rate.

## 3 Part II: Mesoscale Insights into Processing-Nanostructure-Property Relationships

### 3.1 Effects of Biphase Interfaces on Texture Evolution

A promising way to make interface-dominant materials is by severe plastic deformation (SPD). Over the years, many SPD techniques, such as accumulative roll bonding (ARB), accumulative wire drawing and bundling, and equal channel angular extrusion, have been applied to two-phase metals, such as Ag-Fe, Cu-Fe, Ag-Ni, Zr/Nb, and Ag-Cu (Yasuna et al. 2000; Carpenter et al. 2015a, b; Kikuchi et al. 1997; Nizolek et al. 2015).

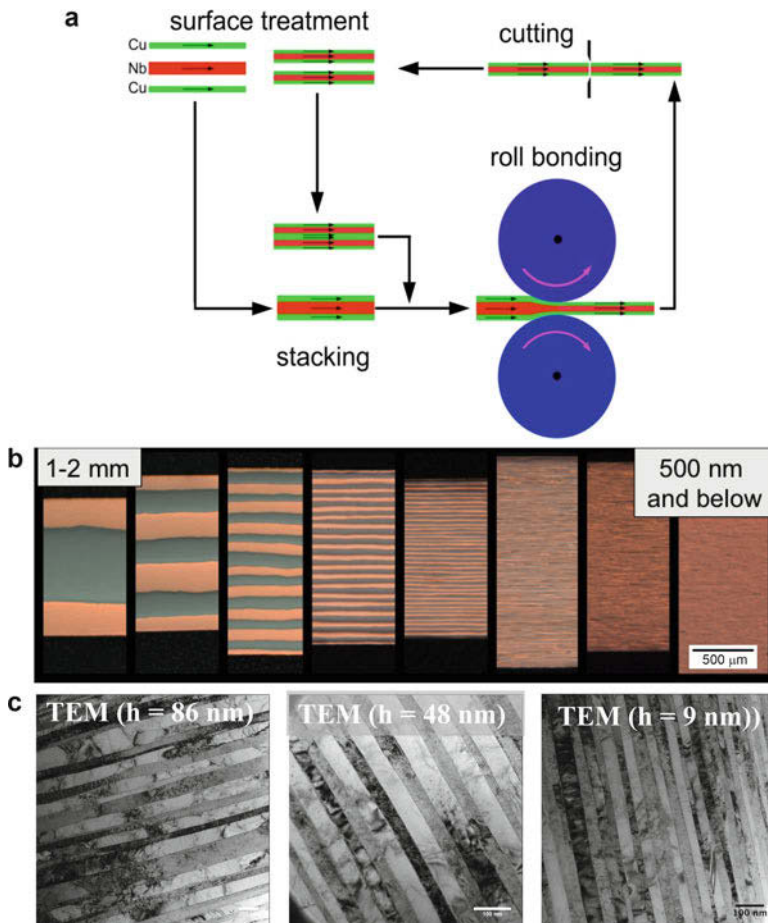
Figure 3a illustrates the substantial microstructural evolution of a two-phase material during the ARB process. The ARB process involves a sequence of repeated rolling, cutting, and restacking. At the beginning of the process, the metals are coarse-grained sheets with many crystals spanning the distance between two


**Fig. 3** (**a**) The severe plastic deformation process, accumulative roll bonding (ARB), used to synthesize. (**b**) Photograph of the Cu/Nb nanolayered composites of controllable layer thickness. (**c**) Transmission electron microcopy (TEM) micrograph displaying the planar Cu/Nb interfaces in an $h = 86$ nm, 48 nm, and 9 nm composites

adjacent Cu/Nb interfaces. With further straining, the spacing h between neighboring bimetal interfaces refines, the bimetal interface density increases, and the grains in each phase become elongated in the rolling direction and finer in the thickness dimension. Figure 3b presents the layer refinement with increasing number of ARB passes for a Cu/Nb composite. Eventually after several passes corresponding to an accumulated strain of ∼10, the layer thickness is refined to submicron dimensions and below, and a single crystal spans the layer thickness (Fig. 3c).

In a few studies, the texture evolution during the ARB refinement process of two-phase laminates (Cu/Nb and Zr/Nb) was studied in order to assess the effect of interfaces on slip or twin activity. Texture evolution during deformation is a result of the activity of slip and twinning in the crystals, and any change in texture indicates
**Fig. 4** Pole figures of the deformation textures measured in the Cu and Nb phase of a layered Cu/Nb composites with individual layer thicknesses of (**a**) $h = 500$ nm and (**b**) $h = 30$ nm. Pole figures of the deformation textures measured in the Zr and Nb phase of a layered Zr/Nb composites with individual layer thicknesses of $h = 106 \mu$ and $h = 41$ nm (Taken with permission from Nizolek et al. (2016) and Carpenter et al. (2015a))

a change in slip or twin activity. These ARB studies used neutron diffraction to measure the texture, as it is a bulk, nondestructive measurement texture technique that enables measurements for layer thicknesses that span from mm to nm. For thick layers (>10 um), the textures of the individual phases corresponded to typical rolling textures, those expected for the phases as if they were rolled alone, as shown in Fig. 4a. However, when the layer thickness reduced below a few microns and the texture strongly deviated from that expected for rolled phases alone. These highly oriented textures of the phases within the nanolayered Cu/Nb composites and Zr/Nb composites made by ARB are shown in the form of pole figures in Fig. 4b. The textures, particularly for the Cu and Zr phases, were strong, containing only a few special rolling components as opposed to the several rolling components commonly expected of rolled single-phase Cu and Zr. Evidently the deformation of the grains and their slip activity must have been augmented by their interface.

These highly oriented textures are associated with the development of a predominant interface with a crystallographic character ranging from $\{1\text{-}12\}<\text{-}111>$FCC$||$:$\{112\}<1\text{-}10>$BCC to $\{\text{-}4\ \text{-}4\ 11\}<11\ 11\ 8>$FCC$||$:$\{112\}<1\text{-}10>$BCC. The crystal orientations correspond to common rolling components in FCC Cu, called C and D, and in BCC Nb called I. In texture nomenclature, they are conventionally indicated as $\{$C:$\{1\text{-}12\}<\text{-}111>$ and D:$\{\text{-}4\ \text{-}4\ 11\}<11\ 11\ 8>$ and I (I:$\{112\}<1\text{-}10>$), given by the crystallographic plane and direction that align with the rolling plane
**Fig. 5** Ordered interfaces after extreme strains. High-resolution transmission electron microscopy micrographs of preferred Cu/Nb interfaces: (**a**) {112}<111 >Cu||{112}<110> Nb and (**b**) {551}<10 1 1 > Cu||{112}<110 > Nb. The crystallography of the facet planes is indicated respectively (Taken with permission from Zheng et al. 2013)

and rolling direction. Borrowing this nomenclature, these interfaces were denoted as those ranging from C/I interfaces to D/I interfaces, indicating that the C or D rolling components in Cu are joined to the I rolling component in Nb. The selection of these particular Cu and Nb components is interesting since the many other stable rolling components in Cu and Nb did not appear. Last, these interfaces were observed to be atomically pristine and ordered (see Fig. 5), which is another observation not expected of interfaces formed after severe plastic deformation.

To help understand the texture transition in Cu/Nb, electron backscatter diffraction (EBSD) analysis was used to locate orientations and phases within the microstructure. The EBSD analysis revealed that the transition is coincident with attainment of layers that are spanned by only one grain. In the coarser, micron-layered ($h = 45$ μm, 20 μm, and 8 μm) ARB Cu/Nb composites, several grains still spanned the layers. Within these composites, those Cu grains joined to the bimetal interface, called the interface grains, had predominantly C and D orientations, and those Nb grains had the I component Fig. 6b. The internal bulk grains away from the interface and bounded only by grain boundaries had a typical rolling texture Fig. 6a. This result indicates that the severe plastic straining process of ARB created preferred C/I to D/I interfaces even in the thicker layered composites.

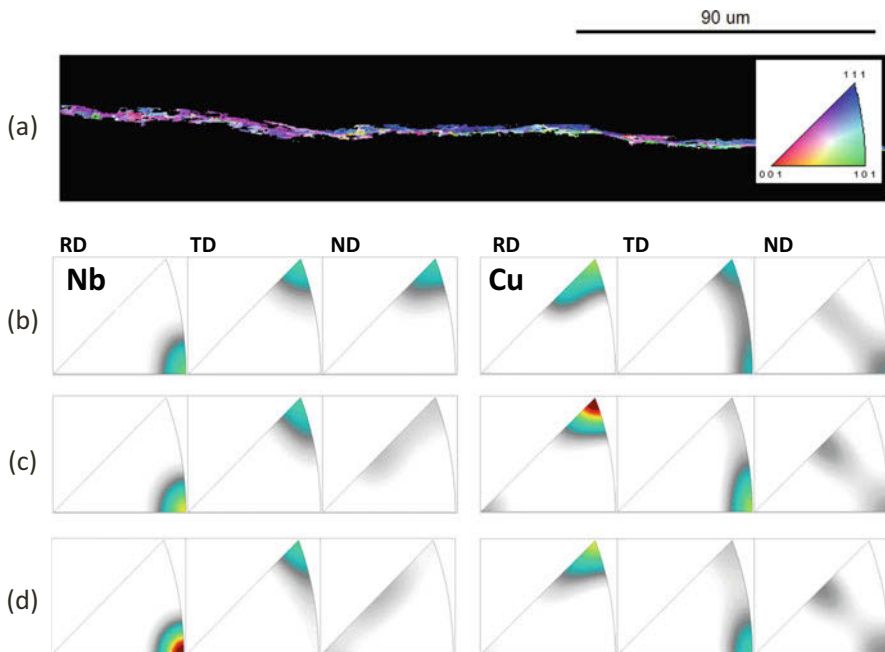
To date, there is no standard theory to explain the development of a preferred texture in an interface-dominant polycrystal produced via rolling or large-strain metal-forming processes. The texture analyses show that the crystals joined by these interfaces correspond to well-known stable orientations in rolling. These are special orientations in which the crystals can plastically deform with negligible lattice reorientation. Based on this idea, the concept of *orientation-stable interfaces* was proposed; that is, for other deformation modes apart from rolling, the character of orientation-stable interfaces, the crystals on both sides are deforming yet neither is reorienting, so the interface character is preserved. When either or both crystals reorient, then the interface character is not plastically stable.


**Fig. 6** (**a**) EBSD showing the texture of interface only grains ($h = 45\,\mu$). (**b**) Inverse pole figures showing the texture of the Nb phase and Cu phase in thick polycrystalline layers. (**c**) Inverse pole figures showing the texture of the interface grains in the Nb phase and interface grains in the Cu phase in thick polycrystalline layers. (**d**) Inverse pole figures showing the texture in the Nb phase and Cu phase in the 200 nm layered composites (Taken with permission from Carpenter et al. 2014)

The concept of mechanical stability for an interface can be tested using CPFE. With this technique, the structures and crystallography of the grains, grain boundaries, and bimetal interfaces can be directly represented in the calculation, and the result is the spatially resolved displacement and orientation gradients at the subgrain scale. Figure 7 shows a few example cross-sections of Cu/Nb microstructures simulated using CPFE. The central grain pair indicated in the figure makes up part of the interface formed between two polycrystalline layers in the simulation volume. It is given a special Cu/Nb orientation relationship and interface plane prior to orientation stability calculations. These deformation simulations account for the differences in elastic anisotropy, viscoplastic flow behavior, and crystallographic slip systems in individual crystals Cu and Nb. Some of the key assumptions made were that the bimetal interfaces and grain boundaries are constrained to maintain compatibility and the rolling deformation is idealized as plane strain compression. The observation of co-deformation and no signs of interface failure support the former assumption. The latter assumption has been shown valid for the material in the center of the sheet away from direct contact with the rolls (Zecevic et al. 2016).

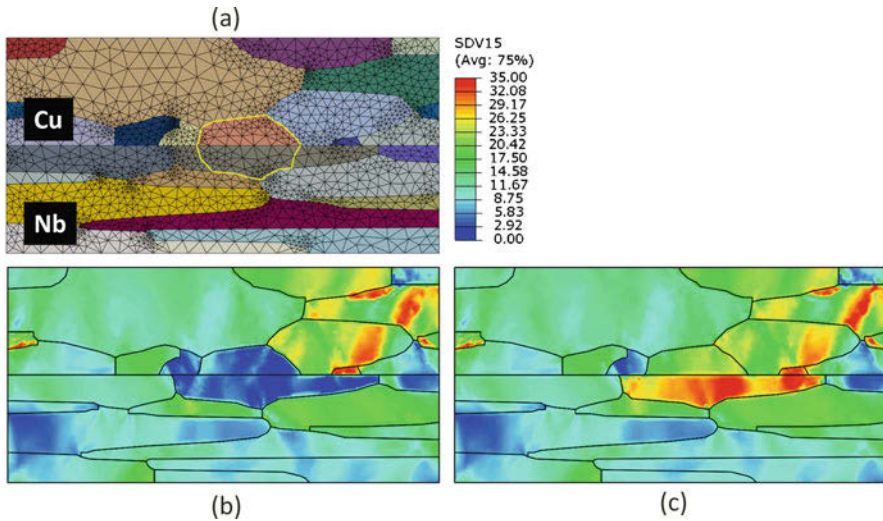
To examine plastic stability from these deformation simulations, the absolute lattice reorientation angle from the original starting orientation is calculated and


**Fig. 7** Crystal plasticity finite element mesh models of a two-phase layered composite (**a**) model of a grain structure mapped from experimental data and (**b**) reorientation maps of two-phase grain structures deformed in plane strain compression. The top phase is Cu and the bottom phase is Nb. The central embedded bicrystal outlined in yellow has a prescribed starting interface crystallography. In (**a**), the crystallography corresponds to the C/I interface and in (**c**) the KS interface, which is a low-energy interface characteristic of PVD Cu/Nb nanolayered composites. The crystallographic orientations are overlaid onto the original mesh seen in (**a**). The deformed mesh is not shown (Taken with permission from Mayeur et al. 2014)

mapped onto the original (undeformed) microstructure. In these maps, blue means small amounts of lattice reorientation (<6°), whereas yellow to orange correspond to large reorientations (>25°). As an example, Fig. 7b, c compares the reorientation maps for two different interfaces (C/I and Kurdjumov-Sachs (KS) interfaces). The C/I interface maintains good plastic stability in the polycrystalline environment, apart from some variation in misorientation near the grain boundaries. In contrast, the KS interface ({111}<110>Cu||{110}<111>Nb), which develops in the Cu/Nb PVD nanolayered foils, develops relatively large and inhomogeneous reorientation fields. This result suggests that these interfaces, once created, can remain stable, as the layers are refined from microns to nanometers.

When the grains are bounded only by interfaces, such as in the ultrafine grain layers ($h < 2$ μm), the grains become even more constrained and phase stability compromised further. To investigate the plastic stability of the grains in this scenario, Fig. 8 shows the calculation for the same two Cu/Nb interfaces, created by grains lying between two adjacent interfaces, using the same color scheme for the reorientations. For the C/I interface created in ARB, the reorientations are minimal and homogeneous. Again, the analysis predicts that the KS interface is plastically unstable. In fact, the CPFE bicrystal model predicts that the PVD interface reorients toward the C/I interface after large rolling reductions, which is a testament to the stability of the C/I interface.
**Fig. 8** Reorientation maps of bicrystals deformed in plane strain compression. The top crystal is Cu and the bottom crystal is Nb. The starting interface orientation relationships for these bicrystals correspond to the (**a**) C/I interface and (**b**) KS interface, which is a low-energy interface characteristic of PVD Cu/Nb nanolayered composites. The crystallographic orientations are overlaid onto the original mesh. The deformed mesh is not shown (Taken with permission from Mayeur et al. 2015)

Taken together, mesoscale modeling using CPFE finds that the compatibility constraint of code-forming layers in two-phase laminate composites can select favored interface crystallographic characters, ones that exhibit orientation stability. These orientation-stable interfaces persist at the interface in coarse layers and remain dominant as layers refine to be one grain thick.

## 3.2    Incorporating Slip/Interface Interactions into Crystal Plasticity Models

An important boundary/dislocation process is slip transmission. It is a mechanism for transferring slip from the crystal on one side of the interface to the crystal on the other side, thereby facilitating plastic deformation in polycrystalline materials. Some grain boundaries or interfaces are more efficient than others at transferring slip, and in this way, the type of interface that exists in the material can profoundly affect plastic flow and ductility.

Given its importance, many experimental studies on polycrystalline metals have studied slip transmission across grain boundaries and bimetal interfaces (Wang et al. 2008, 2012; Beyerlein et al. 2015; Hunter et al. 2018). The general consensus is that in most cases, slip transmission across a boundary is difficult. Thus, dislocations are not expected to freely pass from one crystal to another across an interface via any pathway.

Considering a two-phase crystalline material, slip transmission across a bimetal interface is possible at the head of a pileup that has developed in a coarse-layered composite, in which pileups tend to generate. However, if the layers are too fine to support pileups, slip transmission is expected to occur at the very fine scales (<10 nm) when the stresses become sufficiently high (Misra et al. 2005). In fact in the finest of nanolayered composites, slip transmission can, therefore, play a role in determining the strength of the composite.

There are various scenarios in which to describe slip transfer across an interface. In coarse crystals, dislocations belonging to one slip system α in crystal A can pile up at an interface and invoke nucleation of dislocations on another slip system β on the other side in crystal B. Alternatively, if the crystal is too fine to develop a pileup of dislocations, the stress field of an approaching α dislocation in crystal A can promote nucleation of a β dislocation on the other side in crystal B. In a related scenario, the impinging α dislocation in crystal A is first absorbed into the interface, and then a β dislocation may emit into crystal B in order to lower interface energy. The energetics depends largely on how the interface restructures the core of the absorbed dislocation.

Two factors determine whether slip transmission occurs when a dislocation intersects with an interface. One factor is geometric, having well-aligned slip planes and slip vectors, and the other factor mechanical, possessing driving forces directed into and out of the interface. The number of such favorable pathways across an interface would depend on the crystallographic character (five-parameter description including the orientation relationship and interface plane) of the interface and its orientation with respect to the loading state. An interface character that provides a significant barrier to slip has little to no efficient transmission pathways. In contrast, an interface character that readily transfers slip has many favorable transmission pathways and provides little resistance to slip.

An interface can evolve with deformation to be either more or less favorable for slip transfer. A 3D full-field, spatially resolved CP technique is well suited for modeling microstructure and texture evolution in two-phase materials with bimetal interfaces, but many conventional versions do not take into account the effect that interface/slip interactions can play in microstructural evolution.

Recently, a first attempt was made to examine the effect of slip transmission on slip activity in the adjoining crystals and in turn the evolution of interface character (Mayeur et al. 2015). The authors incorporated into the two-phase CPFE model, a combined geometric and local stress criterion for slip transmission across an interface. It was based solely on the degree of alignment of their slip planes and slip directions on either side of the interface and whether or not the local mechanical driving forces supported the flux into and out of the interface (Misra et al. 2004).

The CPFE model with slip transmission was applied to study the texture evolution in Cu/Nb nanolayered composites during rolling. It was seen in studies of texture evolution in processed nanolayers that at the finest scales ($h = 20$ nm and below), texture experienced a final transition (Zheng et al. 2013). In the Cu/Nb composites, a particularly odd interface of G/I with a {515}<1 -10 1>|| {1-2-1}<101> interface character had formed and become orientationally stable,

**Fig. 9** Reorientation maps of bicrystals deformed in plane strain compression and with slip activity controlled by slip transmission. The top crystal is Cu and the bottom crystal is Nb. The starting interface orientation relationships for these bicrystals correspond to the (**a**) C/I interface and (**b**) G/I interface. The crystallographic orientations are overlaid onto the original mesh. The deformed mesh is not shown. The legend is the same one as that shown in Fig. 8
while the previously studied C/I interface and D/I interfaces orientationally unstable (Zheng et al. 2013). It was anticipated that the change in slip activity in the Cu and Nb phase may be due a transition from slip within the crystals to a prevalence of slip transmission across the crystals as the layers became fine.

Figure 9 shows reorientation maps for the C/I and G/I interface with slip transmission-dominated slip as calculated from the model. To see the effects of slip transmission, these maps can be directly compared to maps in Fig. 8 calculated with the standard CPFE and ordinary slip. In all cases, it was found that slip transmission across the interface significantly altered slip activity. The alteration causes the C/I interface (and D/I interface as well) to become unstable (reorientations greater than 12°). In contrast, the G/I interface maintained its character in rolling. The results show that the G/I interface is stable with and without slip transmission-dominated slip, even though the slip activity in these two cases is not the same.

To summarize, the mesoscale model analysis indicates that the transition in texture evolution to a particular stable interface was the result of slip transmission across the interface. Slip transmission can predominant at the finest scales, and when it does, it can affect texture evolution, producing crystalline orientations unlike those expected when conventional slip processes are prevalent.

The slip transmission-dominated calculations assume that only slip systems belonging to favorable slip transmission pathways are active. In actuality, the constraint may be less severe as the interface can supply dislocations by other means (e.g., direct nucleation at triple junctions). Coupling all relevant interface-driven plasticity phenomena, from dislocation nucleation, annihilation, transfer, and storage, has yet to be done. It would be a challenge especially well suited for mesoscale modeling approaches to take.

## 3.3 Nanocrystalline Materials

Nanocrystalline (NC) metals are another example of a boundary-dominant metal. NC are polycrystalline materials that have grain sizes smaller than 100 nm and for decades have attracted a lot of attention because of their ultrahigh strength and hardness, being several times that of their coarse-grained counterparts (Dalla Torre et al. 2002; Ebrahimi et al. 1999; Hughes et al. 1986; Schuh et al. 2002; Schwaiger et al. 2003; El-Sherik et al. 1992; Xiao et al. 2001; Godon et al. 2010; Champion et al. 2001; Chen et al. 2006; Das et al. 2006; Khan et al. 2008; Shen et al. 1995; Youngdahl et al. 1997; Youssef et al. 2004; Nizolek et al. 2016). These experimental reports have shown that the yield strength of NC metals increases with decreasing grain size $D$ for $D$ larger than a critical size, e.g., 10 nm. Most often this size effect on strength closely follows an empirical Hall-Petch (H-P) relationship, in which the yield strength is inversely proportional to the square root of D. Figure 10 shows a compilation of strength data from many studies on NC Cu and NC Ni on a H-P plot. The variability among the studies originates from different measures of strength used, manufacturing methods, and other microstructural features, such as texture or variability in grain size.

NC metals are exceptionally strong because they contain an unusually high density of grain boundaries (GBs), which act as sources and sinks for dislocations and significantly modify dislocation motion. In situ transmission electron microscopy (TEM) and molecular dynamics (MD) studies of deformed nanocrystalline materials have provided insight into how dislocations move within the nanograins (Kumar et al. 2003a, b; Li et al. 2009). They suggest that the prevailing dislocation

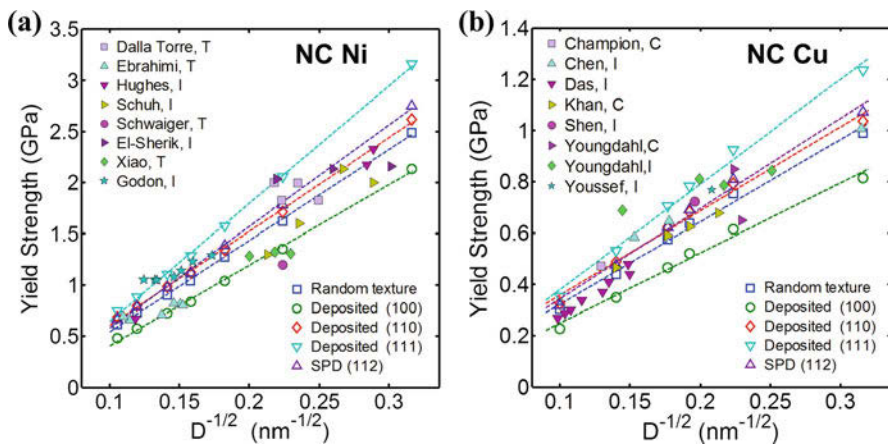

**Fig. 10** (**a**) Comparison of predicted yield strengths with experimental results on NC Ni from various groups. (**b**) Comparison of predicted yield strengths with experimental results on NC Cu from various groups. The dashed line represents the Hall-Petch fit to the calculated yield strength. Experimental data were obtained by nanoindentation marked with an "I," compression marked with a "C" for tension marked with a "T." (In nanoindentation tests, the yield strength was approximated as hardness divided by 2.7)

motions are very different than those in coarse-grained materials. First, dislocation-dislocation interactions and dislocation accumulation seldom happen within nano-sized grains. Second, the plastic deformation proceeds by discrete and separated dislocation slip events, in which a dislocation originates at a grain boundary, glides across the grain unhindered, and recovers at an opposing grain boundary.

NC materials can be made in different ways, and each can lead to different textures. Electro- or physical vapor deposition results in a highly textured NC material, where one set of planes is aligned along one direction and the remaining axes are otherwise randomly oriented in the other two orthogonal directions (Meyers et al. 2006). Plastic deformation (by shearing, rolling, or extrusion) tends to produce even stronger textures than deposition, where the interface planes correspond to the rolling (or shearing) plane and the two in-plane directions are highly aligned with the rolling (or shearing) direction (Nizolek et al. 2014). On the other hand, other methods for making NC metals, such as ball-milling and consolidation processes, produce nearly randomly oriented textures (otherwise known as "no texture") (Khan et al. 2008).

Understanding the degree of coupling between texture and nanograin deformation is important for interpreting reports on strength-grain size scalings in NC materials. In most strength studies performed on the same NC material, such as those in Fig. 10, samples with different grain sizes do not necessarily have the same texture, or quite often, samples from different studies with the same average grain size have different textures due to processing differences. A few recent studies, dedicated to analyzing both texture and size scaling in NC materials, have reported a strong texture effect. Dalla Torre et al. (2002) investigated two commercial NC Ni samples with the same grain size ($\sim$20 nm) and clearly demonstrated that the strong (100) and weak (100) initial textures can result in non-negligible differences in yield strength, ultimate tensile strength, and plastic strain. Godon et al. (2010) studied the effect of crystallographic texture on the relationship between grain size and flow stress in NC Ni. Their experimental results showed three distinct regimes in the Hall-Petch plot, corresponding to samples with a (100) texture, (110) texture, and random texture. They concluded that differences in Hall-Petch slope resulted from differences in the deformation mechanisms induced by texture.

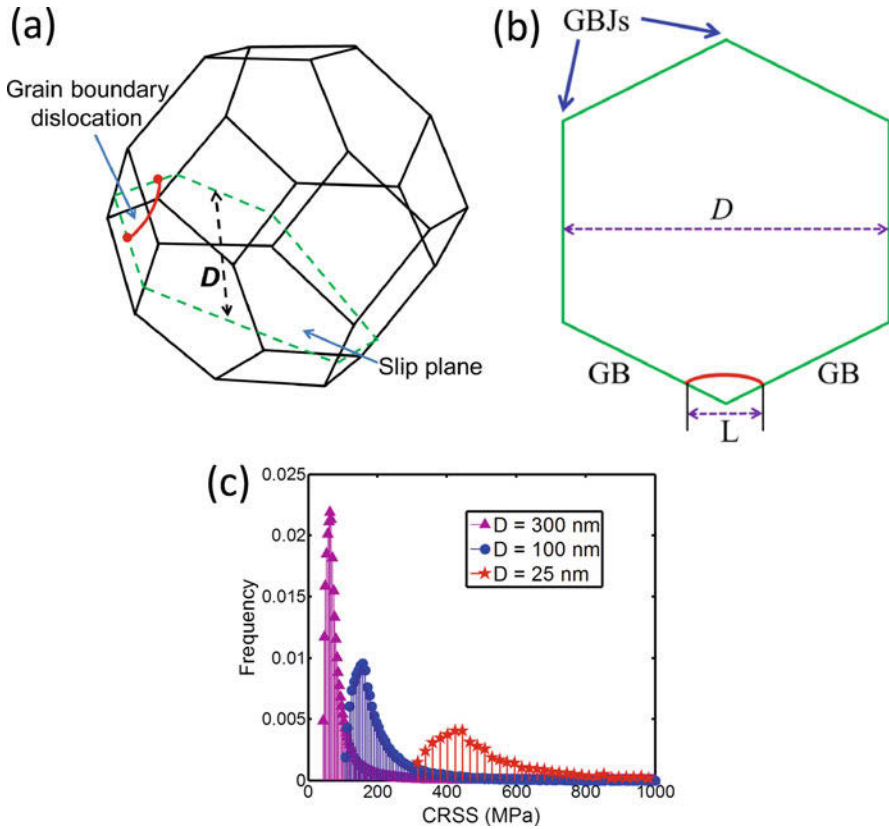
The physical picture provided by experiment and atomic simulation implies that the dislocation processes in NC are closely tied to the availability of dislocation sources in the GBs and orientation of the dislocation glide planes with respect to the grain boundaries. On this basis, texture effects ought to be stronger in NC metals than they are in coarse-grained (CG) metals. CP-based techniques are well suited for assessing coupled texture and grain size effects in NC materials and how they are coupled to determine material strength. As discussed in Sect. 2.4, the common CRSS models for activating slip with crystal plasticity-based models, however, apply to coarse-grained materials, and these models assume that slip initiates and propagates homogeneously within the grains, without resolving the individual contributions of the dislocations. The mesoscale modeling challenge, therefore, lies in how to represent the dislocation glide processes in NC materials so that texture/grain size influences can be properly replicated in simulation.


**Fig. 11** (**a**) Schematic of a dislocation source emanating from a grain boundary triple junction in a nanograin. The grain is embedded in a polycrystal, and the grain boundary facets that it makes with the neighboring grains give it a shape of a tetrakaidecahedron. (**b**) Schematic of a dislocation source (red) at a grain boundary triple junction. The length L is the dislocation source length. The shape of the grains is assumed to take on a regular hexagon. (**c**) Comparison of the probability density distribution of CRSS in NC Cu with grains sizes of 20 nm, 100 nm, and 300 nm (Taken with permission from Yuan et al. 2015)

Recently Yuan et al. (2015) developed a discrete-slip-crystal-plasticity-based CPFE model in which slip occurs in discrete slip events exclusively by individual dislocations emitted statistically from the grain boundaries. Within the model, the shape of the nanograins is assumed to be tetrakaidecahedron, that is, a truncated octahedron, such as the one shown in Fig. 11a. In this case, some dislocation glide planes assume a hexagon shape, while others would adopt a pentagon shape. Within this plane, dislocation sources are present in the grain boundary as double-pinned dislocation segments of length $L$ emanating from the triple junctions as illustrated in Fig. 11b.

Given the length $L$, of the double-pinned GB source, the characteristic stress to bow out the segment to an unstable configuration is given by Foreman's formula (Foreman 1967):

$$\tau_{CRSS} = \frac{\mu b}{2\pi L} \log\left(\frac{L}{r_0}\right) \tag{14}$$

where $\mu$ is the effective shear moduli of the crystal and $r_0$ is the core radius of the dislocation. Once emitted from a GB, the dislocation glides unhindered to the opposing grain boundary producing a shear strain given by

$$\gamma_{discrete} = c\frac{b}{D} \tag{15}$$

where $c$ is a scaling parameter independent of grain size ($c = 1.2$ in their work), $b$ is the magnitude of the Burgers vector, and $D$ is grain size.

These source lengths $L$ are statistically distributed where $L$ can be no shorter than a dislocation core $L_0$ and no longer than $D$ the diameter of a grain. Combined with the expression for the activation stress in Eq. (14) leads to a distribution for CRSS. Figure 11c is an example of a CRSS distribution for three different grain sizes, when $L$ is assumed to be equal likely to lie between $L_0$ and $D$. As shown, by virtue of statistical source lengths from grain boundaries, dislocation activation becomes harder (the statistical mean increases) and more variable (the statistical dispersion increases) as $D$ decreases.

Yuan et al. (2015, 2016a) applied the discrete-slip-CPFE model to study the combined effects of grain size and texture on the strength of NC materials. As common in CPFE simulations for coarse-grained materials, glide on multiple planes is permitted and dictated by the current stress state in the grain, and its current orientation and grain-grain interactions are taken into account. However, in the discrete-slip model for nanomaterials, during deformation, for each GB junction, a GB source is randomly assigned a $\tau_{CRSS}$ from the corresponding $\tau_{CRSS}$ distribution (Fig. 11c). Without loss of generality, the statistical CRSS model is applied to the case in which the GB sources are inexhaustible. After emission of a dislocation on slip system $s$ from a GB source, a new GB source must take its place in order to emit another dislocation on the same slip system. After emission, a new $\tau_{CRSS}$ is reassigned for a potential slip event. As validation, with only the core radius and strain rate sensitivity used as material input, the model is able to reproduce the entire stress-strain curve measured for a few grain sizes of NC Cu, as shown in Fig. 12.

The discrete-slip CPFE simulation model was employed to understand the effects of grain size and texture on NC material strength in simulation, the deformation was applied in one of three directions at a strain rate typical of most laboratory studies ($10^{-4}$/s). Additionally, as mentioned the reported NC studies (see Fig. 10), the initial textures very likely vary due to differences in processing. To account for processing-related texture effects, these simulations began with different types of initial textures, either random or highly oriented, deposited textures. The

**Fig. 12** Comparison of experimental and calculated stress-strain curves for texture-free NC Cu with various grain sizes. (Experiment data are taken from Khan et al. 2008) (Taken with permission from Yuan et al. 2015)
orientations in the model material for the former case of a random texture were numerically generated. For the latter case of a highly oriented texture, a set of deposited {hkl} textures, where the {hkl} planes are aligned along the *z*-direction and nearly isotropic in the *x-y* plane, were created. These include deposited {001}, {110}, and {111} textures.

Figure 10 presents, along with the strength data from several studies, the model results for the 0.2% yield stress taken from the calculated stress-strain curves for the different loading directions and initial textures (Yuan et al. 2016b). The results bound the corresponding experimental data. The important implication is that initial texture differences in NC samples alone can result in a significant dispersion in strength.

The straight line that the predictions form on this plot for each initial texture shows an emergence of a $D^{-1/2}$ Hall-Petch scaling in the calculated yield strength. The Hall-Petch relationship prevails for all initial textures and materials studied, with the only difference being a change in the Hall-Petch slope. Further, the model finds that the more intense the texture (more preferred orientations), the larger the Hall-Petch slope, indicating greater strength sensitivity to grain size reduction.

A commonly used metric for relating texture intensity to the anisotropy in strength is the Taylor factor $m_T$. It is defined as the inverse of the average of the (five) largest Schmid factors in each grain, which is then averaged over all grains. It is thus a purely geometric factor that depends on loading direction and initial texture. For instance, for the z-direction for the {111} texture, $m_T^z = 3.44$. The model results suggest that the H-P coefficient can be expressed as a product of a material-dependent parameter and a geometric one, i.e., $\alpha m_T$, giving the following Hall-Petch law

$$\sigma \propto \alpha m_T D^{-1/2} \quad (D < 100 \text{ nm}) \tag{16}$$

For Ni and Cu, $\alpha$ is, respectively, 3.22 GPa• nm$^{1/2}$ and 1.14 GPa• nm$^{1/2}$. If for instance, the plastic anisotropy measure is chosen to equal the difference between the z-direction and x-direction yield strength, $\psi = |\sigma_z - \sigma_x|$, then from Eq. (16), the following expression for the H-P coefficient can be written

$$\psi = \alpha \Delta m_T D^{-1/2} \tag{17}$$

where $\Delta m_T = \left| m_T^z - m_T^x \right|$ . For a purely random texture (no texture), then $\Delta m_T$ is zero and the anisotropy is zero. Otherwise, for a material with a texture, $\Delta m_T$ is nonzero. Equation (17) indicates that when the material possesses a strong texture, the plastic anisotropy associated with a textured material can increase as the grain size reduces. This outcome is a demonstration of a mesoscopic effect, involving an interaction of two mesoscale microstructural features.

## 3.4    Nanotwinned Materials

Nanotwinned (NT) metals are another class of boundary-dominant materials, like NC metals. Their structure is comprised of a large density of twin boundaries, spaced usually 5–80 nm apart. These metals have gained much attention due to reports of excellent strength and hardnesses, four to six times higher than those of their bulk counterparts, while exhibiting reasonable ductility (Lu et al. 2004, 2009a; Beyerlein et al. 2014). They are also found to be harder than NC or ultrafine-grained forms of the same material and possess outstanding thermal stability (Zhang et al. 2005, 2007; Anderoglu et al. 2008), electrical conductivity (Chen et al. 2007), and fatigue resistance (Pan et al. 2013; Pan and Lu 2014).

Most NT materials have an FCC crystal structure, such as Cu and Ag, and are formed by deposition techniques (e.g., electrodeposition, magnetron sputtering) (Shen et al. 2005; You et al. 2011). The nanotwinned microstructure is comprised of relatively large diameter $D$ grains (1–5 μm) that are laminated with twins with an average nanoscale thickness of $\lambda$ (5–80 nm) Fig. 13). There are two types of NT materials: columnar and equiaxed. In equiaxed NTs, the grains are randomly oriented, while in columnar-grained NTs, the grains form as columns aligned along the NT growth direction. They consequently have very different textures. The TBs and {111} poles are randomly oriented in the equiaxed NTs, while they are highly oriented in the columnar NT, being narrowly dispersed about the NT growth direction.

It is generally known that fine nanoscale dimensions of the twin lamella give the NT its high strength. NT materials deform by the glide of (partial or full) dislocations within the twin lamellae on {111}<110> slip systems or on the TB planes. The formation and glide processes are unlike those in coarser twinned or coarse-grained materials. Many MD simulations on deformed NTs (Dao et al. 2006; Jérusalem et al. 2008; Mirkhani and Joshi 2011, 2014; Xie et al. 2015; Zhu et al. 2011, 2015) have revealed that GBs and the GBJs, where GBs meet, are
**Fig. 13** (**a**) TEM images of an equiaxed Cu NT and (**b**) a columnar Cu NT (Taken with permission from Lu et al. (2009b) and Zhu et al. (2015))

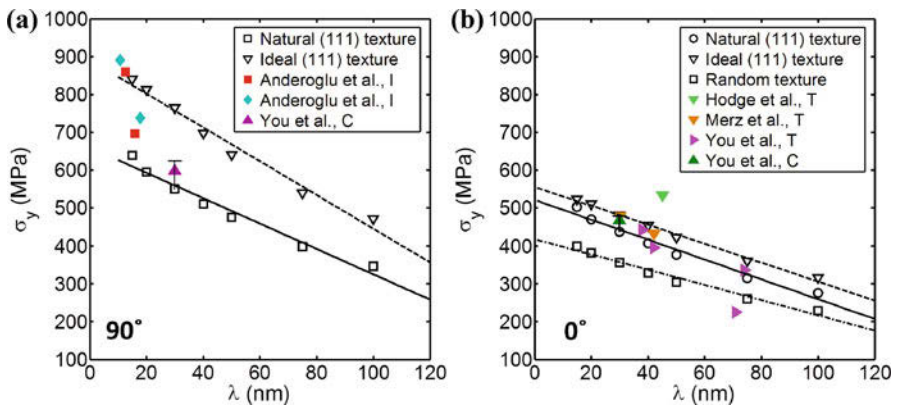

**Fig. 14** Comparison of experimental and calculated yield strengthens for columnar-grained NT Cu (**a**) under 90° compression and (**b**) under 0° compression. The error bars on the calculated strengths for $\lambda = 30$ nm cover results for $D = 500$ nm to 3000 nm. Experimental data were taken from various studies on Cu NT as indicated by solid symbols (Taken with permission from Yuan et al. 2016)

the favorable dislocation nucleation sites. The motion of the dislocations that must glide between adjacent TBs is constrained and the nanotwin thickness $\lambda$ limits the distances traveled. As with NC metals, the formation of dislocation pileups in such a confined space is unlikely.

These mechanisms of deformation indicate that the strength of NTs would depend on the TB spacing (or equivalently, the nanotwin thickness $\lambda$) as well as the as-processed texture (whether {111}||NT or random). Effects of $\lambda$ size and texture are not explicitly examined in many studies. A compendium of NT strengths, measured by indention, compression, or tension, from various studies, is given in Fig. 14. While it appears that strength increases with decreasing $\lambda$, the data are not sufficient to extract a well-defined $\lambda$ scaling. Strengths tested normal (90°) to

**Fig. 15** Experimental results from You et al. and calculated stress-strain curves for columnar-grained NT Cu with twin thickness $\lambda = 30$ nm and different grain sizes $D$ (Taken with permission from Yuan et al. 2016)
the TBs or parallel (0°) to the TBs are shown in separate plots, since the strengths in these two directions could be dissimilar. In one study, performed by You et al. (2013), the yield strength of columnar-grained NT Cu was shown to be highly anisotropic. When the loading orientation is perpendicular to the TBs (90°), the yield strength is 600 MPa, 25% higher than 0° (see Fig. 15). In contrast, equiaxial-grained NT Cu exhibits near-plastic isotropy because of the randomly oriented twin layers (Lu et al. 2009b).

Recently Yuan et al. (2016b) advanced a mesoscale CP technique to examine the effect of NT $D$ and $\lambda$ and initial texture on NT deformation response, strength, and strain hardening and to investigate the underlying mechanisms. CP, in general, permits the crystalline nanostructured to be modeled closely to the experimental one. At the highest scale is the polycrystal, an aggregate of grains of diameter $D$. Every grain is laminated by multiple NTs, each separated by a (111) twin plane and possessing the FCC twin-matrix orientation relationship. Among the grains, the NT (111) twin planes differ in orientation with respect to the sample, according to a specified texture, e.g., randomly in the case of no texture or highly aligned with the growth direction in the case of columnar NTs. Figure 16 shows a CP model for a columnar NT.

As is common with CP models, at the finest scale, within an individual lamella, plastic deformation is mediated by dislocation motion on crystallographic planes. For FCC crystal structure common of these NT, there are 12 possible slip systems in FCC crystals. With respect to the {111} TBs, there are three slip systems that lie parallel to the TB plane, denoted here as *TB-parallel slip*, and nine slip systems that lie inclined to them, called *TB-inclined slip*.

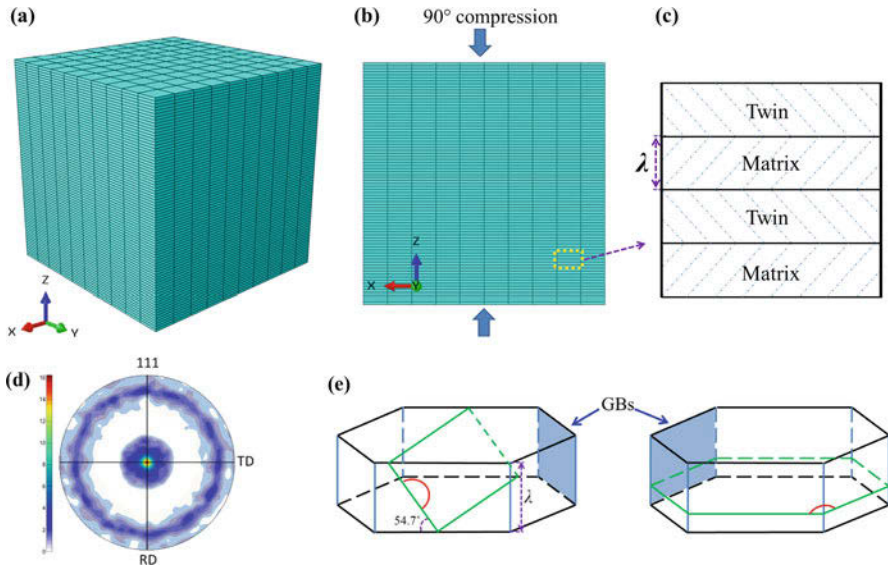
In many CP techniques, slip on these planes is assumed to activate homogeneously in the crystal and the amount of slip incurred after activation is not explicitly dependent on lamellae size. The slip model used in Yuan et al.'s CP technique (Yuan et al. 2015) (see Sect. 3.2) was modified to account for discrete slip events, where dislocations are emitted from grain boundaries in NT materials and both $\lambda$ and D affect the amount of slip.


**Fig. 16** (**a**) Schematic of a NT Cu sample with columnar grains. (**b**) Plane view of the NT Cu sample. The compression perpendicular to the columnar axis is defined as 90° compression. (**c**) A portion of a single columnar grain including twin/matrix structure. (**d**) {111} pole figure of the initial texture of the columnar-grained NT Cu. This texture is used to initialize the model microstructure prior to application of the load. (**e**) Schematic of a twin lamella in one grain with a dislocation nucleating from GB on an inclined slip plane (left) and from a GBJ on a parallel slip plane (right) (Taken with permission from Yuan et al. 2016)

Figure 16 shows the model geometry for the case of a columnar NT and, in more detail, a schematic of an individual twin lamella that is $\lambda$ thick. As shown, the cross-section of a twin lamella is modeled as a hexagon. The grain size corresponds to the shortest distance $D$ between two opposing facets of the hexagon corresponding to the grain size $D$. The six sides of the twin lamella are grain boundary (GB) planes. Each lamella has six grain boundary junctions (GBJs), where two neighboring grain boundaries meet.

As mentioned earlier, both GBs and GBJ contain sources for dislocations, which are double-pinned source length lying in the planes or across the junctions. Using the twin lamellae model in Fig. 16, as a GB source, source length $L$ must lie along the intersection line between the slip plane and the grain boundary. These GB sources can supply dislocations on all 12 planes – the 3 TB-parallel slip systems and 9 TB-inclined slip systems. For the TB-parallel planes, the GB source lengths can physically range from $L_0$ to $D$. For the TB-inclined planes, the GB/slip plane intersection line is bound between the two adjacent coherent twin boundaries $\lambda$, and thus, the possible source lengths range from $L_0$ to $\lambda/\sin\theta$, where $\theta$ is the angle between the inclined slip plane and twin plane. For the GBJ sources, the line where two adjacent grain boundaries of the same grain meet, as shown in Fig. 16e. The line does not intersect any TB-inclined plane and therefore are geometrically not

permitted to emit dislocations on them. The GBJ source line does intersect one of the TB-parallel planes. Since each end of the GBJ source length $L$ can lie on one side of the junction, the length $L$ of the GBJ sources can range from $L_0$ to $D$. Finally, the stress to emit the source of $L$ is given in Eq. (14). Statistical variation in $L$ leads to a statistical distribution of activation stresses.

Once emitted from the GB or GBJ source, $D$ or $\lambda$ determines the amount of slip the dislocation delivers. The TB-parallel systems provide a shear of $b/\lambda$, and the TB-inclined systems can shear by $b/D$, where $b$ is the magnitude of Burgers vector for the material (e.g., for Cu, $b = 0.362$ nm).

With the above formulation, the CP technique considers two NT length scales, twin thickness $\lambda$ and grain size $D$, and their size effects on two phenomena, dislocation emission, and the amount of slip per emission. For demonstration the simulations considered the 0.001/s room temperature, strain rate tests by You et al. (2013) on Cu. The model NT Cu initial texture was taken from their study and corresponds to one naturally found in most as-deposited NT materials, wherein the {111} poles of the twin lamellae are dispersed with in 25° about one axis (denoted as the natural {111} texture). Figure 15 compares the model with the stress-strain curves from You et al. (2013) for the 0° and 90° cases. It is worth noting that apart from the nanostructure length scales and textures, the only parameters that were provided to the model were the strain rate and power-law exponent and for Cu, the moduli, and Burgers vector. The grain diameter and $\lambda$ in the model corresponded to those in the actual sample $D = 3000$ nm and $\lambda = 30$ nm. As shown, other grain diameters ($D = 500$ nm and 1500 nm) were also tested to assess the effects of $D$ in this case. The model suggests little dependence on $D$, which can be anticipated, since comparatively the very fine nanotwin thickness $\lambda$ would have more impact on dislocation emission.

To further investigate processing texture effects, the calculation for NT material with $\lambda = 30$ nm and $D = 3000$ nm (in Fig. 15) was repeated for a weaker texture, i.e., no starting texture (random) or a stronger one, an ideal (111) starting texture. Without an initial texture (i.e., random texture), the difference between the strengths for the 90° and 0° was negligible. This result is consistent with reports on equiaxial-grained NT Cu, which exhibits near-plastic isotropy because of the randomly oriented twin layers (Lu et al. 2009b). In contrast, with an ideal (111) initial texture, the plastic anisotropy is significant, with the 90° test being the stronger of the two, as seen in the calculations with the natural, in experimentally measured texture, and in the experimental mechanical tests. The results find that texture causes the 90° test to have the stronger flow stress than the 0° test.

Based on the foregoing results, it would be expected that the same anisotropy prevails for all values of $D$ and $\lambda$ provided the texture does not change. The effect of NT $\lambda$ was examined with the model for the three types of textures: the random texture, the experimental (natural) texture Fig. 16d, and the ideal (111) texture. The comparison made in Fig. 14 finds that these three sets of calculations collectively span the values of NT strengths reported in the literature, which likewise are derived from samples bearing one of these types of initial textures.

Several interesting implications can be made from the calculations. First, the equiaxed NTs are the weakest and those with the ideal {111} texture NTs are

stronger. The model results suggest that for all initial texture types, the yield strength scales inversely with λ. Yet a cross-effect arises since texture is observed to affect the sensitivity of strength to reductions in λ. The size effect in λ is seen to intensify as the texture sharpens from the no-texture case (weakest effect of size on yield strength) to the case with an ideal {111} texture (strongest effect of size on yield strength). For instance, with the strong, highly oriented (111) texture, the often measured 90° strength for columnar NTs would increase much faster with decreasing λ than equiaxed NTs. Last, the size effect is anisotropic. The 90° strength has a stronger size scaling with λ than the 0° strength. Consequently, the yield anisotropy for the columnar NT, defined as the difference in yield strength between the 90 and 0° tests, increases as λ decreases. As a consequence, finer twin thicknesses would lead to a higher propensity to shear band.

## 3.5    Nanolayered Thin Films

One popular class of interface-dominant materials are nanolayered composite thin films. These materials have a 2D structure and are comprised of a layered stack of dissimilar metals, wherein the individual layer thickness has nanoscale dimensions (usually $h < 100$ nm), and hence the density of interfaces is unusually high (Beyerlein et al. 2012, 2013a, d, 2015; Monclús et al. 2013). Studies on the structural properties of nanolayered films report exceptional properties compared to those of their constituents or volume average values of their constituents, such as strengths that are over five to ten times higher, hardness values that are several orders of magnitude higher, and greater microstructural stability in harsh environments, such as irradiation, impact, or elevated temperatures (Beyerlein et al. 2013a; Mara et al. 2008; Mara and Beyerlein 2014; Han et al. 2013a; Misra et al. 2004, 2007).

As a result of the deposition technique, the films have a special microstructure that is unlike those found in traditional polycrystalline materials and even the single-phase nanocrystalline materials discussed earlier (Sects. 3.2 and 3.3). They are usually made by deposition techniques, such as physical vapor deposition (PVD), which enable fabrication of multilayers with individual layer thickness of nanoscale dimensions, uniformly across the film (Fig. 17). Typically, one grain spans an individual layer, but in the plane of the layer, the layers are polycrystalline. The interface bears a certain crystallographic character, usually low in interfacial energy, and the crystal orientations are highly aligned, giving the film a strong texture. The interfaces tend to be atomically ordered, comprised of relatively few defects, such as misfit dislocations, compared to grain boundaries (Beyerlein et al. 2013b, c; Wang et al. 2013; Kang et al. 2012).

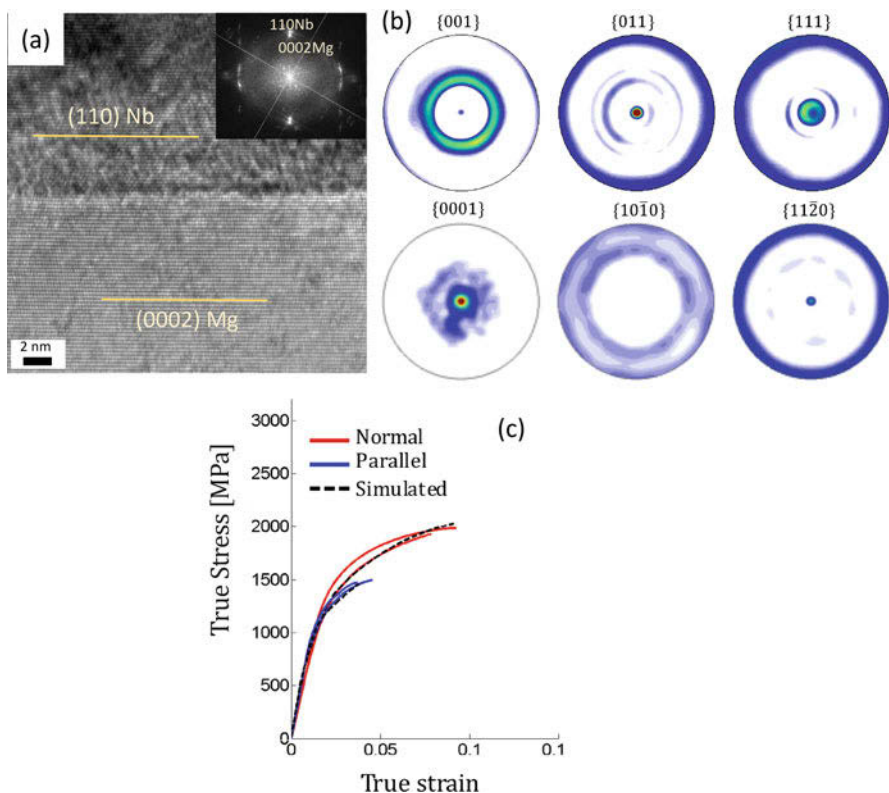
Like in conventional, coarse-grained metals, plasticity in these biphase nanolayered films occurs by dislocation glide. However, the nanoscale dimensions of the layers are close to the size of dislocations. The exceptional plastic properties of nanolayered composites, over the coarse counterparts, are a result of the frequent and close interactions of the dislocations with the bimetal interfaces.


**Fig. 17** (**a**) HR-TEM images taken of the (**a**) 50 nm/50 nm HCP Mg/BCC Nb. (**b**) Initial pole figures of the XRD measured textures of the HCP Mg (50 nm) on the top row and Nb phase in the bottom row. (**c**) Comparison of the predicted and measured stress-strain curves from micropillar compression for the 50/50nm Mg/Nb composite (Taken with permission from Pathak et al. (2017) and Ardeljan et al. (2018))

With crystallographic slip as the main deformation mechanism, the 2D-layered architecture and the strong texture together alone would then be expected to result in substantial anisotropy in strength and other deformation properties. Yet, anisotropy in structure properties is not often studied since testing the thin film samples in different directions is not as straightforward as it is with bulk samples. The few studies in which anisotropy were investigated show considerable anisotropy in yield, strain hardening, and ultimate strength (Nizolek et al. 2016; Pathak et al. 2017). Figure 17 presents results from a recent report on the anisotropy of Mg/Nb nanolayered PVD films. From these films, micron-diameter pillars were fabricated using a focused ion beam (FIB)-based technique and tested in compression to obtain the composite mechanical response. Micropillar compression tests were carried out with the compression axis either (i) normal or (ii) parallel to the Mg/Nb interface planes. In both directions, these materials exhibited outstanding strength, 50% stronger than that of coarse-grained counterparts or a volume average of their

strengths. The composites also exhibited anisotropy in their flow response with the flow stress in the normal direction being 30% higher than in the parallel direction.

In general, crystal plasticity-based techniques are suitable models for calculating the microstructural evolution (texture, layer distortion) during the deformation of layered polycrystalline microstructures. In fact, in recent years, a few applications of CP modeling have led to insights into texture effects. In Al-Fadhalah et al. (2005), a two-phase VPSC model was applied to study texture evolution in rolled PVD Cu/Nb films, showing that texture evolution at a fine scale corresponded to maintenance of the KS orientation relationship at the Cu/Nb interface. In another study, two-phase VPSC successfully showed that the substantial tensile anisotropy in Cu/Nb nanolaminates was the result of the strong texture that developed during processing (Nizolek et al. 2016). A CPFE model for Cu/Nb was used to show that the two common interfaces found in PVD Cu/Nb films did not maintain their crystallography under rolling (Mayeur et al. 2014; Beyerlein and Mayeur 2015). Another Cu/Nb laminate CPFE model was employed to quantify the reductions in micropillar compression strength of Cu/Nb nanolaminates with increases in temperature (Monclús et al. 2013). While calculations from these CP modeling studies explained some trends seen in experiment, predictions of the actual yield strength and flow response were not possible. The constitutive laws traditionally used in CP-based models consider dislocation processes in coarse-grained materials and thus are not appropriate for processes taking place in very fine crystals of nanoscale dimension.

In these nanolayered composites, typically with layer thicknesses $h < 50$ nm, the interfaces are spaced sufficiently close, which is only one order of magnitude than the width of the dislocation core. The interfaces confine the movement of the dislocations, forcing them to thread through the layers, depositing in the interfaces as they pass by. This glide mechanism that has been observed in these nanolaminates materials and is termed confined layer slip (CLS) (Misra et al. 2005; Li et al. 2012).

Recently Ardeljan et al. (2018) proposed a CPFE-based model crystal plasticity model with the $h$-dependent critical resolved shear stresses according to CLS. This CPFE-CLS model employs the CLS model (Misra et al. 2005) to define the CRSS for every slip system operating at a crystalline point. Following the CLS formula, the CRSS for a slip system $s$ is given by

$$\tau_{\text{CLS}}^s = \tau_0^s + A^s \frac{\mu^s b^s}{h^{s\prime}} \ln\left(\frac{\text{ch}^{s\prime}}{b^s}\right) + \frac{f^s b^s}{h^{s\prime}} \tag{18}$$

The first term $\tau_0^s$ represents the sum of a friction stress and resistance from other obstacles, which would not be significantly altered by strain. The second term comes from the CLS mechanism and bears a $\ln(h)/h$ dependence, and results from the resistance encountered by the dislocation as it propagates through the layer. The last term, i.e., $f^s b/h\prime$, results from the deformation of the interface caused by the threading dislocation. Based on previous works that have applied the CLS model to multilayers, the expected order of magnitude for $\tau_0^s$ is 10–100 MPa, for $A^s$ is $10^{-2}$–$10^{-1}$, and for $f^s b$ is 1–3 J/m$^2$.

**Fig. 18** The CPFE model meshes for (**a**) the 50–50 nm Mg/Nb composite. The model contains one layer each of Mg and Nb. Bottom images show zoomed-in view of the microstructure indicating different grain aspect ratio (Taken with permission from Ardeljan et al. 2018)
The key length scale introduced in the CLS-CRSS model is $h^{s'}$, the distance along the slip plane of slip system $s$ from one interface to the next. It depends on the orientation of the crystal with respect to the interface normal and the layer thickness $h$. Consequently the CLS-CRSS embodies a dependence on texture, and the CLS-CRSS can evolve with texture through its dependence on $h'$ and with deformation of the layers through its dependence on $h$.

The CPFE-CLS model was applied to understand the mechanisms responsible for the yield, strain hardening, and plastic anisotropy in the Mg/Nb composites shown in Fig. 17c. As is common for the crystal plasticity contribution to the constitutive law, the slip and twin families need to be specified a priori. For HCP Mg, the three main slip modes made available for HCP Mg are basal $\langle a \rangle$ slip, prismatic $\langle a \rangle$ slip, and pyramidal $\langle c + a \rangle$ {1122}⟨1123⟩ slip. For BCC Nb, the two slip modes made available are {110}⟨111⟩ slip and {112}⟨111⟩ slip.

As discussed in Sect. 2.2, part of the effort is the explicit representation of the microstructure in the micropillar sample. Figure 18 shows the CPFE model of the Mg/Nb bilayer. It is divided into two equal sections/volumes that represent a layer of the Mg bonded to a layer of Nb. As in the fabricated film, (1) both layers are polycrystalline in plane, and one grain spans the layer thickness. (2) The grains are nearly equiaxed with grains 50 nm thick and 100 nm wide. (3) The initial Mg and Nb phase textures were produced by assigning orientations randomly selected from their corresponding measured textures. (4) Mg and Nb grain pairs share a common {0001}||{011} interface plane.

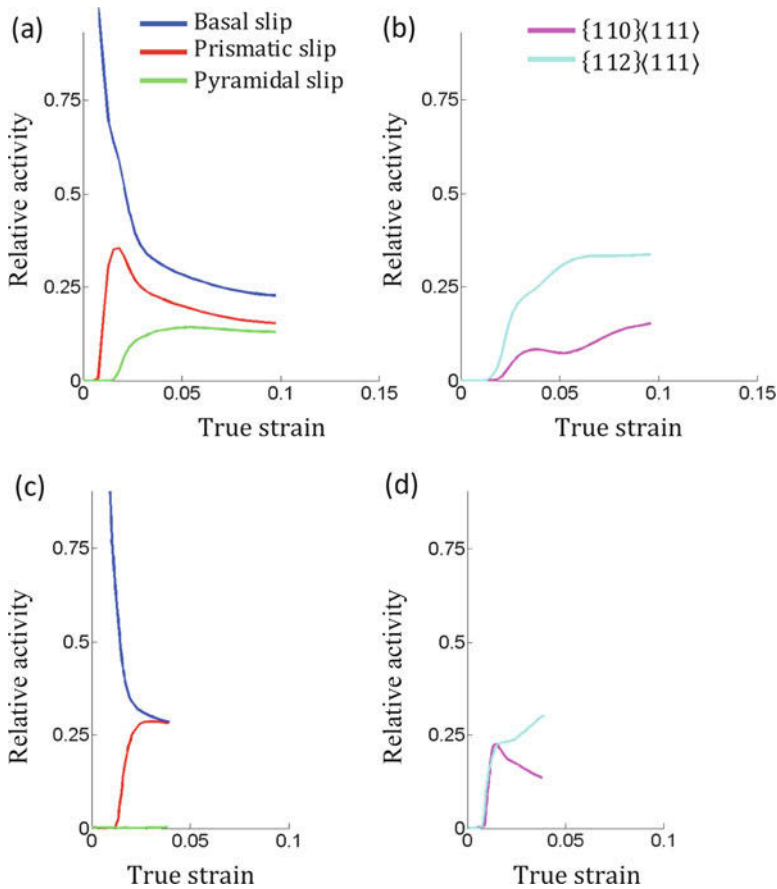
Figure 17c compares the experimental and model stress-strain curves, in which good agreement is observed. Figure 19 shows the relative amounts of slip contributed from the different modes according to the model. In the HCP Mg phase, basal slip prevails, as is expected for pure Mg, from the many reports on the deformation of coarse-grained and ultrafine pure Mg-based systems (Zhu et al. 2008).


**Fig. 19** Calculated slip activity for the 50–50 nm HCP Mg/BCC Nb composites (Taken with permission from Ardeljan et al. 2018)

In the Nb phase, the model indicates that {112} slip dominates the slip activity over {110} slip in both loading directions. Since the {112} and {110} slip modes had the same CLS parameters ($\tau_0^s, A^s, f^s$), the higher propensity for {112} slip is a consequence of texture.

Slip activity calculations in the Mg and Nb also provide insight into the origin of plastic anisotropy, namely, the higher composite flow stress seen in the normal direction than the transverse direction (Fig. 17c). Generally, Nb is the stronger material compared to Mg. The model finds that Nb accommodates proportionally more applied strain in the normal loading than parallel loading, which would alone cause normal loading to give rise to a higher flow stress than parallel loading. In addition, more ⟨c + a⟩ slip in the Mg phase is activated under normal loading than under parallel loading. In Mg, pyramidal ⟨c + a⟩ slip has the highest CRSS compared to prismatic and basal slip, and thus, its higher activity would explain the larger yield in normal loading than parallel loading.

Last, an interesting finding is the source of strain hardening. Since the texture did not change, geometric hardening would not have contributed. Analysis of slip activity and the deformation of the layers indicate that the strain hardening is due to a combination of a reduction in $h$ and change in texture. The hardening is higher in the normal case than parallel case, since in the normal case, the reduction in $h$ during deformation is more severe.

# 4    Part III: Areas for Mesoscale Processing-Microstructure Modeling

Thus far, this chapter has discussed the latest developments in 3D, mesoscale CP-based modeling techniques, and some recent advancements in the ability to model the role mesoscale microstructural features, such as grain (orientation, size, and shape), grain boundaries, twin boundaries, and interface properties, play in the generation of local stresses states and deformation mechanisms during mechanical processing or straining. As is common in modeling efforts, models and their capability to inform and predict could benefit from a number of extensions.

For the mesoscale techniques reviewed here, useful future modifications concern the ability to model the effects of microstructure on the onset (when), formation (where), and migration of boundaries within an explicit 3D microstructure. The list of possible stress-induced phenomena that would introduce internal microstructural boundaries during processing is long: nucleation and growth of voids, development of localized slip bands and shear bands, phase transformations, recrystallization, grain growth, and twins. Also included in this area is the need to account for interactions between dislocations and twins with grain boundaries, interfaces, or precipitates. The number of possible defect/interface reactions that could affect microstructural evolution is long as well. While many of these aspects have been studied intensively and widely using atomic-scale simulation, representing the role of such highly resolved atomic-scale reactions into a mesoscale model is lacking. At the same time, new strategies are needed to overcome the numerical issues involved in dynamically creating and evolving boundaries in explicit microstructure mesoscale models. Below we briefly describe some new and upcoming strategies for tackling these areas.

The heterogeneous stress and microstructural states in a strained material can lead to the dissipation of energy in the form of voids. The study of void growth in crystals and crystalline boundaries has been an intensely studied topic in atomic-scale simulation, discrete dislocation dynamics, phase-field, finite elements, and continuum mechanics (Needleman 1972; Koplik and Needleman 1988; Gurson 1977; Tvergaard and Needleman 1984). Yet, among the modeling techniques available to date, using explicit microstructural CP-based modeling in the study of voids in 3D single crystals and polycrystals is relatively new. In single crystals, these techniques are beginning to probe the effects of void size and orientation on the strain to initiate void growth and on growth rates (Wan et al. 2005; Yu et al. 2010; Ha and Kim 2010; Potirniche et al. 2006; Liu et al. 2007; Han et al. 2013b;

Yerra et al. 2010; Schacht et al. 2003; Mbiakop et al. 2015; Srivastava and Needleman 2015; Pushkareva et al. 2016). In polycrystals, the effect of anisotropic plasticity on void growth rates (or onset of collapse) in tension (or compression) loading states can be accessed (Lebensohn and Cazacu 2012). Looking forward, incorporation of voids would lead to the ability to design processes that do not prematurely lead to failure or process-aware microstructures that postpone fracture.

Deformation twinning is another stress-induced deformation mechanism that introduces boundaries inside crystals. The various schemes for modeling twin reorientation reviewed here, however, were designed for mean-field techniques, and therefore, none of them are intended to explicitly account for twin boundary formation. Up to now, advancing CP models for discrete twins with a 3D microstructure has been hindered by the lack of 3D microstructural representation codes. Very recently, a few microstructural models of discrete twin domains within individual grains have been developed (Ardeljan et al. 2015b, 2017; Abdolvand and Wilkinson 2016; Cheng and Ghosh 2017). With these techniques, studies on the local stress fields and dislocation activity around twin lamellae have shed light on the effects of size and local grain neighborhoods on the propensity for twin growth Fig. 20. Although the twin lamellae can be explicitly inserted, expanding the twin domain dynamically in CPFE can be computationally intensive. CP method advancement for growing discrete twins with a 3D microstructure has been hindered by lack of efficient geometry and mesh manipulation tools and the fact that the mechanisms underlying the nucleation and propagation of twin domains and the relevant driving forces are still being studied.

Many high-performance alloys (e.g., Mg alloys, Al alloys, and superalloys) contain multiple phases of different sizes, which introduce many heterophase

**Fig. 20** Twin formation and thickening with respect to the surrounding neighboring grains in the 3D model of α-U under compression in the z-direction with (**a**) one 5% twin lamella and (**b**) one of 2% and another of 3% volume fraction. The insert shows the distributions of normalized resolved shear stresses along the most dominant twin plane in the twin direction for the red interior grain (Taken with permission from Ardeljan et al. 2015b)

boundaries. For example, Inconels contain γ′, γ″, and δ precipitates, varying in chemical composition, size, and shape. Interactions of discrete dislocations with precipitates have been studied via atomistic, discrete dislocation dynamics, and phase-field methods (Beyerlein and Hunter 2016; Gao et al. 2015). With CP-based models, the effect of precipitates is commonly represented via a change in the CRSS (Shenoy et al. 2008; Ghorbanpour et al. 2017; Nugmanov et al. 2018; Lentz et al. 2015), which models phenomenologically the effect of precipitate size on whether the dislocation can shear it or not. CP can also provide a way to calculate the mechanical stress, strain, and strain rate fields within the individual crystals as a result of elastic and slip on crystallographic slip systems in each phase as well as the differences in deformation across the boundary. Yet to benefit the design of advanced alloys by microstructure control, advancements in CP modeling toward incorporating the role of dislocation/interface interactions in slip activity would be recommended.

## 5    Conclusions

Over the years, mesoscale materials modeling approaches have been built to elucidate the role played by microstructure, e.g., grain shape, grain orientation, grain size, internal grain boundaries, and interfaces, in processing-microstructure-property relationships of polycrystalline materials. Many high-performance polycrystalline materials of intense interest for future engineering applications are inherently or microstructurally complex, warranting advancements in such mesoscale deformation models beyond the standard versions. This chapter aims to highlight the latest developments in 3D, mesoscale CP-based modeling techniques, and the challenges they have overcome. In particular, some recent advancements in the ability to model the role that mesoscale microstructural features, such as grain (orientation, size, and shape), grain boundary, and interface properties, play in the development of local stress states and deformation mechanisms during mechanical processing or straining are described and discussed. Examples cover studies that have employed and extended mesoscale 3D, full-field spatial resolved computational models to investigate processing-microstructure relationships in boundary-dominant materials. These include the influence of bimetal interfaces on microstructural evolution. Also presented and discussed are advancements made to mesoscale techniques to study microstructure-property relationships in boundary-dominant materials. Particular problems addressed include the effects of grain size and shape and layer and twin thickness on dislocation emission and propagation. The chapter ends with a discussion of possible directions and strategies future mesoscale modeling efforts could take to advance capability and value in the design of advanced materials.

# Adaptive Physics Refinement at the Microstructure Scale

# 52

Timothy C. Germann

## Contents

**Abstract**

A long-sought goal of computational materials science and engineering has been a simulation framework that spans all necessary length and time scales, potentially from electronic structure to structural engineering, providing the appropriate level of physics fidelity where needed and enabling the user to trade off accuracy and computational time in an optimal manner. Analogous to adaptive mesh refinement methods that dynamically (and automatically) coarsen and refine a computational mesh based on local requirements, *adaptive physics refinement* methods utilize higher-fidelity physics models as needed, e.g., replacing a phenomenological constitutive model with a direct polycrystal

plasticity simulation. While there have been several demonstrations of similar concurrent multiscale methods over the past 20–30 years, only now is a more general capability becoming viable due to advances in algorithms and computer architectures and middleware. In this chapter, we briefly review this history, focusing on two methods in particular: the heterogeneous multiscale method and adaptive sampling. The computational workflow, data, and runtime requirements of these methods are used to identify key enabling technologies that have recently gained widespread adoption, including task-based programming models, heterogeneous computer architectures, database, and machine learning algorithms.

# 1 Introduction

Multiscale modeling techniques, in which different levels of theory are combined to provide higher accuracy in regions where required, while utilizing more computationally efficient models elsewhere, have a long history in computational science. Perhaps the most notable of these is the hybrid quantum mechanics/molecular mechanics (QM/MM) method for computational chemistry (Warshel and Levitt 1976), whose developers were awarded the 2013 Nobel Prize in Chemistry for "the development of multiscale models for complex chemical systems." In the 1990s, similar techniques were developed and applied to solid-state materials by coupling atomistic and finite element methods. A common prototypical application was to fracture mechanics, combining a long-range nonlinear stress field described by a continuum finite element model with an atomistic description of a crack tip (Kohlhoff et al. 1991) or even extended to a third level of theory by using a tight-binding model for bond rupture in the macroscopic, atomistic, ab initio dynamics (MAAD) technique (Abraham et al. 1998; Broughton et al. 1999). For the reader interested in these and related techniques, including the quasicontinuum (Tadmor et al. 1996; Miller and Tadmor 2002) and coarse-grained molecular dynamics (Rudd and Broughton 1998) methods, a number of comprehensive reviews exist (Lu and Kaxiras 2005; Bernstein et al. 2009; Miller and Tadmor 2009).

# 2 The Heterogeneous Multiscale Method

Motivated by these and other multiscale, multiphysics approaches, E and Engquist introduced the broader heterogeneous multiscale method (HMM) framework, in analogy to the "homogeneous" multigrid methods in which the same physical model is employed at different scales (Weinan and Engquist 2003a, b; Weinan et al. 2003, 2007). In most previous multiscale methods, different models are applied to different physical regions, for instance, a molecular dynamics (MD) region and a finite element (FE) region, with some overlap, handshaking, or bridging region where consistency is maintained. In contrast, HMM uses detailed microscopic models to provide the necessary closure relations for general macroscopic conservation laws. As with the representative atoms ("repatoms") of the quasicontinuum

method, fine-scale (typically MD) models are employed for each element where a macroscopic constitutive model may either be unknown, too expensive to evaluate, or locally invalid, e.g., due to crystal defects or chemical reactions. In a typical approach, a finite element or finite volume model enforces continuum conservation laws for mass, momentum, and energy, while local MD simulations for each element, at each time step, provide average momentum and energy fluxes as statistical time averages, assuming a separation of scales and ergodic dynamical behavior.

## 3    Scale-Bridging Strategies Using Polycrystal Plasticity Models and Adaptive Sampling

Plastic anisotropy (i.e., a mechanical response which depends upon the orientation of the constituent grains) is an important property that is closely tied to a polycrystalline material's microstructure and determines how that material deforms under extreme mechanical conditions. Traditionally, macroscale finite element simulations represent this effect using (static) phenomenological plasticity models which have been parameterized from experiments and/or a more realistic polycrystal plasticity model, for a fixed microstructure. For scenarios involving the coupling of plastic anisotropy with microstructure evolution, direct multiscale embedding has been employed (e.g., Segurado et al. 2012), analogous to the original HMM approach (Weinan et al. 2007) in which every material element resorts to a lower length-scale calculation, every time step. However, the computational cost of such a direct embedding becomes prohibitive as one moves from relatively simple homogenization assumptions to models with higher physical fidelity and correspondingly higher computational expense.

Microstructural effects can be explicitly considered in micromechanical models, with different degrees of fidelity and numerical efficiency, using polycrystal plasticity formulations. The simplest and most efficient Taylor model assumes identical deformation throughout all single crystal grains in a representative volume element (RVE) of the material, typically consisting of a number of grains ranging from 50 (providing a coarse representation) to 1000 (refined), and it is insensitive to the spatial arrangement of the grains within the RVE. Given the strain of each grain (which is known from the applied boundary conditions), the Taylor model gives the stress response as an average of the stresses at the grain level, obtained by solving one system of five nonlinear equations for each grain. A typical refined Taylor computation therefore involves the solution of 1000 decoupled $5 \times 5$ systems of nonlinear equations, requiring on the order of milliseconds on a single modern CPU core.

This Taylor scheme, while computationally efficient, unrealistically neglects interactions between grains. To address this limitation, more elaborate homogenization schemes like the viscoplastic self-consistent (VPSC) model (Lebensohn and Tomé 1993) have been proposed. VPSC considers every grain as an ellipsoidal inclusion embedded in a homogenized effective medium (HEM). Like the Taylor

model, VPSC results do not depend on the spatial arrangement of grains. The HEM properties and the strains and stresses of the grains are not known a priori, but must be obtained iteratively, involving a weighted average of the responses at the grain level. A typical refined VPSC calculation involves 3–5 iterations, each requiring the solution of 1000 coupled $10 \times 10$ systems of nonlinear equations, i.e., less than a second on a single core.

Both the Taylor and VPSC models have an important limitation in common: they are mean-field approaches in which the morphology of the grains is either neglected (as in Taylor) or a simplified grain shape is assumed (ellipsoidal, as in VPSC); and the influence of the specific neighborhood of a given grain is either neglected (as in Taylor) or averaged out (by means of the HEM assumption, as in VPSC). Alternatively, a full-field viscoplastic model based on Fast Fourier Transforms (VPFFT) (Lebensohn 2001) is able to explicitly treat complex grain morphologies and topologies, in a relatively efficient way compared with other full-field approaches such as the crystal plasticity finite element method (CPFEM). The VPFFT approach is based on the use of FFTs to efficiently calculate convolution integrals between a Green's function associated with a reference homogeneous medium and a suitably defined polarization field. Since the polarization depends precisely on the unknown micromechanical fields, an iterative scheme is used. All fields are mapped onto a 3-D regular grid, typically consisting of a number of voxels ranging from $16 \times 16 \times 16$ (for a coarse representation) to $64 \times 64 \times 64$ (refined) or potentially even greater. A typical refined VPFFT calculation involves 10–20 iterations, each iteration consisting of direct and inverse FFTs calculated over the regular grid, and the solution of one $5 \times 5$ system of nonlinear equations per voxel, requiring several minutes on a single processor core. This computation time can be reduced to a few seconds at the expense of losing fidelity by using a coarse grid (see Table 1).

To overcome the high computational cost of directly embedding such polycrystal plasticity models, Barton et al. (2008) developed a scale-bridging methodology that employs adaptive sampling (AS), mitigating the computational expense of direct embedding by building a database of material response as a function of polycrystal microstructure as a simulation proceeds. Whenever a response is needed (typically for each material element, each time step), this database is queried, and if existing database entries are sufficiently close to the new state, the result is interpolated using kriging or another interpolation method. (How one defines "sufficiently close"

**Table 1** Single-core CPU time measured for different polycrystal plasticity models and fidelities of the microstructure description

|  | Mean field representation | |
| --- | --- | --- |
|  | Coarse (50 grains) | Refined (1000 grains) |
| Taylor | 1.8 ms | 35 ms |
| VPSC | 5 ms | 100 ms |
|  | Full field representation | |
|  | Coarse ($16^3$ grid) | Refined ($64^3$ grid) |
| VPFFT | 2.3 s | 148 s |

requires uncertainty quantification analyses, as discussed below in Sect. 4.3.) The original AS implementation was based on the relatively simple Taylor model, which does not account for texture evolution by slip and twinning. Recently, Barton et al. (2015) unified the VPSC model with a discrete harmonic (DH) representation of crystallographic texture and the AS embedding strategy, integrating all three models in the ALE3D finite element code (Noble et al. 2017). The DH-based representation of texture and its evolution was the key to define a database that is representative of the microstructure, is of manageable size, and can account for the rapid texture evolution produced by deformation twinning. This implementation achieved two or more orders of magnitude in wall-clock speedup, compared with direct interrogation of VPSC by the finite element model.

In addition to the increased computational expense of the higher-fidelity poly-crystal plasticity models, two additional computational considerations should be noted. First, the increased model complexity (and reality) is associated with an increase in the number of input parameters required to describe the material microstructure. For instance, the recent ALE3D-AS-DH-VPSC implementation (Barton et al. 2015) just mentioned represents the material texture with a DH expansion; adding higher-order harmonics provides an increasingly accurate description but also introduces many more coefficients. The application of this approach to predict texture-induced anisotropy effects on the final shape of heavily textured Ti bars bent along different directions required a 60-dimensional input space for a sixth-order expansion. The dimensionality is even greater for the spatially resolved VPFFT model, so one must consider the trade-off between accuracy and dimensionality for reduced dimensionality approximations.

This increased dimensionality is in part the original motivation and promise of AS methods: precomputing and parameterizing a model that covers this space are computationally prohibitive and unnecessary since, in practice, the points queried during any particular calculation tend to fall on a low-dimensional manifold of this many-dimensional parameter space (Barton et al. 2011). However, the input space dimensionality introduces additional burdens on both the database lookup and the interpolation method. In addition to these challenges for the AS layer, the history dependence also requires that the coarse-scale model (e.g., ALE3D) tracks the evolving microstructure at each material point.

On future exascale (and beyond) supercomputers, one may be able to afford a spatially resolved VPFFT polycrystal plasticity model, but such calculations are today prohibitive due to computational cost (several minutes per fine-scale model, whereas a coarse-scale time step should ideally take no more than a few seconds) and dimensionality challenges. As an intermediate step between the simple Taylor model and the still-intractable VPFFT model, current state-of-the-art efforts use the intermediate mean-field VPSC plasticity model. The single-core runtime (10–100 ms) is roughly comparable to what we expect each VPFFT calculation to take on an exascale-era node, and the intermediate input space dimensionality (tens of parameters) provides a smooth migration pathway from the simple Taylor model (with only a few parameters) to VPFFT (with hundreds to thousands of input parameters).

# 4    Recent Extensions and Applications

## 4.1    Spatial Adaptive Sampling

The key insight that enables adaptive sampling to offer substantial performance gains is that during any given simulation, the fine-scale microstructure queries follow a low-dimensional manifold of a high-dimensional input space, gradually varying in space and time, aside from shocks and other discontinuities. This enables a frequent reuse and interpolation of recently computed and accessed fine-scale evaluations and kriging models. However, as just mentioned, the potentially high-dimensional input space introduces challenges both in quickly accessing previously computed nearby results and in developing reliable interpolation models. Instead of interpolating over this input parameter space, another option is to interpolate over *physical* space, which of course is at most three dimensional. This approach has been proposed and successfully demonstrated in Rouet-Leduc et al. (2014) and is illustrated in Fig. 1. In these initial demonstrations, previously computed fine-scale results are not stored, nor are kriging interpolation models developed; instead, at each macroscale time step, the required constitutive data is reconstructed by interpolating an automatically determined subset of fine-scale simulations on the $d \leq 3$-dimensional subdomain. As time progresses, one can predict which fine-scale sample points will be required, for a given target accuracy. These authors demonstrated that spatial adaptive sampling can reduce the number of fine-scale simulations (and thus the total computational cost) by three orders of magnitude, compared to direct HMM.

## 4.2    Practical Applications to Molecular Solids

Following the move of two of the key developers of the original adaptive sampling methodology (Arsenlis et al. 2006; Barton et al. 2008, 2011; Knap et al. 2008)

**Fig. 1** Schematic illustration of the spatial adaptive sampling scheme applied to the simple problem of elastodynamic shock propagation in one dimension. (**a**) Shock propagation dynamics occurs on macroscopic space and time scales. Red dots denote representative microscopic regions of the system, each of which is modeled by $\simeq 1000$ atoms of a defect-free fcc Cu crystal. (**b**) The heterogeneous multiscale method (HMM) integrates conservation laws to determine the dynamical evolution of the macroscopic fields. Constitutive data is provided by the stochastic estimates of microscopic molecular dynamics simulations, performed on a regular grid. (**c**) In spatial adaptive sampling, the location of microscopic simulations is dynamically adapted to increase the accuracy and efficiency of the HMM simulation (Rouet-Leduc et al. 2014). Permission from Elsevier

from Lawrence Livermore National Laboratory to the Army Research Laboratory, it has been adopted and further developed there in recent years (Knap et al. 2015, 2016; Barnes et al. 2017a, b). Their primary application has been to model low-velocity Taylor anvil impact tests for molecular solids, in particular energetic materials below the threshold for chemical reactions (Barnes et al. 2017b). Their concurrent hierarchical multiscale (HMS) scale-bridging framework combines three loosely coupled components: a microscopic model, a macroscopic model, and the scale-bridging "glue." At the continuum scale, ALE3D (Noble et al. 2017) is an arbitrary Lagrangian-Eulerian hydrodynamics code. At the fine scale, an interface to the LAMMPS code (Plimpton 1995) has been developed that provides on-demand calculation of material response given an arbitrary state point (e.g., density and internal energy). ALE3D and this LAMMPS integrated materials engine (LIME) (Barnes et al. 2017a) are then coupled via a stand-alone evaluation module that is responsible for collecting microscopic model evaluation requests from the microscopic model, scheduling their evaluation given available computational resources, and communicating their results back to the macroscopic model.

## 4.3   Algorithmic Challenges

Adaptive sampling methods introduce several algorithmic challenges, including how one identifies "nearby" previous fine-scale evaluations that can be used for interpolation, how this interpolation from the microstructure-response database is done, and how one determines whether interpolation is sufficiently accurate, or if a new fine- scale model evaluation must be launched.

The problem of finding neighboring points in a possibly high-dimensional space has been intensely addressed by the computer vision community (Shakhnarovich et al. 2006). A key decision is whether one requires an exact nearest neighbor search or whether an approximate nearest neighbor search suffices. The original adaptive sampling implementations stored a database of kriging models rather than the more numerous set of fine-scale evaluation results. Consequently, an exact neighbor search (using a metric-tree database) was used to find the (single) kriging model whose centroid was closest to the queried point. This approach has the advantage of enabling the reuse of kriging models that are very expensive to construct but also introduces complications including (1) how to use new fine-scale model evaluations to update a kriging model; (2) when to merge neighboring kriging models or, more typically, split an overextended kriging model into two separate models; and (3) how to smoothly switch from one kriging model to another for intermediate query points. As a result of these complications, other difficulties due to dimensionality and scalability, and estimates of the database size for the two approaches, more recent efforts have evaluated an alternative implementation in which the fine-scale model outputs are stored in the database directly, rather than the subsequent interpolation models.

Consequently, an approximate nearest neighbor search will suffice to identify enough neighboring points to compute an interpolated estimate. Among approxi-

mate nearest neighbor search algorithms, locality sensitive hashing (LSH) (Andoni and Indyk 2008) is a leading method. Despite offering good (theoretical) scaling with dimension and data size, LSH requires many hyper-parameters to tune and is not suited for the inhomogeneous data expected for our microstructure-response data sets. Instead, one promising alternative approach would use a forest of search tress, specifically either k-d trees, as implemented in the Fast Library for Approximate Nearest Neighbors (FLANN) (Muja and Lowe 2014), or a forest of v-p trees, as implemented in the Proximity Forest (O'Hara and Draper 2013). Preliminary tests by our group show both methods to work well, as measured by the fraction of exact nearest neighbors correctly identified and by the number of trees required.

Kriging, or Gaussian process regression, models were originally designed for geospatial interpolation and used in prior adaptive sampling work. However, kriging scales poorly with dimensionality and will be unlikely to work as we move from the few-dimensional input parameter space of the simpler proof-of-concept models (Barton et al. 2008, 2011; Knap et al. 2008) toward the $O(10^3 - 10^4)$-dimensional space of other applications. As a result, simpler local linear or quadratic interpolants, which will work well for smooth functions such as the microstructure-response surface, have been evaluated. Error estimates, which are provided (with some assumptions) by kriging algorithms, can be obtained by sampling different sets of neighbors, e.g., from differently randomized search trees.

This error estimate can then be used to decide whether the interpolation result is sufficiently accurate to use or a new fine-scale evaluation is required. A naïve (and common) approach is to reject the interpolated result if this error estimate exceeds a chosen threshold. Applying such a uniform threshold at each local microstructure-response query is well defined but not necessarily what is optimal from a global perspective. For instance, as a material is deforming, the microstructure evolution and shape of the material may be more (or less) sensitive to errors in the underlying plasticity description in some regions at any given time, and thus a tighter (or looser) error tolerance would produce the same overall response. In this global perspective, one needs to define a metric (or metrics) to evaluate the accuracy of a simulation, as by comparing the final material shapes resulting from a dynamic loading experiment.

This leads to the well-defined goal of increasing the accuracy of a predicted quantity of interest (QoI). When a computational model is used to predict a material property or process, the QoI can be thought of as a functional of the constitutive laws being used. In a general case, the QoI depends on a set of input parameters (e.g., geometry, environmental conditions, etc.) and a set of constitutive functions (e.g., stress-strain relationship). Optimal UQ (OUQ) strives to find the optimal bounds on quantities of interest given the information at hand and to enable the optimal design of computational experiments (Owhadi et al. 2013). To address model uncertainty, Strachan et al. (2013) have recently developed a functional uncertainty quantification (UQ) approach that enables the estimation of uncertainties in the predictions due to the use of low-fidelity materials models. One practical use of functional UQ has been for MD simulations performed using the Lennard-Jones

potential, inferring thermodynamic properties corresponding to different potentials without requiring additional simulations (Reeve and Strachan 2017).

# 5   Computational Requirements for Task-Based Scale-Bridging

From a computer/computational science perspective, the exploration of dynamic, asynchronous, concurrent approaches is critical as we move toward exascale, since the massive concurrency involved will introduce processor performance variability, operating system (OS) jitter, and a plethora of soft, hard, and silent errors that will make tightly coupled bulk synchronous approaches increasingly unviable. Instead of this traditional parallel programming approach where the programmer is responsible for assigning equal amounts of work to each MPI process, more loosely coupled asynchronous models where the work is overdecomposed, and the runtime system responsible for distributing and balancing the work given task and data dependencies, will enable a more efficient use of resources, as well as much improved fault tolerance.

Based upon these concerns about the physics fidelity and architectural trends toward massive concurrency, heterogeneity, and asynchronous, dynamic approaches rather than traditional bulk synchronous parallel models, adaptive physics refinement such as HMM or AS, whereby a coarse-scale simulation dynamically spawns fine-scale simulations as needed, are attractive. This strategy is crucial for capturing how the macroscale, bulk response is influenced by microstructural detail. Thus, in a high strain-rate loading problem, a finite element calculation may spawn finer-scale crystal plasticity or atomistic models as needed when the available empirical constitutive model is inadequate. The basic workflow of such a concurrent scale-bridging application workflow is illustrated in Fig. 2 and involves a coarse-scale simulation, dynamically spawned fine-scale simulation tasks, a database for storing the results of fine-scale tasks, and an adaptive sampling layer which queries the database, interpolates results, and decides when to spawn new fine-scale tasks. This approach to increased physics fidelity via embedded scale-bridging imposes several requirements upon the underlying computational software stack, including task-based programming and execution models, runtimes, and databases.

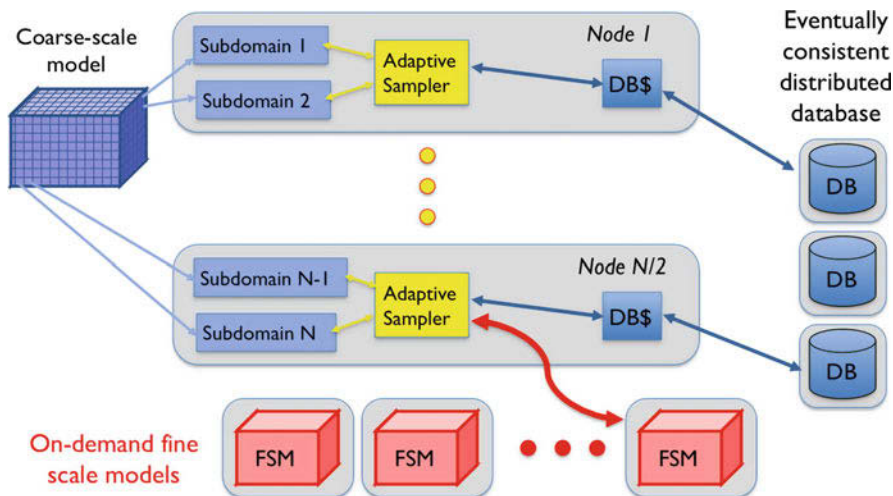
This approach has generated an increasing amount of interest in the material mechanics community, where several groups are actively developing various related methods, alternatively referred to as kriging, surrogate model, or metamodel construction. In particular, computational materials programs such as Advanced Simulation and Computing/Physics and Engineering Models (ASC/PEM), the Materials Genome Initiative (MGI), Integrated Computational Materials Engineering (ICME), the Advanced Manufacturing Initiative, etc. all recognize that improving physical fidelity, rather than extending time or length scales by brute force, is the greatest driver for increased computational power. In addition, such concurrent scale-bridging approaches are being developed in several other materials science contexts, not to mention other computational science domains.


**Fig. 2** Components of a scale-bridging application. A coarse-scale model runs across multiple nodes, each utilizing adaptive sampling to either spawn fine-scale models (FSM) as needed or interpolate previous fine-scale responses stored in a database (DB), consisting of an on-node cache (DB$) and a distributed database

Examples include interpolation-based MD potentials (Bartók et al. 2010; Trott et al. 2014), including a recent demonstration with on-the-fly database construction and interpolation (Li et al. 2015) and on-the-fly kinetic Monte Carlo approaches (Henkelman and Jónsson 2001; Trushin et al. 2005; Xu et al. 2011). As other researchers have noted (Barton et al. 2011; Knap et al. 2015, 2016; Alowayyed et al. 2017), such methods have computational workflows that are drastically different from traditional, tightly coupled bulk synchronous programming (BSP) approaches to scientific computing, as we will detail below.

## 5.1    Workflow Requirements

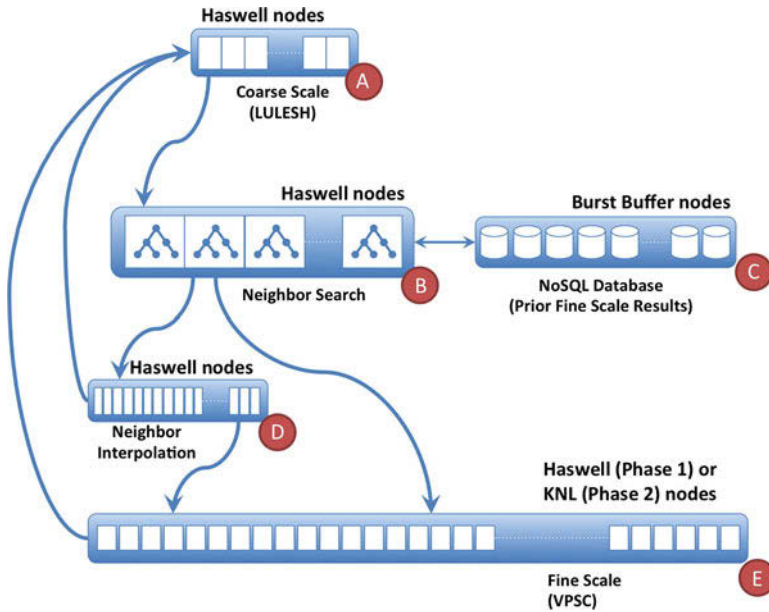
The structure and workflow of one recent prototype application, the task-based scale-bridging code (Tabasco) which was demonstrated by the Exascale Co-design Center for Materials in Extreme Environments (ExMatEx) on the heterogeneous Trinity supercomputer, is shown in Fig. 3. Out of the five individual components (A-E) comprising the application, two (A and E) represent the two physics scales: the LULESH coarse-scale (A) and VPSC fine-scale (E) codes. (LULESH Karlin et al. (2013) is a proxy application for ALE3D, representing the basic Lagrangian hydrodynamics computation without the full complexity of a production code.) The remaining components (B-D) implement the heart of the adaptive sampling approach and are what dramatically reduce the number of expensive fine-scale calls needed during each time step.


**Fig. 3** Structure and workflow of the task-based scale-bridging code (Tabasco) prototype as implemented on the heterogeneous Trinity supercomputer

These components each require a different number of nodes, and this node usage can vary with time. Additionally, as shown in the diagram, each component is best suited to a particular type of node (on Trinity, either Haswell, KNL, or burst buffer). In addition, some components are long-lived and stateful (A–C) while others are ephemeral and stateless – running for a short time only, returning their results to another component, and exiting. This dynamic and asynchronous computing approach requires a task-based programming model. We have explored a number of such models as candidates to implement our prototype. These programming models are responsible for allocating resources to components, scheduling and managing the execution of tasks within components, and communicating results between components.

In order to better understand the application flow, we will walk through the execution of a single time step (again, refer to Fig. 3).

1. At the beginning of the time step, each mesh element of the LULESH coarse-scale computation (A) requires a material stress to advance its state. This stress (and other quantities, such as texture evolution parameters) must be computed by the VPSC fine-scale component. In a brute force approach, each coarse-scale cell would spawn a fine-scale call (E) to provide the required stress for that cell.
2. Adaptive sampling improves dramatically on the brute force approach by dynamically launching a fine-scale call only for mesh elements where it is required. Due

to the evolving nature of the physics, many previously computed fine-scale call values continue to be useful into the future on mesh cells at a similar state in the computation.

3. Three components (B-D) are used to implement the adaptive sampling method. As each fine-scale request from LULESH (A) arrives, an approximate neighbor search (B) is executed. This search, distributed and executing on many nodes concurrently, searches a set of trees for neighbors of the query point. As the search traverses the trees, it retrieves previously computed fine-scale results for these neighboring points from a NoSQL – or key/value – database (C).

4. If a sufficient number of neighbor points are found, a fast interpolation (D) can be performed in an attempt to generate a suitable approximation to the required stress (and texture evolution). If the interpolation fails, or if there are an insufficient number of neighbor points, a new VPSC fine-scale call (E) is dynamically spawned.

5. If interpolation is successful, the stress is returned to the requesting LULESH coarse-scale (A) element. If a new VPSC fine-scale call is required, its value is similarly returned to its requesting element, and in addition it is queued for eventual insertion into the search tree structure and database, where it can be used for subsequent interpolation attempts. (Note that, while our adaptive sampling approach reduces overall fine-scale calls by 90%, the remaining 10% will still consume the lion's share of the prototype's execution time – especially in the case of more complex response models like VPSC. Acceleration of these fine-scale calls, using KNL nodes on Trinity or GPUs on Sierra, provides a performance leveraging opportunity to substantially reduce this remaining execution time.)

6. When all requesting coarse-scale cell requests have been fulfilled, new points queued for insertion are added to the search trees and database, coarse-scale mesh element updates are executed, any needed coarse-scale neighbor exchanges are performed, and the computation advances to the next time step.

The use of adaptive sampling as a scale-bridging technique presents significant challenges in the management of computing resources, including the scheduling of tasks performing fine-scale model evaluations and the management of the dynamic, distributed database containing previous model evaluations. Because the corresponding workflows are difficult to predict a priori, the ability to generate example workflows is the first step in the characterization of more general scenarios.

## 5.2    Runtime Requirements

Many, if not most, of today's scientific simulation applications are developed using a fairly limited set of software technologies: a standard programming language such as C, C++, or FORTRAN (possibly along with node-level acceleration APIs like CUDA or OpenMP and solver libraries such as Trilinos), MPI for communication, and a static scheduler, such as Slurm or Moab, to execute the computation on the machine. Should a developer need to load balance their computation, they need to

provide this functionality themselves. Similarly, fault tolerance requires programmers to periodically write data to disk (or use in-memory checkpointing Glosli et al. 2007) for later recovery. Likewise, communication patterns are generally fixed – dynamic communication patterns must be designed and implemented by the programmer.

Modern runtime systems can provide much of this functionality as a collection of independent "system services." These services support "programming in the large" – coupling multiple diverse components of a dynamic multiscale computation and orchestrating its execution on the system. These services, by category of functionality, are:

- Scheduling: concurrent, asynchronous, adaptively executing computational components, launched on-the-fly, and exiting when complete.
- Discovery: locating system resources based on application-supplied requirements (e.g., provide a list of all nodes with GPU accelerators).
- Messaging: setup and teardown, on-the-fly, dynamic, adaptive communication links between components of the calculation.
- Caching: services for temporarily storing data, perhaps in-memory, and retrieving it from anywhere in the computation. Caching can help prevent duplicate computation or store data to be used for recovery from faults. Caching can also be used for communication. Instead of sending messages, processes can store their data in the cache for retrieval by other processes.
- Fault detection: working with the application, operating system, and hardware, detects faults in the system and provides facilities for application notification or automated restart.

In general, there are two ways in which these services (or subsets of them) are implemented. First, there are distributed monolithic systems that are closely tied to a programming language or model (e.g., Charm++, X10, Chapel, CnC, or Erlang). These systems include a runtime component that implements features of the programming models such as scheduling, communication, data distribution, etc. (These system-level runtimes should not be confused with low-level runtimes provided by component-level programming languages such as CUDA or OpenMP, which often provide the same conceptual features but at a much finer level of granularity.) Second, there is a more loosely coupled approach that uses various single-function software, usually open source, to build an integrated, dynamic system. This approach is closer to what industrial developers (e.g., Netflix, Facebook, LinkedIn, Google, etc.) use to build cloud- or web-based scalable systems.

To explore this design space, the Exascale Co-Design Center for Materials in Extreme Environments developed a simplified CoHMM "proxy application" for the basic HMM method (ExMatEx 2015a) and implemented it with a variety of programming models, runtimes, and database backends (Roehm et al. 2015; Pavel et al. 2015). As a monolithic approach, the Erlang programming language provides the desired features in a single language and runtime system. For the fine-scale molecular dynamics tasks, the simplified CoMD proxy was used (ExMatEx

2015b). An alternative, cloud-based approach used a more diverse set of tools including Apache ZooKeeper (for discovery, scheduling, and process tracking), node.js to manage the overall execution of the code, and multiple NoSQL databases (MongoDB, memcached, Riak, Couchbase) to cache data for fault tolerance. In both cases, the implementations simply managed the dynamic coupling between the coarse- and fine-scale components of CoHMM. All of the mathematical computation was done in the component-level APIs that those components used (e.g., MPI or OpenMP).

The 2013 Los Alamos IS&T Co-Design Summer School, comprised of six students with backgrounds in both computer science as well as physics, refined the CoHMM and CoMD proxy apps and used them to test a variety of runtime systems from industry and academia. They evaluated software that acts as the "glue" between the coarse- and fine-scale components of CoHMM, whose simplicity allowed us to investigate a wide swath of software technologies – both monolithic and cloud based. These evaluations focused on some of the primitive features described above: scheduling, communication, caching, and fault tolerance. Various schedulers were tested against how well they supported dynamic and adaptive task scheduling.

In addition, fault tolerance was implemented using two approaches. In the first, process-level case, the runtime system detects the crash of a fine-scale CoMD process, and the system restarts it from its initial conditions (potentially on another node) without crashing the entire application. In the second case, an in-memory database (again, Redis) is used to periodically cache particle positions from each CoMD process. If the runtime system detects a crash, the CoMD process is restarted from the conditions encapsulated in the most recently cached particle positions – not from the initial conditions. These developments also enhanced our original test applications; fault tolerance was added to the Erlang version, and our cloud version now uses the proven Redis database.

## 5.3    Database Requirements

Achieving maximum performance for Tabasco relies on a database of fine-scale calculations to enable multidimensional interpolation (kriging) and avoid additional, costly, fine-scale computations. Initial explorations by Barton, Knap, and colleagues at LLNL (Barton et al. 2008, 2011; Knap et al. 2008) used a hand-coded database to cache fine-scale computations. Since then, distributed NoSQL databases (Sadalage and Fowler 2012) have become ubiquitous in web and cloud applications and are attractive (primarily the key-value store variations) based on their ease of use, community support, and potential performance.

As with the exploration of task-based programming models and runtime systems, CoHMM has been used to explore APIs and functionality of key-value stores. CoHMM is a tractable proxy for these explorations and matches the algorithmic structure of the Tabasco target scale-bridging application. Keys are formed by concatenating truncated floating point parameters from the coarse-scale code, effectively binning the fine-scale values. Alternatively, distributed tree-based

approximate nearest neighbor (ANN) techniques are in principle better suited to adaptive sampling access patterns and also remain amenable to distributed database implementations.

Multiple versions of CoHMM have been implemented, primarily using the Redis (2018) NoSQL database. Redis was chosen for its ease of installation, simple interface, and adequate performance. This integration of Redis into CoHMM successfully achieved reductions on the order of 90% in the number of fine-scale calculations. A number of issues require further exploration before committing to any particular database: performance, non-transactional semantics, and support on target petascale platforms.

The performance of a single-node Redis database is more than adequate for CoHMM, where fine-scale calls take several seconds to execute, and thus the database performance is not stressed. As we move to much faster fine-scale calculations (on the order of 10 ms), absolute performance will become a challenge. However, early experience indicates that many of these potential databases will provide adequate performance for this problem. For example, a single-node Redis database on a MacBook Pro can support about 70,000 queries per second, or about 14 $\mu$s per query. Other distributed databases (e.g., Aerospike 2017 and RAMCloud Ousterhout et al. 2010) can support queries at rates exceeding 500,000 per second. This throughput, though, is measured at the database server. Ultimate throughput must account for network latency which may, over TCP/IP, be the primary bottle-neck. RAMCloud's use of Infiniband network technology could support very low latencies if required but may be more difficult to use than commodity databases. Finally, we note that actual production applications may actually employ more accurate and costly fine-scale models, thereby reducing latency requirements on the database. By "skeletonizing" CoHMM, replacing real coarse-scale (e.g., LULESH) and fine-scale (e.g., CoMD, VPSC, or VPFFT) codes with tunable null-value functions, one may experiment more broadly with database performance by dialing up or down the costs of these fine-scale tasks.

A second potential issue with NoSQL databases is that they generally don't support transactional semantics but are instead "eventually consistent." This means that the database only guarantees that a write will eventually be readable by a client. It is possible that a query for an in-flight write will fail. Compared to traditional, synchronized databases, NoSQL databases are easier to implement, faster, and more scalable because of these semantics. Eventual consistency doesn't appear to be a problem for our scale-bridging application. If we suffer a miss on a fine-scale query, we can simply rerun the fine-scale computation for that query. In practice, we haven't noticed problems within CoHMM due to eventual consistency. However, without a sophisticated in-band logging capability and post execution analysis, it is difficult to calculate a miss rate. To date, no NoSQL databases provide this logging framework.

A third and potentially serious issue is that of system support for NoSQL databases. These databases were designed with commercial datacenters in mind (i.e., web and cloud applications). They typically use TCP/IP for networking and are installed into operating environments that are tolerant of diverse, and continuously

evolving, system software. Current HPC systems typically use Infiniband for networking and enforce a strict limitation on available system software, which may heavily restrict the set of usable NoSQL databases and how they are used. The ExMatEx project explored this issue in two ways. First, they successfully installed Redis and ran CoHMM on multiple HPC platforms including LANL's Darwin cluster (a heterogeneous prototyping platform), LLNL's Vulcan (IBM BlueGene/Q), and LLNL's Cab (Intel Xeon-based). Second, they explored possible mitigation approaches in case the database cannot be run in a distributed fashion (e.g., due to lack of TCP/IP). In this case, node-local copies of the database may be run with periodic MPI-based, cross-system merges. Another mitigation approach may be to use an LRU eviction policy on local databases to keep their memory requirements tractable. Such experience with a nontraditional scientific computing use of databases in an HPC environment may influence long-term requirements for future extreme scale systems.

In addition to reducing required computation, NoSQL databases can be used for a number of other optimizations or additional functionality. While most NoSQL databases run in an ephemeral, in-memory mode – they disappear at the conclusion of a calculation – some are able to persist to NVRAM or rotational storage (as in the use of a burst-buffer backed database on Trinity). In this case, once fine-scale response database has been built and captured, it can then be used subsequently on similar problems (e.g., design parameter studies for additive manufacturing). New fine-scale calls would only be required when the current parameter study deviates significantly from the one (or many) that preceded it and pre-populated the microstructure-response database, which is mostly used in a query-only mode. Second, the captured database could be used for fault tolerance. Instead of checkpointing the problem at each time step, a persistent database could be used to advance a restart without ever executing a single fine-scale call. The ExMatEx project experimented with this possibility early in the project by caching the particle positions of a long-running CoMD task, thereby enabling a restart upon detection of a failure. Third, in situ analytics can be performed along with the computation by concurrently accessing the database using the same task-based and system capabilities as the computation does.

## 6    Future Directions

As this chapter has hopefully conveyed, there is a promising future for adaptive physics refinement methods in materials modeling, as well as several practical technical challenges, spanning materials science, applied mathematics, and computer science. Among these, modern machine learning techniques offer one attractive alternative for the traditional kriging interpolation models, which as mentioned suffer as the input parameter space dimensionality increases to hundreds, thousands, or beyond. The increasing heterogeneity of computer architectures, both at the processor and system scales, and asynchronous task-based programming models

and runtimes, is both a challenge to conventional scientific software codes that have been developed in the massively parallel era of the past 20–30 years and a tremendous opportunity for novel approaches to scientific simulation as we enter the exascale computing era.

# Synchrotron Capabilities to Understand Microstructure of Additively Manufactured Materials: Challenges and Opportunities for Modeling and Simulations

Anthony D. Rollett

## Contents

**Abstract**

From the perspective of modeling and simulation, additive manufacturing is an unambiguously multiscale problem. Regardless of whether the 3D printing is accomplished via melting, or polymerization, or with binders, the scale of the process is submillimeter, which means that dozens to thousands of layers are accumulated while making a part. Variations in geometry mean that the path followed by the light or electron beam (except in the case of whole layer-based illumination) result in highly variable time intervals between successive overlapping heat inputs. Particularly in the case of processes that melt powders, this can result in deviations from the expected heat input that lead to defects. Taking microstructure to be the totality of the structure of crystal(s) and defects,

A. D. Rollett (✉)
Department of Materials Science and Engineering, Carnegie Mellon University,
Pittsburgh, PA, USA
e-mail: rollett@cmu.edu

this means that using simulation to predict microstructure requires calculations at multiple scales: it is not feasible to simulate microstructure development at the submillimeter scale with, e.g., grains, orientations, and pores, when the part extends to centimeters in all dimensions. Synchrotron radiation is well suited to probing the unit processes involved in additive manufacturing, and so a focus on the submillimeter scale of materials processing provides a useful framework for evaluating needs and prospects for modeling and simulation.

# 1    Introduction

This chapter is intended to introduce the reader to the techniques that are most useful for characterizing additively manufactured materials and the implications of recent results for modeling and simulation. The techniques emphasize crystalline materials, which mean mainly metals and ceramics. Similar challenges exist for additively manufactured polymers, and bioprinting is particularly interesting because of the rapid development that existed at the time of writing. Although synchrotron radiation has seen less development for these applications, it is expected to be equally impactful in the future. The techniques that are discussed include x-ray micro-computed tomography (xμCT), wide-angle X-ray scattering (WAXS), high-energy diffraction microscopy (HEDM), residual stress (RS), and dynamic X-ray radiography (DXR). The various investigations have brought, e.g., new knowledge about unexpected precipitation behaviors in Ni-based alloys and keyhole formation in selective laser melting systems.

Additive manufacturing (AM) covers a substantial range of technologies for making prototypes, intermediate forms, and final parts in nearly all materials. Several books and review articles are available that, to varying degrees, explain how the technologies work (Gibson et al. 2010). In a simplified view, the AM field has been moving from mainly prototyping objects with polymers to manufacturing final parts in both polymers and metals that require only minimal finishing (Wohlers 2017). Complexity of the design and part count reduction, along with rapid introduction to market, all favor AM methods. Focusing on metal parts, small size is helpful because the build rate in the dominant powder bed machines is of the order of 3 mm/h, which means that tall builds have to run for a few days. Increasing the build rate is, of course, a major thrust of the machine makers. Other technologies such as wire feed, which is based on either electron beam or laser welding, allow much larger parts albeit with less resolution and more significant post-processing. Binder jet technologies avoid melting with its inevitable residual stress but require binder removal and sintering. Other technologies are being developed such as precision metal droplet deposition (Murr and Johnson 2017).

Simulation of such processes is self-evidently multiscale even for just the deposition phase: metal powder bed, for example, requires melting many meters of melt lines, each of which is of order $200 \times 100\,\mu m$ in cross section (width × depth). Adjacency of the melt lines allied with the melting through each layer to (at least) the layer beneath means that the thermal history of each location requires several lines

and layers to be simulated. Simulating the entire build sequence is also necessary, however, for computing residual stress, distortion, as well as heat buildup that affects the actual thermal history required for predicting microstructure. Accordingly, it is common to consolidate the steps such that an entire layer (or set of layers) is treated as a single thermal event. Notwithstanding these challenges, many reports of such simulations were already available at the time of writing (e.g., Promoppatum et al. 2017). Moreover, validation is also being done at various scales demonstrating that predicted thermal histories are feasible (e.g., Beuth and Klingbeil 2001). Residual stress has been shown to be predictable, but thermal distortion is considered to be more challenging for metals because the bed temperature is typically low compared to the melting point (e.g., Szost et al. 2016; Mukherjee et al. 2016). This is in contrast to polymer printing with powders where the effective melting temperature is low in relation to the bed temperature such that thermal stress and distortion are less serious.

## 2   Synchrotron Capabilities

As stated above, the main capabilities that are distinctive to synchrotron-based X-rays are micro-tomography (CT), wide-angle X-ray scattering (WAXS), small-angle X-ray scattering (SAXS), high-energy diffraction microscopy (HEDM), residual stress (RS), and dynamic X-ray radiography (DXR). We now briefly review their respective capabilities to inform microstructure development in additive manufactured materials.

### 2.1   X-Ray Micro-tomography (CT)

Computed tomography at the micron- and nanoscales is a widely used method for the nondestructive characterization of the internal structure of materials. At coarser scales, neutrons (e.g., Cao et al. 2016) and muons (Muon Tomography 2017) are also useful although the author is not aware of an application as yet to AM. It is most effective for large density contrast since it mostly depends on the Beer–Lambert law to measure variations in absorption, aided by phase contrast to detect sharp changes in density (Gursoy et al. 2014). The primary application to AM is for measuring porosity where pores constitute an important defect in materials used in structural applications (Hudák et al. 2016; Eylon and Strope 1979; Scarlett et al. 2016a, b). A pore is a stress riser under tensile load and, above a size of about 10 $\mu$, may act as the source of a fatigue crack as has been documented in many reports on additively manufactured materials (e.g., Leuders et al. 2015). Fatigue is a classic extreme value problem in the sense that the originating defect can be traced to the largest defect available in the material, for which there is a large literature (Weibull 1951). Here again, synchrotron tomography is useful for providing datasets that can then be used to perform simulations of the mechanical response at the relevant length scale (Cunningham et al. 2017b; Kantzos et al. 2018). Figure 1 shows two views of a set
**Fig. 1** (**a**) Tomograph of packed Ti-6Al-4V particles with randomly assigned colors. (**b**) Tomograph of packed Ti-6Al-4V particles (gray outlines) as in (**a**) with voids (pores) colored red for emphasis

**Fig. 2** Schematic diagram of μSXCT setup at 2-BM beamline at Argonne National Lab's Advanced Photon Source
of powder particles of gas atomized Ti-6Al-4V, which is a material commonly used in the aerospace and medical industries; the average size is about 60 μm, which is typical of powders used in laser or electron beam powder bed machines. Panel (a) shows the exterior surface of each particle with randomly assigned colors for contrast; panel (b) shows each void or pore (inside a particle) colored dark red for emphasis. With such fine powders, the sub-micrometer resolution available for high-Z materials with synchrotron radiation is particularly helpful for resolving particles across the full range of size.

Although X-ray micro-CT can be readily performed with laboratory systems, synchrotron-based CT provides better resolution when the sample cross section fits within the beam. Since the latter is typically about 2 mm across, the sample size is quite limited; Fig. 2 provides a schematic view where it is important that

the synchrotron X-ray beam is parallel, by contrast with most lab-based systems that use a diverging beam to be able to illuminate larger samples. Nevertheless, synchrotron CT has shown that porosity in metal powder bed materials has at least main sources. These are (a) a residual porosity inherited from the powders used (Cunningham et al. 2017a), (b) lack-of-fusion porosity that occurs when the melt pools do not overlap sufficiently and some locations are never melted (Tang et al. 2017), and (c) keyhole porosity that arises from excessive penetration by the laser or electron beam (Cunningham et al. 2017b). This parsing of porosity development into distinct regimes contrasts with the more typical approach of relating it to energy density, which is the energy deposited per unit length of weld bead: the energy density is a continuous variable, but recent work supports the existence of thresholds for the number density of pores. The latter also is consistent with the concept of process windows in power-velocity space (Vasinonta et al. 2006), which suggest that there is a range of power-velocity combinations for any given machine and material that yield good-quality builds. The process window is typically an elongated patch whose long dimension corresponds to a particular ratio of power to velocity (Montgomery et al. 2015). Finally, porosity in metal powders has been shown to be ubiquitous (Cunningham et al. 2017b) and in gas atomization at least is a direct consequence of the impingement of high-velocity gas jets that break up the liquid metal stream into fine droplets.

One of the attractive features of AM is the ability to print arbitrarily connected materials over a wide range of densities relative to the material of construction. In powder bed AM, the extensive freedom implied in this approach is constrained by the requirement for a minimum cross section and the difficulty inherent in overhangs, i.e., printing solid material on top of a significant area of unmelted powder. Despite these limitations, numerous results have been published on lattice structures, with a number of original approaches to optimization of the structures (e.g., Calignano 2014). In a lattice, the individual struts in a lattice vary in cross section and have partially melted powder particles attached to their surfaces. The shrinkage associated with solidification and subsequent thermal contraction also results in distortions of the product relative to the original design (Dunbar et al. 2016). As is well-known, the extent of this distortion depends on preheat, the so-called support structure and many other factors. Higher preheat decreases the extent of thermal contraction. Support structures both allow overhanging sections to be printed and attach the part to the baseplate. Such attachment means that the part can be heat treated on the baseplate for stress relief via creep prior to cutting through the support structure to separate it. Synchrotron CT has also proven to be useful for measuring the quality of lattices because it can directly measure the entire 3D structure. Bormann et al. (2013) published an elegant approach in which they continually acquired radiographs as they heated a lattice structure printed in NiTi used as a scaffold for tissue ingrowth. The authors found substantial deviations of the scaffold from the intended design with more locations exhibiting excess material than vice versa. As Khairallah et al. (2016) have pointed out, this is unsurprising because the melting pool tends to pull particles in at its periphery and partially melted particles are likely to be outside the target melting volume.

Brun et al. (2013) reported a similar investigation for polycaprolactone scaffolds, including a comparison between a conventional fabrication method and 3D printed materials.

Carlton et al. (2016) used X-ray micro-CT with in situ tensile testing to investigate damage and fracture in 3D printed stainless steel. They found that the porosity distribution could have a major effect in the sense that specimens with large and inhomogeneous pore distributions exhibited fractures that started from the existing voids. In specimens with low void content, however, the fracture behavior was unaffected by homogeneous distributions of small pores. Sandgren et al. (2016) used micro-CT to study fatigue crack growth in Ti-6Al-4V that had been printed in a powder-feed machine.

## 2.2    Wide-Angle X-ray Scattering (WAXS)

Cakmak et al. (2016) used wide-angle X-ray scattering at the APS to measure texture in electron beam-printed IN718, a Ni-based superalloy, which exhibited strong fiber textures parallel to the build direction (BD). The strong fiber textures with <100>//BD were consistent with the strongly columnar microstructures observed. Although synchrotron-based X-rays have some advantages for texture determination because of its penetrating power, a combination of EBSD and lab-based X-ray pole figures are effective for most investigations.

## 2.3    Small-Angle X-ray Scattering (SAXS)

One notable advantage of synchrotrons is the availability of high-energy X-rays with high intensities, which allows deep penetration and therefore substantial volumes to be interrogated. Many alloys are heat treated, most often to develop increased strength or to arrive at an optimum combination of strength and toughness. Additively manufactured metals often exhibit heat treatment responses that differ from those established for conventionally processed material. As an example, the Ni-based alloys IN718 and IN625 are known to be hardened by such phases as $\gamma'$ and Laves, with carbides and the $\delta$ phase being more important for grain size control. Zhang et al. (2017) used SAXS to study the homogenization kinetics for the major alloying elements, i.e., Ni, Cr, Nb, and Mo. Using the characteristic streaking patterns, they determined that most of the segregation is confined to a region within 6 nm of the center of each dendrite. Correlation analysis between the successive SAXS images provided quantitative information about the kinetics of the diffusion-controlled homogenization process. Similarly, Xue et al. (2015) used SAXS to detect precipitate formation under high cooling rate conditions in Ti-48Al and an an Al-Cu-Mg alloy. The hardening response in IN625 was further investigated by Idell et al. (2016) and Lass et al. (2017) who used conventional methods to determine that the $\delta$ phase was dominant from the outset. Rather than appearing heterogeneously at grain boundaries, the $\delta$ phase precipitated throughout the material in the form of

disc-shaped plates with a well-defined orientation relationship with the matrix. Idell et al. (2015) performed a similar study on IN718 and noted that synchrotron-based SAXS was again useful for measuring the progress of the precipitation process because of the large flux and high energy of the X-rays.

## 2.4    High-Energy Diffraction Microscopy (HEDM)

There are several diffraction-based techniques that use synchrotron X-rays to map polycrystalline microstructures at various levels of resolution (Rollett and Barmak 2015). high-energy diffraction microscopy (HEDM) is one class of those techniques that itself exists in two major variants. One of these is known as near-field HEDM (nf-HEDM) because the detector is placed relatively close to the sample such that the locations of diffraction spots are as sensitive to the point of origin of the diffracted beam in the sample as it is to the diffraction order (i.e., which crystallographic plane). The sample is rotated in front of the beam to excite a large (at least 20) number of beams from each location; the beam is generally planar, to limit the number of spots in each view. A simulated annealing algorithm sifts through the potential orientations in the material to match as large a fraction of the spots as possible and index the orientation at each point in a regular grid (Li and Suter 2013). The far-field variant of HEDM (ff-HEDM) acquires data from a detector whose position is far enough from the sample that Bragg rings are obvious, which greatly facilitates indexation of orientations, but close enough such that deviations of individual spots from the standard position give information on both the center of mass of each diffracting grain and the (average) elastic strain (Bernier et al. 2011). Again, the sample is rotated in front of the beam so that the spot position varies as each grain rotates around the rotation axis. The reconstruction provides information on each grain in a similarly nondestructive manner to nf-HEDM with additional information about the state of elastic strain but not a 3D orientation map (by analogy to EBSD (Schwartz et al. 2000).

Quoting from Rollett and Barmak (2015), there now exists a way to reconstruct "the orientation map of a material from diffraction data acquired with high energy x-rays that can penetrate the full cross-section of a sample up to about 1 millimeter thickness. This means working with beams with energies between 10 and 100 keV that may be focused or parallel, monochromated or broad (white) spectrum and so on. One essential difference between such a technique and other orientation mapping methods, e.g., EBSD (Schwartz et al. 2000), is that illumination of a volume with many grains means it is infeasible to obtain an individual diffraction pattern for each point. Instead, one must infer the orientation of each point by fitting to the entire set of points in real space that have contributed to a (large) set of diffraction patterns. To set the scene for this method, it is convenient to contrast "far-field" from "near-field" approaches. In far-field synchrotron microscopy, the detector is placed of order 1 m away from the sample (for energies in the range 20–100 keV) such that several Bragg rings are imaged. Orientation mapping in 3D that distinguishes grain shapes from merely centers of mass, however, requires the

near-field approach in which the detector (or effective imaging surface) is placed at distances of a few millimeters from the specimen, such that many diffraction peaks are acquired up to a high order of reflection. A flat monochromatic beam illuminates the entire cross section of a sample, which is generally a wire no more than 1 mm in diameter. For both ff- and nf- approaches, the sample is rotated in 1° (or less) steps through a range of 180°, and a diffractogram is acquired at each rotation angle integrated over the interval to ensure that all points in the illuminated volume contribute equally to the dataset as a whole. This data acquisition process results in a large set of diffractograms for each layer, all of which contain information from (potentially) all locations. Note that no specimen preparation is required."

In ff-HEDM, precession of diffraction spots around the rotation axis provides information on the center of mass of each diffracting grain. The deviation of spots from their nominal locations on each ring provides information on elastic strain. The reconstruction of an orientation map consists in searching orientation space for all locations in the illuminated layer simultaneously while using the match between simulated diffraction spots and measured spots as the measure of completeness or confidence in the result (Bernier et al. 2011; Sharma et al. 2012a, b). For the nf-HEDM approach, Li and Suter (2013) built upon multiple previous works to devise an efficient, multiscale method for performing reconstructions and arriving at a 3D orientation map as a stack of layerwise maps. This provides direct information on grain shape but does not resolve elastic strain; the typical resolution is 0.1° in orientation with 2 μm in each layer and 4 μm in the stacking direction. These limits are determined by the detector resolution and beam thickness, respectively. A variant of HEDM can be described as very-far-field HEDM (Lienert et al. 2011), in which a single diffraction spot is imaged on a detector placed a few meters from the sample such that its shape can be monitored as a function of time, temperature, loading, etc.

Recently, researchers in this area have moved to combine the far-field (ff-HEDM) and near-field (nf-HEDM) variants of HEDM. As one example, ff-HEDM (Bernier et al. 2011) can be performed on a 3D volume, which provides a list of grains with their centers of mass and orientations (as well as elastic strain). This list can then be used to "seed" the nf-HEDM reconstruction, which saves substantial computation time because the search in orientation space is otherwise a very time-consuming process. The nf-HEDM reconstruction then provides a more accurate spatial map of the polycrystal microstructure. Such a map provides the basis for instantiating full-field micro-mechanical simulations. Turner et al. (2017) used the data from such a combined experiment (Turner et al. 2016) to instantiate full-field finite element simulations. Comparison of the calculated elastic strains with the measured values showed good agreement. However, they were not able to incorporate the residual elastic strain present in the undeformed material. Consequently, they had to compare changes in strain values using the initial values as the reference point. Following previous efforts to incorporate residual stresses as eigenstrains (e.g., Salvati et al. 2017), Pokharel and Lebensohn (2017) demonstrated that it is possible to approximate the initial (residual) strain at the grain scale via an eigenstrain calculation based on Eshelby, which is important as most measurements of elastic strain on annealed polycrystalline materials have revealed

appreciable levels of residual strain, e.g., Oddershede et al. (2010). Nevertheless, the eigenstrain calculation (Pokharel and Lebensohn 2017) is only the first step toward accommodating such residual strain (stress) conditions into simulations of polycrystal deformation as well as the challenges of understanding their origins. This suggests that modeling of the materials processing that precedes the production of annealed material may be helpful for testing the various hypotheses that have been put forward.

## 2.5    Residual Stress (RS)

The extensive literature on residual stress makes it clear that it is a significant issue in welding. The main reason is that the deformation induced by the heating around the melt pool is not fully reversible. Above a certain temperature, nearly all materials relax such that, at the maximum temperature in the heat-affected zone of a weld, the strain is low (relaxed) and the subsequent cooling results in thermal contraction. The contraction is an eigenstrain that generates stress once the material has cooled below the stress relaxation temperature, i.e., below the point where rapid creep occurs. Of course, the magnitude of the residual stress and its tensorial character depends on the geometry and the extent to which the material around the weld is constrained, but this provides the basic picture. In most cases where deep penetration (with a keyhole) is not being used. The melt pool is semicircular in cross section, and most of the variation in stress is related to the length to width ratio (Gratzke et al. 1992). As already mentioned, additive manufacturing technologies that use selective melting (with lasers or electron beams) are essentially micro-welding processes that focus on melting and consolidation of powders, rather than joining. Therefore, the issues around residual stress in AM have the same physical basis as in welding. Significant contributions abound such as Mach et al. (2017) who have demonstrated that synchrotron radiation can be effectively used to measure the spatial variation in the full elastic strain tensor (from which stress can be derived).

The application to additive manufacturing arises naturally through the fact that SLM is, to some approximation, a process that deposits successive solidified layers of order 50 $\mu$m thick. The shrinkage associated with each layer results in a residual stress that tends to impose a biaxial shrinkage on the part. As mentioned elsewhere, the AM machine manufacturers typically recommend the use of preheat which is commonly much higher in electron-beam machines than in SLM. Whitesell et al. (2016) describe the use of high energy x-rays for residual stress measurement using a laboratory source. Park and Okasinski (2017) discuss techniques for measuring the elastic strains in a spatially resolved manner with synchrotron radiation. The basic idea consists of using a slit to select in which part of the sample a diffracted beam originates. With conical slits, a region of order 150 $\mu$m long can be isolated within the path traversed by the input beam. Park and Okasinski (2017) report on the use of spiral slits that give better performance despite only allowing small portions of each Bragg ring to reach the detector. Nevertheless, the spiral slits rotate to capture an entire Bragg ring. The authors point out that the spiral slits are particularly

helpful for materials with crystal symmetry lower than cubic because each set of conical slits must be constructed for the specific Bragg angles of interest. The experiment described in this paper was on a test article, however, and no application for additively manufactured material has yet been reported.

Mishurova et al. (2017) describe a typical test piece consisting of an arch or bridge that was $8 \times 10 \times 20$ mm in height $\times$ depth $\times$ length. The part was printed from Ti-6Al-4V powder in an SLM machine, and measurements were made at several locations, which meant that the spatial resolution that could be attained was not explored although the closest spacing was 0.5 mm between beam locations. The measurements were performed at a synchrotron in Germany with a white beam in the energy range 10–150 keV. Their main result was that low energy densities, implying higher speed and lower energy, resulted in significantly higher stresses with maximum elastic strains approaching $2.10^{-3}$, which corresponds to stresses a bit under 1 GPa. Not surprisingly, the residual strain state changed after the part was removed from the baseplate, which reflects the removal of the constraint imposed by the latter.

There is significant literature regarding modeling of residual stress. In its more direct form, the thermal history is simulated by the passage of a moving heat source, often simplified to that of a moving point source. This latter simplification has the advantage that the analytical Rosenthal solution is available (Rosenthal 1941), which allows for straightforward calibration against experimental data for melt pool size (Promoppatum et al. 2018). Standard algorithms are applicable, and a wide variety of commercially supported finite element codes are being used. Simulating thermal distortion requires solution of the thermomechanical problem, which in turn means that the mechanical and thermal properties of the material must be known with sufficient accuracy up to the melting point. Heigel et al. (2015) mention the need for a "measurement-based convection model" in order to obtain accurate results. Since the development of thermal strains depends, as mentioned above, on the variation in strength over temperature, another challenge is the lack of detailed data on mechanical properties such as creep strength, Poisson ratio, modulus, etc. close to the melting point. The assumption of a point heat source is unlikely to be accurate, given that there is strong evidence for deep penetration (keyhole) conditions, e.g., Trapp et al. (2017), which results in a large aspect ratio in the melt pool and, effectively, a line heat source. There are, of course, many papers being published that model the powder bed modeling process with varying degrees of completeness. Lindgren et al. (2016), for example, provide a relatively complete such example that includes residual stress calculation as well as material properties.

## 2.6    Dynamic X-Ray Radiography (DXR)

All processes acquire new meaning when they can be visualized directly. The high-speed, highly localized melting and refreezing associated with selective laser or electron beam melting used in many 3D printing machines is no exception. Many valuable experiments have been conducted with high-speed optical imaging

**Fig. 3** Illustration of the arrangement for passing a high-energy X-ray beam through a sample of order 1 mm thick with or without powder placed on top for experiments to investigate selective laser melting (Zhao et al. 2017)

systems that look down on the process (e.g., Furumoto et al. 2013). Nevertheless, significant assumptions must be made about the temperature fields where pyrometry is attempted and filtering of the images is typically required. The advent of direct high-speed radiography as presented by Zhao et al. (2017) promises to transform this area. The sample is confined between transparent carbon plates in a vacuum-capable chamber with windows for the X-rays and a fiber-optic feedthrough for the 520 W laser; the laser system is of the same type as used in SLM machines (Fig. 3). Using a $2 \times 2$ mm pink X-ray beam at beamline 32ID at the APS and a high-speed imaging system, they imaged local spot melting over a range of power levels, with and without powder. The expulsion of powder particles was visualized along with direct measurement of the velocities, thus illustrating the importance of gas flow within SLM machines for limiting the redeposition of particles. The formation of the melt pool and vapor cavities was readily apparent. Figure 4 illustrates the sequence of events (Zhao et al. 2017) as the laser strikes, a melt pool forms, powder particles are ejected, and finally a void is left behind as the elongated melt pool freezes. Such a void is characteristic of end-of-track defects in welding, and it also provides a scenario for the systematic arrays of voids that are sometimes observed in SLM (Groeber et al. 2017). Lately, a scanning system has been added (Parab et al. 2018) that opens up the possibility of studying a wide range of power levels and speeds that would be relevant to the practice of SLM.

There exists a substantial literature on modeling melt pools in welding, laser drilling, and additive manufacturing. Khairallah et al. (2016) and Tan and Shin (2015) are two examples of large-scale multi-physics simulations that include heat flow, fluid flow, and gas flow. Khairallah et al. (2016) specifically address the smaller scale of selective laser melting and note the importance of surface tension (and its temperature dependence) and recoil pressure from evaporation. Tan and Shin (2015) emphasize the somewhat larger scale of welding and show the variety of keyhole shapes that result from variations in power and speed. Not so well-known outside this area is the fact that a keyhole is not necessarily a simple cylindrical depression but adopts more complicated, elongated shapes especially at high traverse speeds.
**Fig. 4** Successive frames from an experiment in which a static laser beam impinges on a Ti-6Al-4V sample with powder on top. A melt pool forms, powder particles are ejected from the powder bed, liquid is ejected from the pool, and a void forms as the somewhat elongated melt pool freezes (Zhao et al. 2017)

Notwithstanding the many contributions in this area, there are many opportunities to explore additional aspects of melting at high speeds, particularly with respect to the effects of powders.

## 2.7    Dynamic X-Ray Diffraction

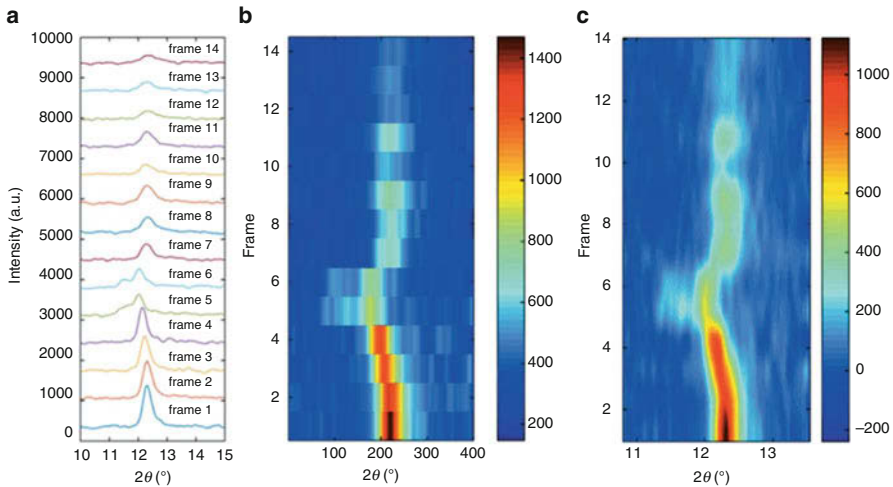
Kenel et al. (2016a, b) performed high-speed diffraction experiments on Ti-48Al at the Paul Scherrer Institute. A custom-designed support was used for the sample


**Fig. 5** Example of results from a high-speed diffraction experiment on a NiTi alloy sample that was subjected to dynamic deformation, reproduced from Sun and Fezzaa (2016). The frame rate was 20 kHz, and the color maps show both the shifts in Bragg angle and the loss of intensity as deformation proceeds. More specifically, (**a**) shows a series of intensity traces, (**b**) is a color map of intensity for frame number versus diffraction angle (binned over the same range as in (**c**)), and (**c**) is a smoothed version of (**b**)

with laser heating to induce melting which approximated the conditions of SLM. They were able to show that solidification proceeded directly to $\alpha$ and $\alpha_2$ with $\gamma$ appearing shortly thereafter. The temporal resolution was of order 10 ms, which was sufficient for the material studied. Zhao et al. (2017) described an even higher-speed experiment with approximately microsecond resolution on Ti-6Al-4V in which they were able to not only measure the melting and resolidification to the high-temperature BCC $\beta$ phase with subsequent transformation to the HCP $\alpha$ phase but also image the progress of the melting and freezing. Thanks to the use of sample dimensions and a focused laser source of the same type used in SLM, they were able to achieve similar cooling rates, etc. to those in actual additive manufacturing machines. Kenel et al. (2017) followed this with a similar high-rate diffraction experiment on high-rate melting and refreezing of Ti-6Al-4V. The lower frame 1 kHz rate and high-sensitivity detector used in this case allowed them to identify the formation of the $\alpha'$ martensitic phase, as well as evolution in the $\beta$ phase. They used the same support structure as in their previous experiment, however, so the conditions were partially representative of AM. The high-speed diffraction results reported by Zhao et al. (2017) were based on developments by Sun and Fezzaa (2016), and Fig. 5 shows in more detail what sort of variations in diffraction can be observed on a 20 kHz timescale.

# 3      Impact on Modeling and Simulation

The foremost need in modeling and simulation is for improvements in the prediction of distortion of parts. This is not a simple task: whereas prediction of thermal histories is reasonably straightforward, computing the actual displacements is not reliable. Temperature fields depend primarily on the heat source(s) and the thermal properties, which are generally well-known. Computing the resulting distortions, however, is much more challenging because additional temperature- and strain rate-dependent properties, such as yield strength, Poisson ratio, and creep rate, must be well defined all the way up to the melting point. Such properties are challenging to measure and many materials are not well characterized.

The high-speed diffraction experiments that are now feasible suggest that a substantial forward modeling effort is needed to simulate the X-ray scattering and move toward a more complete understanding of the dynamic microstructural evolution. Forward modeling of diffraction is practiced in many different areas, but the actual physics that must be included for accurate simulation of any specific experiment depends strongly on the circumstances.

In addition, multiscale modeling of the relations between microstructure and thermomechanical properties, as well as computer simulations of microstructure evolution benefits from the synchrotron experimental studies. For example, X-ray diffraction results such as atomic structure, lattice parameters, and local ordering provide input to atomic and mesoscale modeling of microstructural features. Furthermore, tomography results provide rich validation data for mesoscale simulations of microstructure evolution.

# 4      Conclusions

Most of the ways in which synchrotron X-ray radiation experiments can contribute to advancing our understanding of the additive manufacturing processes have been explored, at least in a preliminary sense. Given the high cooling rates found in additive manufacturing especially with SLM, there is a high likelihood that this area of activity will continue to evolve rapidly and that synchrotron radiation will play a major role in elucidating the scientific challenges associated with additive manufacturing. Wide-angle and small-angle X-ray scattering have been used to measure microstructural evolution and in particular diffusion and precipitation processes. Dynamic X-ray radiography (DXR) has been used to image the melting and refreezing processes directly, with complementary experiments on high-speed diffraction. Notwithstanding the limited volumes that can be scanned, computed tomography (CT) has made numerous contributions thanks to the high spatial resolution available with synchrotron X-rays as well as the relatively high throughput that is feasible. More advanced techniques such as high-energy

diffraction microscopy look likely to make a contribution to 3D characterization of AM materials in the near future. Synchrotron X-ray radiation experiments provide valuable information for setting up and validating atomistic and mesoscale computer simulations of microstructure evolution.

**Abstract**

Superior energy and power density, low toxicity, and enhanced shelf life have contributed to the popularity of lithium ion batteries as energy storage devices in the electronics and automobile industries. However, next-generation lithium ion batteries will require even higher energy densities to meet ever-increasing demands for longer battery life. Owing to its extremely high theoretical specific capacity (approximately ten times larger than that of conventional anode materials) and low electrochemical reduction potential ($-3.04$ V with respect to $H/H^+$ reference electrode), lithium metal is a highly attractive candidate as an anode material for next-generation lithium ion batteries. However, challenges such as dendrite growth, which can lead to short circuits or capacity loss from electrical isolation of growths, have prevented widespread commercial use of lithium metal electrodes. Successful commercialization will require stabilization of lithium deposition. Devising strategies to achieve this goal will require an understanding of the fundamental mechanisms that govern electrochemical deposition and dendrite propagation and which span multiple length scales. Building on experimental observations, several mathematical models have been developed to evaluate the roles of a variety of physical phenomena (such as electrochemical reaction, diffusion, migration, mechanical stress and strain, and surface tension) in lithium deposition processes. The present chapter provides an overview of these approaches for modeling lithium deposition and dendrite growth, summarizes their findings, and discusses remaining questions and future directions for dendrite modeling.

# 1 Introduction

For the development of a sustainable economy and to minimize global warming and solve future energy problems, significant emphasis is being given on the implementation of renewable energy sources. Energy storage devices are of utmost importance for achieving this reality. The intermittent renewable energy sources require high energy density devices for storing excess energy produced at times of low demand and supplying stored energy during times of peak consumption. Appropriate storage devices are particularly needed to power automobiles with nonfossil energy sources.

The scientific community has known about electrochemical cells, in which energy can be stored in the form of chemical energy and extracted as electrical energy (Blomgren 2017), for almost one-and-a-half centuries. However, their usage

in commercial devices became popular only around 50 years ago with the advent of rechargeable lead-acid batteries (Rahn 2013; Blomgren 2017). In the last quarter of the twentieth century, the nickel-cadmium and nickel-metal hydride batteries came to the market. These offered higher energy density than lead-acid based chemistries (Rahn 2013), and their lower weight and toxicity made them good options for hand-held electronic devices – the first-generation mobile phones and laptop computers used these nickel-metal hydride-based batteries. Towards the end of the last century, Sony revolutionized the energy storage industry with the commercialization of the first battery based on lithium ion chemistry (Blomgren 2017). It not only contained significantly higher energy and power density, but also demonstrated higher efficiency than the lead-acid and nickel-metal hydride based chemistries (Rahn 2013). The enhanced shelf life, higher capacity retention over multiple cycles, and negligible memory effect have made the lithium ion chemistry a significantly superior option in the electronics industry. However, in the automobile industry, the commercially available lithium ion batteries are far behind gasoline engines in terms of energy and power density (Gallagher et al. 2014). Significant improvements over the present-day lithium ion batteries are required for successful electrification of the automobile industry (Gallagher et al. 2014).

## 1.1 Brief History and Future Directions of Lithium Ion Battery Technology

Sony Corporation first commercialized lithium ion batteries in 1991, using a carbon-based anode, lithium cobalt oxide cathode, and organic liquid electrolytes solvents (Blomgren 2017). Both the cathode and anode material store lithium through an intercalation mechanism, and the ions shuttle between the two electrodes during the charge and discharge process. Carbon was used as the anode material due to its low electrochemical potential (with respect to $Li^+/Li$) and ability to store lithium without the formation of dendrites. In the first commercially successful version, the lithium ion chemistry was able to demonstrate an energy density of 200 Wh/l (Blomgren 2017). This was sufficient for powering electronic devices, but not good enough for running electric vehicles.

To reduce the cost and toxicity associated with cobalt-based cathode materials, several other transition metals have been investigated as cathode materials. For example, nickel-rich cathodes are being used widely for their high capacity, and manganese-rich cathodes have also been investigated for their high stability. Presently, certain combinations of nickel, manganese, and cobalt ($Ni_xMn_yCo_{(1-x-y)}$) are used as lithium ion battery cathodes to combine their intrinsic properties of high capacity, enhanced electrochemical stability, and large electronic conductivity, respectively (Myung et al. 2017). These advanced cathode materials are capable of demonstrating energy densities in the range of 400 Wh/l, which are sufficient to meet the needs of short range electric vehicles (Blomgren 2017; Myung et al. 2017).

In order to overcome the range anxiety associated with the present-day electric vehicles, the energy density of existing lithium ion batteries must be improved. It can be achieved in several ways, some of which are listed below:

(a) Increasing the window of operation for cell potential. This can be achieved by charging the cell to a higher voltage and extracting some excess lithium from the cathode (Myung et al. 2017). This has the disadvantage of disrupting the crystal structure of the cathode material through the removal of oxygen from the lattice sites. This irreversible change leads to high capacity only at the first cycle.
(b) Decreasing the anode potential can also lead to a larger potential window of operation (Xu et al. 2014). Only lithium metal itself demonstrates a lower potential than graphite. Hence, a transition in the anode material, from conventional graphite to lithium metal, is of utmost importance for increasing the energy density of present-day electric vehicles.
(c) Increasing the specific capacity of cathode and anode active materials used in the electrode. Due to their higher specific capacities, nickel-rich NMC and NCA type cathode materials have been investigated thoroughly (Nitta et al. 2015; Myung et al. 2017). From the perspective of the anode, specific capacity can be improved by replacing graphite with either lithium, or silicon/tin (Si/Sn) based active materials (Nitta and Yushin 2014).
(d) Adoption of "beyond lithium ion" chemistries, such as lithium-sulfur- and/or lithium-air-based batteries (Gallagher et al. 2014). These future-generation technologies use lithium metal as the anode material and some unconventional cathode material. For example, lithium-sulfur cells use phase changing sulfur as the cathode that can consume theoretically sixteen electrons during a discharge process. Lithium oxygen/air batteries demonstrate almost zero theoretical weight of the cathode, giving them an excessively high energy density almost comparable to that of gasoline.
(e) Replacement of liquid electrolytes by solid-state ceramics- or polymer-based electrolytes (Kerman et al. 2017). Due to the higher safety associated with nonliquid electrolytes, they might allow the removal of certain extra safety devices required for the liquid electrolytes. This extra space can be used for inserting extra cells and increasing the pack level energy density. Solid-state electrolytes can also help to accelerate the implementation of lithium metal anodes.

## 1.2    Lithium Metal as the Negative Electrode

Most of the above techniques for increasing energy density involve lithium metal as an anode, as it possesses an extremely low electrochemical potential of −3.04 V with respect to hydrogen reference electrode, and theoretical specific capacity of 3870 mAh/g, which is almost an order-of-magnitude higher than the conventional graphite based anodes (375 mAh/g) (Xu et al. 2014; Lin et al. 2017). It should be noted that lithium metal anodes were actively researched in the second half of the

last century for usage in lithium ion batteries, but did not see commercial success due to several issues (Blomgren 2017; Cheng et al. 2017):

(a) Loss of electrolyte due to reaction with the anode surface and formation of a solid electrolyte interface, which leads to significant capacity fade
(b) Formation of dead lithium that does not participate in the electrochemical reaction and can potentially lead to capacity fade if excess lithium is not used
(c) Growth of dendritic protrusions that can penetrate through the separator and short the cell
(d) Thermal runaway due to internal shorting and subsequent explosion of the cell

Nucleation and propagation of dendritic protrusions during lithium deposition are connected to all of these problems. Significant research has been conducted to understand and prevent these phenomena. For example, it was demonstrated that the use of a small amount of hydrofluoric acid within the electrolyte as an additive results in the formation of a mechanically stiff lithium-fluoride layer on top of the metal anode, which can stabilize the metal-electrolyte interface for tens of cycles (Takehara 1997). Later it was hypothesized that nonuniform lithium deposition at the electrode-SEI interface and subsequent rupture of the solid electrolyte interphase layer result in the nucleation of the lithium dendrites (Aurbach 2000). Addition of stiff protective layers along with the separator can prevent growth of dendritic protrusions. Some examples of such protective layers are sulfur and nitrogen co-doped graphene (Shin et al. 2015) and alumina ($Al_2O_3$) deposited on top of lithium (Peng et al. 2016). Covering the lithium surface with polymer networks or carbon nano-spheres can help to minimize the nonuniform lithium deposition or SEI formation, respectively (Zheng et al. 2014; Peng et al. 2016). There have also been several research efforts to alter the transport properties of electrolytes (conductivity, diffusivity, and transference number) in order to prevent the growth of lithium dendrites. For example, plasticizers have been added within polymer electrolytes to improve conductivity near room temperature conditions for stabilizing lithium deposition (Khurana et al. 2014). Nanoparticles have also been added within the liquid electrolyte to immobilize the anions and increase the lithium transference number, which helps to maintain higher anion concentration near the anode (Lu et al. 2012). However, to the best of the authors' knowledge, no conclusive product or strategy has been developed that can ensure stable deposition of lithium for thousands of cycles with minimal capacity fade.

Next-generation polymer or solid-state ceramic electrolytes were not readily available in the earlier efforts, but now make practical lithium metal anodes appear to be more achievable. However, preliminary experimental studies at the lab scale still show the formation of lithium dendrites through these nonliquid electrolytes (Harry et al. 2016; Kerman et al. 2017). Better design of these electrolytes may be able to stabilize the lithium deposition process.

Furthermore, different dendrite morphologies have been observed, varying according to the type of electrolyte, operating conditions, and applied overpotential (Harry et al. 2016; Cheng et al. 2017):

(a) Mossy deposits form at low current densities. This is usually associated with lithium deposition at the base of the dendrite. If the lithium deposition process is charge-transfer controlled, moss-like deposits are expected to form (Bai et al. 2016).

(b) Needle-like protrusions, which evolve during deposition at higher rates, are usually associated with deposition at the tip of the protrusion. In mass transfer limited lithium deposition processes, needle-like dendrites are observed to form (Bai et al. 2016).

(c) Tree-like dendritic growths have also been observed and are usually attributed to the presence of surface inhomogeneity.

(d) Globular dendritic protrusions have also been reported during deposition under the influence of mechanical stress (Harry et al. 2016).

Among all the different possible microstructures, needle-shaped dendrites have the largest potential to penetrate through the separator, get in contact with the cathode, and short the cell (Li et al. 2014; Bai et al. 2016). Hence, even if dendrite growth is unavoidable, it is important to control the lithium microstructure that evolves during the deposition process and possibly operate the cell only under conditions in which it forms only mossy deposits. In order to develop strategies for controlling the lithium deposition process, it is important to understand the overall lithium dendrite nucleation and growth mechanisms.

## 1.3   Mathematical Models for Lithium Dendrite Nucleation and Growth

Extensive research on electrochemical deposition of lithium and subsequent dendrite growth over the last several decades has been able to establish correlations between various operating conditions and dendrite microstructures (Cheng et al. 2017; Lin et al. 2017). Based on thermodynamic and kinetic understanding of the electrochemical reduction process, it is possible to develop mathematical models that can capture the experimental features observed during deposition of metallic lithium (Chen et al. 2015; Wood et al. 2016). Although nucleation and growth mechanisms may vary according to the nature of the electrode and electrolyte, the deposition mechanism of lithium metal generally can be divided into two parts:

(a) Nucleation of lithium
(b) Growth of dendritic protrusions

In this book chapter, different mathematical models used for predicting the nucleation of lithium ions will be discussed in Sect. 2. Different mathematical models to capture the growth of dendritic protrusions in contact with liquid and nonliquid (polymer and ceramic) electrolytes will be discussed in Sects. 3 and 4, respectively. Some unsolved questions that can help to better understand the metal

deposition process on top of the lithium anode will be discussed in Sect. 5. Finally, the future outlook in terms of modeling nucleation and propagation of dendrites will be summarized in Sect. 6.

## 2    Dendrite Nucleation Models

Classical nucleation theory (CNT) has been widely used to capture the lithium nucleation process on top of surfaces assumed to be free of defects (Paunovic and Schlesinger 2006). An alternative theory of instantaneous or progressive nucleation has been developed to describe the case in which surface defects provide nucleation sites for lithium dendrites (Paunovic and Schlesinger 2006; Stark et al. 2013).

Note that these theories were developed for liquid electrolyte systems. In the presence of solid electrolytes, nucleation should be affected by the extra mechanical work needed to deform the nearby electrolyte or the current collector. Under the assumption that the current collector deforms elastically, Motoyama et al. found that the overpotential for deposition increased almost linearly with Young's modulus of the current collector (Motoyama et al. 2015).

### 2.1    Classical Nucleation Theory

Under CNT, nucleation proceeds only when it decreases the total Gibbs free energy of the system (Mullin 2001). Contributions to the total free energy include electrolyte displacement, lithium deposition, and the formation of new interfaces between the surface and electrolyte and the newly deposited lithium.

Based on these considerations, Ely and García determined (Ely and García 2013) a critical radius above which a hemispherical lithium deposit becomes thermodynamically stable and below which the nucleus should spontaneously dissolve (Schmickler and Santos 2010). However, the deposition process also consumes additional energy in the form of a larger overpotential (Mullin 2001; Paunovic and Schlesinger 2006) to overcome the kinetic barrier associated with the transformation of ionic lithium (in solution) to atomic lithium (on the substrate), along with surface tension in the case of curved surfaces (Monroe and Newman 2003; Ely and García 2013). Using a modified Butler-Volmer equation incorporating the influence of surface curvature (Monroe and Newman 2003) on reaction current, Ely and García determined a kinetic critical radius at which the influences of nonnegative applied overpotentials and surface curvature are balanced. This critical radius is inversely proportional to the overpotential (Ely and García 2013) and usually larger than the critical thermodynamic radius. Stable growth is expected for lithium nuclei larger than the kinetic critical radius, although those larger than the thermodynamic critical radius can coalesce with neighboring nuclei and become stable (Ely and García 2013). Experiments have confirmed that size of lithium nuclei decreases with increasing overpotential (Sano et al. 2014; Pei et al. 2017).

## 2.2    Instantaneous and Progressive Nucleation of Lithium

When surface defects are present, lithium deposits initially on these defect sites and may grow due to further deposition of metal or through coalescence with other nearby nuclei (Paunovic and Schlesinger 2006; Stark et al. 2013). Assuming that the rate of nuclei formation on defect sites is linear in the number of available sites, the fast kinetics ("instantaneous nucleation") limit suggests that almost all preexisting active nuclei start growing simultaneously with the initiation of metal deposition (Paunovic and Schlesinger 2006; Schmickler and Santos 2010; Stark et al. 2013). The slow kinetics ("progressive nucleation") limit, on the other hand, corresponds to a gradual, approximately linear increase in the number density of nuclei over time (Stark et al. 2013). These number densities, along with assumptions about nucleus shape, can be used to estimate (Paunovic and Schlesinger 2006; Schmickler and Santos 2010; Stark et al. 2013) current density and nucleus size at earlier times where the nuclei are isolated, and later after neighboring nuclei have merged.

## 3    Dendrite Growth Models: Liquid Electrolyte

Dendritic growth of existing lithium deposits in electrochemical cells using liquid electrolyte solutions has been modeled using a variety of approaches, addressing phenomena ranging from the atomic level to that of electrochemical cells. This section surveys these techniques, beginning from the smallest length scale and proceeding through successively larger length scales.

### 3.1    Atomic-Scale Modeling

Ozhabes, Gunceler, and Arias (Ozhabes et al. 2015) constructed a density functional theory (DFT) model of crystalline surfaces in contact with electrolyte solution represented by a continuum approximation and calculated surface energies and lithium surface diffusion energy barriers for a range of SEI materials. It was found that the spatial arrangement of compounds with small anions, particularly halides, allowed for lower energy barriers and that for most compounds, larger energy barriers were associated with larger surface energies (and so greater thermodynamic stability, since dendrites increase surface area). In addition, they reported that longer times for cells to short-circuit were correlated with larger diffusion barriers, which are expected to prevent atoms from diffusing quickly enough to prevent dendrite growth.

### 3.2    Molecular Scale Modeling

Molecular-scale models are suitable for simulating situations in which small amounts of material are deposited. They have been used to explore the possibility of reducing dendrite growth rates by the use of pulsed current charging.

Mayers and coworkers created (Mayers et al. 2012) a 3D Monte Carlo (MC) simulation of dendrite growth in a hemispherical SEI region surrounding a hemispherical electrode tip. Cations diffusing within the simulation domain were allowed to deposit, with a probability determined from free energy considerations, upon collision with the electrode tip or with previously deposited metal atoms. Lower reaction probability allowed cations, on average, to diffuse more deeply through the growing coating on the electrode surface, increasing deposition density. Similarly, short charging pulses combined with long rest periods encouraged denser dendrite growth.

Aryanfar and coworkers constructed (Aryanfar et al. 2014) a similar 2D MC model of dendrite growth, but with transport of lithium ions in solution determined by a combination of diffusion and migration. Pulsed-current simulations of dendrite growth on a planar electrode suggested that pulses of appropriate length and separated by appropriate time intervals can reduce dendrite growth rates.

Although not modeling lithium deposition, Li and coworkers constructed (Li et al. 2017) a 3D molecular dynamics (MD) simulation of electrolyte solution (LiTFSI dissolved in propylene carbonate) to observe interactions among the different species. They found that the application of pulsed electric fields influenced the coordination of lithium ions by anions and that lithium ion diffusivity was improved by reduced coordination. Experimental cells that were cycled with pulsed currents showed more stable behavior and more uniform deposition relative to those cycled under constant current conditions.

## 3.3    Continuum Modeling

Simulations at the continuum scale typically involve larger, faster-growing dendrites with smooth surfaces. Models at this scale typically are formulated as partial differential equations describing the local phenomena of interest, although Yamaki et al. proposed (Yamaki et al. 1998) a qualitative lithium dendrite growth mechanism based on a wide array of experimental observations, consisting of the following steps: lithium deposits nonuniformly due to surface irregularities and nonuniform ionic conductivity of the protective surface film. The resulting mechanical stress drives transport of lithium atoms within the surface, which emerge as whiskers through breaks in the film. Finally, when the whisker coverage becomes sufficiently dense, additional lithium deposits preferentially on defects and irregularities on the whiskers.

Liu and Lu simulated (Liu and Lu 2017) the growth of a two-dimensional dendrite coated with a growing SEI layer. SEI thickness changed through electrochemical reaction and strain of the underlying surface and was reflected in resistance contributions to the surface overpotentials used to determine reaction rates. The electrode reaction was additionally influenced by a hydrostatic stress term related to the surface energy and local curvature. Relatively high reaction rates at the dendrite tip, driven by surface curvature, initially caused local SEI thinning due to expansion of the underlying lithium region. The thinned SEI region, with a lower electrical

resistance, in turn favored further reaction at the dendrite tip. At the base of the dendrite, compressive stress increased SEI thickness, which slowed local lithium deposition and created depressions relative to the surrounding material. The same mechanisms led to dendrite formation at SEI-deficient locations in otherwise flat electrode surfaces.

Applying dilute solution theory and the Poisson equation in a 1D model of a symmetric cell at steady-state, but not insisting on electroneutrality, Chazalviel observed (Chazalviel 1990) quasineutral conditions over much of the cell, but a sharp drop in potential near the cathode, with a low concentration of cations and a very low concentration of anions. Unlike in corresponding experiments, the applied potential did not affect current density as current was determined almost completely by diffusion. This discrepancy was attributed to dendrite growth, the rate of which was expected to match the anion migration speed near the cathode, based on dynamic simulations. This concept was further explored through simulations of a 2D control volume, with periodic boundary conditions, moving with the tip of a thin, straight metal dendrite growing at a steady speed. Below a critical separation distance, the solution between dendrites was depleted of ions due to dendrite growth, which proceeded at the expected rate matching the anion velocity. Above the critical separation distance, it was reasoned that the growth rate would be faster than the anion velocity, but that the presence of ions between dendrites would lead to branched growth, in turn reducing the separation distance toward the critical distance.

## 3.4    Phase Field Modeling

The dynamic models of continuum dendrite growth previously surveyed here involve calculation of precise surface positions. However, simulation is often computationally expensive for irregular interfaces (Provatas and Elder 2010; Acharya 2016). Phase field modeling can be a less expensive alternative (Chen 2002). Rather than tracking interfaces, phase field models calculate "order parameters" to represent phase identity, typically with one phase assigned a value of 0 and the other assigned a value of 1 in a two-phase system. Regions with noninteger order parameter values can be interpreted as interface regions of finite thickness. To model electrochemical systems, phase field models are typically based on a phenomenological free energy functional written in terms of field parameters (Ferguson and Bazant 2012), e.g., concentration, electric potential. For an interface-moving problem, the Cahn-Hillard equations (for variables representing conserved quantities) and the Allen-Cahn equations (for non-conserved variables) are used to express the relationship between field parameter values and the estimated total free energy. Interface movement is simulated by decreasing the total free energy of the system over time.

The application of phase field modeling to electrochemical systems is an area of ongoing research. Guyer et al. (2004a) made one of the earliest attempts to model electrochemical interface evolution by Allen-Cahn kinetics, in which they

studied the charge separation on the interface and compared to the classic Gouy-Chapman-Stern model to demonstrate effectiveness. In a subsequent paper, Guyer et al. (2004b) further explored the kinetic behavior of a phase field model for an electrodeposition process. As a typical solid-liquid interface problem, lithium dendrite growth has also been extensively modeled using the phase field method. Similarly, Cogswell (2015) investigated dendrite growth patterns by adapting the Marcus theory of microscopic charge transfer to achieve quantitative agreement with Faradaic reaction kinetics, fractal growth dimension, and radius of curvature on a zinc electrode. Cogswell also indicated that small exchange current density could reduce the growth of dendrites. To investigate electrode-electrolyte interface evolution in a lithium ion battery, Liang et al. (2012) proposed a phase field model in which they simplified the Allen-Cahn equation by assuming that the interface velocity is proportional to decay in free energy. Following the same approach, Liang et al. (Liang and Chen 2014) then studied the morphologies of lithium deposits during cell charging processes and found that the growth of lithium deposits has a very strong directional tendency, which can be greatly accelerated by the existence of a large concentration gradient. García et al. (Ely et al. 2014; Jana et al. 2015) developed a phase field model to describe the growth kinetics and distribution of lithium electrodeposits on a graphite electrode surface and found that the rate of electrodeposition at the tip of an isolated dendrite to be higher than that on the surrounding electrode. Chen et al. (2015) also proposed a new phase field model to study dendrite growth out of a surface during electrodeposition, in which they formulated Butler-Volmer kinetics for lithium deposition using the electrochemical potentials of each species. A very similar general phase field modeling approach was also developed by Bazant et al. (Ferguson and Bazant 2012; Bazant 2013; Smith and Bazant 2017), in which electrochemical processes (including generalized Butler-Volmer kinetics) as well as generalized chemical kinetics were modeled to provide a quantitative description of lithium iron phosphate phase transition behavior.

The phase field method can be used to easily model complex interface shapes and topology changes. It is particularly suited for studying phase evolution, morphology changes, or splitting and merging of diffusion fields in electrochemical systems (Chen 2002; Acharya 2016). It can combine a variety of physical effects into governing equations that can be solved by straightforward numerical methods without complicated interface handling. However, it should be recognized that the phase field method also comes with disadvantages. Although phase field models offer a deeper connection to fundamental thermodynamics than other modeling methods, applying these techniques to electrochemical systems tends to involve very stiff, high-order partial differential equations requiring small numerical time step sizes that make it impractical to simulate realistic time intervals (Provatas and Elder 2010). Multiscale numerical methods that can resolve the thin interfaces inherent in phase field models while also capturing microstructure evolution on realistic time scales are presently under development (Provatas and Elder 2010), potentially making it possible to overcome some of the present challenges of modeling electrochemical systems.

## 3.5    Cell Level Modeling

Finally, some authors have modeled dendrite growth at the cell level. Rather than modeling the growth of individual dendrites, they computed quantities such as spatially varying deposition rates.

Tang and coworkers used (Tang et al. 2009) a 2D macro-homogenous model containing a graphite negative electrode, separator, and lithium cobalt oxide positive electrode (through a boundary condition), to investigate the possibility of nonuniform lithium deposition on realistically shaped anodes. As the current density at the positive electrode interface was nonuniform, an iterative scheme was used to ensure consistency between the cell potential and the fixed applied current at each timestep. When positive and negative electrodes were of equal width, lithium deposition at the end of charging was more likely near the negative electrode edge, while increasing the negative electrode width beyond a critical distance discouraged deposition.

Wood and coworkers constructed (Wood et al. 2016) a 1D continuum-level model of a Li-Li cell. Movement of electrode/solution interfaces was determined by lithium dissolution and deposition rates, and the relationship between surface overpotentials and current densities at these interfaces was given by the Butler-Volmer equation, modified with a coefficient describing surface roughness, along with an effective rate constant representing a weighted average of rate constants for electrode surface areas with fast and slow kinetics. The surface morphology was assumed to evolve with total current passed, representing the growth and merging of neighboring lithium protrusions. A Coulombic efficiency parameter was used to account for electrical isolation of "dead lithium" during stripping. Good agreement between simulation results and corresponding cycling experiments was reported.

## 4    Impact of Mechanical Stress on Dendrite Growth: Nonliquid Electrolytes

Liquid electrolyte solutions do not provide mechanical resistance to the formation and propagation of dendrites. These can lead to formation of electrically isolated dead lithium or cause catastrophic failure by internally short circuiting the cell.

Use of nonliquid electrolytes has been proposed to reduce dendrite growth by encouraging uniform deposition on lithium metal electrodes (Monroe and Newman 2005) and eliminates the fire hazard associated with leakage of flammable liquid electrolytes (Cheng et al. 2017). From the microstructural perspective, nonliquid electrolytes can be divided into two categories: (a) structurally homogeneous and (b) structurally heterogeneous electrolytes. Most electrolytes based on poly(ethylene-oxide) (PEO) or poly (acrylonitrile) (PAN) belong to the first category, whereas solid-state electrolytes, such as the ceramic-based $Li_7La_3Zr_2O_{12}$ (LLZO) and $Li_{10}GeP_2S_{12}$ (LGPS), which possess grain-interior/grain-boundary microstructure, belong to the second category. Block-copolymers with nanoscale microstructural features belong to the first category, because these heterogeneities do not impact

the dendrite growth process (Inceoglu et al. 2014). However, micron-sized grain-interior/grain-boundary microstructural heterogeneity found in ceramic solid-state electrolytes can impact the lithium deposition process through current focusing at the electrode-electrolyte interface (Kerman et al. 2017). Hence, dendrite growth mechanisms in structurally homogeneous and heterogeneous electrolytes could differ significantly and require separate modeling approaches.

## 4.1   Structurally Homogeneous Electrolytes

Nonliquid electrolytes provide mechanical resistance in the form of compressive stress to the growth of dendritic protrusions. In addition, this compression can change their shapes from needle-like (under liquid electrolytes) to a globular (usually observed in homogeneous polymer electrolytes).

The magnitude of the compressive stress depends on the elastic modulus of the electrolyte. Increasing the electrolyte modulus by even one order of magnitude can significantly slow the growth rate of dendritic protrusions (Harry et al. 2016). Figure 1 shows that stiff block-copolymer electrolytes (SEO, consisting of PEO stiffened with polystyrene) with elastic modulus around 10 MPa at 90 °C reduce the rate of growth of lithium protrusions relative to PEO-based electrolytes, which has elastic modulus values near 1 MPa at elevated temperatures. It is clearly important to incorporate mechanical stresses in models of dendrite growth into nonliquid electrolytes.

**Fig. 1** (**a**) Comparison between the rate of increase in height of dendritic protrusions observed in PEO-polymer and PEO/SEO block-copolymer-based electrolytes. Use of the SEO-based block-copolymer, with a higher elastic modulus value, resulted in significantly slower growth of the dendritic protrusion. (**b**) Dendritic protrusions were observed to be globular rather than needle-like when using high modulus polymer electrolytes. (Reproduced from Harry et al. 2016, Copyright 2016 by The Authors of Harry et al. 2016 under CC BY 4.0 terms, see http://creativecommons.org/licenses/by/4.0/)

One contribution of mechanical resistance to dendrite growth comes from electrode curvature/surface tension, which can be incorporated into the Butler-Volmer equation through its impact on the overpotential (Monroe and Newman 2003). The effect of surface curvature on dendrite growth is more prominent for polymer electrolytes than in liquids because of higher surface energy densities at lithium-polymer interfaces (about 1.5 J/m$^2$) (Monroe and Newman 2003) as compared to lithium-metal/liquid-electrolytes (about 0.1 J/m$^2$) (Liu and Lu 2017). The following Butler-Volmer equation was derived after incorporating the effects of surface curvature (Monroe and Newman 2003):

$$i_{BV} = i_{0,ref} \exp\left(\frac{2\alpha_c \gamma \overline{V}}{rRT}\right)\left[\exp\left(\frac{\alpha_a F \eta_s}{RT}\right) - \exp\left(-\frac{\alpha_c F \eta_s}{RT}\right)\right]. \qquad (1)$$

Here, $i_{BV}$ is the local reaction current density at the interface, $i_{0,ref}$ is the reference exchange current density, $\gamma$ represents surface energy density for the interface between the electrode and electrolyte, $\overline{V}$ is the partial molar volume of lithium within the electrolyte, $r$ represents the radius of the dendritic protrusion, $R$ indicates the universal gas constant, $T$ denotes temperature in Kelvin, $\eta_s$ signifies the surface overpotential, and $\alpha_a$ and $\alpha_c$ represent the anodic and cathodic transfer coefficients, respectively. The surface overpotential term is expressed as $\eta_s = \phi_s - \phi_e - U_0 + (2\gamma \overline{V}/rF)$, where $\phi_s$ is the solid phase potential, $\phi_e$ indicates the electrolyte phase potential, $U_0$ is the open circuit potential of the electrode, and $(2\gamma \overline{V}/rF)$ is the contribution of the surface curvature to the local overpotential (Monroe and Newman 2003).

The magnitude of $i_{BV}/i_{0,ref}$ as a function of the overpotential without the curvature term ($\eta = \phi_s - \phi_e - U_0$) is shown in Fig. 2. The dependence of

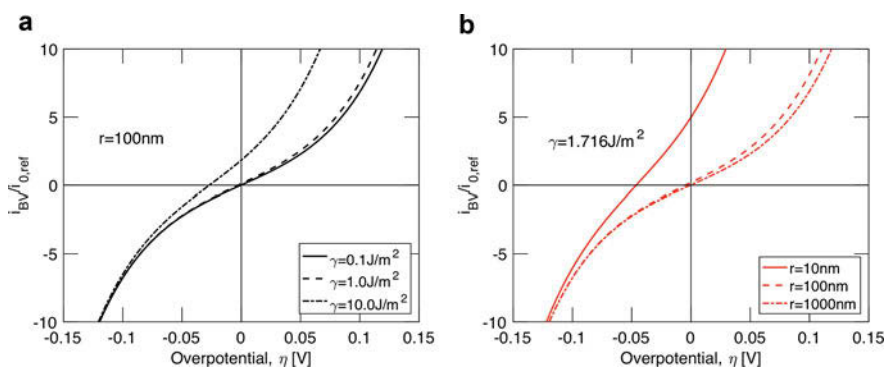

**Fig. 2** Variation in reaction current density with respect to overpotential after incorporating the effects of surface energy within the Butler-Volmer equation. (**a**) Impact of surface energy density on the overall reaction current density. Increasing surface energy enhances the anodic current. (**b**) Impact of protrusion size on the total reaction current density. Smaller lithium nuclei (r~10 nm) can easily dissolve back into the solution even under small cathodic overpotentials

the current-overpotential curve on surface energy density is shown in panel (a); increasing the value of $\gamma$ leads to higher anodic reaction current and a decreased cathodic current. Similarly, as demonstrated in panel (b), decreasing the radius of the dendritic protrusion helps to increase the anodic component of the reaction current density. Hence, the surface energy component works to stabilize the dendritic protrusions. For high surface energies ($\gamma \sim 10$ J/m$^2$), as well as extremely small dendritic protrusions (r$\sim$10 nm), anodic current is observed under small magnitudes of cathodic overpotential, which can play a significant role in the stable deposition of metals.

Furthermore, deformation of the adjacent nonliquid electrolyte was estimated to produce a local stress-induced change in electrochemical potential ($\Delta \mu_{e^-}$) (Monroe and Newman 2004, 2005):

$$\Delta \mu_{e^-}(x) = -\frac{1}{2} \left( \overline{V}_{Li} + (1 - t_{Li+}) \overline{V}_{Elec} \right) \left\{ \gamma \kappa + \vec{n} \cdot \left[ \vec{n} \cdot \left( \tau^{Li} - \tau^{Elec} \right) \right] \right\} + \\ + \frac{1}{2} \left( \overline{V}_{Li} - (1 - t_{Li+}) \overline{V}_{Elec} \right) \left( p^{Li} + p^{Elec} \right).$$

(2)

Here, $\overline{V}_{Li}$ and $\overline{V}_{Elec}$ represent the partial molar volumes of lithium and electrolyte salt, $\gamma$ is the surface energy, $\kappa$ represents local curvature, $\vec{n}$ indicates the normal vector at the lithium-electrolyte interface, $x$ denotes position on the interface, and $t_{Li+}$ stands for the lithium transference number. Also, $\tau$ represents the deviatoric stress tensor and $p$ indicates hydrostatic stress (both of which are influenced by elastic modulus values), and superscripts *Li* and *Elec* correspond to the lithium metal electrode and electrolyte, respectively. A Butler-Volmer equation incorporating the effect of this stress-induced change as well as of curvature is given in Monroe and Newman (2005). As discussed in the following subsections, several computational studies have been conducted to understand the propensity of lithium dendrite growth under the assumption of elastic or elastic-plastic deformation of the metal electrode and solid electrolyte system.

### 4.1.1 Elastic Stress Evolution in Lithium Metal Electrodes

Under the assumption of linear elastic deformation of both the metal electrode and electrolyte, Monroe and Newman solved the mechanical equilibrium equation to estimate the magnitudes of tensile and compressive stresses within the lithium metal and electrolyte, respectively (Monroe and Newman 2005). They concluded that electrolytes with shear modulus values twice that of lithium may be able to stabilize the deposition process (Monroe and Newman 2005). Following this approach, Barai et al. investigated the importance of initial stress state at the electrode-electrolyte interface (Barai et al. 2017a), introducing an alternative initial condition that could describe at least two plausible physical scenarios:

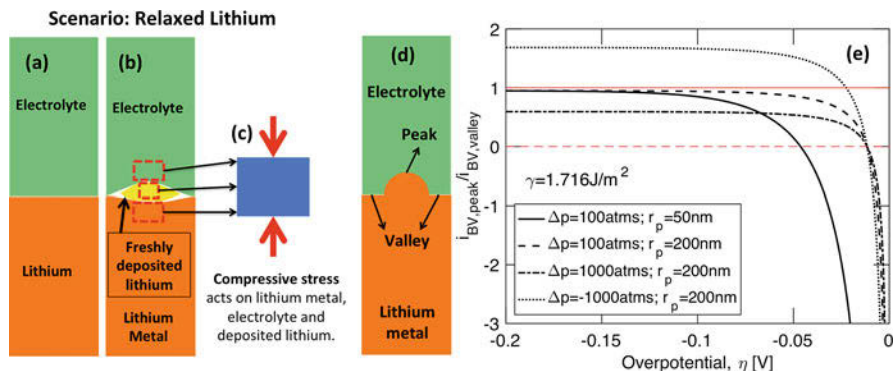
(a) A lithium protrusion begins as a small imperfection on the electrode, leading to local compressive stress upon cell assembly.


**Fig. 3** Schematic diagram demonstrating stress evolution, location of peak and valley, and ratio of current density between them. (**a**) After assembly, flat lithium metal and electrolyte in a stress-free relaxed condition. (**b**) During lithium deposition, new metal pushes the lithium downward and the electrolyte upward. (**c**) Evolution of compressive stress within electrode, electrolyte, and lithium dendrite nucleus. (**d**) Location of "peak" and "valley" for a dendritic protrusion. (**e**) Ratios of reaction current densities at the peak and valley versus reduction overpotential. Points below the solid red line correspond to stable deposition, while those above correspond to dendrite growth. The region below the dashed red line corresponds to dissolution of the peak. Hence, it may be beneficial to operate the cell at very small reduction overpotentials (around −10 mV) to eliminate preexisting dendritic protrusions. (Adopted from Barai et al. 2017a; Reproduced with permission from *Journal of the Electrochemical Society* 164 (2) A180 (2017), Copyright 2017, The Electrochemical Society)

(b) During lithium deposition, newly deposited metal pushes apart neighboring electrode and electrolyte, inducing local compressive stress (sketched in Fig. 3a–c).

Under both scenarios, lithium metal, solid electrolyte, and the dendritic protrusion experience compressive stress (Barai et al. 2017a). It should be noted that the two studies described here assumed operation at extremely low applied current densities and neglected the impact of concentration and potential gradients on the overall reaction current.

The general computational framework, developed by Monroe and Newman, assumes that the lithium nucleus appears as a small perturbation on top of the electrode surface (Monroe and Newman 2004, 2005) (see Fig. 3d). The top of the protrusion will be called the "peak," (reaction current $i_{BV, peak}$) and the flat surface surrounding the protrusion will be called the "valley" (with reaction current $i_{BV, valley}$). If the reaction current at the peak is greater than that in the valley (($i_{BV, peak}/i_{BV, valley}) > 1$), the dendritic protrusion is expected to grow. Otherwise, for ($i_{BV, peak}/i_{BV, valley}) < 1$, stable deposition of lithium is expected to occur. Ratios of total reaction current at the peak over that in the valley are shown in Fig. 3e. The solid red line indicates the stability limit. Data points lying above and below the line correspond to dendrite growth and stable deposition, respectively. In the figure, $\Delta p$ and $r_p$ indicate compressive hydrostatic stress and protrusion radius. It

is evident that increasing the magnitude of compressive stress helps to stabilize the dendritic protrusion. The size of the protrusion has a smaller impact on the current ratio at higher overpotentials. In this particular analysis, the magnitude of hydrostatic stress at the peak is double that observed in the valley. Under very low overpotentials, $\eta < 10$ mV, reaction currents at the peak and valley act in opposite directions. This can be explained by referring to Fig. 2b, which shows that at smaller reduction overpotentials, anodic reaction current occurs at the dendritic protrusion while cathodic current appears at the valley. It may be beneficial to operate the cells under these conditions to obtain very stable deposition of lithium metal.

All of the analyses previously discussed in this subsection used small-deformation mechanics. Harry et al. collected a time series of static X-ray microtomography images of a lithium dendrite growing into a solid electrolyte region and calculated mechanical stresses in the electrolyte region using large-deformation mechanics (Harry et al. 2016). Compressive stresses were found near the protrusion tip, while tensile stresses were found at the base. As shown in Fig. 3e, compressive force decreases the magnitude of reaction current density, whereas tensile stress increases it. Hence, polymer electrolyte should suppress growth at the peak and enhance growth at the base (Harry et al. 2016), consistent with formation of globular dendrites (shown in Fig. 1b).

### 4.1.2 Elastic-Plastic Stress Evolution in Lithium Metal Electrode

Under the assumption of elastic deformation, cells containing stiff electrolytes may experience very high stresses (in the range of GPa) (Monroe and Newman 2005; Barai et al. 2017a). However, stresses of this magnitude cannot be sustained by lithium metal or solid electrolytes. Ductile materials deform plastically and brittle electrolytes experience fracture beyond their yield and ultimate strengths, respectively. Hence, it is very important to model elastic-plastic deformation and rupture observed in lithium metal and electrolyte to correctly estimate stresses acting at electrode-electrolyte interfaces.

Elastic-plastic deformation has been observed in both metallic lithium and polyethylene oxide (PEO)-based electrolytes (Geng et al. 2002; Schultz 2002). Plastic deformation is irreversible in nature and consumes extra energy (see Sethuraman et al. (2010) for a similar outcome in silicon anodes). Figure 4a, b shows the experimentally observed elastic-plastic stress-strain relations that occur in lithium metal and PEO electrolyte. A nonlinear isotropic strain hardening law has been applied for both materials (Barai et al. 2017b):

$$\sigma_y = \sigma_0 + H\varepsilon_{pl}^m. \tag{3}$$

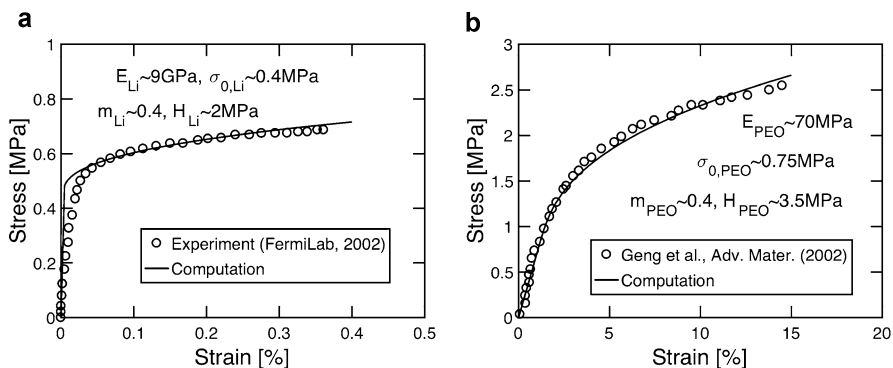
Here, $\sigma_y$ is the yield stress, $\sigma_0$ is the initial yield strength, $H$ indicates the hardening modulus, $m$ denotes the hardening exponent, and $\varepsilon_{pl}$ indicates the equivalent plastic strain. The initial yield strength, hardening modulus, and hardening exponent are material-specific parameters. Appropriate parameter values were estimated by fitting to experimental data (Barai et al. 2017b).


**Fig. 4** Elastic-plastic deformation observed in different materials, and the corresponding computational isotropic nonlinear hardening models and parameter values, for (**a**) lithium metal, and (**b**) PEO. (Reproduced from Barai et al. 2017b: Barai et al., *Physical Chemistry Chemical Physics* (2017) **19** 20493 with permission from the Royal Society of Chemistry)

For high-modulus polymer electrolytes, plastic deformation of the lithium dendritic protrusions and the nearby electrolyte is possible. Plastic flow of lithium from the protrusion peak to the surrounding valley region can lead to decreased protrusion height. High modulus electrolytes lead to suppression of dendritic protrusions in two different ways, as reflected in Eq. (1) (Barai et al. 2017b):

(a) The cathodic current obtained from the Butler-Volmer equation (shown by the blue line in Fig. 5a) decreases where compressive stress becomes high.
(b) Decrease in protrusion height due to plastic deformation of lithium metal reduces the component of reaction current induced by the concentration-overpotential gradient (shown by the red squares in Fig. 5a).

The combined effect is denoted by the black line in Fig. 5a, which also indicates that stable deposition of lithium may be possible if the elastic modulus of polymer is approximately 20 times larger than that of lithium.

As shown in Fig. 5b, the rapid decrease in current ratio actually occurs at lower, intermediate electrolyte modulus values, which lead to plastic deformation of lithium but elastic deformation of electrolyte. Figure 5b demonstrates that a threefold increase in the initial yield strength of present-day PEO can help significantly in suppressing growth of protrusions (Barai et al. 2017b).

Other research groups have also studied the impact of elastic plastic deformation of lithium metal on the growth of dendritic protrusions. The Butler-Volmer equation was modified by incorporating surface curvature and including a model of plastic deformation (Ferrese and Newman 2014; Jana and García 2017). The dendrite growth process was divided into two categories (Jana and García 2017): (i) tip controlled growth governed by concentration-overpotential limitations and (ii) base-driven growth that occurs due to plastic deformation of lithium. It was concluded

**Fig. 5** (**a**) With increasing electrolyte modulus, mechanical stress-induced reduction in reaction current (blue line), as well as the drop in protrusion height due to plastic deformation of lithium and corresponding impact on reaction current (red line) helps to stabilize the lithium deposition process (net effect shown by black circles). (**b**) Increasing the yield strength of present-day low modulus polymer electrolytes can effectively suppress the lithium dendritic protrusions. (Reproduced from Barai et al. 2017b: Barai et al., *Physical Chemistry Chemical Physics* (2017) **19** 20493 with permission from the Royal Society of Chemistry)
that large hydrostatic stresses and minimal deviatoric stresses are desirable for suppressing dendrite growth (Jana and García 2017). Simulations including a stiff ceramic separator (with elastic modulus in the range of tens of gigapascals) showed severe plastic deformation of metallic lithium and successful suppression of dendritic protrusions (Ferrese et al. 2012; Ferrese and Newman 2014). It was found that plastic deformation of lithium metal was much more important in suppressing the growth of dendritic protrusions than was elastic deformation or the effect of pressure on reaction kinetics (Ferrese and Newman 2014).

All three studies described here, which incorporated plastic deformation of lithium metal, assumed small-strain and linear strain-displacement relations.

However, significant dendrite growth will cause large deformations, violating the usual small-displacement assumption. Hence, it will be necessary to develop simulations that remove this constraint.

## 4.2   Structurally Inhomogeneous Electrolytes

There are other solid electrolytes that show microstructural heterogeneity. Mechanisms of lithium ion transport, plasticity, and fracture of these heterogeneous solid electrolytes can vary significantly (Stephan and Nahm 2006; Kerman et al. 2017), resulting in dendritic protrusions with different growth mechanisms and morphologies. Electrolytes with inhomogeneous microstructures can be broadly divided into two subcategories: (a) solid-state electrolytes that show distinct grain-interior/grain-boundary microstructure and (b) composite electrolytes in which a polymer matrix is reinforced with ceramic fillers. There are few computational studies on dendrite growth within these structurally inhomogeneous electrolytes, which are relatively new candidates for use in lithium ion batteries.

### 4.2.1   Single-Ion Conducting Solid State Electrolytes

In homogeneous electrolytes (both liquid and polymers), diffusion of anions helps lithium ions move through the electrolyte (Stephan and Nahm 2006). However, in ceramic electrolytes, current is carried only by the lithium ions because the anions are immobilized as part of the stable crystalline structure (Kamaya et al. 2011). Some examples of single ion conducting electrolyte are LLZO and LGPS, which are oxide-based and sulfide-based ceramics, respectively. However, for chemical stability, they are often doped with other elements, such as gallium or aluminum (Rettenwander et al. 2016). Ceramic solid-state electrolytes have extremely high elastic modulus values, making them suitable for preventing growth of dendritic protrusions; LGPS and LLZO have elastic modulus values of around 20 GPa and 150 GPa (Kerman et al. 2017), respectively. However, all of the solid-state electrolytes rupture in a brittle fashion under sufficient stress.

The impact of mechanical stress on dendrite growth was derived earlier under the assumption of homogeneous electrolyte (Monroe and Newman 2004). This model was modified to investigate the impact of dendrite growth within ceramic electrolytes (Ahmad and Viswanathan 2017). Significantly decreased partial molar volume of lithium ions within solid-state-electrolytes impacts the dendrite growth process. It was concluded that dendritic protrusions should not grow for electrolytes softer than lithium (Ahmad and Viswanathan 2017). Due to anisotropy in crystal structure, mechanical stiffness tensors are typically anisotropic. It was further concluded that the anisotropic behavior does not affect the overall regime of stability, but rather simply shifts the stability limits (Ahmed and Viswanathan 2017).

An equilibrium-based computational model demonstrated that propagation of slender dendritic protrusions rupturing a path through the solid-state electrolyte is energetically favorable relative to deposition of lithium on the other side of the electrolyte (Porz et al. 2017), which has also been supported by experimental

observations. The brittle rupture phenomena and low magnitudes of fracture energy were suggested as major factors contributing to the easy growth of lithium dendrites within ceramic single ion conductors. Also, the lack of flexibility of the solid-state electrolytes led to delamination at the electrode-electrolyte interface, which can result in high overpotentials.

### 4.2.2 Composite Polymer-Ceramic Electrolytes

The standard polymer electrolytes (such as PEO) possess neither sufficiently high conductivity nor elastic modulus values for sustained operation with lithium metal anodes at room temperature. However, their amorphous regions conduct lithium ions more readily than do their crystalline regions, so elevating the operating temperature above the melting temperature improves lithium ion conduction. Alternatively, ceramic fillers (such as micron-sized or nanometer-sized $Al_2O_3$ or $SiO_2$) are sometimes introduced to produce polymer-ceramic composites with higher conductivity and elastic modulus at room temperature, which inhibits the crystallization of polymer chains (Stephan and Nahm 2006).

Some nanometer-sized filler particles, such as those composed of $SiO_2$, form three-dimensional networks in which anions are immobilized (Schaefer et al. 2013), increasing the transference number of the electrolyte. Tikekar and coworkers constructed a steady-state model of a cell containing an electrolyte region for which mechanical stress was neglected, but with a specified fraction of fixed anions (Tikekar et al. 2014). During deposition at high current densities, they observed steep potential changes and ion depletion near the cathode, which is thought to drive dendrite growth. Increasing the fraction of stationary anions decreased the electric field strength in this region, particularly at high current densities, which was expected to promote stable electrode surfaces.

## 5   Questions

Even though a significant amount of modeling work has been conducted in the past several decades to understand the mechanisms behind nucleation and growth of lithium dendrites, present understanding is far from satisfactory. The fact that no material or strategy has been developed that can completely stabilize the lithium deposition process reflects this remarkable gap in knowledge. Scientists have been able to develop continuum models that can explain the voltage and current profiles observed during the deposition of lithium (Barton and Bockris 1962; Diggle et al. 1969; Motoyama et al. 2015; Wood et al. 2016; Pei et al. 2017). Other computational models based on phase field and Monte Carlo techniques have also been able to predict the evolution of dendrite morphology under different operating conditions (Chen et al. 2015). Unfortunately, these have not led to stable deposition of lithium on metal electrodes. It is important to ask the correct questions to make reasonable technological progress. A few such questions that scientists should focus on for taking the lithium metal anode technology to its next level are provided here.

It is important to recognize that successful commercial implementation of lithium metal anodes requires stable deposition for thousands of charge-discharge cycles. Dendrites may not grow sufficiently large to short the cell during a single charge step. Usually, multiple charge-discharge cycles are needed for a dendritic protrusion to puncture through the separator and short the cell (Stone et al. 2012; Sharafi et al. 2016). Hence, stable deposition for a single charge-discharge cycle may not guarantee dendrite-free operation. However, a majority of the computational studies attempt to model the growth of dendrites during a single deposition process (Monroe and Newman 2003; Ely et al. 2014). Even if it is possible to stabilize the deposition of lithium on top of flat surfaces, nonuniform dissolution of lithium during discharge may lead to development of sites for dendrite growth during the subsequent charge steps (Wood et al. 2016). Focus should be concentrated on not only the first deposition of lithium, but also the later dissolution and plating steps.

A solid-electrolyte-interphase (SEI) develops at the lithium-electrolyte interface as soon as the lithium metal comes in contact with the organic electrolyte. SEI layer compositions are not known exactly (Cheng et al. 2016). The presence of different domains, adjacent to a metal electrode, with variable lithium ion diffusivity and conductivity can lead to nonuniform deposition at the lithium-SEI interface. Arguments have been made that rupture of the SEI layer allows for enhanced deposition of lithium and dendritic protrusions initiate from these regions (Aurbach 2000). On the other hand, it has also been argued that presence of mechanically stiff lithium-fluoride within the SEI layer can stabilize the deposition process for tens of cycles. Hence, the impact of the metal-electrolyte interphase on lithium deposition has not been completely elucidated. How the SEI layer alters the lithium dissolution process is also not clearly understood. Questions exist regarding how the lithium ions and solvent molecules migrate and diffuse through the SEI layer before reacting with the lithium electrode. Proper computational models should be developed to reconcile the effect of the SEI layer on the lithium dendrite growth mechanism.

From an experimental perspective, it has been observed that moss-like structures form during deposition of lithium at small current densities, whereas needle-shaped dendrites evolve during operation at large current (Bai et al. 2016). Dendritic microstructures obtained through computational means do not always correlate well with the experimental observations. For example, phase-field modeling techniques produce linear dendritic structures at low overpotential, and tree-like structures at higher overpotentials (Chen et al. 2015). This seems not to correlate well with experimental observations. Also, other computational methodologies have observed formation of dead lithium even under cathodic overpotentials (Jana et al. 2015), which is very unlikely in realistic situations. Hence, future models should focus on predicting scenarios that correlate more closely with the experimental observations. Another important feature that has not been thoroughly investigated is the crystal orientation of the lithium surface on which deposition occurs. Proper first-principles-based analysis should be conducted to determine the surface energies of different lithium crystal orientations. The propensity of dendrite formation during deposition on different types of lithium crystal surfaces should be appropriately elucidated.

Limited room temperature conductivity has been a major issue preventing widespread implementation of nonliquid electrolytes in commercial devices (Stephan and Nahm 2006). Recent developments have yielded ceramic solid state electrolytes with room temperature conductivity even larger than that of liquids (Kato et al. 2016). However, there are no computational models that analyze the growth of lithium dendrites within ceramic electrolytes. Some phenomenological models have been developed to elucidate the higher propensity of lithium dendrite growth within ceramic electrolytes (Porz et al. 2017). Dissolution of these dendritic protrusions under anodic overpotential should also be thoroughly investigated. Significant questions remain regarding the cycle performance of lithium anodes with ceramic electrolytes, for example, on the impact of grain boundaries and surface flaws on the overall lithium deposition-dissolution process (Kerman et al. 2017). The abilities of polymer-based solid electrolytes to stabilize the electrochemical deposition of lithium should also be investigated further through computational models. Successful dendrite prevention mechanisms can come from computational models if the physical phenomena of nucleation and growth are understood.

# 6    Outlook

Given the advantages of lithium metal anodes, associated with their low electrochemical potential and high gravimetric capacity, next-generation lithium ion batteries should aim to use these anode materials to increase energy density. The largest issues with lithium metal show up in the form of dendrite growth, formation of dead lithium, and continuous decomposition of electrolyte at the solid-electrolyte interphase layer. Computational approaches should take a leading role in devising strategies to solve these problems. Since the success of a computational model depends on the detailed capabilities of the adopted theory, a good understanding of the physico-chemical phenomena is of utmost importance for the development of an accurate theoretical framework. Taking into consideration that several physical phenomena can occur at the lithium-electrolyte interface, such as mass transport, charge balance, heat transfer, and mechanical equilibrium, multiphysics computational models should be developed to successfully predict the lithium dendrite growth process. Furthermore, the physical phenomena observed during growth of a dendritic protrusion span multiple length scales. For example, nucleation of lithium occurs at the nanometer level. The cathode and the anode are usually placed several microns apart in a cell. To cause a short circuit, a dendrite likewise has to grow by several microns to reach the cathode. To capture all the phenomena that occur over multiple length scales, multiscale computational models should be developed.

DFT models have been widely developed and utilized to understand the behavior of lithium and electrolyte separately, as well as at their interfaces. However, these models are capable of predicting only local features at an atomic scale. The number of atoms required to form a lithium dendrite nucleus is also excessively large for prediction using the DFT and ab-initio molecular dynamic (AIMD) simulation techniques. Hence, it is necessary to use either classical molecular dynamics

(CMD) or Monte Carlo (MC)-based computational procedures for understanding the physical phenomena occurring at nano-scale, with properties measured using the AIMD procedures.

On the other hand, well-developed computational techniques exist for modeling the various physical phenomena observed at continuum (or micron sized) length scales. Usually these continuum models have parameters that need to be determined from experiments or lower length scale simulations.

The majority of bulk materials appear to be homogeneous at the continuum level. However, there may be heterogeneities at the micron or submicron length scales, also known as the mesoscale, which are not visible in the continuum level. The DFT/AIMD-based lower length scale simulations are also not affected by these heterogeneities due to their localized nature and provide parameters for perfect crystals. Realistically, these microstructural heterogeneities give rise to higher stress concentrations or current focusing, which leads to the initiation of dendrites and subsequent failure of cells. Successfully bridging these computational techniques applicable at different length scales, through modeling of mesoscale phenomena, is of utmost importance for developing accurate models. Appropriate predictions of features observed at the mesoscale can lift the significance of computational models to the next level. Faster supercomputers with high computational power can also help to bridge the gap between atomistic and continuum length scales through the modeling of physical phenomena observed at the mesoscale.

# Part VIII
# Stochastic, Coarse-Grained Models of Materials Mechanics

# Incorporating the Element of Stochasticity in Coarse-Grained Modeling of Materials Mechanics

# 55

Eric R. Homer, Ying Chen, and Christopher A. Schuh

## Contents

**Abstract**

Materials are, by their very nature, stochastic. Modeling materials across scales requires models that capture this inherent stochasticity. In this chapter, preceding a section on stochastic, coarse-grained models, we examine the elements of stochasticity and coarse-graining and the different implementations of each. Examples of the methods are also briefly discussed.

# 1    Introduction

In a letter to Max Born, Albert Einstein is famously quoted as saying, "Quantum mechanics is certainly imposing ... but does not really bring us any closer to the secret of the 'old one'. I, at any rate, am convinced that *He* is not playing at dice." (Quote obtained from English translation of Born-Einstein letters (1971).) Einstein was dissatisfied with the probabilistic nature of quantum mechanics and spent most of his later years searching for a unified field theory that could provide a deterministic explanation of matter. In spite of his efforts, overwhelming evidence has been presented in favor of the probabilistic mechanics that govern atomic processes. It is clear also that the stochasticity inherent in these atomic processes influences material processes at larger scales.

Consider the structures and processes presented by Tadmor and Miller (2011) in Fig. 1. These structures and processes span numerous time- and length-scales,

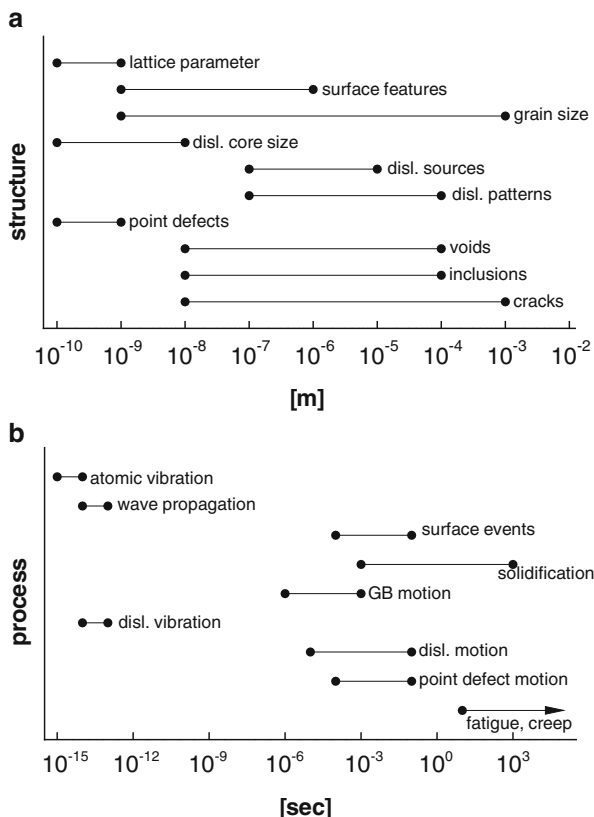

**Fig. 1** (**a**) Length-scales and (**b**) time-scales associated with different structures and processes. (Used with Permission from Tadmor and Miller 2011)

which lead to significant challenges when attempting to model specific materials or processes. Furthermore, the inherent stochasticity of the processes leads to significant challenges in resolving the underlying causes of the behavior. Consider the following behaviors that are influenced by the stochasticity of their underlying collective process:

- Fatigue crack growth: While many of the influencing factors surrounding fatigue cracking are known, crack nucleation and propagation are collective processes that have significant randomness and variability that complicate accurate modeling and prediction (Kozin and Bogdanoff 1989; Ellyin 1997; Beden et al. 2009).
- Strength at small scales: The variability of atomic structure at small scales plays a significant role in the strength observed (Uchic et al. 2004; Packard et al. 2010; Askari et al. 2015). Different microstructural features clearly play a role in this variability, but quantifying the exact influence of each of these features remains a challenge.
- Martensitic transformations: Martensitic transformations in steels and shape-memory alloys are complex, collective processes whose crystallography and influencing factors are fairly well understood. Nevertheless, prediction of which regions transform, and to a lesser extent the variant to which they transform, remains a challenge (Christian 2002; Bhattacharya 2012; Miyamoto et al. 2013).

The above and many more similar phenomena require models that can bridge the so-called meso-scales between atomic-level structure and processes and macroscopic behavior. These models must account for the increased complexity and variability of material behaviors in this range (Yip and Short 2013; Provis 2015) and represent an area of unprecedented challenge and opportunity (Hemminger et al. 2012). This handbook contains three other sections that are focused on bridging this meso-scale divide. These sections include (i) Crystal Plasticity: Atomistics to Macroscale (Cai and Ghosh), (ii) Long Timescale Atomistic Simulations: Accelerated Molecular Dynamics and Adaptive Kinetic Monte Carlo (Perez and Uberuaga), and (iii) Modeling of Microstructure Evolution: Mesoscale Challenges (Stan and Sarrao). Like the techniques presented in this section, these sections also include unique and clever solutions to address the meso-scale challenge.

In this section, we discuss meso-scale modeling approaches that coarse-grain material phenomena. But, in contrast to many meso-scale approaches, we emphasize the inclusion of stochasticity and its critical role in modeling different processes that inherit from the probabilistic nature of matter.

The coarse-graining has the advantage of representing the effective behavior of complex structures in a simpler way; individual atoms and their bonding do not need to be explicitly considered. It also allows modeling of behavior at scales comparable to those employed in experiments.

The stochasticity is incorporated as a result of the fact that so many collective processes in materials appear to behave in a random or probabilistic fashion. Furthermore, many of the processes of interest are infrequent from the perspective

of atomic vibrations. As such, our current understanding and models struggle to explain these processes using deterministic approaches.

In this overview chapter, we detail the coarse-graining and stochastic elements that characterize this class of models that are able to simulate collective phenomena at larger length-scales and on longer time-scales while still accounting for the stochastic nature of the underlying atomic processes. These two elements can be implemented in a variety of ways, and as such, each element is discussed individually. This is followed by a brief summary of implementations of these methods in the chapters included in this section of the handbook, as well as examples available in the literature. Finally, we close with an outlook on stochastic, coarse-grained modeling and discuss challenges and opportunities that exist.

## 2 Elements of Stochastic, Coarse-Grained Models

In defining the uniqueness of these meso-scale models, we find that two components set these models apart. These two components are stochasticity and coarse-graining. In the following sections, we individually discuss the different ways these two elements are often implemented in models.

## 2.1 Coarse-Graining

In all multi-scale modeling efforts, phenomena have to be modeled at different scales in a manner that captures the appropriate behaviors. Coarse-graining is one efficient way of modeling materials at larger length-scales and on longer time-scales. In coarse-graining, atomic behaviors do not have to be considered; instead, their local collective behavior is properly represented in the model with a reduced number of degrees of freedom.

We note the following ways that models frequently implement coarse-graining:

1. Coarse-graining specific objects
2. Coarse-graining regions of material

### 2.1.1 Coarse-Graining Specific Objects

Coarse-graining is often implemented because certain material phenomena are associated with specific structures. For example, many material processes involve material defects, such as vacancies, solute atoms, dislocations, interfaces, etc. In these cases, the behavior of the material is governed by the collective behavior of the atoms in the defect. For example, one can model a dislocation as a line defect rather than the collection of atoms that make up that defect. As such, one can more efficiently model the collective behavior of the defect as an object rather than modeling the individual atomic motions that make up the defect. However, in order to properly capture the physics of the coarse-grained object, it is often necessary to discretize the object on the coarser scale. For example, while treating dislocations

as line defects, dislocation dynamics models usually discretize dislocation lines by nodes or segments; each node or segment can be viewed as representing the collective behavior of atoms making up that segment.

### 2.1.2    Coarse-Graining Regions of Material

In some cases, the material phenomena may not be tied to a specific structure, or the structure may need to be subdivided. For example, in amorphous materials, it is difficult to identify a unit structure for coarse graining. Or in larger defects like grain boundaries or inclusions, one may wish to subdivide the defect into smaller regions. In this case, one can simply coarse-grain a region of material.

When coarse-graining a region of material, one must understand the implications of the length-scale selected. The challenge here is that certain processes that one may wish to model will occur over different length-scales. For example, many processes involve incubation, nucleation, propagation, and growth stages. The nucleation stage can be small while the propagation and/or growth stages involve large regions of material. Coarse-graining can involve multiple scales, but it is usually convenient to pick a single length-scale in order to keep the model simple. Again, the coarse-grained representation of the material may be discretized in the model, and the discretization scheme could change during the simulation to better capture the evolution in material property and in heterogeneous fields. In selecting a region to model any of these processes, one must use care and ensure that the underlying material process is satisfactorily captured; one must determine the ideal balance between resolution and efficiency in modeling.

## 2.2    Stochasticity

As noted in the introduction, many material processes at the meso-scale have collective processes that occur in a random or probabilistic manner. The randomness could be attributed to our incomplete understanding of the physics governing these processes, thereby causing a deterministic process to appear stochastic. The randomness could also be attributed to the underlying probabilistic mechanics of the atoms involved in the collective process. In either case, a stochastic approach to modeling the collective process can both resolve the factors that influence a given process and increase our understanding of the range of behaviors one can expect from a model.

We note the following ways we have observed the incorporation of stochasticity into coarse-grained models, each of which are described in more detail in the sections that follow:

1. Random selection of events from specific probability distributions
2. Deterministic selection of events from specific probability distributions
3. Emerging applications of other methods

### 2.2.1 Random Selection of Events from Specific Probability Distributions

Random selection of events from specific probability distributions is most frequently implemented in Monte Carlo models that utilize Maxwell-Boltzmann probability distributions. These include both standard Monte Carlo (Rollett and Manohar 2005) and kinetic Monte Carlo (Voter 2007) methods.

In these methods, one considers an ensemble of potential states into which the system can evolve. The selection of any given event is accomplished by developing a partition function based on the probability distribution function of interest. As noted, in Monte Carlo methods, the Maxwell-Boltzmann distribution is most commonly used, though other probability distributions can be used (Janssens et al. 2007). Once the partition function is created, the selection of events involves random numbers.

One of the best known applications of Monte Carlo methods is to the kinetic process of diffusion, where particle motions are modeled with a random, or stochastic, walk. Diffusion coefficients can then be obtained from a series of individual atomic jumps (Perondi et al. 1994).

In standard Monte Carlo, a system evolves through equilibrium (often metastable) states, with no knowledge of the transition states separating them. For this reason, time cannot be directly considered, although indirect conversion from Monte Carlo steps to physical time may be attempted by comparing to a known evolution law. While time can be difficult to access by this approach, one gains insight into the most favorable energetic states of the system. Among the many ways to execute this method is the Metropolis algorithm (Rollett and Manohar 2005; Janssens et al. 2007). In this algorithm, a site is selected at random, and then the energy change, $\Delta E$, is calculated for a state change from the starting state to a possible ending state. A random number between 0 and 1 is then compared to the transition probability $\exp(-\Delta E/k_B T)$ based on the Maxwell-Boltzmann distribution. In this probability, $k_B$ is the Boltzmann constant and $T$ is the temperature in Kelvin. If the random number is less than the transition probability, the event is accepted; otherwise it is rejected. This process is repeated over and over to evolve the system. There are different variants of the algorithm for faster execution and for conserved and non-conserved quantities. This type of algorithm has been used to study microstructure evolution extensively.

In kinetic Monte Carlo, a system evolves by consideration of the transition states rather than the equilibrium states. For this reason, time is accessible and one gains insight into the most likely evolution paths. This method typically follows a single implementation and is known as the kinetic Monte Carlo algorithm (Voter 2007). In this algorithm, a system is investigated for all the possible escape pathways that lead out of the current state. The energy change, $\Delta E$, of the transition state relative to the starting state is calculated for all the possible escape pathways. The transition rate $v_o \exp(-\Delta E/k_B T)$ is then calculated for each escape pathway. Note that in contrast to the transition probabilities of standard Monte Carlo, the kinetic Monte Carlo algorithm calculates a rate of successful transitions out of the current state by including a prefactor $v_o$ multiplying the transition probability. The prefactor $v_o$ is an attempt frequency that is typically of the order of the Debye frequency.

The cumulative transition rates, proportional to the partition function, are used to calculate the cumulative probability distribution, from which an event is selected using a random number. The average time for any one of the events to occur is inversely proportional to the cumulative transition rates, but since the probability of executing one of those events in that time interval must be selected from an exponential distribution, the elapsed time is usually selected as $t = -(1/k_{tot}) \ln(r)$, where $k_{tot}$ is the cumulative rate and $r$ is a random number between 0 and 1. This process is repeated over and over to allow the system to evolve by passing through transition states. This type of algorithm is extremely useful for systems with infrequent events.

In both of these cases, random numbers are an integral part of evolving the systems and are used to select events whose probabilities are based on the energetics of the processes of interest.

### 2.2.2   Deterministic Selection of Events from Specific Probability Distributions

Deterministic selection of events from specific probability distributions does not have a normal framework under which it is executed like the Monte Carlo methods do. Instead, these approaches typically use frameworks that are unique to the model and phenomena.

Since each implementation is unique, we briefly describe a basic approach, where local material property values are assigned in a stochastic manner but deformation proceeds based on a deterministic criterion. One such approach was used by Li and Anderson (2016) and is discussed briefly in Sect. 3.2.1. As noted in the introduction, strength at the nanoscale can be highly variable and can therefore be better represented by a strength distribution than a single value of strength (Uchic et al. 2004; Packard et al. 2010; Askari et al. 2015). These strength distributions can adopt some form of a probability distribution as a function of stress. One can use deterministic criteria such as those frequently used in crystal plasticity simulations (Roters et al. 2010) to determine if a given region has reached the condition for yield. But, instead of having each coarse-grained region of the model possess an identical strength value, one can randomly assign strength values as selected from the probability distribution of interest. Thus, strength is stochastically assigned according to a specific probability distribution. However, it is worth noting that we consider this approach to be deterministic selection in spite of the fact that values are randomly assigned. This is because the evolution law is governed by a deterministic comparison of values, and in most cases these values have been randomly assigned at the beginning and do not change during the course of the simulation.

In this way, these models sample physically relevant probability distributions of the property of interest. The models also select each of the events using standard deterministic approaches, and the coarse-grained models evolve accordingly.

### 2.2.3   Emerging Applications of Other Methods

The Monte Carlo methods are certainly the most common implementations of stochasticity in meso-scale models. However, the deterministic selection methods

noted above are increasing in frequency, and there are other methods that are more recently being used to describe the variability and randomness of different processes.

For example, stochastic finite element analysis has been around for some time, and one can use formulations such as polynomial chaos expansion to model the effects of uncertainty and/or variability in model parameters (Ghanem and Spanos 1990). Multi-fractal analysis (Lebyodkin and Estrin 2005) is another technique that uses probabilistic analysis to examine and describe collective phenomena. Random field theory enables modeling of random nonhomogeneous material properties at the meso-scale (Soize 2006; Guilleminot et al. 2009; Kouchmeshky and Zabaras 2010).

These are just a few examples of techniques that can describe stochastic aspects of collective phenomena at the meso-scale. These techniques differ from the two categories noted above for random and deterministic selection of events from specific probability distributions. In both of the categories above, one can point to specific, or discrete, processes that have occurred at any given step. In contrast, the methods noted here are more in line with deterministic methods that incorporate elements of stochasticity and do not deal with specific, or discrete, mechanisms. While different in nature, these methods have notable attributes that make them ideal for modeling some material behaviors and are likely to become more common.

## 3 Implementations of Stochastic, Coarse-Grained Models

This section discusses different implementations of stochastic, coarse-grained models for materials mechanics. We first provide a brief overview of the chapters included in this section of the handbook and the manner in which each implements the elements of stochasticity and coarse-graining. We follow up with a brief overview of other notable examples available in the literature.

### 3.1 Contributions of This Section

#### 3.1.1 Shear Transformation Zone Dynamics Modeling of Deformation in Metallic Glasses

Metallic glasses, also known as amorphous metals, are metallic alloys that have no long-range crystalline structure. As a result, their deformation differs significantly from that of crystalline materials. Metallic glasses exhibit glass-like flow at high temperatures and localized deformation, in the form of shear bands, at low temperatures. The time- and length-scales associated with these behaviors make these materials a challenge to model using atomistic methods or continuum mechanics. In ▶ Chap. 56, "Shear Transformation Zone Dynamics Modeling of Deformation in Metallic Glasses" Li and Homer examine the deformation behavior of metallic glasses using a coarse-grained, kinetic Monte Carlo algorithm. They coarse-grain the system on regions of material, known as shear transformation zones, in which atoms are shown to deform collectively. The kinetic Monte Carlo algorithm is used to evolve the system, where the energetics for the Boltzmann probabilities are based on models for the mechanics associated with shear transformation zones. In their

work they examine the process by which shear bands form, structural factors that influence shear banding, and the manner in which individual shear bands contribute to the overall deformation behaviors that are observed in metallic glasses.

### 3.1.2 Object Kinetic Monte Carlo: A Coarse-Grained Approach to Radiation Damage

Nuclear materials undergo complex processes as a result of the irradiation and accompanying thermal and mechanical conditions. They experience everything from radiation damage, void formation, fission gas generation, and swelling to phase changes, diffusion of species, and chemical reactions with cladding materials. Unfortunately, accurate modeling requires many of these processes to be considered simultaneously. This results in serious challenges when selecting an appropriate modeling technique. In ▶ Chap. 58, "Object Kinetic Monte Carlo (OKMC): A Coarse-Grained Approach to Radiation Damage" by Domain and Becquart examine the radiation damage in nuclear materials using an object kinetic Monte Carlo approach. They model different microstructural features, such as vacancies, voids, and interstitial clusters, as objects. The kinetic Monte Carlo algorithm is then used to control the evolution based on possible material processes. These processes include, among others, vacancy migration and recombination, which are selected from Boltzmann probabilities based on the respective energetics of the process. Using this model they examine the effect of impurities on the evolution of vacancies and ways to model these processes at different scales in combination with atomistic and mean-field approaches.

### 3.1.3 Kinetic Monte Carlo Modeling of Martensitic Phase Transformation Dynamics

Shape-memory alloys, a representative class of superelastic (pseudoelastic) materials, and other materials exhibiting martensitic phase transformations display an interesting ability to accommodate, or impose, deformation through displacive phase transformations. In these materials a high-temperature, austenitic, phase exhibits a different crystal structure than a low-temperature, martensitic, phase. Thus, when a region of the material changes phase, the surrounding material is forced to accommodate the difference in structure, which can be significant. In ▶ Chap. 57, "Kinetic Monte Carlo Modeling of Martensitic Phase Transformation Dynamics" by Chen examines the behavior of a shape-memory alloy using a coarse-grained kinetic Monte Carlo approach. Regions of material are coarse-grained to represent discrete regions that transform collectively. The kinetic Monte Carlo algorithm is then used to evolve the system using Boltzmann probabilities based on the energetics of the phase transformation and accompanying mechanics. The model is used to examine mechanically- and thermally-driven phase transformations, along with their accompanying hysteretic behaviors.

### 3.1.4 The Stochastic Nature of Deformation Twinning: Application to HCP Materials

Hexagonal close-packed (HCP) materials often accommodate deformation using a combination of dislocation plasticity and deformation twinning. Dislocation

plasticity follows well-known laws of initiation and propagation, whereas deformation twinning is less well understood. For example, twin formation appears to be random and is heterogeneous throughout the microstructure. Generating a model that can accurately capture the conditions for nucleation, twin variant selection, and subsequent growth of the twin is challenging. In ▶ Chap. 59, "The Stochastic Nature of Deformation Twinning: Application to HCP Materials" Beyerlein and Kumar examine twinning in HCP materials using a mean-field model that tracks coarse-grained features of a microstructure. Nucleation and growth of twins follow a deterministic law which instigates the various processes as determined from specific probability distributions. The model is used to show that stochastic selection of twin variants more accurately captures experimental observations than alternative approaches. The elements of stochasticity are important in accounting for the large variation of features that impact twinning in HCP metals.

## 3.2 Contributions in the Literature

There are also many notable contributions in the literature and we wish to highlight a few of those here.

### 3.2.1 Quantized Crystal Plasticity Modeling of Nanocrystalline Metals

One recent contribution focuses on dislocation plasticity in metallic alloys. Dislocation plasticity involves the motion and interaction of innumerable linear defects. The mechanics of motion of individual dislocations are well known, but the interaction of large numbers of dislocations remains a challenge. While many methods exist, Li and Anderson (2016) have developed a method where dislocation plasticity is accumulated in quantized amounts. Furthermore, the evolution of the dislocation plasticity is controlled by a deterministic evolution law, but the strengths of coarse-grained regions in the model are assigned from specific probability distribution functions. The model is used to capture several properties of dislocation plasticity that are unique to nanocrystalline metals.

### 3.2.2 Monte Carlo Finite Element Model for Strain Energy Controlled Microstructural Evolution

The formation and evolution of $\gamma'$ precipitates in nickel-based superalloys is a precipitation process that is strongly influenced by strain energy. To model the coalescence of layers, or rafts, of the $\gamma'$ precipitates, Gayda and Srolovitz (1989) developed a combined Monte Carlo-finite element model to include the strain energy in the Monte Carlo energetic calculations. Their model can account for externally applied stresses, surface tension, misfit, elastic inhomogeneity, elastic anisotropies, and temperature. The model shows good agreement with experimentally observed microstructures.

### 3.2.3   A Polynomial Chaos Expansion Based Molecular Dynamics Study for Probabilistic Strength Analysis of Nano-twinned Copper

To demonstrate how polynomial chaos can be used to represent the collective processes of interest in this section, we include this example from Mahata et al. (2016). In their work, they construct a polynomial chaos expansion to represent the influence of twin spacing and twin boundary width on strength in nano-twinned structures. Results from a small number of molecular dynamics simulations are used to construct the expansion, from which a larger variation of parameters is considered. The polynomial chaos expansion model is able to construct robust inferences of parameters that are only partially considered in the molecular dynamics simulations. This approach demonstrates emerging opportunities to incorporate the element of stochasticity into coarse-grained models.

### 3.2.4   Other Noteworthy Publications

Other noteworthy stochastic, coarse-grained models or models with similar approaches have been published. The following list is to illustrate a diversity of applications and methods and is not meant to be comprehensive. These include works by Guilleminot et al. (2009), Kouchmeshky and Zabaras (2010), Talamali et al. (2012), Soize (2012), Zhao et al. (2013), Askari et al. (2015), and Kondori et al. (2018).

## 4   Outlook and Open Challenges

Scientists may one day fulfill Einstein's wish of a unified field theory, but until that day, we must utilize the tools that capture the stochastic nature of materials.

Incorporating the element of stochasticity in coarse-grained models enables collective processes to be modeled in a way that captures their inherent variability, uncertainty, and probabilistic nature. These models are an important part of multi-scale modeling and bridge important length- and time-scales. It is expected that these approaches will fulfill an increasing need as we improve our understanding of quantum and atomistic processes but struggle to apply these to complex systems at the continuum scale. This means that there are a number of open challenges and opportunities that exist. A limited list is included here:

- There are numerous material processes that exhibit stochasticity and may benefit from a modeling approach that accurately captures their inherent nature. A brief list of these include fracture, fatigue crack growth, dislocation interactions with defects, martensitic transformations in steels, and recrystallization. Each of these processes is controlled by well-known energetic processes, but predicting exactly what will happen remains a challenge. Stochastic modeling approaches enable statistics and probabilities to be measured. As a result, new insight can be gained or energetic models can be improved. Furthermore, materials often undergo simultaneous mechanical deformation and kinetic coarsening of grains

and precipitates, both of which are somewhat stochastic processes. Coupled modeling of mechanical and kinetic evolution pathways will be required in order to accurately predict material behavior in many extreme environments.

- Different material processes exhibit different collective processes and probabilities that are best modeled by different approaches. One future area may be to develop coarse-grained, physics-based formulations and determine which modeling approaches are the most efficient or provide the most insight into a given process.

- While stochastic, coarse-grained models are not new, their use has been limited, and they appear to be gaining more attention as computational resources increase in power and capability. Newer applications, like polynomial chaos expansion, are being developed, and newer methods will certainly be discovered. The open challenge then is to determine new methods that allow processes to be modeled more efficiently or discover new methods that enable new material processes to be modeled in a stochastic manner that were not previously possible.

- One other direction that offers tremendous opportunity lies in the integration of these types of stochastic, coarse-grained models in a materials design framework. While the examples are focused on understanding and predicting material response under external stimuli, the models and tools can be further integrated or modified for materials design purposes. While uncertainty in design is gaining increasing interest, integrating variability in design and structure with predictive stochastic models will offer unprecedented opportunity in the design and manufacturing of high-performance materials.

The ultimate benefit of these modeling approaches will be proven by their use and ability to provide new insight into the materials that surround us. We hope the chapters that follow will aid and inspire new approaches and research that keep the community moving forward.

# Shear Transformation Zone Dynamics Modeling of Deformation in Metallic Glasses

# 56

Lin Li and Eric R. Homer

## Contents

## Abstract

A mesoscale shear transformation zone (STZ) dynamics model is presented to investigate the deformation behaviors of metallic glasses that span significant time and length scales. The modeling framework involves coarse-graining STZs, the fundamental deformation unit in metallic glasses, onto a finite element mesh and controlling the stochastic activation of these STZs using the kinetic Monte Carlo algorithm based on the energetics of the glass system. The combination of these two features allows simulating diverse deformation modes of metallic

glasses at large time and length scales while providing a microscopic view of the process that dominates the behaviors. The adaption of the STZ dynamics framework to treat complex phenomena is discussed, including a detailed examination of the shear banding process, simulated contact mechanics, and an examination of the interplay of deformation and structural evolution via the incorporation of a free volume state variable. The chapter concludes with the challenges and future development of the STZ dynamics model.

# 1    Introduction

Metallic glasses exhibit deformation behaviors that are both interesting and challenging to fully characterize. As a result, a complete understanding of this new class of materials requires modeling techniques that can capture the relevant phenomena at the appropriate scales (Rodney et al. 2011; Schuh et al. 2007). The amorphous structures of metallic glasses appear deceptively homogeneous and isotropic when investigated with conventional experimental characterization techniques; the materials don't exhibit typical defect structures, such as dislocation, present in crystalline alloys. Despite the lack of experimental means to directly characterize flow defects, the state of the art in material modeling offers highly accurate methods, from density functional theory and molecular dynamics at atomistic scales all the way up to continuum theories for the deformation of metallic glasses and its connection with amorphous structures.

The deformation of metallic glasses, in particular, the low-temperature shear banding behavior is a typical multiscale phenomenon (Greer et al. 2013), occurring over several length and time scales illustrated in Fig. 1. At the atomic scale, the fundamental units of deformation are atomic rearrangements called shear transformation zones (STZs) (Argon 1979). The STZs are localized both in space, involving only a few tens of atoms, and time, spanning a few picoseconds, which have been captured and extensively studied by atomistic simulations (Falk and Maloney 2010; Rodney et al. 2011). The structural origin of STZs remains elusive, and yet it is believed that the inhomogeneous atomic packing configurations in the amorphous structure lead to a heterogeneous local inelastic response, linking to STZs (Cheng and Ma 2011; Ma and Ding 2016). Figure 1e displays a reconstructed atomic configuration of $Zr_{50}Cu_{45}Al_5$ metallic glasses by hybrid reverse Monte Carlo simulation, revealing a variety of packing clusters including the ideal icosahedron, distorted icosahedron, and face-centered cubic structure. Using molecular dynamics simulations, Ding et al. demonstrate that the regions densely populated with unstable clusters are elastically soft and more susceptible to be STZs (Fig. 1f). Such nanoscale inelastic heterogeneities have been recorded experimentally using dynamic atomic force microscopy (Fig.1b) and nanoindentation (Fig.1c). At the mesoscopic scale, the collective behaviors of STZs lead to various unique deformation phenomena in amorphous materials, such as spontaneous strain localization/shear banding, intermittent dynamics, and power-law distributed avalanches, which receive considerable attention from mesoscale modeling and experiments (Dahmen et al. 2009; Rodney et al. 2011). The connection of these deformation

behaviors to the amorphous structure is beyond short-range orders; the atomic heterogeneities coordinate over a larger scale, translating from the nanometer-scale STZs to their organization into shear bands (Fig. 1g), which usually appear within a few milliseconds and reach a length on the order of a tenth of a micrometer. Finally, at the macroscopic scale, depending on the loading condition, either a single shear band forms as in tension test, or several shear bands form and interact, in case of confined plasticity as in indentation tests, as shown in Fig. 1d, h. The continuum modeling of the deformation behavior of metallic glasses has mostly relied on a flow rule accounting for the evolution of an internal state variable, the free volume, proposed by Spaepen (1977), relating the plastic strain rate to the state of stress and the history of deformation of the glass.

On the modeling front, atomistic simulations are critical in resolving the physics and mechanics associated with individual STZ activations, the nature of STZ-STZ interactions (Falk and Maloney 2010) as well as the incipient stage of shear band

nucleation (Şopu et al. 2017). Unfortunately, the atomistic simulations limit in both time and length scale to simulate the shear banding behaviors at engineering scales. Continuum approaches, on the other hand, can model deformation at engineering scales and provide an ideal comparison to experiments (Su and Anand 2006). However, the presumed constitutive laws can only exhibit phenomena they have been designed to capture, and often the deformation physics that must be introduced is not completely understood. As a result, a mesoscale modeling technique is an important inclusion in modeling the deformation behavior of metallic glasses across the entire spectrum (Rodney et al. 2011), contributing toward a complete understanding of structure-mechanical property relationships in metallic glasses (Hufnagel et al. 2016).

Modeling the amorphous plasticity at the mesoscopic scale, one employs a coarse-grained description of the STZs and accounts for the dynamics of these elementary STZ processes; by averaging out atomistic effects, one can access larger scales in the same way as dislocation dynamics describes crystal plasticity. Rodney et al. have summarized the key ingredients of mesoscale models for amorphous materials, which include a local activation/yield criterion of STZs, an elastic coupling between STZ and amorphous matrix like an Eshelby inclusion, the evolution rule of activation/yield criterion, and a dynamical rule that associates a time scale to the STZ activations (Rodney et al. 2011). Based on the different choices of these rules, the mesoscale models for metallic glasses fall into three categories. First, a depinning model, developed by Vandembroucq et al. (Baret et al. 2002), employs statistical distributions of yield stresses as well as the transformation strains for STZs, driving the evolution of STZs via internal stress arising from the accumulation of Eshelby fields and extremal dynamics. Second, a fluidity model, developed by Picard et al. (2002), uses a constant yield-stress criterion for STZs and incorporates the glassy dynamics based on Maxwellian viscosity through a distribution of characteristic transition rates. Third, an STZ dynamics model (Bulatov and Argon 1994a; Homer and Schuh 2009; Zhao et al. 2013), which is the focus of this chapter, uses an energy-based activation criterion for the STZs and a kinetic Monte Carlo algorithm to evolve the system through Boltzmann statistics.

In this chapter, we discuss the development of the STZ dynamics modeling framework and its applications in various aspects of metallic glass deformation, detailing the techniques used to bridge the relevant time and length scales. In addition, we examine the deformation physics elucidated by this method as well as the mechanics associated with shear banding behaviors.

## 2    STZ Dynamics Modeling Framework

The mesoscale STZ dynamics model treats STZs as the elementary deformation events, and the stochastic activation of the STZs leads to the formation of shear bands at large time and length scales (Homer et al. 2010; Homer and Schuh 2009). This initial development of STZ dynamics framework is inspired by the work of Bulatov and Argon (1994a, b, c). As with Bulatov, the modeling framework

employs two separate elements, coarse-graining and kinetic Monte Carlo (kMC) algorithm, which individually bridge the length and the time scales associated with deformation in metallic glasses. The coarse-graining method centers on the STZ, which consists of a cluster of atoms that exhibit the transient shearing motion consistently in the same manner (Maloney and Lemaître 2004, 2006; Rodney and Schuh 2009; Srolovitz et al. 1983). Then a simulated metallic glass is represented by a system of potential STZs. The coarse-graining enables more efficient sampling of larger system sizes. Meanwhile, to simulate longer system times more efficiently, the transient STZ activation is considered as a transition state between the initial and final equilibrium configurations. Thus, transition state theory (TST) and the kMC algorithm can be employed as long as knowledge of the energetic landscape, including the transition states, is available.

## 2.1 STZ Coarse-Graining with Finite Element Mesh

The STZ coarse-graining is accomplished by replacing the cluster of atoms that represents a potential STZ with a feature of finite element mesh, as illustrated in Fig. 2 (Homer and Schuh 2010, 2009). In this process, three criteria are imposed for proper representation of an STZ using a finite element mesh. First, the coarse-grain representation should approximate the shape of an STZ, which is believed to be roughly spherical. Second, the finite element representation of the potential STZs should allow them to overlap, since the STZ is a transient event and the atoms involved would never be restricted to participate in only one potential STZs. In other words, for a given element, it can participate in multiple STZ activations. Third, the coarse-grained STZ should accurately capture the analytical solution of an Eshelby inclusion (Eshelby 1957). This is supported by the original STZ theory paper, in which Argon modeled the STZ as an Eshelby inclusion (Argon 1979).

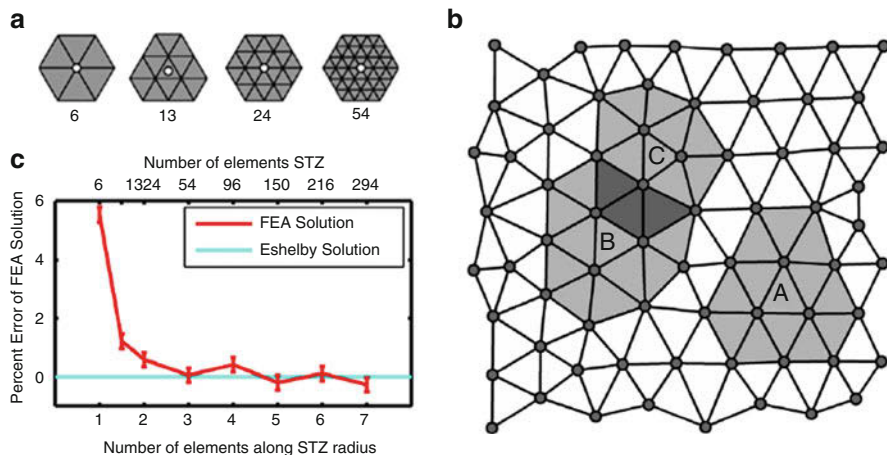
**Fig. 2** Coarse-graining of an STZ (**a**) using features of a finite element mesh in (**b**) 2D or 3D. (Figure adapted with permission from Homer and Schuh (2009, 2010))


**Fig. 3** 2D coarse-graining process. (**a**) Representation of possible STZ definition on the triangular mesh. (**b**) Irregular triangular mesh with 13-element potential STZs highlighted to show how the individual elements in the mesh can be activated by different STZs. (**c**) The accuracy of STZ coarse-graining evaluated by the strain energy difference between finite element method and the Eshelby solution as a function of the size of the STZ (Figure adapted with permission from Homer and Schuh (2009))

Following the three criteria, the implementation of coarse-graining STZs onto 2D and 3D finite element meshes has been achieved (Homer and Schuh 2010, 2009). In 2D, a single STZ is represented by a node and all the surrounding elements or an element and all the surrounding elements on an irregular triangular mesh, shown in Fig. 3a. This representation ensures that the shapes of potential STZs are roughly equiaxed. Furthermore, in this representation, the STZs comprise more than one single element, so that elements in the mesh will be able to participate in multiple STZs. As illustrated in Fig. 3b, three potential STZs, each of 13 elements, are highlighted on an irregular triangular mesh. At any given time step, the elements in the overlap region (between potential STZs B and C) can participate in either event. Finally, the accuracy of the representation is evaluated by comparing to the Eshelby solution for shearing of a long circular fiber in a matrix (plane strain). The percent error of the calculation relative to the Eshelby solution (based on the total system strain energy) is plotted in Fig. 3c as a function of the size of the STZ relative to the mesh. As the results show, convergence is achieved quite rapidly, with STZs containing 13 or more elements exhibiting about 1.5% error or less (Homer and Schuh 2009).

In 3D, a collection of 20–30 tetrahedral elements that all share one common node provides a consistent approximately spherical STZ, as illustrated in Fig. 2b. In this definition, STZs may overlap. When compared with the Eshelby solution, the quadratic tetrahedral element-based STZs are found to provide higher accuracy with the elastic strain energy having 2% error (Homer and Schuh 2010).

The use of a finite element mesh not only enables a coarse-grained description of STZ as a transient flow defect in metallic glasses but also provides flexibility

for further development to incorporate emerging characteristics of STZs. First, one might define an ensemble of STZs with different characteristic volumes. In principle, this could be achieved based on the local size of the elements included in each potential STZ. In this chapter, a single value of volume is assigned to all the STZs in the mesh, but this value could vary with respect to strain rate (Harris et al. 2016) (see Sect. 3.2). Second, the size of STZ activation volume could be related to the level of glass relaxation and damage (Albaret et al. 2016; Boioli et al. 2017) and loading states (Fusco et al. 2010). Adaptive meshing could be used to capture the dynamic evolution of STZ volumes. Third, the elastic response of the system to the STZ transformation strain requires only the use of a linear elastic finite element solver. The use of finite element mesh and finite element solver enables just about any set of boundary conditions regularly used in finite element analysis to be incorporated into the STZ dynamics framework.

## 2.2  STZ Activation Rate

To accomplish the dynamics for longer time scale, the STZ dynamics model considers the coarse-grained STZ activation as a transition state between the initial and final equilibrium configurations, as illustrated in Fig. 4a. The stochastic activation of the STZs leads to deformation on longer timescales. The STZs are thermally activated, and the activation rate is proportional to the Boltzmann probability that the system overcomes the activation barrier between the initial and final equilibrium configurations, defined as

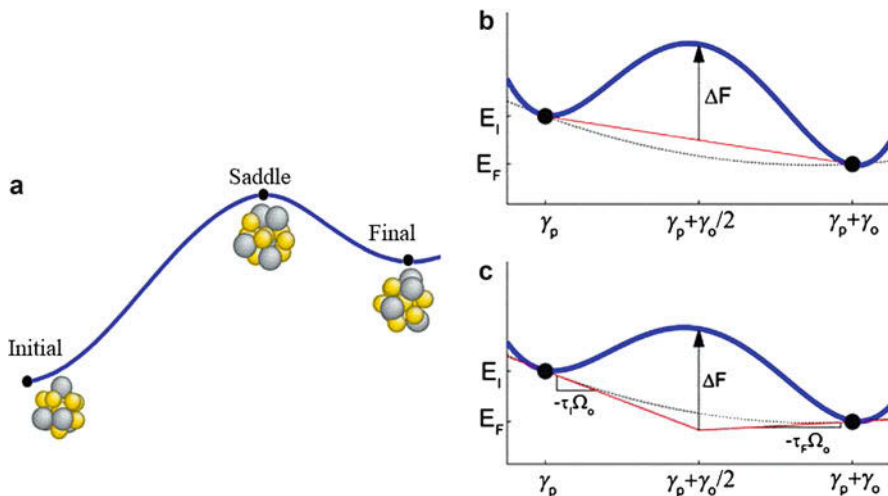

**Fig. 4** (**a**) Illustration of the potential energy landscape and the associated STZ configurations at the initial state, saddle point, and final state. (**b**) Illustration of the traditional approach of identifying the activated state of an STZ. (**c**) The energy landscape model proposed by Bulatov and Argon (1994a). (Figure (**b**) and (**c**) reproduced with permission from Homer et al. (2010))

$$\dot{s} = v_o \exp\left(-\frac{\Delta G}{k_B T}\right) \tag{1}$$

where the prefactor $v_o$ is of the order of the Debye frequency, $\Delta G$ is the activation energy barrier, T is the absolute temperature, and $k_B$ is the Boltzmann constant.

In order to calculate the activation energy barrier for a given transition, one must have knowledge of the transition itself. A traditional approach uses the energy change to model the activation energy, $\Delta G$, by adding a barrier of fixed height, $\Delta F$, to the average of $E_I$ and $E_F$, as illustrated in Fig. 4b. This approach satisfies detailed balance for the reaction because a forward transition traverses the same activated state as the reverse transition.

$$E^I + \Delta G_{I \to F} = E^F + \Delta G_{F \to I} \tag{2}$$

with $\Delta G_{I \to F} = (E^F - E^I)/2 + \Delta F$ and $\Delta G_{F \to I} = (E^I - E^F)/2 + \Delta F$. Unfortunately, this traditional approach of calculating $\Delta G$ requires calculation of the energy in the final state, which is computationally expensive for a large number of possible transitions in metallic glasses.

Bulatov and Argon have provided an alternate formulation for $\Delta G$ by exploiting the fact that the strain energy associated with shearing an STZ is a quadratic function of the transformation strain $\gamma_0$ (Bulatov and Argon 1994a). This quadratic variation in energy, shown as the dashed line in Fig. 4c, can predict the energy in the final state without explicit calculation. Bulatov and Argon simply extrapolate from the initial state, using the slope at that point, to the midpoint of the transition and then add the fixed barrier height, $\Delta F$. The energy difference between the traditional approach and that of Bulatov and Argon is very small (Bulatov and Argon 1994a; Homer et al. 2010). For more detailed explanation, including the requirement of detailed balances, please refer to Homer et al. (2010).

The STZ dynamics framework uses the Bulatov and Argon model and defines the activation energy barrier as

$$\Delta G = \Delta F - \frac{1}{2}\tau \cdot \gamma_o \cdot \Omega_o \tag{3}$$

where the intrinsic barrier height for the reaction, $\Delta F$, is biased by the local shear stress $\tau$, which is obtained by volume averaging the stress over the elements which comprise each potential STZ. The activation volume, $\gamma_0 \Omega_0$, of the STZ is comprised of the transformation strain increment associated with an STZ transformation, $\gamma_0$, and the volume of the STZ, $\Omega_0$. Argon developed a model for $\Delta F$ (Argon 1979), given as

$$\Delta F = \left[\frac{7 - 5v}{30(1 - v)} - \frac{2(1 + v)}{9(1 - v)}\beta^2 + \frac{1}{2\gamma_o} \cdot \frac{\hat{\tau}}{\mu(T)}\right] \cdot \mu(T) \cdot \gamma_o^2 \cdot \Omega_o \tag{4}$$

where the three terms in the brackets define the strain energy associated with shearing of the STZ, the strain energy associated with a temporary dilatation of

the STZ to allow the atoms to rearrange, and the frictional energy associated with the free shearing of the atoms over one another. In the equation of $\Delta F$, $\nu$ is Poisson's ratio, $\beta$ is a ratio of shear to dilatation (usually taken as 1), $\widehat{\tau}$ is the peak interatomic shear resistance between atoms, and $\mu(T)$ is the temperature-dependent shear modulus.

The use of Bulatov's and Argon's energy model allows the STZ dynamics model to explore a large number of transitions without calculating the energy of the final state, resulting in significant computational saving. However, a fixed activation energy barrier would be hard to represent the complex non-equilibrium states in metallic glasses that contain many-body interactions and strong disorder. Methods such as the nudged-elastic band (NEB) (Boioli et al. 2017; Xu et al. 2017) or the activation-relaxation technique (ART) (Fan et al. 2014; Malek and Mousseau 2000; Rodney and Schuh 2009) can be used in atomistic simulations to explore the potential energy landscape and find the exact activation energy barrier from any given equilibrium state. Widely distributed activation energies, depending largely on the processing history, are usually obtained (Rodney and Schuh 2009; Rodney et al. 2011). These atomistic energy barrier search methods are computationally intensive and do not readily translate into mesoscale models. The development of activation energy functional based on the atomistic energy barriers, or their associated features, would be beneficial to enrich the STZ dynamics model.

### 2.2.1 STZ Activation Rate in 2D

The expression for $\Delta G$ given in Eq. 3 defines the energy barrier for an STZ to shear in one direction. Since we are interested in calculating the range of barriers associated with shearing an STZ in any direction in space, the shear stress associated with each unique shear direction must be identified and enumerated.

In 2D, the shear stress for each unique shear direction around a circle can be evaluated using a Mohr's circle construct, which gives the shear stress along any direction of the circle as

$$\tau = \tau_{\max} \sin(\theta) \tag{5}$$

where $\theta$ is the angle to the stress state with stress $\tau$ and which is measured relative to the stress state with the highest principal stress. One can then integrate all shear directions by integrating $\theta$ over the interval $(0°, 360°)$. By combining Eqs. 1, 3, and 5, the integral STZ activation rate becomes

$$\dot{s} = \frac{v_o}{2\pi} \cdot \exp\left(-\frac{\Delta F}{k_B T}\right) \cdot \int_0^{2\pi} \exp\left(\frac{\tau_{\max} \cdot \sin(\theta) \cdot \gamma_o \cdot \Omega_o}{2k_B T}\right) d\theta \tag{6}$$

which evaluates to a modified Bessel function of the first kind, of order zero

$$\dot{s} = \frac{v_o}{2\pi} \cdot \exp\left(-\frac{\Delta F}{k_B T}\right) \cdot I_o\left(\frac{\tau_{\max} \cdot \gamma_o \cdot \Omega_o}{2k_B T}\right) \tag{7}$$

This particular form of the STZ activation rate is convenient because the analytical solution gives the rate for shearing an STZ in any direction in two dimensions with only one function evaluation. One can then use this integral rate in the kMC implementation to determine which STZs are likely to be activated.

### 2.2.2 STZ Activation Rate in 3D

The evaluation of the STZ activation rate in 3D is more complex than the 2D case due to the larger set of possible shear planes and shear directions, as well as the need to only evaluate unique combinations of shear planes and directions. In a generalized form, the integral activation rate can be defined as

$$\dot{s} = v_o \cdot \exp\left(-\frac{\Delta F}{k_B T}\right) \cdot \iiint\limits_{g \,\in\, G} \exp\left(\frac{\tau\,(\sigma,\, g) \cdot \gamma_o \cdot \Omega_o}{2 k_B T}\right) dg \qquad (8)$$

where $g$ is the orientation of any shear plane-shear direction combination belonging to the set $G$ of all unique combinations of shear planes and shear directions. The integral is three dimensional because the specific orientation of a shear plane and shear direction requires three parameters. The shear stress of that orientation $g$ is defined as $\tau(\sigma,\, g)$ to denote the fact that the triaxial stress state that exists in a given STZ must be transformed by $g$ to obtain the shear stress for that given shear plane and shear direction. No analytical solution to the integral in Eq. 8 could be found. The integral is numerically evaluated and tabulated for rapid recall during the modeling process while maintaining an error less than 0.01%. Due to the complexity of this calculation, the details are not discussed here but are available in (Homer and Schuh 2010).

### 2.2.3 STZ Activation Rate with Excess Free Volume as a Local State Variable

The initial implementation of the STZ dynamics framework used a fixed $\Delta F$ for all STZ events. Potentially important effects related to the glass state, e.g., level of glass relaxation and damage, have not been considered. To solve this limitation, local state variables can be included as part of the energetics that describe STZ activations. The purpose of the state variables is to (1) incorporate local activation energy fluctuation that in broad agreement with the widely distributed activation energies of metallic glass and (2) capture the evolution of the structure beyond the redistribution of stress and strain when an STZ is activated. One could choose from a range of state variables, such as atomic stress and strains, topological or chemical order, free volume, and fictive temperature. In the current STZ dynamics framework, a state variable of "free volume" has been implemented (Li et al. 2013, 2014).

The implementation of free volume is based on Argon's original definition of the STZ, in which he includes free volume as a state variable to capture the structural evolution of the system. Particularly, in our adaptation of the STZ dynamics framework, excess free volume, $f_v$, is defined as a normalized quantity where $f_v = 0$ corresponds to no excess free volume above the average polyhedral volume in a

dense random hard sphere glass, while $f_v = 1$ is an upper bound corresponding to a state where an STZ can be activated without accumulating any extra free volume.

The excess free volume influences the energy barrier for STZ activation, and the fixed barrier is modified as

$$\Delta F_{STZ}(f_v) = \Delta F_{shear} + \Delta F_{v0} \cdot g_{stz}(f_v) \tag{9}$$

where $\Delta F_{shear}$ captures the strain energy associated with shear (not dependent upon excess free volume) and $\Delta F_{v0}$ captures the strain energy associated with dilatation and friction of the atoms sliding over each other (dependent upon excess free volume). Equation 9 essentially alters Eq. 4 by recognizing that the first term in the bracket of Eq. 4 is only dependent on shear but not on the magnitude of excess free volume, whereas the last two terms in the bracket of Eq. 4 are dependent upon the magnitude of excess free volume. Furthermore, $\Delta F_{STZ}$ is smaller when greater excess free volume exists since the STZ needs to dilate less and the friction will be lowered. This change in the energy is captured by the function $g_{stz}$, which lowers the activation energy barrier as the excess free volume is increased.

Following a given STZ activation, the excess free volume within the activated STZ is increased since it is believed that the atoms are not able to immediately return to the original magnitude of excess free volume (Li et al. 2013).

In parallel to the activation of STZs, a competing process is introduced as the diffusive rearrangement (and destruction) of excess free volume to capture the effect of structural relaxation in metallic glasses. Following Argon's original model, the rate of diffusive rearrangement is given as

$$\dot{s}_D = (1 - f_v)\, v_D \exp\left(-\frac{\Delta G_D(f_v)}{k_B T}\right) \tag{10}$$

where $\Delta G_D(f_v)$ is the activation energy barrier for diffusive rearrangement, which is dependent upon the current magnitude of excess free volume. Higher excess free volume has a lower energy barrier given that it is farther from the equilibrium state. The quantity $(1 - f_v)$ reflects a decrease of available atomic sites for free volume diffusion as $f_v$ increases. The prefactor $v_D$ for the diffusive rearrangements is of the order of the Debye frequency.

It is noteworthy that the implementation of excess free volume and most other state variables at mesoscale remains phenomenological (Rodney et al. 2011). Metallic glasses do not have structural defects found in crystalline materials, such as dislocations and grain boundaries. The definitions of structural defects in disordered materials are not unique and would require some phenomenological presumptions and fitting parameters. A fundamental understanding is still lacking on the dynamics of inherent glassy structure and its connection with the properties of glasses such as aging or rejuvenation (Fan et al. 2017). It remains difficult to develop parameter-free theories based on defects. Atomistic simulations and experimental measurements at microscopic scale would advance the development of "defect"-level theories and their implementation into the mesoscale model.

## 2.3    Kinetic Monte Carlo Implementation

### 2.3.1    kMC with STZ Activation

Upon calculation of the STZ activation rate, the kMC algorithm (Voter 2007) is used to evolve a system consisting of an ensemble of STZs. In the system, each STZ may experience different local temperature, stress state, and local state when state variables are incorporated. The kMC algorithm proceeds according to the following steps, which are repeated for every transition:

1. Calculate and form a list of activation rates, $\dot{s}_i$, for each of the $i = 1, \ldots, N$ STZs in the ensemble, based on the current state of the system.
2. Calculate the normalized rate $\eta_i$ for each STZ via dividing the individual activation rate by the cumulative activation rate, $\eta_i = \dot{s}_i / \dot{s}_T$, for all STZs. The sum over the normalized transition rates is equal to one, i.e., $\sum_i \eta_i = 1$.
3. Generate two random numbers, $\xi_1$ and $\xi_2$, uniformly distributed on the interval (0, 1).
4. Update the elapsed system time with the residence time for the current configuration calculated according to $\Delta t = - \ln \xi_1 / \dot{s}_T$.
5. Select a single STZ by first defining the cumulative fraction of STZ rates up to and including the rate of STZ $j$ by $H_j = \sum_{i=1}^{j} \eta_i$, and then use the random number, $\xi_2$, to find the STZ which satisfies $H_{k-1} < \xi_2 \leq H_k$. When listed in a successive faction, $\xi_2$ falls on the subinterval in the list of normalized STZ rates, as illustrated in Fig. 5.

**Fig. 5** Schematic of the kinetic Monte Carlo STZ selection procedure. (**a**) How the random number $\xi_2$ can be used to select a single STZ for activation from a list of normalized individual STZ rates, $\eta_1, \eta_2, \eta_3, \ldots, \eta_i$. (**b**) The determination of the overlap, $\eta'$, between $\xi_2$ and $\eta_j$, which selects the angle of shear of the STZ. (Figure reproduced with permission from Homer and Schuh (2009))
6. To select the angle at which to shear the STZ, we first define the value $\eta' = \xi_2 - H_{k-1}$, which represents the magnitude by which $\xi_2$ overlaps the subinterval of the selected STZ, as shown in Fig. 5. The overlap, $\eta'$, is then used to determine the integration limit and further the angle of shear in real space. The detailed explanation of angle selection can be found in Homer and Schuh (2009) for 2D and in Homer and Schuh (2010) for 3D.
7. Apply the appropriate transformation strain to the selected STZ.
8. Calculate the stress and strain distributions and state-variable evolution resulting from the new configuration.

The kMC algorithm can be repeated for an arbitrary number of STZ operations and is efficient because every iteration guarantees a transition. The stochastic nature of the processes will produce a realistic outcome as long as the rate law of the individual event is correct.

### 2.3.2   kMC Algorithm with Competing Processes

The kMC algorithm can easily be adapted to incorporate another type of processes competing with STZ activation to evolve the systems. For instance, after incorporating excess free volume as a state variable, a diffusive rearrangement process is introduced in competition with STZ activation. Upon implementation, at a given kMC step, the transition rates of diffusive rearrangement process will be included in addition to STZ activation to make a list of activation rates in Steps 1 and 2 described in Sect. 2.3.1. In Step 5, either diffusive rearrangement or STZ activation is selected, depending on the subinterval $\xi_2$ falls on in the list of the normalized transition rates. And thus, the two possible processes are exclusive; in each kMC increment, only one of them will be selected. The addition of competing processes is explained in more detail in (Li et al. 2013).

## 2.4   Summary of STZ Dynamics Framework

The STZ dynamics model simulates the stochastic activation of coarse-grained STZs, their elastic interaction leading to organization and accumulation of STZs forming shear bands at large time and length scales. The application of the modeling framework requires several steps to be followed. First, a 2D or 3D finite element mesh is defined to match the geometry of the model material being simulated. Second, potential STZs are mapped onto the finite element mesh based on the coarse-graining criteria discussed in Sect. 2.1. Third, a set of state variables can be assigned on the finite element mesh, influencing the material model and kMC algorithm, as discussed in Sect. 2.2.3. Fourth, implement the kMC algorithm and repeat the following steps:

1. Determine which STZ should be selected for activation, and which shearing angle should be applied, based on the current system state.

**Table 1** Material properties commonly employed by the STZ dynamics framework

| Property/variable | Value |
|---|---|
| Temperature-dependent shear modulus, $\mu(T)$ | $-0.004$ [GPa K$^{-1}$] $\times$ T $+$ 37 [GPa] |
| Poisson's ratio, $\nu$ | 0.352 |
| Debye temperature, $\theta_D$ | 327 K |
| Fixed activation energy barrier, $\Delta F(T)$ | $0.822 \times 10^{-29}$ [J Pa$^{-1}$] * $\mu(T)$ |
| STZ activation volume, $\Omega_o$ | 2.0 nm$^3$ |
| STZ strain, $\gamma_o$ | 0.1 |

2. Impose a characteristic transformation strain to the elements belonging to the selected STZ according to the selected shearing angle.
3. Use finite element analysis to determine the response of the system to the imposed transformation strains.
4. Update the current system state, including stress, strain, and any functional material properties, to reflect the response to STZ activation.

These last four steps involving the kMC algorithm are repeated many times in succession to determine the evolution of the system.

The key material properties and simulation variables used by many of the published STZ dynamics papers are listed in Table 1. The attempt frequency $\nu_o$ is taken as the Debye frequency, which can be calculated from the Debye temperature $\theta_D$. The variables $\mu(T)$, $\nu$, and $\theta_D$ have values for the commonly studied Vitreloy 1 with composition $Zr_{41.2}Ti_{13.8}Cu_{12.5}Ni_{10}Be_{22.5}$ and are obtained from Johnson and Samwer (2005) and Wang et al. (2011b), respectively. Rather than using the complex form of the fixed barrier height in Eq. 4, we reduce $\Delta F$ to a simple functional form that is dependent upon the shear modulus. This functional form is also in line with the cooperative shear model proposed by Johnson and Samwer (Johnson and Samwer 2005). The STZ volume is in the range commonly reported in the literature (Zink et al. 2006), and the STZ strain is equal to the commonly accepted value (Schuh et al. 2007). This list of variables is intentionally kept short to simplify the model and obtain an intended response.

# 3 Applications of STZ Dynamics Model

The STZ dynamics modeling framework provides an opportunity to study many different aspects of metallic glass deformation. Since its original development, the STZ dynamics framework has been adapted for different implementations, including contact mechanics (Packard et al. 2010; Wang et al. 2015) and state-variable free volume evolution (Li et al. 2013; Wang et al. 2015), and for metallic glass matrix composites (Hardin and Homer 2015). In the following section, three applications are chosen to demonstrate:

1. The general behaviors of the STZ dynamics model and the corresponding spatial and temporal correlation of STZ activity that underlies various modes of deformation
2. The physics that control the low-temperature shear banding behavior and how the strain rate influences the shear banding process
3. How nanoindentation can be studied using the STZ dynamics modeling framework to gain insight into nanoscale strengthening in metallic glasses

## 3.1   General Behaviors and STZ Correlations

Metallic glasses exhibit a great variety of deformation behaviors, depending upon conditions (Schuh et al. 2007). The STZ dynamics model is able to capture the general MG behaviors, showing homogeneous deformation at high temperature and localization deformation into the shear bands at low temperature and high stress. A representative 2D model response is illustrated in Fig. 6a. The 3D model can capture the general behaviors as well (for details, please refer to (Homer and Schuh 2010)).

The model response over a range of conditions is well represented by the deformation map for simulation cells subjected to a range of applied stress at various temperatures. An example of deformation map for the 2D model is displayed in Fig. 6b. The regions of homogeneous deformation and inhomogeneous deformation are shaded. In addition, the steady-state strain rate is measured from each simulation, and contours of constant strain rate are overlaid on the map for rates ranging from $10^{-10}$ to $1$ $s^{-1}$. The shading inside each data point presents the strain rate sensitivity. At high temperature, as the stress is increased, the strain rate sensitivity decreases from unity toward zero, reflecting a transition from Newtonian flow to non-Newtonian flow. These are the rheological behaviors that metallic glasses exhibit at high temperature. At low temperature, when stress is low, the strain rates are lower than $10^{-10}$ $s^{-1}$, which we consider to be "elastic" deformation as the inelastic behaviors would be too slow to be captured in experiments. When the stress is high at low temperature, the strain rate sensitivity is extremely low; in other words, the flow stress is nearly the same for various strain rates. This is a consequence of the formation of shear bands, the details of which will be discussed in Sect. 3.2. The deformation map compares favorably with experimental deformation map, in that it captures the basic features of metallic glass deformation (Schuh et al. 2007).

Underlying the diverse deformation behaviors is the different spatial and temporal correlation of STZ activity. Analysis of the 2D simulations of STZ correlations provides significant insight, represented by the time-dependent radial distribution functions (TRDFs), given as

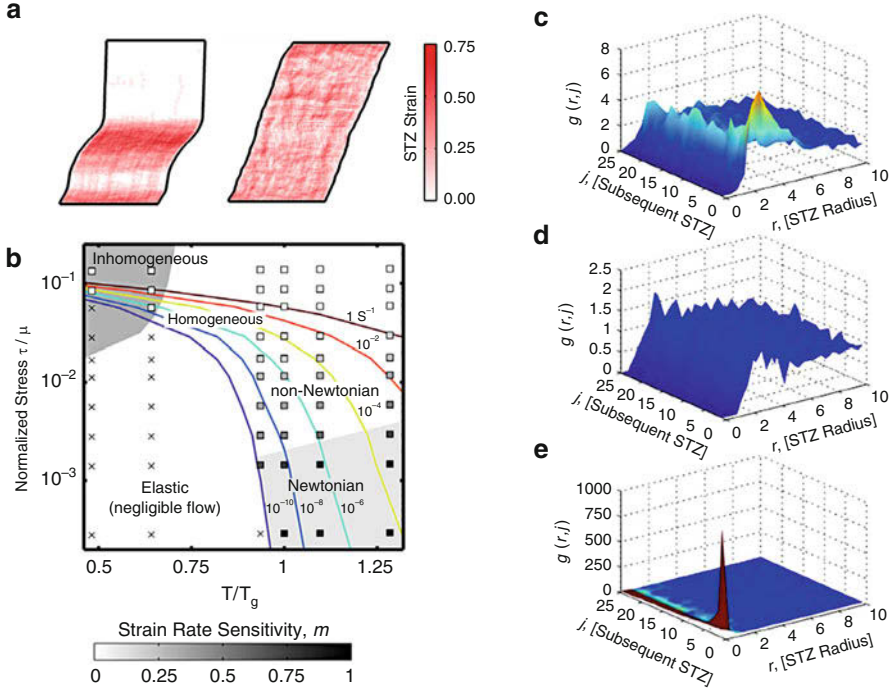
$$g\left(r, j\right) = \frac{n\left(r, j\right)}{q(r)} \tag{11}$$


**Fig. 6** (**a**) The representative responses of the STZ dynamics model at high and low temperatures in 2D. (**b**) Deformation map for Vitreloy 1 constructed from data obtained by 2D STZ dynamics simulations. The STZ correlation behaviors represented by the TRDFs of STZ activation, where the three behaviors and their corresponding conditions are (**c**) nearest-neighbor STZ activation (high stress and low temperature), (**d**) independent STZ activation (high stress and high temperature), and (**e**) self-STZ activation (low stress and any temperature). (Figures adapted with permission from Homer et al. (2010); Homer and Schuh (2009))

where $n(r, j)$ is constructed by binning the number of sequential activations as a function of radius $r$ and time step $j$ and $q(r)$ is a normalization quantity in each bin with the size $dr$, defined as

$$q(r) = \begin{cases} 1 & if \ r \leq \frac{1}{2\pi r dr \rho_{STZ}} \\ 2\pi r dr \rho_{STZ} & if \ r > \frac{1}{2\pi r dr \rho_{STZ}} \end{cases} \tag{12}$$

where $\rho_{STZ}$ represents the overall density of STZ activations, i.e., the total number of STZ activations per unit area. The TRDFs' functions indicate the likelihood of shearing an STZ at nearby position and after a certain number of steps relative to a given STZ activation; magnitudes less than 1 are less likely to occur at a given position and time than if it occurs randomly throughout the simulation cell, and magnitudes greater than 1 are more likely to occur at a given position and time than if it occurred randomly throughout the simulation cell.

The TRDF reveals three basic types of behavior that manifest under different combinations of applied stress and temperature as shown in Fig. 6c–e.

- Nearest-neighbor STZ activation, which is observed for simulations at low temperature and high stress in Fig. 6c. This behavior is characterized by an early, broad peak, spanning $r = 1$–$5$, centered between 2 and 3, indicating the preference for nearest-neighbor activation. This correlated behavior is the source for the shear localization that underlies the macroscopic shear bands observed in experiments.
- Independent STZ activation, which occurs under conditions of high applied stress and high temperatures in Fig. 6d. In this behavior, the TRDF shows no preference for reactivation of STZs atop the first one, since $g(r, j) \sim 0$ at r < 1. Furthermore, the tendency for activation of neighboring STZs is lost; there is no longer a discernible peak in the TRDF. There is no noticeable correlation between STZ activations. As expected, the additional thermal energy cancels the effect of stress concentration that might otherwise cause shear localization. Consequently, the uncorrelated STZ activation leads to homogeneous deformation.
- Self-STZ activation, which dominates at low applied stress and any temperature. As illustrated in Fig. 6e, the TRDF exhibits an extremely pronounced and sharp peak at $r = 0$ and for early time ($j < 4$). The spatial extent of the peak is limited to $r \leq 1$, indicating a large preference for a second STZ activation atop the first. The self-STZ activation is linked to the elastic regime. At low temperatures and low stresses, there is an insufficient tendency for a single STZ to trigger nearest-neighbor activations; thus, the most likely response of the system is for each STZ activation to be instantaneously reversed.

The STZ dynamics model can not only capture the MG deformation behaviors at the macroscopic level, matching the experimental behaviors, but also provide insights at a microscopic level on how STZs interact with one another and how their collective operation leads to the deformation on a macroscopic level. These types of studies demonstrate the strength of a mesoscale model that successfully coarse-grains a process and determine the transitions that control the evolution of the system.

## 3.2 Shear Banding Process at Low Temperature

Among the diverse deformation modes exhibited by metallic glasses, the low-temperature shear banding behavior is of the greatest interest. The limited ductility due to the formation of a catastrophic shear band before failure is the primary issue that hinders the wide application of metallic glass as a structural material (Greer et al. 2013; Schuh et al. 2007). The STZ dynamics model can provide modeling details into the formation of the shear band, which remain unresolved due to the difficulty in accessing the appropriate time and length scales experimentally.

One can study the shear localization process into one shear band in detail (Homer 2014). Snapshots of a 3D simulation cell subject to constant strain rate, uniaxial tension test are shown in Fig. 7. Examination of the simulation results reveals five different stages in the microscopic processes:

(I) Purely elastic, with no STZ activity
(II) STZ clustering, where correlated STZ activations lead to the formation of clusters
(III) Growth following nucleation of a shear band, where all STZ activity transitions from being distributed throughout the simulation cell to being concentrated in the shear band
(IV) Relaxation thickening, which is manifest by the continued thickening of the shear band while the stress is still dropping even after it has propagated across the simulation cell
(V) Flow thickening, which is indicated by the continued thickening of a single shear band at a constant flow stress

Most of the plastic strain is accumulated during the sliding process, indicating that nucleation and initial propagation of a shear band are very brief. Analysis of a thermodynamic model also suggests a specific yield stress that is required to nucleate a shear band, after which the shear band is allowed to grow unconstrained.

In addition to the individual shear band, the STZ dynamics model has been adapted to investigate a collection of shear band events, which leads to the transition in flow serration in the inhomogeneous deformation regime. An interesting deformation phenomenon associated with metallic glass is that the shear band density and degree of flow serration are highly strain rate dependent, though the yield point of these materials is often independent of strain rate for rates up to $10^2 \sim 10^3$ s$^{-1}$ (Schuh et al. 2007, 2004). Low strain rates are characterized by strongly serrated flow, meaning that strain accumulates in the material in temporal bursts accompanied by relaxation stress drops resulting in a jagged stress-strain curve (Dalla Torre et al. 2010; Song et al. 2008). Higher strain rates are characterized by moderately serrated flow, and very high strain rates have little or no flow serration. The mechanisms that underlie the transition are hypothesized to be the competition between shear band nucleation and propagation (Schuh et al. 2004).

The STZ dynamics framework exhibits a yield point that is inherently rate dependent. To correct for this and make the yield point rate independent, the STZ dynamics model is extended to incorporate a strain-rate-dependent STZ volume and activation energy, given by the following log-linear forms:

$$\Omega_0 = -0.2\log_{10}\dot{\varepsilon} + 1.6 \quad \left[\text{nm}^3\right]$$
$$\Delta\text{F} = -0.12\log_{10}\dot{\varepsilon} + 1.07945 \quad [\text{eV}] \tag{13}$$

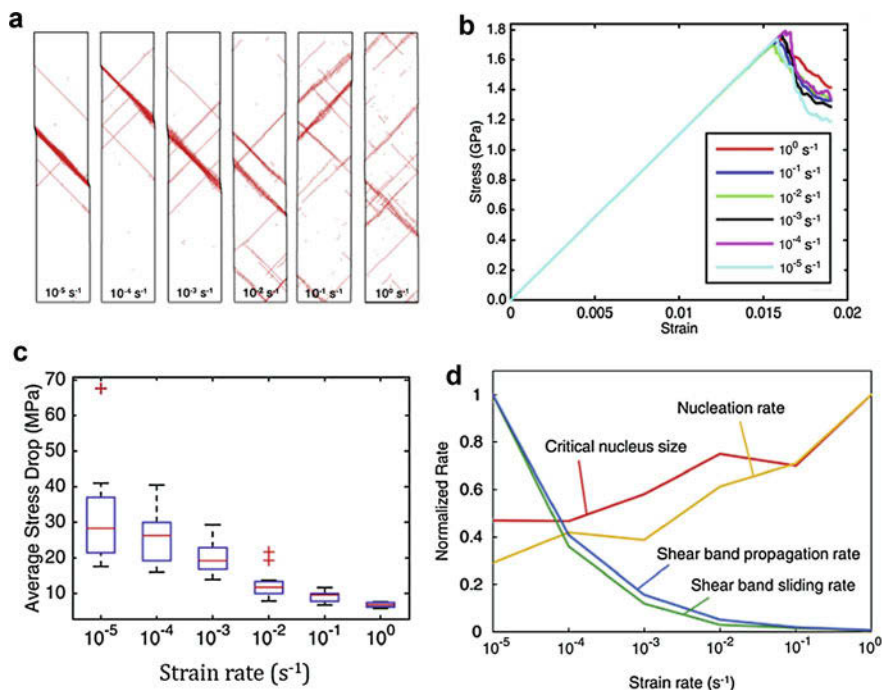
This parameterization of STZ volume and STZ energy barrier as a function of strain rate is not unique but aims to capture physical mechanisms of STZs (Dubach et al. 2009; Harris et al. 2016). The physical origin of the strain rate dependence
**Fig. 7** Shear localization process into one shear band. Numbered snapshots of the model metallic glass at various times during a constant strain rate, uniaxial tensile simulation. Each snapshot includes a semitransparent top and side view of the simulation cell. The evolution of the shear band is divided into four different stages following the initial elastic response. (Figure reproduced with the permission from Homer (2014))


**Fig. 8** (**a**) Example simulations at various strain rates. Note the clear trend of increased shear band density with strain rate, and the increased appearance of free STZs at higher strain rates. (**b**) Stress-strain curves for the six simulations shown in (**a**). (**c**) Box plot of the average stress drop magnitude in each simulation, arranged by strain rate. (**d**) The comparison of median values of the normalized shear band nucleation rate (yellow), shear band propagation rate (blue), and shear band sliding rate (green). (Figure reproduced with permission from Harris et al. (2016))

remains an open question, possibly contributing to the time-dependent structural relaxation (Dubach et al. 2009) or a kinetic feature of the atomic motions associated with an STZ.

A transition of shear band density and morphology is captured by the model with increasing strain rate from $10^{-5}$ s$^{-1}$ to 1 s$^{-1}$. Figure 8a shows a group of six simulations, one from each strain rate studied, with increasing strain rate from left to right. Each simulation is at the final strain value of 1.9%. In general, low strain rates result in fewer, more dominant shear bands, with very few free STZs scattered outside the bands, while high strain rates feature larger numbers of less dominant shear bands, with many free STZs randomly scattered outside the bands. The corresponding stress-strain curves for these six simulations are displayed in Fig. 8b, showing a tightly grouped yield strength around 1.72 GPa. While the yield strengths are similar, low strain rates tend to relax more quickly after yield and have a lower flow stress than high strain rates. Examination of the flow serration regarding stress drop after yielding shows a negative correlation with strain rate (Fig. 8c). This

is in line with the experimental observations: strongly serrated flow at low strain rate and moderately serrated flow at higher strain rate.

Further study of shear band nucleation rates, propagation rates, and sliding rates in each simulation shows a transition from propagation-dominated shear banding at low strain rates to nucleation-dominated shear banding at high strain rates. A summary of the different statistics and their strain rate dependence is illustrated in Fig. 8d, where each rate has been scaled so they can be compared side by side. The underlying cause for the flow transition is hypothesized to be a strain-rate-dependent critical shear band nucleus size that increases with increasing strain rate (Harris et al. 2016). This is best illustrated by examining the stages of shear banding (ref. to Fig. 7). In the nucleation stage (II), STZs appear and begin to cluster into shear band nuclei, which grow and proliferate in the absence of a dominant shear band. If the strain rate is low, then a small critical nucleus size means that the growth stage (III) is reached quickly, and one shear band rapidly propagates across the sample and begins to dominate all plasticity in the sample. Then, in the sliding stage (IV and V), additional plasticity is concentrated in bursts on that dominant band. If instead the strain rate is high, then a large critical nucleus size means that the growth stage (III) is delayed, or skipped entirely, and plasticity continues to be accommodated by nucleation of additional shear band nuclei in the nucleation stage (II). Then sliding stage (IV and V) occurs more gradually as shear band nuclei begin to intersect each other, and plasticity remains relatively diffuse.

In essence, the STZ dynamics model provides insight into the shear banding process, contributing toward a better picture incorporating both kinetic and thermodynamic nucleation criteria of shear band formation. These types of studies demonstrate the strength of mesoscale models in elucidating the micromechanics behind the macroscopic process. Some of these features would be difficult to observe by other techniques.

## 3.3   Nanoscale Strengthening Subjected to Cyclic Nanoindentation

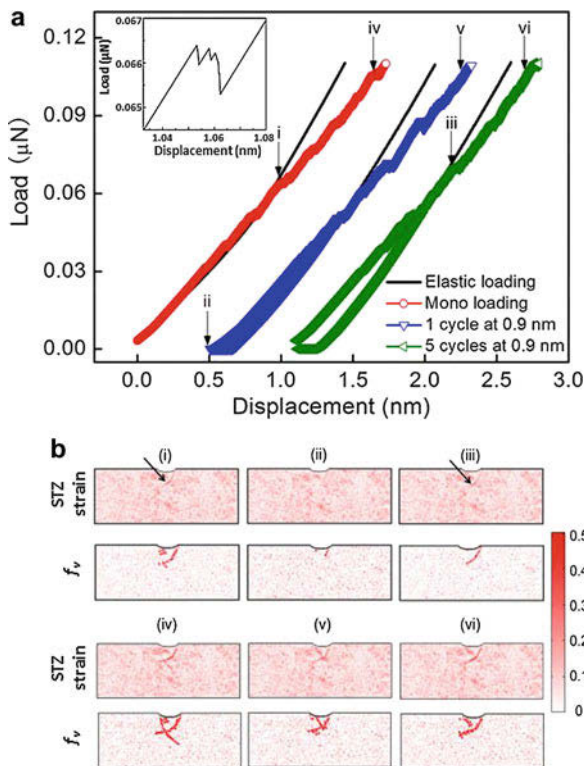
Metallic glasses exhibit a broad range of interesting phenomena due to the inherently complex non-equilibrium states, one of which is that they can exhibit nanoscale strengthening subjected to cyclic nanoindentation in the elastic regime. This has been demonstrated in nanoindentation experiment, showing a statistical increase in strength as a result of cyclic loading at a magnitude before the first significant plastic event (e.g., shear band), signified by a pop-in on the load-displacement curve (Packard et al. 2010, 2008). Interestingly, the cyclic strengthening can only occur if the cycling is of a sufficient magnitude, if the indenter is actually cycled (holding a constant load of equal magnitude and time does not lead to strengthening), and the strengthening saturates after a finite amount of cycles.


**Fig. 9** Simulated nanoindentation results for various loading conditions. (**a**) Load-displacement curves for the monotonic loading, one-cycle and five-cycle loading with the cyclic depth of 0.9 nm. Vertical arrows indicate the points: (i) at the yield of the monotonic loading; (ii) at the reload after the first cycle; (iii) at yield after the five-cycle loading; and (iv), (v), and (vi) at a post-yield load of 0.1 μN for the three loading conditions. The origin of the one-cycle and five-cycle loading curves are shifted for a clear view. The inset shows an enlarged view of load drops around (i). (**b**) The snapshots display the spatial distribution of STZ strain and excess free volume $f_v$ at points (i–vi). Black arrows denote the STZ strain accumulation at (i) and (iii). (Figure reproduced with permission from Wang et al. (2015))

To elucidate the underlying mechanisms that cause the strengthening, the STZ dynamics framework is adapted by including contact mechanics in the finite element analysis solver (Packard et al. 2011, 2010). Furthermore, the model incorporates excess free volume as a state variable, to study the interplay of glass deformation and structural evolution under cyclic indentation tests at an experimentally relevant time scale (Wang et al. 2015).

Results from simulations under various loading conditions are illustrated in Fig. 9. For a clear view, the origins of the load-displacement curves with cyclic loading are shifted to the right. In Fig. 9a, from left to right, the three curves represent the monotonic loading, one-cycle and five-cycle loadings with the cyclic depth of 0.9 nm, respectively. The yield point of each test is indicated by an

arrow, identified by an applicable deviation from the elastic response. The yield load increases with the number of cycles, and after five cycles, it is ∼ 10% higher than that of the monotonic response, which is consistent with the nanoscale cyclic strengthening observed experimentally. Additionally, the snapshots of the spatial distributions of STZ strain and excess free volume at several critical moments are displayed in Fig. 9b. The accumulation of excess free volume can be clearly observed at (i) and (iii), indicating extensive STZ activity prior to the yield point. The cyclic loading can lead to structural change reflected by the annihilation of excess free volume. In a comparison of excess free volume distribution at (i) with (iii), the cluster on the top left in (i) almost disappears after five cycles in (iii). This decrease of excess free volume after cyclic loading gives rise to the mechanical strengthening as a consequence of removal of mechanically weak sites.

The nanoindentation simulation has further been used to detect the cause of nanoscale strengthening subject to cyclic loading. For instance, Fig. 10a displays the cumulative distribution of the yield loads at ten different indentation locations for monotonic and cyclic loadings after one, three, and five cycles, at the cyclic depths of 0.9 nm. Notably, there exists a large distribution of yield loads for monotonic loading, e.g., the minimum yield load is about half of the maximum one. Further, as the number of cycles increases, the distribution curves become sharper and shift to the right particularly at the lower tail, indicating that the "weak" samples are strengthened during cyclic loading. Such effect could be contributed to the removal of the residual stress (Wang et al. 2011a), structural relaxation (Pan et al. 2009), and the arrest of the shear band (Yang et al. 2006). With excess free volume as a state variable, the STZ dynamics simulations demonstrate that the strengthening is directly related to the decrease of large excess free volume sites. When the loading cycles increase from 0 (i.e., monotonic) to 5, the excess free volume is reduced progressively, signified by a left shift of the distribution curves shown in Fig. 10b.

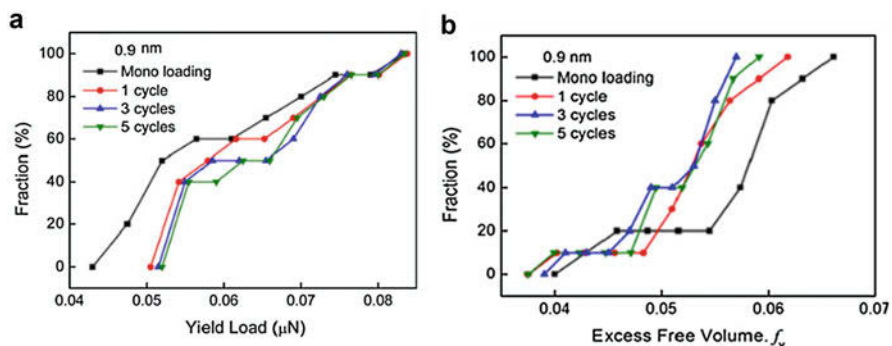

**Fig. 10** (**a**) Cumulative distributions of the yield loads for monotonic loading, and various cyclic loadings after one, three, and five cycles at the cyclic depth of 0.9 nm. (**b**) Cumulative distribution curves of the excess free volume $f_v$ in a selected region for monotonic loading and various cyclic loadings after one, three, and five cycles at the depth of 0.9 nm. (Figure adapted with permission from Wang et al. (2015))

The reduction of excess free volume has been ascribed to the observed cyclic strengthening, since it results in a reduced rate of microplastic events by increasing STZ activation energy. Additionally, the left shift becomes less pronounced after one cycle and saturates after five cycles, which is consistent with the saturation of the strengthening effect. Overall, the STZ dynamics simulations indicate that the energetics and timescales of STZ activity are plausible as a mechanism to cause structural evolution that is consistent with nanoscale strengthening.

The application of a mesoscale technique to investigate the nanomechanics of experiments indicates the strong potential to elucidate phenomena that are difficult to measure by experimental techniques.

## 4    Conclusions and Outlooks

The STZ dynamics model, combining a coarse-grained approach and the kMC algorithm, provides a useful framework to investigate the deformation behaviors of metallic glasses. On the one hand, the coarse-graining enables collections of atoms, or STZs, to be tracked; on the other hand, the kMC algorithm allows the stochastic activation of these STZs based on the energetics of the system. The combination of these two features enables the simulation of deformation behavior at larger time and length scales while preserving a microscopic view of the processes that dominate deformation.

The STZ dynamics model has been used to investigate the deformation behaviors of metallic glasses in a variety of conditions. The modeling technique captures the overall deformation behaviors expected of metallic glasses and the underlying spatial and temporal correlations of STZs that contribute to different deformation modes. The mesoscale model provides details into the formation of individual shear band and the collection of shear band events which leads to the transition of flow serration in the inhomogeneous deformation regime. Insights into nanoindentation experiments are possible through the contact mechanics adaptions. The interplay of deformation and structural evolution is accessed via the incorporation of a free volume state variable.

The STZ dynamics framework will continue to be useful in the investigation of the mechanical behaviors of metallic glasses. Many challenges remain for further development, which includes, among others:

- *Activation energy functional:* The development and implementation of activation energy functionals that more accurately capture the nature and variability of disordered glassy structure and the structural dynamics of metallic glasses.
- *Failure mechanisms:* The failure of metallic glasses involves the strain softening, adiabatic heating, cavitation, and crack formation in shear bands. One could incorporate heat and mass transfer constitutive relations that are capture conditions leading up to failure. One could also include an additional stochastic process for cavitation that precedes crack formation. Finally, once a crack is

initiated, one could model the crack propagation using standard finite element techniques.

- *Adaptive coarse-graining:* Since the scales of STZs and shear bands are different, one could use adaptive meshing to optimize the simulations. Depending on the nature of what is happening, one could coarsen or refine a mesh. For example, after a shear band appears, one could deal with groups of STZs instead of dealing with individual STZs. Mesh refinement/remeshing may be geometrically challenging but can be handled in practice with the use of advanced adaptive meshing algorithms available in finite element packages. Mesh coarsening could also be handled but would require the knowledge of the dynamic evolution of STZ activation volume.

- *Large-scale simulations:* While powerful, current implementations of the STZ dynamics framework are limited in their ability to simulate large structure. A parallel, distributed memory implementation of the STZ dynamics modeling would significantly increase the size of systems that can be examined by the technique. In particular, a different implementation might allow the use of high-performance computing systems. Large-scale simulations would help answer questions about shear banding phenomena beyond the initial stage of shear band formation, which is essential to directly connect with metallic glass toughness and failure at the macroscopic scale.

## Contents

### Abstract

Martensitic transformation is, on the one hand, a pervasive deformation mechanism in both structural and functional materials, and on the other hand, a first-order phase transition that is diffusionless. The transformation from one crystal structure to another takes place by a volumetric change and a large shear. As a result, modeling of the martensitic transformation process requires an integration of thermodynamic, kinetic, and mechanical considerations. Moreover, the transformation process is intrinsically stochastic. Not only is there a competition between nucleation and propagation modes, but there are also

competitions among different ways of transformation and different regions for transformation. In this chapter, an integrated thermodynamic and Kinetic Monte Carlo (KMC) treatment of martensitic transformation is presented. Modeling martensitic transformation as a unit process, the free energy function for potential transformation of each unit is determined. Stress and strain distributions are predicted by the Finite Element method after each unit transformation and are incorporated in the free energy function. A KMC algorithm that incorporates the free energy function in the rate formula is invoked to select a unit to transform and advance the time. The modeling formulation is described in detail, so is the simulation algorithm. Examples of transformation dynamics modeled by this method will be shown.

## 1    Introduction

Martensitic transformation is a solid-state, diffusionless, and displacive phase change that typically involves conversion between different crystal structures (Otsuka et al. 1979; Wechsler et al. 1953). It is common that the austenite phase (which is sometimes also referred to as the parent phase) has a higher symmetry (e.g., the most common symmetry for austenite is cubic, such as B2, D0$_3$, and L2$_1$ crystal structures), while the martensitic phase has a lower symmetry. Reversible martensitic transformations are commonly observed in Shape Memory Alloys (SMAs) such as Ti-Ni, Cu-Al-Ni, Ni-Mn-Ga, Co-Ni-Al, and Fe-Pd (Lagoudas 2008). SMAs can respond promptly and repeatedly to thermal, mechanical, and combined stimuli and switch between two different shapes under thermal or mechanical cycling (Karaca et al. 2007; Otsuka and Wayman 1998; Tadaki et al. 1988). Many ceramics also undergo martensitic transformation, such as tetragonal to monoclinic in zirconia, cubic to tetragonal in lead titanate, and cubic to tetragonal in cristobalite (Kriven 1995). Martensitic transformation is also an important deformation mechanism in many structural metals, such as steels (Tao et al. 2007) and titanium alloys (Jaworski and Ankem 2005). This chapter mainly discusses modeling of reversible martensitic phase transformations in shape memory alloys and ceramics, which can be adapted for irreversible transformation.

Computational models for reversible martensitic transformations are relatively rare. There are several molecular dynamics studies (Guda Vishnu and Strachan 2012; Kastner et al. 2011; Tatar and Kazanc 2012; Zhong et al. 2012), but the length (e.g., 10-30 nm) and time (e.g., nanoseconds) scales accessed are not directly comparable to those (e.g., hundreds of nanometers (Ozdemir et al. 2012) to micrometers in size and milliseconds (Juan et al. 2009) to minutes in time) in most experiments. There are also a number of finite element (Gall et al. 2000; Gall and Sehitoglu 1999; Lagoudas et al. 2012; Manchiraju and Anderson 2010; Manchiraju et al. 2011; Patoor et al. 1995; Wood and Clyne 2006) and phase field (Jin et al. 2001; Levitas et al. 2009, 2013; Mamivand et al. 2013, 2014) models, which can incorporate larger scales but generally tend to lack connections between simulated scales and those intrinsic to transformation. Moreover, the inherent

variability in martensite nucleation and growth and dependence of such variability on microstructure have rarely been taken into consideration in these prior models.

Kinetic Monte Carlo (KMC) is a stochastic modeling method widely used to model microstructure evolution. It has also been used to simulate deformation in amorphous solids which is treated as a stochastic sequence of local inelastic distortions in a lattice model (Bulatov and Argon 1994a, b, c) or a continuum model (Homer et al. 2010; Homer and Schuh 2009). Compared to shear-dominant deformation in amorphous solids mentioned above, martensitic transformation is subject to crystallographic and thermodynamic constraints. In this chapter, a KMC model that treats martensitic transformations as a sequence of stochastic unit processes (Chen and Schuh 2015) is described.

## 2  Model Overview

The stochastic physics-based modeling framework for reversible martensitic transformation (Chen and Schuh 2015) integrates thermodynamic description of transformation, kinetic Monte Carlo (KMC) treatment of phase evolution, and Finite Element Method (FEM) modeling of stress and strain distribution. A thermodynamic energy landscape description of austenitic and martensitic states which governs the transformations is examined in Sect. 3. Section 4 describes how the onset and progression of the transformations are controlled by KMC using a transition-state rate equation that incorporates local thermomechanical state. KMC modeling includes a physical timescale for transformation, enabling the exploration of stochastic transformation dynamics. In Sect. 5, FEM modeling procedures are provided. FEM is utilized to apply the displacive transformations and predict mechanical state everywhere in the material, which allows the local state to affect the transformation sequence. Section 6 discusses some considerations for computational implementation of the model and shows some examples.

The model offers the following unique capabilities: (i) capturing transformation stochasticity, (ii) predicting the evolution in spatial distributions of phases and stress/strain, (iii) predicting transformation process based on energetics incorporating local thermomechanical states, (iv) using a physical time scale and a microstructure length scale, and (v) predicting two-way (i.e., reversible) transformations between austenite and martensite phases.

## 3  Thermodynamic Energy Landscape for Martensitic Transformation

In the following, subscripts of "A" and "M" are used to denote properties of austenite and martensite, respectively. The Gibbs free energies $G_A$ and $G_M$ for austenite and martensite per unit volume as a function of temperature $T$ are illustrated in Fig. 1a. When there is no external stress, $G_A = G_A^{ch} = H_A - T S_A$

**(a) Energy-Temperature Diagram**

**(b) Stress-Temperature Diagram**

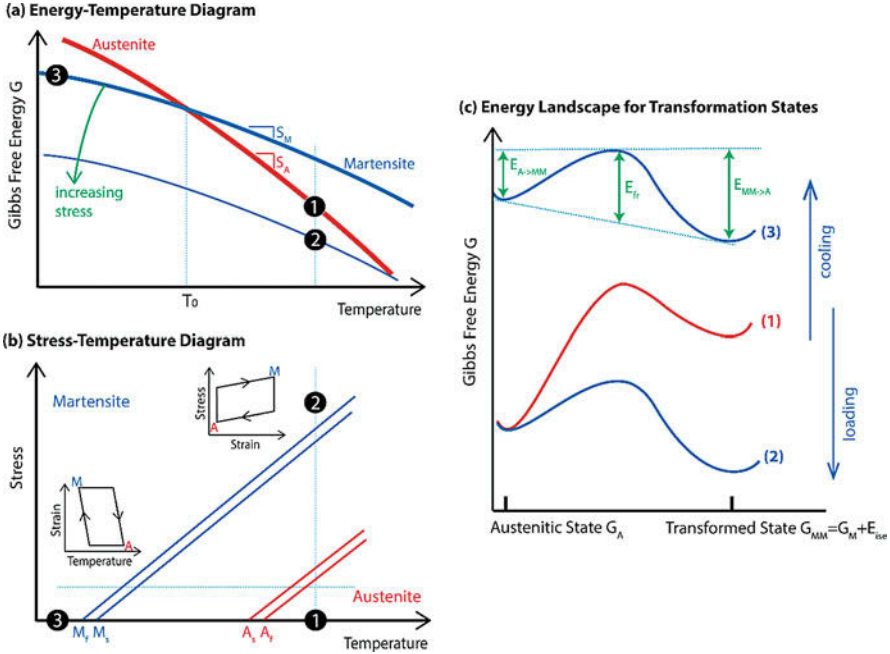
**(c) Energy Landscape for Transformation States**


**Fig. 1** (**a**) The Gibbs free energy for the austenite phase, $G_A$, (in red) and the free energy for the martensite phase, $G_M$, (in blue) as a function of the temperature $T$. $T_0$ denotes the equilibrium temperature at which $G_A = G_M$. $G_M$ decreases with increasing resolved shear stress. (**b**) The stress-temperature phase diagram for martensite and austenite. The insets show strain excursions as a result of thermal cycling or mechanical cycling. (**c**) The energy landscape between the austenitic state and the transformed martensitic state for three different conditions which have been marked in both (a) and (b). Condition 1 corresponds to a high temperature and zero-stress condition; loading from this condition leads to Condition 2 while cooling from this condition leads to Condition 3

(red line) and $G_M = G_M^{ch} = H_M - T S_M$ (bold blue line), where $G_A^{ch}$ and $G_M^{ch}$ are the chemical free energies for austenite and martensite, respectively. The slopes of these lines are the entropy $S_A$ and $S_M$, respectively; $S_A > S_M$ and accordingly $G_A^{ch}$ decreases with $T$ more rapidly than $G_M^{ch}$. Let $T_0$ denote the equilibrium temperature at which $G_{A,0}^{ch} = G_{M,0}^{ch}$ and the transformation enthalpy $\Delta H_0 = H_{M,0} - H_{A,0} = T_0(S_{M,0} - S_{A,0}) = T_0 \Delta S_0$, where $\Delta H_0 < 0$ and the transformation entropy $\Delta S_0 = S_{M,0} - S_{A,0} < 0$. If the change in heat capacity is assumed insignificant, $\Delta H \approx \Delta H_0$ and $\Delta S \approx \Delta S_0$. The difference in chemical free energy at temperature $T$ can be expressed as

$$\Delta G^{ch} = G_M^{ch} - G_A^{ch} = -\Delta S_0 (T - T_0) \tag{1}$$

when $T < T_0$, $\Delta G^{ch} < 0$ and martensite is the thermodynamically preferred phase (e.g., state 3 marked on the blue curve in Fig. 1a); when $T > T_0$, $\Delta G^{ch} > 0$ and

austenite is the stable phase (e.g., state 1 marked on the red curve in Fig. 1a). Upon application of an external stress that leads to a resolved shear stress $\tau$ on the habit plane (in the elastic regime before yielding), we estimate $G_A \approx G_A^{ch}$ and $G_M \approx G_M^{ch} - \tau\gamma_0$ because the elastic strain is insignificant compared to the transformation simple shear strain $\gamma_0$. $G_M$ decreases with increasing stress, shown by the thinner blue line in Fig. 1a.

$$\Delta G = G_M - G_A = \Delta G^{ch} - \tau\gamma_0 = -\Delta S_0 \left(T - T_0\right) - \tau\gamma_0 \qquad (2)$$

It is now possible to have $\Delta G < 0$ and accordingly a stable martensitic state even when $T > T_0$ so long as $\tau$ is sufficiently high. For example, at the same temperature, the stable phase changes from austenite (marked as state 1 in Fig. 1a) to martensite (marked as state 2 in Fig. 1a) under finite $\tau$. A third term, $P\varepsilon_V$, where $P$ is the pressure, may be introduced into Eq. (2) for transformations involving a significant volumetric strain $\varepsilon_V$.

The effect of temperature and stress is further depicted in the stress-temperature diagram in Fig. 1b, where the three states marked in Fig. 1a are also highlighted. At low temperatures and high stresses, martensite is more stable, while at high temperatures and low stresses austenite is the preferred phase. Conversions between the two phases can be achieved by many ways of thermomechanical excursions, such as thermal cycling under no stress, thermal cycling at a finite stress, and isothermal mechanical cycling. When there is no stress, transformation from austenite to martensite under cooling is characterized by a martensitic start temperature $M_s$ and a martensitic finish temperature $M_f$, and reverse transformation from martensite to austenite upon heating starts at the austenite start temperature $A_s$ and completes at the austenite finish temperature $A_f$. At a constant stress, phase conversion induced by thermal cycling is accompanied by a recoverable strain as illustrated in the bottom inset in Fig. 1b, leading to the so-called two-way shape memory effect. Similarly, mechanical cycling at a constant temperature leads to a phenomenon called superelasticity, which describes the recoverability of stress-induced strain (see the top inset in Fig. 1b) due to the reversibility of the phase conversion.

Martensitic transformation involves energy penalties, rendering the free energy of the transformed state, $G_{MM}$, different from that of the martensite phase, $G_M$. The difference between them corresponds to the recoverable part of the energy penalty, which is defined as $E_{ise}$, whose subscripts "ise" stand for contributions from interfacial energy, surface energy, and elastic strain energies.

$$E_{ise} = \gamma_i A_i + \Delta\gamma_{sf} A_{sf} + E_{el} \qquad (3)$$

where $\gamma_i$ is the austenite/martensite interface energy per unit area and $A_i$ is the change in interfacial area density. For an austenite domain surrounded by $n_A$ and $n_M$ austenite and martensite nearest neighbors, respectively, $A_i = (n_A - n_M)A_b$, where $A_b$ is the area density of each domain boundary. $\Delta\gamma_{sf} = \gamma_{sf}^M - \gamma_{sf}^A$ is the difference in surface energy per unit area, and multiplies the specific surface area $A_{sf}$; this term

pertains to the intersection of the phases with free surfaces and is usually considered negligibly small (Chen and Schuh 2011). $E_{el}$ is the increase in elastic strain energy density. Let's define

$$G_{MM} = G_M + E_{ise} \approx G_M^{ch} - \tau\gamma_0 + E_{ise} \qquad (4)$$

as the free energy of a transformed martensitic state. During transformation from the initial austenitic state with free energy $G_A$ to the transformed state with free energy $G_{MM}$, there is energy dissipation mainly resulting from the frictional work $E_{fr}$, which is irreversible and is positive in both transformation directions (Bonnot et al. 2008; Ortín and Planes 1988; Wollants et al. 1993).

Figure 1c shows the energy landscape for transformation between the initial and the transformed states, with an arbitrary reaction coordinate along the x-axis (which may be viewed as transformation strain). It is constructed by imposing a kinetic barrier with height equal to $E_{fr}$ above the average of $G_A$ and $G_{MM}$ (as demonstrated for curve #3 in Fig. 1c). With the energy maxima corresponding to the activated state being $(G_{MM} + G_A)/2 + E_{fr}$, and further utilizing Eqs. (2) and (4), the activation energy barriers for transformations between the two states can be written as

$$\begin{cases} E_{A\to MM} = \left[\frac{1}{2}(G_{MM} + G_A) + E_{fr}\right] - G_A = -\frac{1}{2}\Delta S_0(T - T_0) - \frac{1}{2}\tau\gamma_0 + \frac{1}{2}E_{ise} + E_{fr} \\ E_{MM\to A} = \left[\frac{1}{2}(G_{MM} + G_A) + E_{fr}\right] - G_{MM} = \frac{1}{2}\Delta S_0(T - T_0) + \frac{1}{2}\tau\gamma_0 - \frac{1}{2}E_{ise} + E_{fr} \end{cases}$$
$$(5)$$

where $E_{fr}$ may be treated as an intrinsic frictional resistance to transformation (i.e., a constant), allowing $E_{A\to MM}$ and $E_{MM\to A}$ to be determined at a given time. $E_{fr}^{A\to MM} = E_{fr}^{MM\to A} = E_{fr}$ is assumed for simplicity. The energy barriers for forward transformation (A → MM) and reverse transformation (MM → A) have opposite trends with respect to changes in the temperature $T$ and the stress $\tau$.

The three curves in Fig. 1c are for the same three conditions highlighted in Fig. 1a, b. Consider condition 1 (high temperature and zero stress) as the initial condition (red curve). $G_A$ is much lower than $G_{MM}$, and the stable state is the austenitic state. With decreasing temperature (from condition 1 to condition 3), both $G_A$ and $G_{MM}$ increase, but $G_A$ increases more rapidly than $G_{MM}$. With sufficient cooling, $G_A$ becomes higher than $G_{MM}$, and the transformed state becomes the preferred state. During cooling, $E_{A\to MM}$ decreases and $E_{MM\to A}$ increases as $\Delta S_0 < 0$ in Eq. (5). When $E_{A\to MM}$ becomes sufficiently low, thermal activation may overcome the barrier enabling transformation from the initial austenitic state to the martensitic state. On the other hand, upon loading from condition 1 to condition 2, $G_A$ remains nearly the same as the temperature is not changed while $G_{MM}$ decreases rapidly and becomes lower than $G_A$ when the applied load is sufficiently high. A high resolved shear stress $\tau$ also leads to a decrease in the energy barrier $E_{A\to MM}$ so that transformation to the martensitic state is not only thermodynamically preferred but also kinetically possible. On both curve #2 and curve #3 in Fig. 1c, the energy barrier for reverse transformation, $E_{MM\to A}$, is very high, suggesting that reverse transformation is possible but with a very low probability.

In Eqs. (2), (4), and (5), the resolved shear stress $\tau$ depends on the specific habit plane and shear direction and can be different for different martensite variants. For $i$th and $j$th variants, Eq. (2) leads to $G_{M_j} - G_{M_i} = (\tau_i - \tau_j)\,\gamma_0$. The energy barrier for $MM_i \to MM_j$ conversion may be determined in a similar manner to Eq. (5):

$$E_{MM_i \to MM_j} = \frac{1}{2}(\tau_i - \tau_j)\,\gamma_0 + E'_{fr} \tag{6}$$

where $E'_{fr}$ is the frictional work associated with inter-variant conversion. By the same token, extension to polycrystalline systems requires identification of transformation shear planes and directions in each grain.

## 4        KMC Modeling of Transformation Progression

KMC is an iterative modeling method. The modeling steps in each simulation step/iteration are provided in the flow chart in Fig. 2.

In each modeling iteration, the activation rates (in 1/s) for transformations between austenite and the $i$th martensite variant state are obtained by multiplying an attempt frequency $\nu_0$ with the activation probability.

$$\begin{cases} \omega_{A \to MM_i} = \nu_0 \exp\left(-\frac{E_{A \to MM_i}\Omega_0}{kT}\right) \\ \omega_{MM_i \to A} = \nu_0 \exp\left(-\frac{E_{MM_i \to A}\Omega_0}{kT}\right) \end{cases} \tag{7}$$

where $k$ is Boltzmann's constant and $\Omega_0$ can be considered a fundamental domain volume for a "unit" of transformation. The activation rate for inter-variant state conversion can be calculated similarly.

$$\omega_{MM_i \to MM_j} = \nu_0 \exp\left(-\frac{E_{MM_i \to MM_j}\Omega_0}{kT}\right) \tag{8}$$

The cumulative activation rate $\omega$ is the summation of individual activation rates of the $N_A$ austenite domains and $N_M$ martensite domains in the model system containing $N_A + N_M$ domains.

$$\omega = \sum_{n=1}^{N_A}\left(\sum_{i=1}^{N_V}\omega_{A \to MM_i}^n\right) + \sum_{m=1}^{N_M}\left(\omega_{MM_i \to A}^m + \sum_{j=1}^{N_V-1}\omega_{MM_i \to MM_j}^m\right) \tag{9}$$

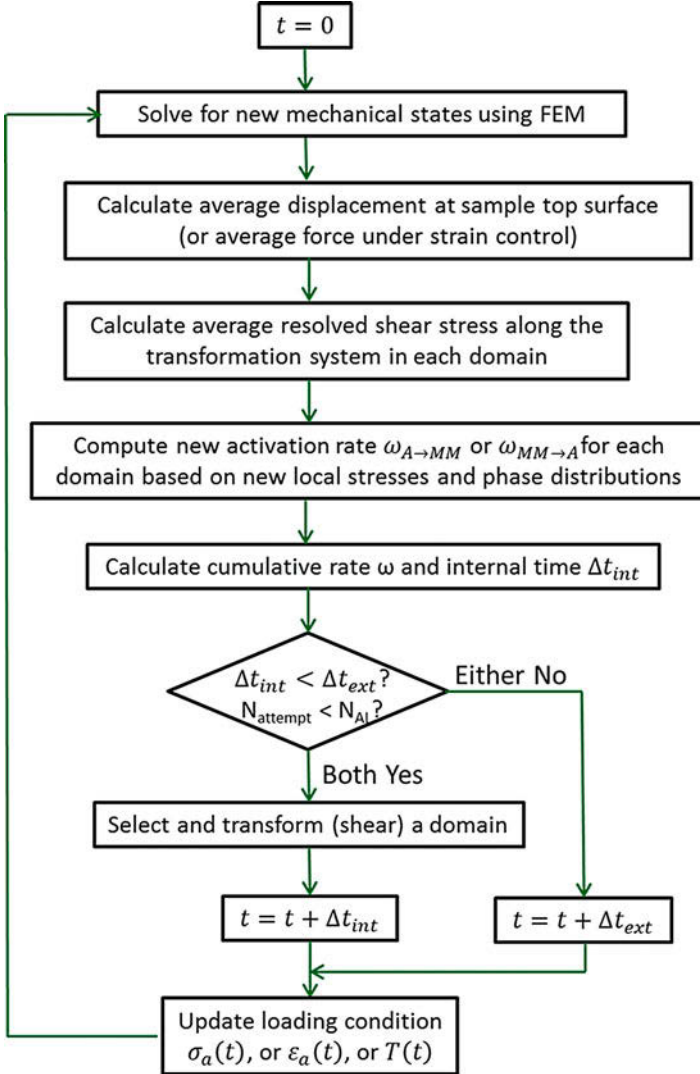
where $N_V$ is the number of martensite variants. An austenite domain may transform to any of the $N_V$ martensite variants, while a given martensite variant may transform to either austenite or any of the other $N_V$ -1 variants. Forward and reverse transformations are treated "equally," i.e., they are both permitted at any time.


**Fig. 2** Flow chart of the modeling algorithm

A uniform random number $\xi_1 \in (0\ 1]$ is used to determine the internal or residence time.

$$\Delta t_{int} = -\frac{\ln\xi_1}{\omega} \tag{10}$$

In the conventional KMC algorithm, an event is carried out in each simulation iteration and the timescale is advanced by $\Delta t_{int}$. However, $\Delta t_{int}$ in some iterations

may become extremely large. Therefore a second timescale, $\Delta t_{ext}$, is introduced and is referred to as the external time scale. $\Delta t_{ext}$ is a simulation parameter. The magnitude of $\Delta t_{int}$ relative to $\Delta t_{ext}$ determines whether a transformation event will occur or not in the present simulation step.

$$
\begin{cases}
\text{if } \Delta t_{int} > \Delta t_{ext} : t = t + \Delta t_{ext} \text{ and no event occurs} \\
\\
\text{if } \Delta t_{int} \leq \Delta t_{ext} : t = t + \Delta t_{int} \text{ and an event occurs}
\end{cases}
\tag{11}
$$

When $\Delta t_{int} > \Delta t_{ext}$, no event occurs and the timescale is advanced by $\Delta t_{ext}$. This allows one to update the boundary conditions in a more continuous manner and also capture the critical transformation stresses or temperatures. When $\Delta t_{int} \leq \Delta t_{ext}$, an event occurs and the one to be carried out is selected using the activation rate array as is normally done in KMC. The activation rates for all possible events are calculated using Eqs. (7-8) and are strung together to a total length $\omega$, with each event occupying a distance on the string equal to their individual activation rate. A second uniform random number $\xi_2 \in (0\ 1]$ is generated, and the vector from the origin to a distance $\xi_2 \omega$ along the string points at the event to be executed. After the transformation event, time is increased by $\Delta t_{int}$ and boundary conditions are updated.

## 5    FEM Modeling of Unit Transformation and Stress Distribution

### 5.1    Boundary Conditions

To simulate stress-induced or thermally-induced transformation, the applied stress or the temperature should change with time. They could be updated in each simulation step using the KMC time $t$ determined in Eq. (11). For example, an applied uniaxial stress $\sigma_a(t)$ is

$$
\sigma_a(t) = \sigma_{max} - |\dot{\sigma}_0 t - \sigma_{max}| \ (0 \leq t \leq 2\sigma_{max}/\dot{\sigma}_0)
\tag{12}
$$

where $\dot{\sigma}_0$ is a stress ramping rate and $\sigma_{max}$ is the maximum stress on the triangular loading curve common in experiments. Both loading and unloading segments are considered in Eq. (12). Under thermal cycling, the temperature $T$ first decreases at a ramping rate $\dot{T}_0$ from an initial high temperature $T_i$ to a low temperature $T_e$ and then returns to $T_i$. The temperature is varied in each simulation step according to

$$
T(t) = T_e + |\dot{T}_0 t + (T_e - T_i)| \ \left(0 \leq t \leq 2\left(T_i - T_e\right)/\dot{T}_0\right).
\tag{13}
$$

During thermal cycling, $\sigma_a$ can be either kept at zero, in which case thermally induced transformations are studied, or held at a constant value, which can lead to stress-assisted two-way shape memory effect. The transformation latent heat could

be assumed immediately exchanged with the environment when appropriate, and in this case the sample has a uniform temperature $T$ everywhere.

It is desirable that the boundary conditions be kept simple. For example, when a sample is subject to a uniaxial load, the stress at its top surface could be updated in each simulation step according to Eq. (12) while keeping its bottom surface constrained in the loading direction and its side surfaces free without any constraint.

## 5.2     Application of a Unit Transformation

Displacive martensitic transformation in a domain is implemented as a mandatory, stress-free distortion. The system subsequently relaxes by partitioning and balancing stresses with the surrounding region. This is analogous to the determination of the back stress in the classical Eshelby problem demonstrated in Fig. 3a. In the absence of an external stress, an elliptical region is subject to a mandatory positive shear and then the system is allowed to equilibrate and relax. Positive shear stress develops ahead of the vertices of the ellipse as these regions deform in order to accommodate the shear in the elliptical region, while negative shear stress (in blue) develops inside the sheared/transformed region due to the resistance to shear in the surrounding region. Figure 3b shows the shear stress distribution after a hexagonal region transforms when the far-field resolved shear stress is about 270 MPa. Despite the positive far-field shear stress, the shear stress in the transformed martensite region is negative (in blue), leading to a decrease in the activation energy barrier for reverse transformation, $E_{MM \to A}$ (Eq. (5)). On the other hand, the shear stress immediately outside the transformed region is positive and is very high, resulting in a reduced energy barrier for forward transformation,

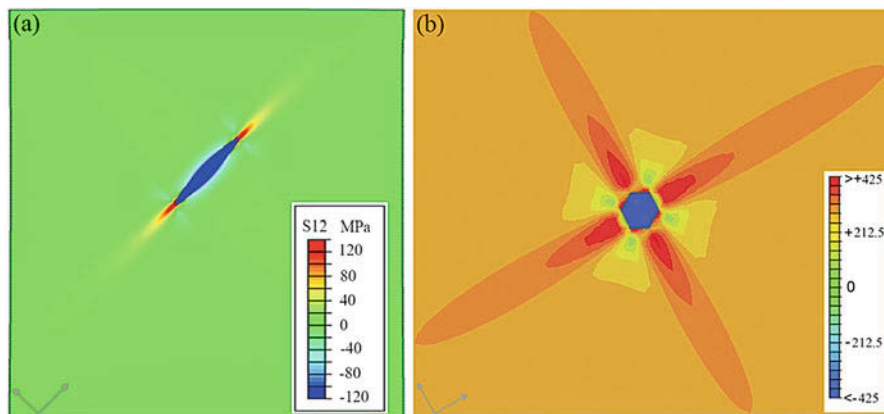

**Fig. 3** (**a**) Shear stress (in MPa) distribution after the system relaxes from a stress-free mandatory shear in an elliptical region along the major axis of the ellipse in the absence of an external stress. (**b**) Shear stress (in MPa) distribution after the system relaxes from transformation in a hexagonal region at a finite external stress

$E_{A \to MM}$ (Eq. (5)). In the subsequent simulation step, there will be competition between reverse transformation of this martensite region and forward martensitic transformation in the surrounding regions.

After each transformation event, the redistributed stresses are then used to calculate new activation rates and the time increment in KMC. Each simulation step ends with an updated boundary condition, and in the case of $\Delta t_{int} \leq \Delta t_{ext}$, a new phase configuration as well.

## 6     Example

### 6.1     Martensitic Transformation in Cu-Al-Ni SMAs

In this section, we will demonstrate the model using Cu-Al-Ni SMA as a model material. In this material, austenite has a $D0_3$ crystal structure (see Fig. 4a) and is often denoted as $\beta_1$. The deformation gradient matrices for lattice dilation and distortion associated with martensitic transformation from $\beta_1$ to $\beta_1{}'$ are provided in Eqs. (14) and (15), respectively, both of which are expressed for the martensite coordinate system shown in blue in Fig. 4a.

$$F^1 = \begin{bmatrix} 1.062 & 0 & 0 \\ 0 & 1.0232 & 0 \\ 0 & 0 & 0.918 \end{bmatrix} \tag{14}$$

$$F^2 = \begin{bmatrix} 1 & 0 & 0 \\ 0.1154 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{15}$$

From Eq. (14) the volumetric strain (i.e., $F_{11}^1 \cdot F_{22}^1 \cdot F_{33}^1 - 1 = -0.25\%$) associated with the transformation is determined to be negligibly small. On the other hand, Eq. (15) leads to a large simple shear with a magnitude of 11.54%. Therefore, for simplification, transformation is implemented as a simple shear $\gamma_0 = 0.1154$ on $\{\bar{1}10\}$ planes and along <110> directions in austenite. In Eq. (7), the transformation unit volume $\Omega_0$ is taken as 6.5 $nm^3$ and the attempt frequency $\nu_0$ is taken as $2 \times 10^{10}$ $s^{-1}$. In other materials where martensitic transformation also involves large dilation and volumetric strain, the full strain tensor should be taken into consideration.

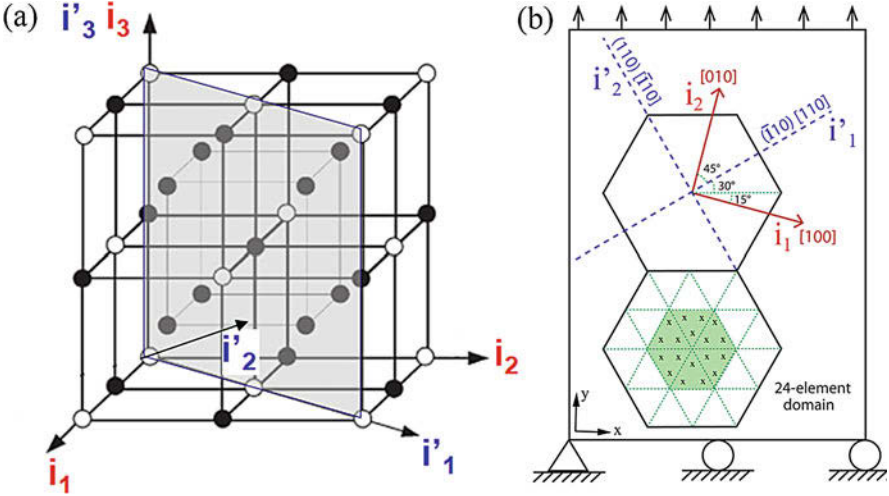
A challenge with modeling martensitic transformation lies in the lack of information on mechanical properties of the martensite phase. The example demonstrated in this section assumes that elastic properties for austenite and martensite are the same and that the model material is a two-dimensional single-crystalline solid under a plane strain assumption. The austenite phase is an elastic solid with cubic (nonisotropic) symmetry and therefore has three independent elastic constants: $C_{11} = 143.1$ GPa, $C_{12} = 124.3$ GPa, and $C_{44} = 94.1$ GPa (Sedlák et al. 2005), which lead


**Fig. 4** (**a**) The D0$_3$ crystal structure for the Cu-Al-Ni alloy. ○ denote Al atoms, • at the edge center and body center (1/2, 1/2, 1/2) are mostly Cu atoms and some are Al atoms, while • in the center in each sub-unit are mostly Cu atoms and some are Ni atoms. The deformation gradient matrices in Eqs. (14-15) are written for the i'$_1$, i'$_2$, i'$_3$ martensite coordinate system. (**b**) Model setup in the example. The two-dimensional sample is fixed at the bottom left corner, constrained vertically at the bottom, and subjected to a uniaxial strain $\varepsilon_a(t)$ at the top surface. Its side surfaces are free, while its top and bottom surfaces are constrained as a plane. Each transformation domain is a hexagon whose lines of symmetry (dashed lines) correspond to the transformation system {1$\bar{1}$0} < 110>. Each domain is meshed with 24 elements, among which the six in the center (the crosses are their integration points) are used to calculate the average resolved shear stress for this domain

to Young's modulus $E = 27.5$ GPa, the Poisson's ratio $\nu = 0.4648$, and the shear modulus $G = 94.1$ GPa. Plasticity is not considered as martensitic transformation usually occurs at stresses much lower than the yield stress. However, local yielding is possible, and this effect could be an interesting direction for future extension of the model.

## 6.2    Computational Considerations

Partition of the simulation cell into nonoverlapping domains is desirable as each location in the material is associated with a phase identity at any given time. Each domain may be further meshed with one or more elements in the FEM implementation. The progression of the transformation is simulated as successive transformation in different domains, and the material volume involved in each transformation event could be allowed to vary from event to event depending on the spatial stress distribution. In this section, the demonstrations are from a

simple hexagonal tessellation of the material; each hexagonal domain is a phase transformation unit, and only a single domain is involved in each transformation event. The model setup is illustrated in Fig. 4b. Each domain is further meshed with 24 triangular plane strain, 6-node quadratic elements, and stresses at the three integration points inside each element are solved. Due to the noncircular domain geometry, stress concentration develops near domain edges and corners (see Fig. 3b). To exclude such (unphysical) stress concentration spots, only the six elements in the center of each domain are used in the calculation of the average resolved shear stress in a domain. With this approach, mechanical interactions across phase boundaries can be captured by using a sufficiently small domain size; in principle, the domain size should be much smaller than the sample and characteristic scale of the evolving microstructure in order to accurately capture the pattern in phase and stress evolution.

To avoid severe local distortion near or at the corners of the specimen, a top layer and a bottom layer are prohibited from transforming. Domains in these layers are set up as austenite initially, and their transformation rates ($\omega_{A \to MM}$) are assigned as zero regardless of their local stress state. They never transform as a result, providing both elastic accommodation and constraint for the transforming material in between and promoting side surfaces as nucleation sites.

The stored elastic energy in the sample, $E_{el}$, in Eq. (3) is incorporated indirectly. For example, consider a potential forward transformation in a domain that would result in high stresses in its surroundings and therefore a very high $E_{el}$ and a high $E_{ise}$. Instead of raising the energy barrier $E_{A \to MM}$ in Eq. (5) to hinder the transformation, the model may allow the domain to transform. But it will likely revert to austenite immediately because the driving force for reverse transformation will be high and $E_{MM \to A}$ will be low due to the resulting high local stress $\tau$ ($\tau$ is incorporated in the evaluation of transformation energy barriers as shown in Eq. (5)). This approach is computationally much more efficient than determining $E_{el}$ for each domain, which requires carrying out every possible transformation and calculating the resulting change in the strain energy of the sample. Therefore, $E_{ise}$ for each domain is reduced to $\gamma_i A_i$, the change in austenite/martensite interface energy. An alternative approach is to evaluate $E_{el}$ analytically using some kind of volumetric average of Eshelby predictions for multiple scenarios based on neighboring phase identities. This approach is in principal similar as the approach above but with a modified value of $\gamma_i$.

It is typical for the KMC model to get trapped in the "superbasin" composed of many frequent events with much lower energy barriers for a large number of iterations before the system experiences a rare process and escapes out of the "superbasin" (Chatterjee and Voter 2010). In the present model, frequent and rapid phase flipping may occur during transformation in either direction when there is some sort of metastable phase configuration. It is reasonable to impose a limit $N_{AL}$ on the number of attempts allowed at each stress level. A transformation event occurs only if $\Delta t_{int} \leq \Delta t_{ext}$ and $N_{attempt} \leq N_{AL}$; otherwise $t$ will be increased by $\Delta t_{ext}$ to increase the driving force for transformation in one direction in subsequent steps.

## 6.3    Superelasticity (Mechanically-Induced Transformation)

In this section, modeling results for transformation under a constant strain rate are presented for the simplified case of a single martensite variant. This boundary condition is used frequently in experimental studies that explore rate effects in SMAs (Otsuka et al. 1976; Ueland et al. 2012; Van Humbeeck and Delaey 1981; Yin et al. 2013) and also allows one to capture possible stress relaxation behavior. Under a constant strain rate, the transformation should occur gradually over a period of time because transformation strain increases with martensite fraction.

Snapshots of the phase evolution and the corresponding shear stress distribution are shown in Fig. 5 for both the forward transformation (top two rows in Fig. 5) and the reverse transformation (bottom two rows in Fig. 5). Martensitic transformation starts in the center of the sample. Under a constant strain rate, formation of long plates that span across the sample leads to a higher overall transformation strain and more stress relaxation compared to shorter plates at corner regions that are constrained by the buffer layers at the top and the bottom of the sample, which may play a similar role as unfavorably oriented grains that do not transform within the range of the applied load. The corner regions partially transformed at higher strains (e.g., $\varepsilon = 0.04$-$0.052$) and retained some austenite until very high applied strains. In other regions, new martensite plates formed at relatively low strains and grew and impinged at higher strains. Formation of a martensite plate usually leads to extensive stress relaxation. During reverse transformation, the corner regions reverted to austenite first, and formation of austenite plates results in stress spikes.

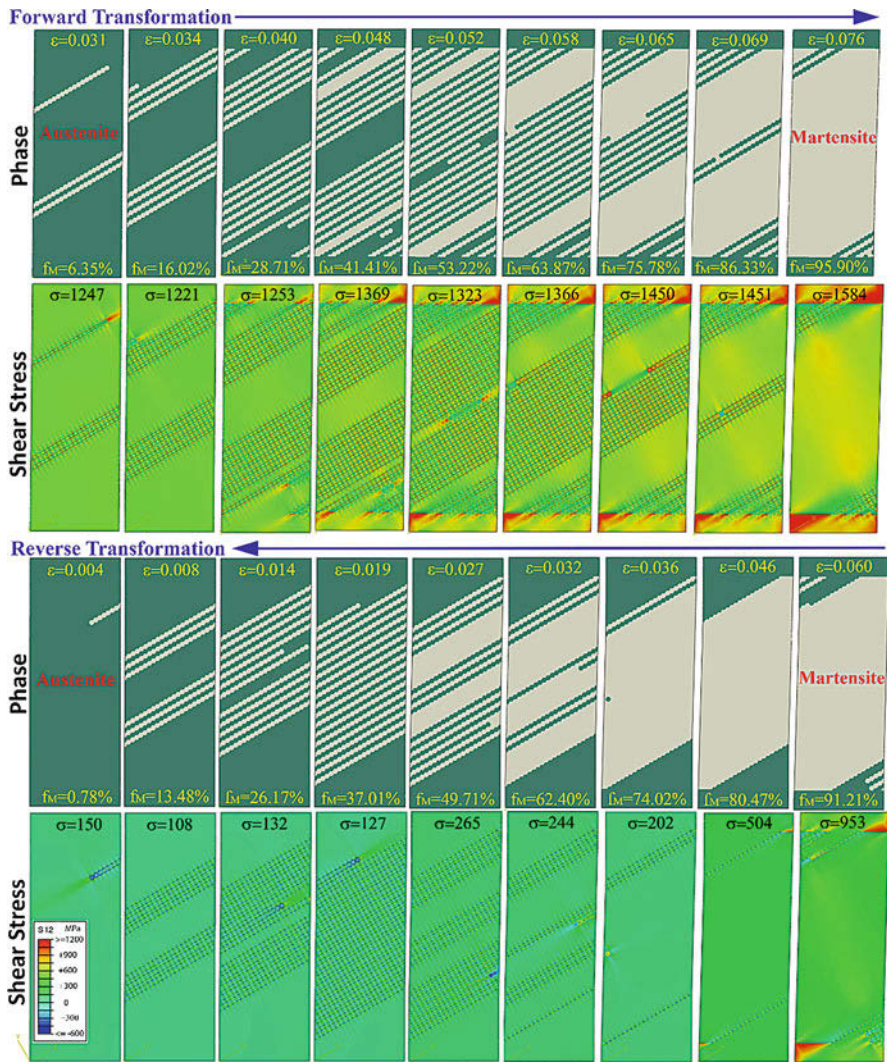
The corresponding superelastic stress-strain curve obtained is presented in Fig. 6a. Frequent stress fluctuations are seen during both forward and reverse transformations in Fig. 6a showing sudden stress drops (rises) during forward (reverse) transformation, each followed by a period of elastic loading (unloading) with a slope parallel to that of the initial elastic loading curve. Numerous small serrations are seen in Fig. 6b, where martensite fraction $f_M$ is plotted as a function of strain $\varepsilon$. Overall, martensite fraction $f_M$ still seems linearly related to strain $\varepsilon$ (e.g., linear fitting of the forward transformation data in Fig. 6b yields $f_M = 20.61(\varepsilon - 0.0268)$), but a linear relationship is no longer accurate because $f_M$ increases in a discontinuous manner. $f_M$ actually increases or decreases by a small percentage at a constant $\varepsilon$ and then pauses over a range of $\varepsilon$ before increasing or decreasing at another constant $\varepsilon$. The insets in Fig. 6b show how the overall external stress $\sigma$ changes with $f_M$. During forward transformation, the increase in $f_M$ always results in a decrease in $\sigma$, which subsequently increases at a constant $f_M$. Therefore, with increasing applied strain, strain increment is first achieved by elastic deformation of the sample, leading to an increase in $\sigma$ and a reduction in the free energy of martensitic state, $G_{MM}$. Subsequently, martensitic transformation occurs in some regions of the sample and the resulting transformation strain fulfills the strain increment requirement, leading to relaxation of the elastic stress developed prior to transformation. Stress relaxation has indeed been observed in tensile testing of small SMA microwires under a constant slow strain rate (Ueland et al. 2012). During reverse transformation, the decrease in $f_M$ always leads to


**Fig. 5** Phase configurations (austenite in green and martensite in beige) and the corresponding resolved shear stress distributions during forward transformations (top two rows of figures) and reverse transformations (bottom two rows of figures) in a mechanical cycle under a constant strain rate. The strain $\varepsilon$ and stress $\sigma$ (in MPa) values in the figure titles are uniaxial strain and stress values for the sample. $f_M$ is the volume fraction of martensite

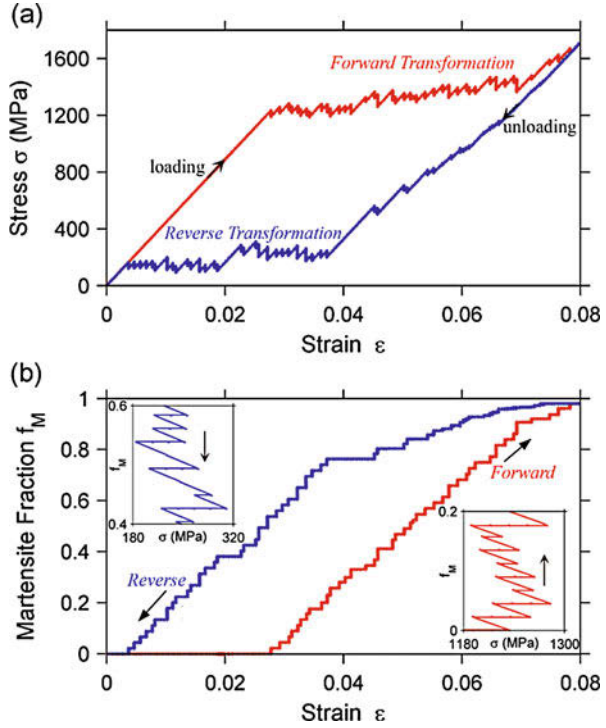
an increase in $\sigma$, which subsequently decreases at a constant $f_M$. Strain reduction is first realized by elastic unloading, which in turn raises the driving force for reverse transformation. Eventually reverse transformation takes place, meeting the strain reduction requirement by the recovered transformation strain. The stress rises rapidly and then the next iteration begins.

**Fig. 6** (**a**) Superelastic stress-strain curve showing complete strain recovery after unloading. Transformations are accompanied by stress fluctuations. (**c**) Martensite fraction $f_M$ as a function of strain. The insets plot $f_M$ as a function of stress; forward and reverse transformations lead to load drops and increases, respectively


## 6.4     Thermally-Induced Transformation

The modeling framework presented in Sects. 2, 3, 4, and 5 can also be applied to simulate thermally-induced transformation, either in the absence of an external load or at a constant load. The example in Fig. 7 below shows simulation results for forward and reverse transformation in a thermal cycle when there is no applied load. The material properties are the same as specified above in Sect. 6.1. For simplicity, only two martensite variants with opposite transformation shear strains are permitted. The equilibrium temperature $T_0$ is set to 500 K. The temperature $T$ is set to 800 K initially and then is gradually decreased to 200 K before it is increased back to 800 K.

The fractions of two martensite variants, $f_M^1$ and $f_M^2$, are plotted as a function of the temperature $T$ in Fig. 7a. During cooling, $f_M^1$ and $f_M^2$ remain zero until $T$ decreases to about 300 K when $f_M^1$ and $f_M^2$ increase simultaneously to slightly above 0.4. The phase configurations during cooling are shown in Fig. 7b–e. It can be seen in these figures that plates of the two martensite variants nucleate simultaneously and grow in alternating patterns. As the two variants have opposite transformation strains, the alternating pattern in Fig. 7b–e enables self-accommodation among the variants and minimizes the macroscopic strain in the sample. Both variants

**Fig. 7** (**a**) The fractions of martensite variant 1 and variant 2, $f_M^1$ and $f_M^2$, as a function of temperature under no external stress. $T_0$ is the equilibrium temperature which is set as 500 K. (**b**–**e**) Phase configurations during cooling, showing transformation from austenite (in green) to martensite (the two variants are plotted in red and beige)
transform back to austenite upon heating and the reverse transformation is complete at about 750 K, yielding a temperature hysteresis. Transformation temperatures and thermal hysteresis are normally measured experimentally by Differential Scanning Calorimetry (DSC), which however cannot predict evolution in phase configuration. The modeling framework presented here offers a complementary method for studying thermally-induced martensitic transformation.

## 7 Conclusions

This chapter presents a mesoscale kinetic Monte Carlo (KMC) model framework for modeling the dynamics of reversible martensitic transformation in shape memory alloys and ceramics. The model may also be adapted to study martensitic transformation in structural materials in which case incorporation of plastic deformation mechanisms is essential. The modeling framework integrates KMC with thermodynamic description of transformation and Finite Element (FEM) prediction of mechanical states. The thermodynamic energetics governing martensite transfor-

mations induced by temperature changes or an applied stress are examined, and the energy landscapes for transformation states are developed. Thermodynamics is related to kinetics through a rate equation that is commonly used to describe thermally-activated phenomena. KMC provides FEM a new phase distribution as well as a new timescale (and thus new boundary conditions). The thermomechanical distribution determined from FEM in turn leads to changes in the energy landscape for the transformation states.

Computational implementation of the model is realized and presented. Martensitic transformation occurs by a mandatory displacement, which is mainly a shear, and is modeled as a unit process that takes place in one domain at a time. After each unit transformation event, the boundary conditions are updated according to the new timescale and the new stress states in the sample are calculated by FEM. The new phase configuration and stress distributions are used to determine the activation rate for each domain based on a transition state approximation for the energy landscape of the transformation states. The KMC algorithm is then used to select the next domain to transform and determine the time increment. This iterative simulation method therefore performs virtual in-situ testing under mechanical, thermal, and combined stimuli and predicts simultaneous evolution in phase and thermal-mechanical states in the sample using physical time and length scales comparable to those involved in experiments. It in particular captures inherent transformation stochasticity during both nucleation and growth stages.

The capability of the model is demonstrated by using it to simulate mechanically-induced reversible transformation (superelasticity) and thermally-induced transformation (in which case multiple variants are introduced) in plane strain two-dimensional specimens. Although not demonstrated, the model can also easily simulate mechanically-induced transformation followed by reverse transformation during heating (one-way shape memory effect) as well as transformations induced by thermal cycling at a constant stress (two-way shape memory effect). The model predicts phase and stress evolution during the entire incubation, nucleation, and growth process of the new phase. It also predicts (rather than enforces) both forward and reverse transformations with a stress or temperature hysteresis and with complete recovery. The predicted critical transformation stresses or temperatures are related to fundamental thermodynamic properties of materials. Stress relaxation and spikes are observed during transformations under a constant applied strain rate.

This modeling approach could significantly augment mesoscale computational capabilities that connect microstructures to macroscopic thermomechanical properties. The model is capable of capturing dynamic mechanical interactions between microstructure and stochastic transformation quantitatively and addressing issues of transformation kinematics in the presence of defects. An important direction for future research is to elucidate various size effects and defect effects (e.g., grain boundary effects) on martensitic transformation utilizing the KMC modeling method described in this chapter.

## Abstract

Object kinetic Monte Carlo (OKMC) approaches allow one to explicitly coarse grain atomic processes to simulate the evolution with time of the system/microstructure. This class of methods is quite versatile and can be used to model different processes where the motion of atoms in a given microstructure and their interaction with sinks and traps of the microstructure lead to changes such as phase transition or modification. In this chapter, the method is presented as applied to radiation damage modeling. Along with a description of the technique, we discuss the different pathways possible to couple OKMC with smaller- as well as larger-scale methods and conclude with a brief enumeration of what we believe are the issues for future development.

# 1  Introduction

Kinetic Monte Carlo (KMC) is a family of methods based on Markov/stochastic processes intended to simulate the time evolution of some processes occurring in nature, typically processes that occur with a given known rate, used as inputs to the

algorithm (Voter 2007). This method is typically applied at two scales: the atomistic scale, where the processes that can take place are the ones atoms undergo during the evolution of a microstructure, and the mesoscopic scales, where the microstructure is coarse grained into objects that can evolve on a lattice or not. It is now clearly established that high-energy particles such as the ones produced in a nuclear reaction interact with matter and lead to nuclear reactions, displacement of atoms, as well as ionization and excitation of atoms (Was 2017). In the case of metallic alloys, the displacement of atoms is the main aging mechanism in irradiated components (pressure vessel, internals, or cladding for fission reactors; divertor or blanket for fusion reactors) as the displacements of atoms lead to the formation of point defects (PD), the evolution of which with time will induce changes in the microstructure. The interaction between radiation-induced point defects and solute atoms leads to solute atoms and point defect fluxes which drive the microstructure evolution with time and induce changes in the mechanical properties. Microstructure modeling techniques dedicated to radiation damage studies thus focus on the evolution of these point defects. In fact, these techniques, as applied currently, aim at modeling the microstructure evolution under irradiation by looking at the point defect and point defect cluster evolution and distributions. At the mesoscopic scale, the species under consideration are defects whose atomic-level features are disregarded, except insofar as they influence the mechanisms, whereby the defects migrate or react between themselves and with sinks (Was 2017). The two techniques the most used are mean field rate theory (MFRT) (Ghoniem) and object kinetic Monte Carlo (OKMC), which is the subject of this chapter. OKMC methods sit at the center of the microstructure multiscale modeling picture as they have links with lower-scale methods (e.g., atomistic ones) and upper-scale ones (phase field, MFRT). Indeed, OKMC coarse grain lower-scale atomic simulations and can be coarse grained into MFRT or plasticity/mechanics modeling.

The chapter is structured as follows: we will start by briefly describing what is meant by microstructure evolution under irradiation and the modeling techniques used for that purpose. We will then present the KMC method as it is applied to objects and describe the ingredients of the models. In the fourth section, we will discuss different approaches to model alloys as well as ways to couple the OKMC to lower- and higher-scale techniques. Finally, in the fifth section, we conclude by providing what we believe are future directions and perspectives of the technique. Some of the existing OKMC codes are briefly presented in the Appendix A.

## 2   Radiation Damage Evolution

### 2.1   Physical Processes Involved in Radiation Damage

Radiation damage is caused by high-energy particles, neutrons, or ions, penetrating materials and interacting with their nuclei or their electrons. As mentioned briefly in the introduction, the interaction can lead to nuclear reactions (transmutations) and thus the formation of new elements, ionization and excitation of atoms, as well as

atomic displacements. The first two outcomes (atom transmutation and excitation) need to be modeled at the scale of nuclei or electrons and will thus not be discussed here. The third one (atomic displacements) results in the creation of a large amount of point defects, vacancies, and self-interstitial atoms (SIAs), isolated or in clusters within displacement cascades. This is referred to as the primary damage. These point defects are created in overconcentration and flow into the materials and interact with each other as well as solute atoms and defects of the microstructure such as dislocations, grain boundaries, or surfaces. The primary damage evolution into voids and dislocation loops is the so-called matrix damage. Besides the matrix damage, the point defect oversaturation has other consequences. First, it can lead to a radiation-accelerated diffusion making the system return faster to its equilibrium state. Second, because of the tendency of point defects to eliminate on sinks (e.g., dislocations, grain boundaries, surfaces), the concentration of PD near the sinks is lower than the average concentration which results in concentration gradients inducing a flow of PD.

As the microstructural changes induced by the atomic displacements result from the evolution of the point defects that have been created, methods aiming at modeling the microstructure evolution focus on point defect motions rather than atoms. Different methods are available which are briefly described in the next section.

## 2.2    Simulation Techniques of Irradiated Microstructures

The formation of the primary damage, referred to as the "source term" in mesoscale methods such as KMC or MFRT, occurs too quickly ($\sim$10–20 ps), and the displacement cascade sizes are generally too small, to be observed experimentally, but molecular dynamics (MD) simulations have proven to be a powerful tool to model displacement cascades and investigate the creation and morphology of the defects created, their mutual interaction, and, to some extent, i.e., at very short times, also their evolution (Becquart et al. 2018). However, because of the short timespan covered by MD simulations (10–20 ps for volumes large enough to contain a few displacement cascades, i.e., of the order of tens of nanometers), other computational tools must be used to extend the study up to the formation of experimentally resolvable damage features. One natural way of speeding up the calculations while keeping the information at the atomistic scale is the atomic kinetic Monte Carlo approach (AKMC) (Becquart and Soisson 2018; Becquart and Domain 2010). The AKMC method is based on the residence time algorithm (RTA), also known as the BKL method (Bortz et al. 1975) (for Bortz, Kalos, and Lebowitz) developed by Young and Elcock to model the evolution of vacancies in binary ordered alloys (Young and Elcock 1966). This algorithm is used to evolve a set of atoms and point defects in a simulation box by point defect jumps $i$, occurring with thermally activated frequencies. AKMC simulations (see recent reviews in Becquart and Domain 2010; Soisson et al. 2010; Becquart and Wirth 2012) have shown to be especially useful to model systems of a few million atoms on the appropriate

timescale, because they deal with the jumps of atoms or point defects, not the lattice vibrations. AKMC is thus a powerful technique to study the microstructural and microchemical evolution of alloys controlled by diffusion processes in all kinds of conditions (e.g., thermal aging, irradiation) (Becquart and Soisson 2018). This approach naturally takes into account the correlations between successive jumps, inherent to the process of diffusion (Allnatt and Lidiard 2003). A consequence is that a very large number of jumps have to be performed to model the motion of a point defect cluster as shown, for instance, in Athènes and Bulatov (2014) in the FeCu system. To overcome this problem, mesoscale approaches of the KMC method, such as the OKMC, have been developed. OKMC is defined as a coarse-grained method because atoms are not explicitly treated in contrast with atomistic KMC. It is also based on the residence time algorithm applied this time to objects: the microstructure is described in terms of objects which are the intrinsic defects (vacancies and self-interstitials) or impurities and their clusters which are located at known (and traced) positions in a simulation volume. The events are all the possible actions that these objects can perform and the reactions that they may undergo, such as migration (in most cases – isotropic diffusion – a random walk with small jumps corresponding to nearest neighbor distance in the crystal), dissociation (emission of a smaller defect from a bigger one), clustering of like defects or of defects and impurities, and annihilation between opposite defects (self-interstitials and vacancies). The probability for a migration event is given by the appropriate jump frequency.

Very similar coarse-grained KMC models are the event KMC (EKMC) (Lanore 1974) which do not treat individual migration jumps explicitly and where the evolution of the system is driven by reactions (events) between objects.

Finally note that mean field rate theory (MFRT) is another mesoscopic approach largely used to simulate the evolution of microstructure under irradiation. MFRT models do not deal with the explicit position of defects but with the averaged concentration of defects in a small volume at a given position in the material. They take into account the presence of gradients of concentration and hence, in some sense, deal with the spatial dependence of the evolving defect distribution.

Figure 1 presents the different methods currently used to model material microstructure evolution under irradiation. Each of the phenomena involved in the microstructure or plasticity evolution has a characteristic time and length scale that range from nanometers and picoseconds for the displacement cascades up to micrometers, for the grain sizes and hours to years for the experiment duration or the lifetime of components. Consequently one needs to choose the appropriate modeling technique that is the most efficient or at least capable of simulating one of these phenomena.

## 2.3    Microstructure Modeling by Kinetic Monte Carlo Techniques

As stated in the introduction, KMC techniques aim at modeling the behavior of point defect and point defect clusters which, for the most common cases, migrate in the
**Fig. 1** Different methods, physical phenomena, timescales, and length scales required to model the evolution of microstructures under radiation damage conditions

material via the jumps of point defects. We now present the method as it is applied in AKMC, i.e., when all the atoms are explicitly taken into account, for the sake of simplicity. For a thermally activated process such as point defect diffusion, the jump frequency is given by:

$$\Gamma = \nu e^{-\frac{E_a}{k_B T}} \tag{1}$$

where $\nu$ denotes the attempt frequency and T the temperature and $E_a$ corresponds to the activation energy of the jump or the migration energy obtained as the difference between the energies of the system at the saddle point and in its initial configuration. Such a description is derived from the theory of thermally activated processes and is justified when the thermal fluctuations are smaller than the activation energies: $k_B \ll E_a$.

According to harmonic transition state theory (Vineyard 1957), the attempt frequency can be expressed as:

$$\nu = \frac{\prod_{j=1}^{3N-3} \nu_j}{\prod_{j=1}^{3N-4} \nu_j^*} \tag{2}$$

In this expression $\nu_j$ and $\nu_j^*$ are the normal frequencies for vibrations at the local minimum and saddle states, respectively, and $N$ is the number of atoms. Typical values for the migration of isolated point defects in metals are around $10^{12}$–$10^{13}$ s$^{-1}$ ($\sim$ Debye frequency).

Knowing the frequencies of all possible defect jumps in the system, the algorithm proceeds by choosing one of them according to its probability and evaluate the time necessary for the jump to occur using the residence time algorithm (RTA)

that will be described in the next section. Originally applied to the migration of vacancies in binary alloys, the AKMC method can be applied to any point defects as well as foreign interstitial atoms (FIA) such as C, N, He, and H (that do not need point defects to diffuse) and substitutional solute atoms. The microstructure evolves via elementary mechanisms, i.e., point defect jumps or solute jumps in the case of interstitial solutes. Vacancies and self-interstitials can jump from one lattice site to another lattice site (typically first nearest neighbor sites); solute interstitials lie on an interstitial sublattice and jump on this sublattice. Typically one atom is assumed to move, and the rates of possible transitions are determined from the local environment around the moving atom. During the course of the simulation, the probabilities of all the possible jumps are calculated, and one migrating event is chosen, at each time step, by extracting a random number, according to its probability.

## 3   OKMC Method and Principles

The OKMC method proceeds as the AKMC, except that instead of making atoms and point defects evolve individually, clusters of point defects evolve as a whole as one single object. Figure 2 compares the two approaches, whereas the main differences between OKMC and EKMC are represented in Figs. 3 and 4.

Diffusion can be treated as a random walk on a lattice or off lattice in OKMC and as a direct reaction in EKMC (Fig. 3). Consequently, in OKMC, reactions are treated when objects are below a specific interaction distance, whereas all possible reactions are considered and computed in EKMC (Fig. 4). Schematically, in OKMC, all events are elementary events as exposed below, whereas in EKMC they are coarse grained in reaction events. One consequence is that 1D or anisotropic diffusion is easy to implement in OKMC.

### 3.1   General Principles

The objects treated in the OKMC model have defined center-of-mass positions in space, which can correspond to lattice sites or not, and (when they are supposed to) they migrate. They can be point defects and point defect clusters, interacting with solute atoms to form mixed complexes, traps that can be introduced to simulate

**Fig. 2** Simple comparison between AKMC and OKMC. The arrows are the possible moves of each square which represents, for instance, a single vacancy for AKMC and the same 6 vacancy clusters for OKMC that can also undergo an emission event

**Fig. 3** Simple comparison between OKMC and EKMC for the diffusion of the small object (the large object is considered as immobile). In OKMC, the reaction can occur after a random walk of the small object, i.e., as a series of elementary reactions. The only event is the reaction of the small object with the big one in EKMC. (See Appendix A for more details on the EKMC)

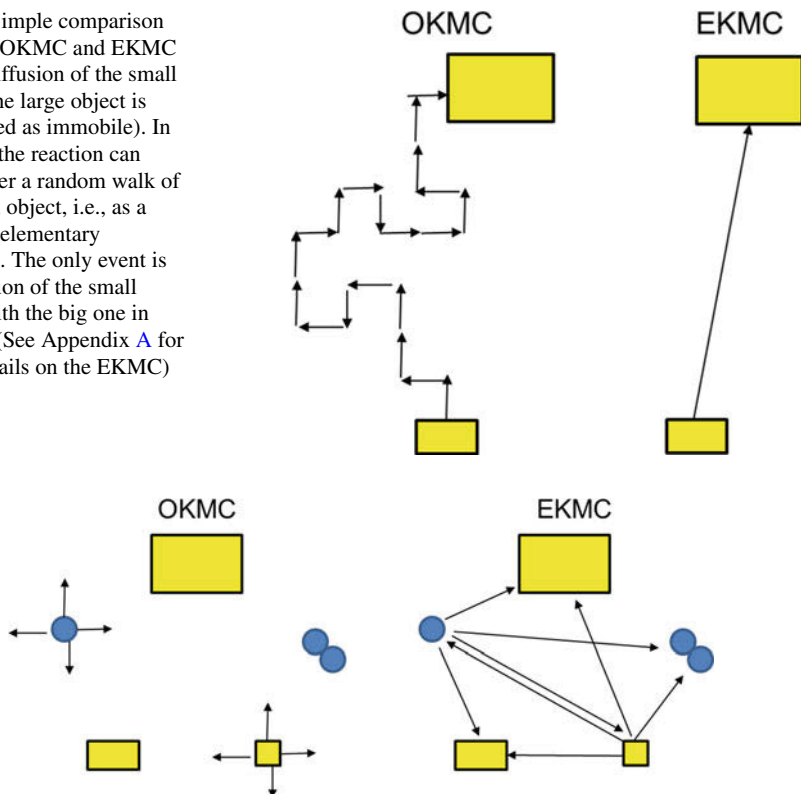

**Fig. 4** Simple comparison between OKMC and EKMC considering only the small objects as mobile (monovacancy in yellow and mono-SIA in blue). For OKMC the arrows represent the different jumps and for EKMC the different reactions. (See Appendix A for more details on the EKMC)

the effect of interstitial impurities and other objects of the microstructure such as dislocations and grain boundaries (Fig. 5). Depending on the level of detail required, the objects can have different shapes. For instance, they can be 3D spheres for nanovoids, 2D platelets for SIA loops, and stacking fault tetrahedra (SFT) for the defects found in face-centered cubic metals (Domain et al. 2004; Nandipati et al. 2015).

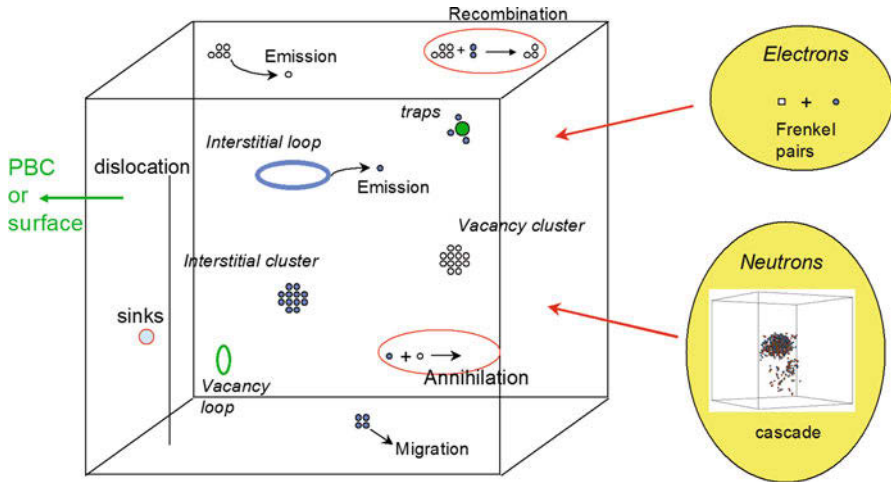
Each object and microstructure feature has a size, and an interaction volume (Fig. 6), equivalent to a distance between objects that takes into account the shape of the objects. In most cases the elastic interactions are taken into account implicitly, and effective interaction volumes/sizes are considered that are slightly larger than the object's real size. Depending on the code, two objects interact when their reaction volume overlap or when they touch each other. The interaction volume is directly related to the object sink strength (Jansson et al. 2013) which characterizes the interaction of migrating species with mobile or immobile features


**Fig. 5** OKMC representation of a typical microstructure under irradiation

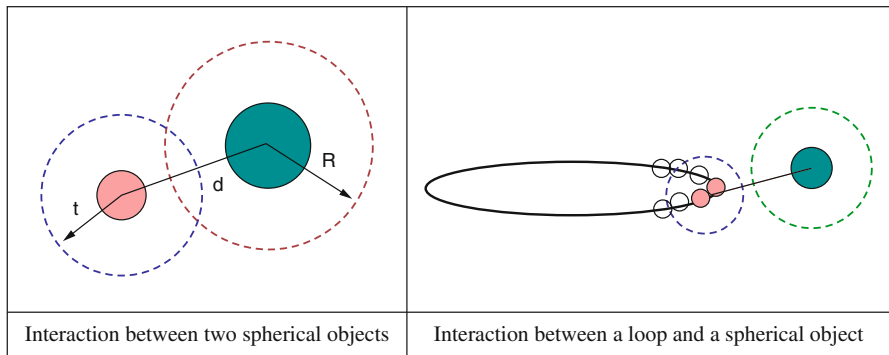
| Interaction between two spherical objects | Interaction between a loop and a spherical object |


**Fig. 6** Object interaction for different shapes. Typical values for single point defects in transition metals are R $\sim$ 5 Å, and the core radius of a dislocation is about 5 Å

of the microstructure (Sect. 4.5.2). Note that elastic effects can be taken into account more specifically, as discussed in Sect. 5.

During the simulation, events can occur, whose probabilities of occurrence are expressed in terms of frequencies (in s$^{-1}$). From the set of all possible events $i$ of each object $n$ among the N objects in the system, each with a known rate of occurrence, $\Gamma_{n,i}$, a total rate, $R$, is computed:

$$R = \sum_{n,i} \Gamma_{n,i} \tag{3}$$

A Monte Carlo step is initiated by selecting an event from all the events by drawing a random number between 0 and $R$. The value of this number determines

which event is selected. If more than one object can undergo the selected event, one is chosen at random. Once the event and the corresponding object are selected, the appropriate actions are performed to make that event occur, and the time is updated, by adding a time increment proportional to the inverse of $R$.

The associated time-step length $\delta t$ and average time-step length $\Delta t$ is given by:

$$\delta t = \frac{-\ln r}{R} \quad \Delta t = \frac{1}{R} \tag{4}$$

where $r$ is a random number in [0,1].

## 3.2    Mechanisms and Events Occurring During Radiation Damage

The most common events that need to be considered in an OKMC model of irradiation are:

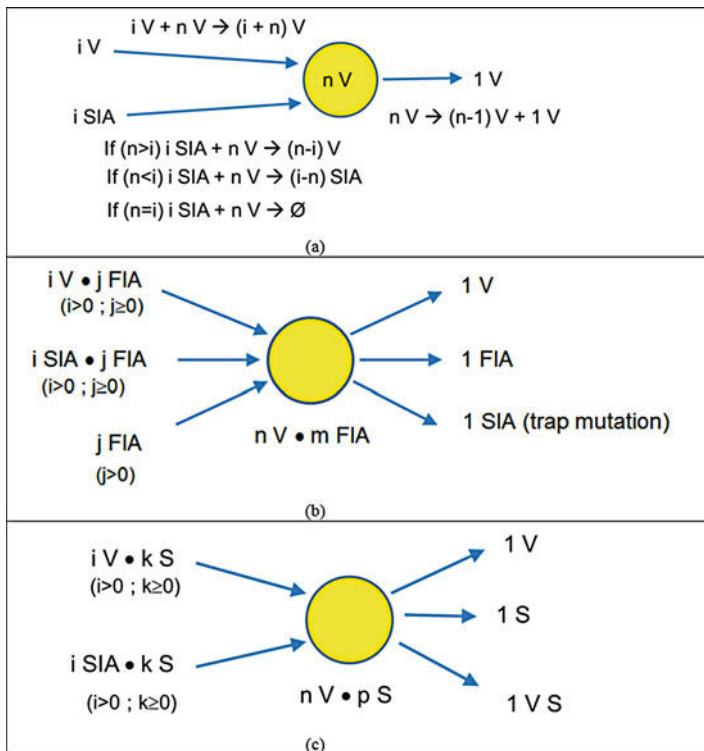
- **Migration**, i.e., jump to a neighboring site. The defects execute random diffusion jumps (in one, two, or three dimensions depending on the nature of the defect) with a probability proportional to their diffusivity, which has to be known for all mobile species.
- **Recombination** with objects of opposite type (i.e., SIA with vacancies) or aggregation with other objects (e.g., point defect clusters and complexes including solute atoms and FIAs).
- **Dissociation/emission** (when the object size is larger than 2) of one element (e.g., a single vacancy or single SIA) from the object.
- **Trapping** of objects at traps to model in a simple way microstructure features or heterogeneities such as impurities or specific solutes (e.g., carbon in steels) or precipitates (e.g., carbides in steels).
- **Annihilation** at free surfaces, grain boundaries, dislocations, or other sinks.
- **Trap mutation**, a common event observed in metals filled with noble gas (most often helium atoms (alpha particles) in fusion and fission conditions for structural materials and Xe or Ar in uranium oxide fuel pellets). Helium atoms are strongly repelled by metallic atoms and as consequence they have a propensity to form clusters. When too many He atoms are aggregated together, the system needs to relieve the strain created by the interstitial elements by the ejection of one or more matrix atoms leading to the formation of one or more Frenkel pairs (FP), i.e., vacancies and SIAs. As He binds very strongly to vacancies, the He cluster will be trapped by the vacancy it created and will not be capable of moving. This is thus a self-trapping (ST) event as the binding energy of the helium cluster with the vacancy is usually quite large. If one or more vacancies are already associated with the He cluster, the same mechanism can take place which is usually referred to as trap mutation (TM) or loop punching, if more than one SIA is created (when many SIAs are emitted at the same time, they are usually bound together also and form a dislocation loop). These FP creations make He clusters and He vacancy


**Fig. 7** (**a**) Possible reactions at a vacancy cluster containing n vacancies. (**b** and **c**) Events (reaction and emission) at a complex object consisting of n vacancies, m foreign interstitial atoms (FIA), or p solute atoms (S): nV•mFIA or nV•pS

(nHe.mv) clusters be nonsaturable traps for themselves unlike what is observed for hydrogen atoms, for instance. Self-trapping and trap mutation consist thus in the simultaneous creation of a vacancy and a SIA; the latter remains bound to the He clusters (De Backer et al. 2015).

Figure 7 summarizes the main different recombination and dissociation events an object can undergo for (a) a vacancy cluster (nV), (b) a complex vacancy-FIA cluster (nV.mFIA), and (c) a complex-solute cluster (nV.pS). This schematic graph shows the increase in complexity when a FIA or a solute is associated to point defects and point defect clusters and the necessity to define a much larger number of events (and parameterize them).

The simulation of irradiation can be treated as the occurrence of *external events*, which then depend upon the kind of irradiation that is simulated: to simulate electron irradiation Frenkel pairs are introduced at random with the proper rate; for a neutron irradiation, displacement cascade debris are introduced also at random with the proper rate. For an ion implantation simulation, one has to take into account the

implantation profile, and the cascade debris are thus introduced according to the profile. All external events are characterized by rates $P_m$ (for event m), corresponding to the production rate ($P_m$ = (number of external events/cm$^3$/s) × (simulation box volume)). Since each of these external events occurs at a known rate, their rates are added to the computation of the total rate.

Jump, dissociation/emission, detrapping and trap mutation are considered as thermally activated processes, characterized by an activation energy $E_{a,n,i}$ and an attempt frequency $\nu_{n,i}$. Their rates, for object n and event i are obtained as:

$$\Gamma_{n,i} = \nu_{n,i} \exp\left\{-\frac{E_{a,n,i}}{kT}\right\} \tag{5}$$

For the object jump, the activation energy is its migration energy, $E_m$. For the emission from either a trap or an object, the most typical method is to take the activation energy $E_a$ as the sum of the binding energy, $E_b$, of the escaping entity (e.g., that of a single vacancy or SIA from a cluster) and its migration energy $E_m$; $E_a = E_m + E_b$. Note also that in a real diffusion event, on a real lattice, the particle emitted has to perform several jumps to escape the source object. This can be accounted for by placing the escaping object at a distance such that, at the following step, both recombination with the initial object and diffusion away are possible; thus $\Gamma_{n,i}$ is only an approximation of the escaping probability. If one wants to compare directly with rate equation models, the emitted particle is placed at a random position in the simulation box (Stoller et al. 2008).

Trapping and annihilation of defects with opposite defects or at sinks, as well as aggregation into larger clusters, take place spontaneously whenever the involved objects come to a mutual distance smaller than a reaction distance, which is equal to the sum of the capture radii associated to each of the two objects. The most typical sinks are free surfaces, grain boundaries, and dislocation lines (segments). As a small part of matter can be simulated using OKMC, specific shapes can be used for the simulation box in order to reproduce experimental samples as illustrated in Fig. 8.

Dissociation and emission events have an activation energy often taken to be equal to the sum of the migration energy $E_m$ plus the binding energy between the emitted defect and a cluster of the size that remains after emission, $E_b$. The corresponding rate is:

$$\Gamma_d = \nu_0 \exp\left(-\frac{E_m + E_b}{k_B T}\right) \tag{6}$$

Regarding the reaction between defects, it is generally assumed that they are diffusion limited. That is, the reaction occurs as soon as the two objects are within a pre-defined capture radius, but no energy barrier is associated with the reaction. These events occur therefore only on the basis of geometrical considerations (overlap of reaction volumes) and do not participate in defining the progressing

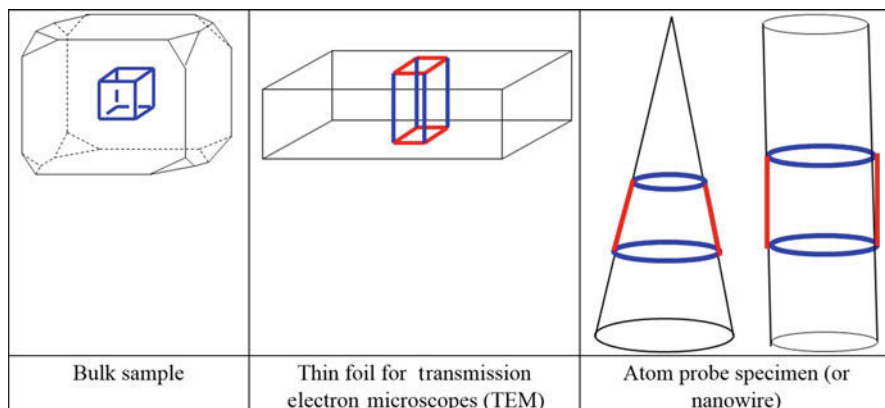
| Bulk sample | Thin foil for transmission electron microscopes (TEM) | Atom probe specimen (or nanowire) |


**Fig. 8** Specific sample shapes that can be simulated; periodic boundary conditions are applied on blue faces and free surfaces on red faces

of time. Events of this type also include the absorption of objects by sinks (e.g., impurities, dislocations, grain boundaries).

Grain boundaries, which act as sink for point defects, can be simply assimilated as free surfaces, as in Valles et al. (2017) where all the defects that reach the four lateral surfaces of the simulation box were removed out of the box or introduced using the average grain size method, inspired by Heinisch's work (Heinisch and Singh 2002) sometimes referred to as the finite PBC according to Soneda et al. (2003): when PBC are applied, whenever a mobile object has moved a distance larger than the average grain size, it is eliminated.

Dislocations can be introduced as segment(s) whose length is established according to the dislocation density to be simulated. In simple models, they act as linear sinks for point defects with a given recombination radius. Another approach could consist in considering dislocations as traps rather than sinks for specific objects, but this requires to then characterize the interaction mechanisms and the associated energies. Dislocation loops can be simulated by objects of toroidal shape, characterized by their major and minor radii and their orientation (Jansson et al. 2013).

The physical inputs of the model are thus the migration and attempt frequencies of all the objects that can form, their interaction volume, and the dissociation energies of all the possible objects that can be emitted.

# 4    Applications

## 4.1    Treatment of Impurities and Foreign Interstitial Atoms

One difficult issue in microstructure modeling is the comparison with experiments as real materials are far from being perfect and even the purest materials contain

impurities. One typical example is the long debate that existed regarding the migration energy of the vacancy in pure Fe, where two values were proposed all based on careful experiments. It was later shown that the highest value was the vacancy migration energy for Fe containing a slight amount of C acting as traps for the vacancy. Indeed, in a very pure Fe, Vehanen et al. (1982) found a vacancy migration energy of 0.55 eV, whereas Schaefer et al., in Fe containing a slight amount of impurities measured a value of 1.28 eV (Schaefer et al. 1977). One way to account for these impurities is to use effective parameters. For instance, one can use 1.3 eV as the migration energy of the vacancy in "real Fe" as real Fe will contain C as shown in an OKMC simulation of a vacancy diffusing in a pure Fe matrix (Becquart et al. 2010) containing immobile traps representative of C atoms. However, such an approach is quite limited as the concentration of the impurities is not taken into account. A more realistic method consists thus in introducing traps with appropriate binding energies and capture radius (Jansson and Malerba 2013, 2014). Note that this approach is limited to "slow" FIAs such as C and N in Fe or W at low enough temperatures. At temperatures where C and N can easily move or for fast-diffusing interstitials such as He and H in Fe and W, one needs to consider them as another object type that can move and form clusters, associated or not with point defects. In the case of rigid lattice approaches, the interstitial species will move on specific sublattices. The trap concentration can vary according to the aging or the dose, as done, for example, in Castin et al. (2018) to simulate transmutation and formation of Re in W alloys.

## 4.2 Taking into Account Solute Effects: "Gray Alloy" Approach of the Microstructure

The effect of solute atoms or alloying elements can be modeled using the so-called "gray alloy" approach. The "gray alloy" approach consists in a homogenization of the alloy composition. The alloy properties are described as in the case of pure metals by diffusion coefficients and binding energies characteristic of the alloy considered. More precisely, the migration energies, attempt frequencies, and binding energies of point defects and point defect clusters that locally depend on the environment (i.e., the number of solute atoms) of the moving species are considered to be the same everywhere (the local environment is neglected), and an effective value is considered. In this approach all the solutes can be treated in an effective way, or one can treat one solute (usually the one with the largest impact on the microstructure evolution) explicitly and all the other ones as part of the "gray alloy." A typical example is carbon in dilute Fe alloys. Because carbon interaction with vacancies is very large, carbon is usually treated explicitly, whereas Cr or Mn and Ni can be modeled as part of the "gray alloy." In this approach, one can have effective properties depending on the alloy composition. They are usually applied to the whole simulation box; however, it is possible to use it locally to model concentration gradients in a cellular approach of the method. The "gray alloy" approximation has been used, for instance, to model to predict the nanostructure

evolution under neutron irradiation in both reactor pressure vessel (RPV) and ferritic/martensitic (F/M) steels modeled, respectively, in terms of Fe-C-MnNi and Fe-C-Cr alloys (Chiapetto et al. 2015a, b). The effect of the substitutional solutes of interest was translated into modified parameters for the mobility of defect clusters. More precisely, the interstitial loop mobility was defined by an effective mobility which depends on the solute concentration. Using this approach, the origin of low-temperature radiation hardening (and subsequent embrittlement) was investigated, and the results support the hypothesis that solute clusters segregate on immobile interstitial loops, which act as heterogeneous nucleation sites for the formation of the NiSiPCr- and MnNi-enriched cluster populations (Chiapetto et al. 2015a). It was also shown that the introduction of Cr in F/M steels enhances recombination and suppresses the formation of vacancy voids. These results explain the link between the non-monotonic SIA diffusivity with %Cr and the experimentally observed radiation-induced swelling (Chiapetto et al. 2015b).

## 4.3   Taking into Account Solute Effects: Beyond the "Gray Alloy" Approach

In a "gray alloy" approach, the effect of solutes is introduced assuming that it changes the properties of the objects. This technique is rather simple and has been refined in a model that contains a more explicit description of solute atoms in dilute alloys (Castin et al. 2017). In this new approach, solute atoms are explicitly introduced in the matrix; however only single point defects are allowed to interact with them in first approximation. Point defect clusters still assume the gray matrix, i.e., they do not interact with the solute atoms, and their properties are effective properties depending upon the alloy composition. When either a single vacancy or a single SIA catches a solute atom (found within its radius of interaction), the latter is removed from the matrix and incorporated into the objects, thereby redefined. Another approach has been proposed (Domain et al. 2004) for low-content FeCu alloys: in the case of objects containing both point defects and solute atoms, the emission of either a single vacancy, a mixed vacancy-solute pair, or a single solute can be considered. In that later case, it is the remaining object that moves away from the emitted solute.

Solute concentration can be also accounted for using cellular KMC which seems to be particularly adapted for alloys. This method can be seen as the coarse graining of AKMC for solutes coupled to OKMC for defects, linked by transport coefficients. The system is decomposed in cells, defined by a local solute concentration, and solute exchange between neighboring cells is controlled by flux coupling with point defects. This method has been recently applied to Cu precipitation in Fe under thermal aging (Garnier and Nastar 2013) and spinodal decomposition in FeCr (Dopico et al. 2015; Rodríguez-Martínez et al. 2017). With this method direct simulation of the initiation of germination (for precipitation or spinodal decomposition) is not treated as the initial germ is smaller than the cell size. Possible solutions to this issue are to perform standard AKMC to initiate the

germination and switch to cellular KMC or initially reduce the size of the cells. The acceleration factor is found to be around two or three orders of magnitude for the cases investigated so far.

## 4.4  Downscale Coarsening: Coupling the AKMC with OKMC

The OKMC approach is sometimes used within a lower scale method as proposed in Castin et al. (2011) and later Pannier (2017) where the AKMC is coupled with the OKMC in the same code, thus producing a hybrid AKMC-OKMC code. In Castin et al. (2011), the precipitation of Cu in Fe was simulated using the following scheme: Cu clusters above 15 atoms are considered as objects, for which migration and dissociation events are defined and have specific, size-dependent, and thermally activated frequencies. Matching between the fully atomistic and the coarse-grained approach is achieved by using a neural network that provides all the necessary parameters for large Cu clusters, after a training on atomistically informed results. The same approach has been very recently developed to model the evolution of complex Fe alloys and more precisely the formation of solute-rich clusters representative of RPV steels, under irradiation (Pannier 2017). In this work, it was observed that about 80% of the jumps done in AKMC simulations of Fe alloys under irradiation concerned quasi-immobile clusters, the motion of which does not impact much the microstructure evolution and more precisely the formation of solute-rich clusters. Hence, losing details concerning the description of this type of object might not drastically change the stochastic trajectory of the simulation. As a consequence, such large clusters have been treated as objects. In the case of pure iron, when a group of first nearest neighbor point defects has a size (in number of point defects) higher than the user-defined object cutoff, all these point defects are considered as one object. The individual jump frequencies of the point defects associated to an object are null. Frequencies for migration and emission are associated with each object and obtained by a series of AKMC simulations. Migration is performed by moving the whole cluster by a first nearest neighbor distance and emission by putting the emitted point defect in a position near the object. When the size of an object changes, the object returns to the AKMC state. This AKMC relaxation is required because it allows the objects to return to an energetically more favorable configuration rather than being stuck in an atypical geometry. Figure 9 illustrates the hybrid AKMC-OKMC approach applied in Pannier (2017).

## 4.5  Upscale Coarsening: Using OKMC to Feed MFRT

### 4.5.1  Using the OKMC to Obtain the Source Term

As already mentioned in Sect. 2.2, MFRT is another possible approach widely used to model the evolution of microstructures under irradiation. A primary difference between the two methods is that spatial information about individual objects is maintained in OKMC, while only spatially averaged information is used in the
**Fig. 9** Illustration of the hybrid AKMC-OKMC method, for a 9-vacancy cluster and a 7-vacancy + 2 solute cluster (Pannier 2017). The 9-vacancy cluster (top) or the 7-vacancy and 2-solute cluster (bottom) are treated as single objects in the hybrid AKMC-OKMC. These two objects can then undergo two kinds of events. They can move as a block or emit a point defect or a solute. The emitted species are, in the next KMC step, treated in the AKMC approach. The remaining object, depending on its size, will be treated in the OKMC or in the AKMC manner. In the latter, the point defects and solutes will be treated individually

MFRT. Furthermore, OKMC algorithms deal with the explicit spatial dependence of the evolving defect distribution, whereas MFRT models do not deal with the explicit position of defects, but they deal with the averaged concentration of defects in a small volume at a given position in the material. MFRT models do however take into account the presence of gradients of concentration, and hence, in some sense, the spatial dependence of the evolving defect distribution is not fully lost. The source term however must be carefully estimated. Indeed, neutron or ion irradiations lead to the formation of cascade debris composed of isolated defects and defect clusters in

a confined region (of few 10 nm), and this spatial correlation has an important effect on the long-term evolution of the microstructure (Souidi et al. 2011). As MFRT cannot treat these spatial correlations, OKMC are often used to coarse grain the primary damage and obtain the source term (Heinisch 1983; Becquart et al. 2010; Adjanor et al. 2010; Jourdan and Crocombette 2012) for MFRT models.

### 4.5.2    Using OKMC to Evaluate Sink Strengths

The sink strength is a notion typically used in rate theory models to describe the interaction of migrating defects with the features characterizing the microstructure of the material (e.g., voids, dislocations, grain boundaries). The sink strength of each type of microstructural feature is proportional to the square of the inverse of the mean distance covered by the migrating species before it interacts with the feature, in general by being absorbed or trapped. It is a priori a function not only of the type, shape, orientation, size, and concentration of the sinks but also, and sometimes crucially, of the dimensionality of the motion of the migrating species (three-dimensional (3D) versus one-dimensional (1D) or mixed 1D/3D migrating defects). KMC techniques have the advantage of going beyond the mean field approximation, by explicitly and spontaneously taking into account spatial correlations between the elements of the physical system. They implicitly reproduce, among other phenomena, the effect of sinks or traps for migrating species, characterized by a given geometry and spatial distribution. They can thus provide directly the sink strengths of any microstructural features, provided, of course, that the feature is accurately introduced in the OKMC model (Heinisch et al. 2007; Malerba et al. 2007; Jansson et al. 2013; Hou et al. 2016; Ahlgren and Bukonte 2017; Carpentier et al. 2017).

## 5        Future Direction and Perspectives

Difficulties in applying the OKMC algorithm are not due to the method itself, which is fairly straightforward. They stem from the fact that all the possible events that each object can undergo according to a specific physical mechanism, their probability, and their properties must be pre-defined. The key point of this method is thus to determine the effective parameters from atomic models, for instance, as well as all the relevant mechanisms that can happen. It is important to stress that OKMC does not have the capability to predict structures or events that are not explicitly included in the model (unlike ab initio, molecular dynamics (MD) simulations or KMC methods with on-the-fly event catalog building capacity (Trochet et al. 2015; Henkelman and Jónsson 2001).

Another issue that needs to be stressed out is that the simulations are quite long and can last days to weeks. To parallelize efficiently the codes for complex microstructures is a challenge which has first been tackled to independent moving species (walkers) in an OKMC framework by Martínez et al. (2008). The same method has been applied more recently by Martin-Bragado et al. (2015) to OKMC, for a more realistic case of an isochronal annealing of Fe after electron irradiation.

Indeed, this kind of experiment can be simulated with such an algorithm as the initial distribution of point defects is homogeneous. There exists thus specific conditions where parallelizing is efficient as shown also in Jiménez and Ortiz (2016) where an OKMC code has been parallelized on GPU for a simple model considering only recombination and no "particle" clustering. However, for the time being, the efficiency of parallelizing OKMC simulations has not been proved for realistic situations, i.e., situations where objects with very different properties and in particular diffusion coefficients covering orders of magnitude have to be considered. To reach meaningful irradiation doses (>0.1 dpa) with realistic fluences, one still has to resort to homogenized rate theory methods based on the mean-field approximation (Marian et al. 2017). Furthermore, despite being capable of handling system sizes larger than the AKMC method, it is still difficult to model microstructures in which low-density objects or very large objects are formed in OKMC. At the moment, the order of magnitude of the concentration limit is around $10^{-15}$ cm$^{-3}$. Below this concentration, it is once again, more efficient to turn to MFRT techniques (Jourdan et al. 2014).

In the case of multicomponent alloys, the explicit treatment of all the solutes that can form a wide variety of complex objects composed of point defects and several solute types is also a challenge as the more objects, the more parameters in the OKMC model. Furthermore, the object shapes can also have some impact which adds another level of complexity in their treatment. These issues can benefit from AKMC simulations that can be used to obtain laws regarding the formation and interaction of these objects or other techniques such as the one proposed by Bonny et al. (2017). They developed a mean field model to obtain the energetics of point defect clusters in perfect random alloys and computed the dissociation energy of small vacancy clusters in FeCr and FeCr-2%W alloys, considered to be model alloys for Eurofer steels. They concluded that the dissociation energy is not expected to vary by more than 0.1 eV in the 0–10% Cr and 0–2% W composition range and thus that a mean field approach could be used in these situations.

The elastic effects can, in some cases, significantly bias the system evolution. An exemplary case is the interaction of dislocation loops with the surfaces of the thin foil samples used in TEM (Fikar et al. 2017a, b) or the interaction between point defects and semi-coherent interfaces (Vattré et al. 2016). OKMC is well-suited to incorporating long-range elastic interactions because the spatial location of defects can be tracked with high accuracy. One way proposed by Hudson et al. (2005) is to include them as a bias to the diffusive motion of mobile species. The work done by the elastic force over the course of the anticipated jump is calculated and used to bias the jump probability. Other, more explicit methods exist. One possibility is to take them into account when estimating the interaction between two objects as proposed by Mason et al. (2014) where it was shown that the experimental microstructure obtained by irradiating an ultrahigh purity with a very low fluence of self-ions could only be reproduced in OKMC if the elastic interactions between loops are taken into account. Another method, proposed by Vattré et al. includes the elastic interactions in the estimation of the activation barriers (Vattré et al. 2016). According to Carpentier et al. (2017), the impact of the elastic interactions on the

diffusion properties and their effect on the bias is mostly due to the anisotropy at the saddle point position. Elastic effects due to individual defects can also be evaluated by lower-scale methods such as MD as proposed in Chang et al. (2013, 2015) or continuous methods such as phase field (e.g., Rouchette et al. 2014). The corresponding sink strength and bias obtained with these different methods can then be introduced in OKMC simulations by considering, as mentioned in Sect. 3.1, effective sizes for the objects that take into account elasticity in an effective manner.

To conclude, OKMC are versatile and powerful methods to study complex systems with many different reactions and possibilities. The coupling between AKMC and OKMC is one way of taking into account the details of object structure when it matters (e.g., nuclei) as well as speeding up the evolution of large objects by coarse graining the individual defect jumps into a collective evolution. However, homogenization and further coarse graining is still necessary to reach the high doses and/or low-flux characteristics of situations encountered in nuclear reactors.

## A.1 Appendix: OKMC Codes Dedicated to Radiation Damage Studies

We now very briefly describe some of the codes developed and used for radiation damage studies in metals.

### A.1.1 JERK

The event kinetic Monte Carlo code JERK was one of the pioneering codes developed at CEA by Lanore (1974). In this approach the lattice is ignored, and the objects have continuous coordinates. The elementary events are binary encounters of two objects, emissions of a mobile object from a source such as a cluster or a surface. Probability laws are defined for each event. A typical simulation step consists of following the evolution of the object population over a macroscopic time interval. This is achieved by building the list of all possible events which may happen within the time interval, processing the events in the order of increasing delays and refreshing the event list after each event has been processed. When the event list is exhausted, the partners that did not react are displaced according to macroscopic diffusion laws (Barbu et al. 2005). This code has been used to model isochronal annealing in Fe (Mason et al. 2014) and FeC (Jourdan et al. 2011).

## A.1.2   BIGMAC

The kinetic Monte-Carlo code BIGMAC was developed at Lawrence Livermore National Laboratory by Johnson in collaboration with Caturla and Díaz de la Rubia (Johnson et al. 1998). This code has been used by different research groups to study many systems. BIGMAC tracks the locations of defects, impurities, and clusters as a function of time without relying on a lattice structure (it is however possible to modify the code to include a lattice if necessary). In addition, no hardwired reactions are introduced in the code, thereby allowing the user to directly define any type of system: this versatility allows the study of complex systems. The disadvantage of this approach appears for very high doses, where large defect clusters are formed, since it requires large memory to store the matrices for all defect reactions.

One key feature of BIGMAC is the recent implementation of the cellular approach (Caturla et al. 2016): the simulation box is divided into smaller boxes (cells) with different Cr content. The alloying element is thus treated in terms of average local concentrations, which are given (in atomic %) for each cell. Another peculiarity of the code consists in the fact that jump probabilities for the defects depend on the local solute concentration, as well as on the concentrations of neighboring cells. The cellular OKMC is a priori the ideal framework to introduce explicitly the dependence on local concentration of parameters that describe stability and mobility of point defects and their clusters, making its application to concentrated alloys such as high-Cr F/M alloys ideal.

## A.1.3   Lattice Kinetic Monte Carlo (LAKIMOCA)

LAKIMOCA code is a KMC as well as a Metropolis Monte Carlo package developed in standard C by Domain at EDF R&D in 1998. It has been extensively described in Domain et al. (2004). LAKIMOCA can take into account a large number of objects (defect clusters, solute atoms, vacancy-solute clusters, grain boundaries, dislocations, etc.) and exists in two versions: atomistic kinetic Monte Carlo (AKMC) or object kinetic Monte Carlo (OKMC), according to the nature of the object considered as mobile. The code allows easy introduction of different classes of immobile traps (mimicking trapping nano-features, as well as dislocations) and sinks (i.e., features like dislocations and grain boundaries where point defects and clusters can disappear), characterized by specific geometrical shapes (spheres, infinite cylinders, surfaces, etc.). The mobile objects (or more precisely their center of mass) are located on a lattice that can be bcc, fcc, and hcp and can jump from one lattice site to a first neighbor lattice site. The starting configuration can be created by the code itself with random distributions of initial defects and/or solute atoms or can be given by the user. LAKIMOCA can simulate damage production from electron, ion, and neutron irradiation. Neutron irradiation is simulated by a mixed flux of Frenkel pairs and defect cascade debris.

### A.1.4 Modular Monte Carlo (MMonCa)

MMonCa is an open-source kinetic Monte Carlo simulator developed by Bragado (Martin-Bragado et al. 2013). It is developed in C++ and distributed mainly for Linux (Ubuntu) sytems. MMonCa contains a Lattice KMC module, used mainly for simulation of epitaxy, and an off-lattice Object KMC module, used for simulation of damage irradiation in many materials. The presence of physical defects that diffuse in space implies the need to include diffusion as a transition rate and to define algorithms for space migration and particle interaction. The space is divided in small prismatic elements using a tensor mesh. Space is assumed to be homogeneous (in material, temperature, etc.) inside each small element. Each element obtains its material definition by calling a user-defined procedure that specifies the material structure in the simulation. In this way, very complex shapes containing different materials can be simulated. This approach is of particular interest in the case of concentrated alloys. Furthermore, the cellular OKMC algorithm initially developed in BIGMAC has been introduced in MMonCa, as well.

### A.1.5 KSOME

KSOME is a flexible and lattice based code patterned after the original FORTRAN code ALSOME (Heinisch 1983) developed by Heinisch. Objects of interest include vacancies, SIAs, interstitial impurities, and clusters of these defects. The objects are characterized by their type, size, shape, position, and orientation (Nandipati et al. 2015).

### A.1.6 McHERO

McHERO stands for Monte Carlo simulation of helium-bubble evolution and resolutions (Takahashi et al. 2010). It is based on kinetic Monte Carlo (KMC) techniques to simulate migration and coalescence of He bubbles and interactions with distinct three-dimensional geometric features of the material. The kinetics of bubble migration and coalescence include Brownian motion as well as bias-driven migration, such as in a stress or temperature gradient. The diffusion coefficients of helium bubbles are converted into probabilities of the occurrence of the events. The event is in this case the diffusion of a bubble within a time step $\delta t$. The probabilities are then summed up to find the total probability of the events. The total probability is used to normalize the probability of each event.

### A.1.7 MATEO

The hybrid atomistic/object KMC code MATEO is written in C++ and has been developed by Castin at SCK•CEN (Castin et al. 2017). Its OKMC approach is built upon the same philosophy and fundamental hypotheses (in terms of lattice-defect

and microstructure description, reproduction of neutron irradiation, etc.) as the LAKIMOCA code, but it has been refined in a model that contains a more explicit description of solute atoms (Castin et al. 2017). Solutes are explicitly introduced in the matrix, in an AKMC fashion, but only single point defects are allowed to interact with them. Point defect clusters still assume the gray matrix. When either a single vacancy or a single SIA catches a solute atom (found within its radius of interaction), the solute atom is removed from the matrix and incorporated into the object, which is then redefined into a new one. Finally, the solutes are reintroduced in the atomic matrix when the carrying point defect interacts with another object, i.e., either during a recombination event with an opposite kind of defect or merging with another defect of the same kind. Globally, solute transport is thus implemented in a way, which can be regarded as a compromise between providing atomistic-level description and keeping the evolution of the predicted microstructure from the gray alloy model.

**Abstract**

Deformation twinning is an important mode of plastic deformation in hexagonal close-packed (HCP) materials. Experimental observations indicate that these twins occur heterogeneously across the polycrystalline microstructure during deformation. The variation is too substantial to be authentically represented by average values, advocating the use of statistical analyses and stochastic models in the studies of HCP material deformation response. This chapter reviews recent efforts to explain the origin of the stochastic nature of twinning and to analyze and simulate deformation twinning in HCP materials from this perspective.

# 1    Introduction

Hexagonal close-packed (HCP) polycrystals deform by two mechanisms: the glide of dislocations and expansion of deformation twins (Beyerlein et al. 2014; Partridge 1967; Yoo 1981; Yoo and Lee 1991). Both dislocations and twins are confined to proceed on particular crystallographic planes and directions in a given crystal. To deform the crystal, dislocations glide on these planes. Twins, on the other hand, shear the atoms on these planes causing them to reposition into a configuration that is crystallographically reoriented from the original crystal. The high-resolution transmission electron microscopy (HR-TEM) image in Fig. 1a shows the twin-parent relationship for $\{10\bar{1}2\}$ tensile twin in HCP Zr and is illustrated in Fig. 1b. Strain is imposed as the twin domain grows in size (Beyerlein and Tome 2010; Capolungo et al. 2009; Kumar et al. 2018). Compared to slip, twins greatly affect the mechanical response (Proust et al. 2007; Salem et al. 2006; Wang et al. 2013a; Wronski et al. 2018), formability and ductility (Barnett 2007a, b; Kumar et al. 2017d), and failure mechanisms (Simkin et al. 2007; Yang et al. 2008; Yin et al. 2008) of HCP metals. Figure 1c presents a typical example of how twinning can affect the mechanical response of an HCP alloy (AZ31 Mg) (Wang et al. 2013a). As shown, many details, such as yield stress, strain hardening, and ultimate strength, are affected by twinning.

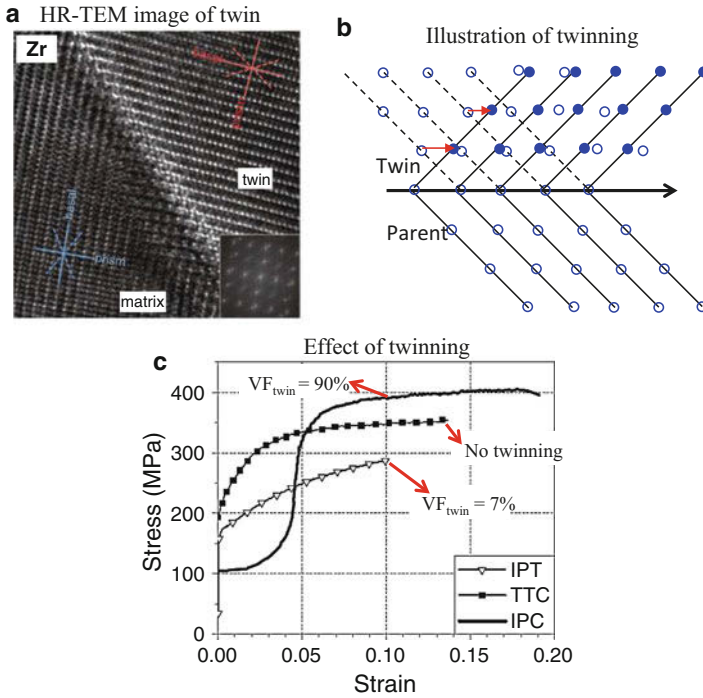
Both mechanisms, slip and twinning, occur heterogeneously across the crystal. Heterogeneity in slip is evident at nanometer to micron scales. Dislocations glide in arrays within slip bands that are nanometers in thickness. As deformation proceeds, dislocations can form patterns consisting of dislocation-rich areas separating nearly dislocation-free areas (Agnew et al. 2002; Akhtar and Teghtsoo 1971; Bay et al. 1992; Hughes and Hansen 1997; Kuhlman-wilsdorf and Hansen 1991; Kuhlmann-Wilsdorf 1999; Kumar and Mahesh 2012). Highly resolved microscopy techniques,


**Fig. 1** (**a**) High-resolution TEM image of the twin-parent orientation relationship for the {1012} twin in HCP Zr (Morrow et al. 2014c). (**b**) Schematic of the shearing of atoms that form the twinned lattice from the parent lattice. (**c**) Example showing the effect of deformation twinning on the stress-strain response of HCP AZ31 Mg alloy (Wang et al. 2013a)

such as TEM, can be used to observe individual dislocations and patterns of dislocations within deformed grains and grain boundaries.

Compared to slip, however, the heterogeneity in twinning is evident at much larger scales, such as those of the polycrystal (Barnett et al. 2012; Beyerlein et al. 2010; Capolungo et al. 2009; Kumar et al. 2018; Wang et al. 2013c). The nonuniform nature of twinning can be easily recognized at the resolution of most standard microscopy and diffraction techniques, such as EBSD and optical microscopy. For instance, for Mg ($c/a = 1.624$), the twin reorientation and local shear associated with the most common tensile twin is 86° and ∼13%, respectively. Large sections of one grain can contain multiple twin domains, whereas another grain of seemingly similar properties (size, shape, orientation) contains no twins. Even in the same grain, the twin thickness can vary easily by two or three times. Twins can expand into neighboring grains. At this larger polycrystal scale, the heterogeneity in dislocation slip would not be discernable.

The widespread heterogeneity in twinning has motivated the use of statistical analyses to understand the role of microstructure, such as grain orientation and grain size, on twinning (Barnett et al. 2012; Beyerlein et al. 2010; Capolungo

et al. 2009; Kumar et al. 2018; Wang et al. 2013c). The apparent sensitivity to local heterogeneities in stress has inspired the use of in-situ testing and simulation techniques to reveal how twin lamella form and expand within a polycrystalline microstructure during deformation (Cheng and Ghosh 2015, 2017a, b; Hazeli et al. 2013; Khosravani et al. 2015; Morrow et al. 2014a, b, c; Wang et al. 2010a, 2011, 2012, 2013b; Wu et al. 2016). Many crystal plasticity models have advanced to incorporate the stochasticity in twin formation and growth, finding better agreement in stress-strain response and microscopy data than the conventional deterministic approach for twin activation (Abdolvand et al. 2015a, b; Abdolvand and Wilkinson 2016; Ardeljan et al. 2015; Beyerlein et al. 2011, 2012; Beyerlein and Tome 2010; Kumar et al. 2017b; Niezgoda et al. 2013, 2014).

The aim of this chapter is to summarize the recent advancements in understanding the formation and growth of deformation twins and likely explanations for the apparent stochastic nature of deformation twinning. The chapter is structured as follows. It begins with a brief review of statistical analyses of large microstructural data sets of materials that twinned during deformation. Next, the modeling methods that have been used to date to simulate twins in HCP polycrystals are briefly introduced. The chapter ends with examples from these calculations and key findings on the role of microstructure and local stresses on twin formation, propagation, and growth.

## 2    Twinning as a Stochastic – Sequential Process

Statistical analysis of twin and stochastic analysis of twinning dynamics can be used as a way toward better understanding of twinning. For many decades, analyses of microscopy data and deformation models have taken a deterministic approach to treating deformation twinning and only recently have they incorporated stochastic aspects, showing noticeable improvements in prediction. The statistical analyses and companion modeling efforts will be discussed in the following sections.

### 2.1    Dynamic Processes of Twinning

The twinning process can be viewed broadly as taking place in three stages. Witnessing these stages in situ is challenging, and in lieu of displaying actual experimental images, a schematic of these stages is provided in Fig. 2, where for simplicity only one twin in one grain is shown. Stage 1 is the creation of an embryo (nucleation), which begins at the atomic scale. Twin nucleation models assume that the twinning partials, needed to create a twin embryo, form directly from the dissociation of pre-existing dislocations. The initiating dislocations may be lattice dislocations (Capolungo and Beyerlein 2008; Cohen and Weertman 1963; Jagannadham 1976; Mahajan and Chin 1973; Mendelson 1972; Priestner and Leslie 1965) or dislocations found in grain boundaries (Barrett and El Kadiri 2014; Beyerlein et al. 2011, 2012; Wang et al. 2014) or moving dislocations that have impinged on bi-phase interfaces (Beyerlein et al. 2013; Zheng et al. 2012). The
**Fig. 2** Schematic showing three basic sequential steps involved in the formation of twin lamella (Kumar et al. 2015). (**a**) Nucleation, formation of twin nuclei at a given grain boundary; (**b**) propagation, propagation of a twin nucleus into the parent crystal; (**c**) growth, migration of the twin boundary and thickening of the lamella

stresses needed to support these reactions are relatively high, requiring localized stress concentrations, generated for example, at the head of dislocation pile ups.

Stages 2 and 3 involve twin growth and the migration of twin boundaries. In stage 2, growing twin embryos, initially nanoscale to submicron in size, propagate under stress into the grains, often spanning the entire crystal and terminating at the other grain boundaries bounding the same grain (Beyerlein and Tome 2010; Capolungo et al. 2009; Kumar et al. 2018; McCabe et al. 2009). In stage 3, these terminated twins begin to propagate and expand. They can grow either by thickening, so their width increases or by transmitting, a process by which a second twin forms on the other side of the grain boundary where the first twin and grain boundary meet.

Both twin nucleation and expansion can occur only if the combination of required stresses and sufficient density of defects are present. Both aspects, mechanical and material in nature, can vary statistically in space and in time in a deforming microstructure and can result in the statistical appearance of a twin or twins in a grain.

## 2.2  Statistical Features of Deformation Twins

In a polycrystal, grains vary in size, crystallographic orientation, and local grain neighborhood. Most commonly considered microstructural variables that affect the propensity for twinning are grain orientation, grain size, and grain neighborhoods. Using EBSD, twins of thicknesses greater than ∼10 nm can be easily seen. As mentioned earlier, analyses of twins using EBSD data on deformed materials typically find twin lamellae that span the grain completely and are bound by grain boundaries.

Due to the statistical nature of twinning, in order to develop reliable statistical correlations between twin properties and grain microstructure from EBSD data, thousands of grains and twins would need to be analyzed. With the advent of automated EBSD techniques, a twinning microstructure that has formed in thousands of

deformed grains can be assessed relative rapidly facilitating creation of statistically significant data sets. With such data, statistical analyses have been carried out to identify correlations between properties of the twinning microstructure (variant, twin thickness) with the grain microstructure (grain size, grain orientation, and grain neighborhood).

In recent years, statistical analyses of twins have been carried out on a number of HCP metals, Mg, Zr, and Ti, and also Mg alloys (Barnett et al. 2012; Beyerlein et al. 2010; Capolungo et al. 2009; Ghaderi and Barnett 2011; Juan et al. 2015; Kacher and Minor 2014; Khosravani et al. 2015; Kumar et al. 2016a, 2017c, 2018; Shi et al. 2015a, c; Tsai and Chang 2013). The general finding is that while grain size and grain orientation can be strongly correlated with the propensity of twinning, the correlations are not as strong as those expected from a deterministic point of view. For instance, the following are found: (1) not all favorably oriented grains twin, (2) some not favorably oriented grains twin, (3) only 40% of twin variants have highest Schmid factor, (4) not all grains of the same orientation twin, (5) twinned grains contain variable numbers of twins, (6) not all grains of the same size twin, and (7) twins have variable thickness.

To elucidate the statistical variation in twinning grain to grain, the statistical results of $\{10\bar{1}2\}$ tensile twin in HCP Mg and Zr are discussed in the following sections. The materials examined are high-purity polycrystalline Mg and Zr with similar initial textures and, hence, similar grain misorientation distributions (Beyerlein et al. 2010; Capolungo et al. 2009). The Mg has a strong basal texture resulting from rolling, where most of the basal poles are aligned within 30° of the normal direction of the sheet. The Zr has a similar strong basal texture, which was developed via clock rolling rather than conventional rolling (Kaschner et al. 2006). Both materials were compressed at $10^{-3}$/s in an in-plane direction to activate $\{10\bar{1}2\}$ twinning. In order to develop a sufficient number of incipient twins in many grains, Zr was compressed at 77 K to 10% strains, and Mg was compressed at room temperature to 3% strain. Figure 3 shows the sample EBSD images of the twinning microstructure of the deformed Mg and Zr. Using an automated EBSD software, large data sets were generated by analyzing several distinct EBSD scans (Beyerlein et al. 2010; Capolungo et al. 2009). The number of grains and twins investigated totaled 2339 and 8550 for Mg, and 639 and 1065 for Zr.

## 2.3    Statistical Analysis of Crystallographic Orientation Effects

Grains are considered to be well oriented for twinning by a given twin type if they have one or more of the six twin variants bearing a high Schmid factor (e.g., >0.33). From a deterministic viewpoint, the twin variant in a grain most likely to form is the one that has the highest Schmid factor. The Schmid factor (SF) of observable twins is the most common parameter quoted in association with twinning. This reference is especially true when discussing whether twin activation obeys an "Schmid criterion," that is, one that is activated by a resolved shear stress in the twin plane and in the twinning direction (TRSS). The SF is defined as the ratio

**Fig. 3** Sample EBSD images of deformed (**a**) Mg and (**b**) Zr metals showing the activation of tensile twining (Beyerlein et al. 2010; Capolungo et al. 2009). To activate sufficient number of twins, Mg and Zr samples compressed along rolling direction to 3% at RT and to 10% at 77 K, respectively

(a) Pure Mg at 3% compression

TT Direction

100 μm

(b) Pure Zr at 10% compression

20 μm
between the TRSS and the value of the macroscopic tensile or compressive stress. The SF varies between $-0.5$ and $0.5$. It provides a geometric measure of how well a twin system is oriented with respect to an external axial stress. Twins belonging to a given grain are classified by their variant and its rank, 1–6, in decreasing order of their SF. If twin activation obeys a Schmid criterion based on the macroscopic applied stress, the twin would correspond to variant 1, the variant having the highest SF among the six in a grain. In this section, the effect of grain orientation as reflected by its SF on twinning formation, growth, and variant selection is discussed.

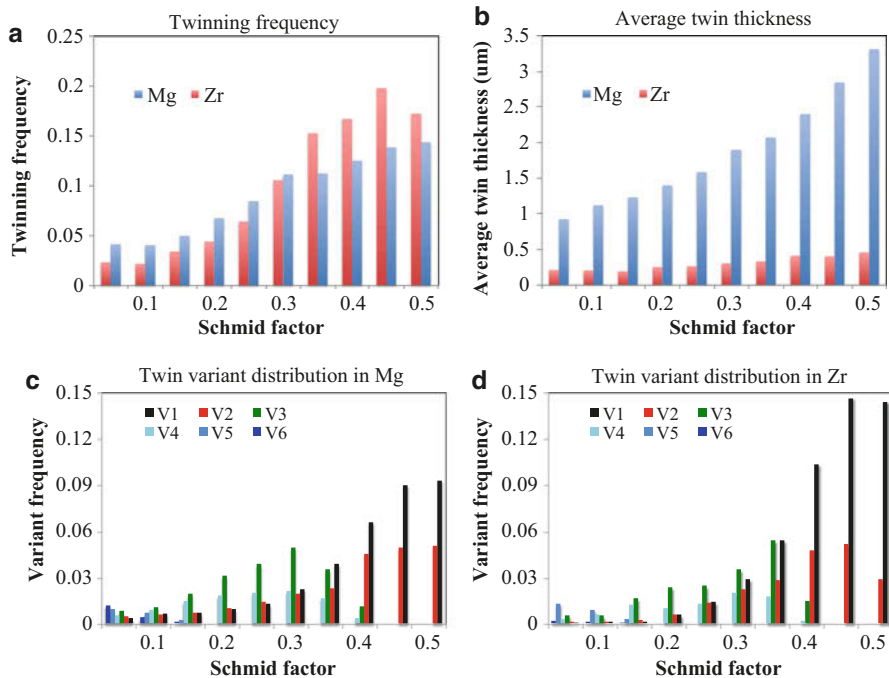
Figure 4a plots the twinning frequency taken from large data sets on twinned Mg and Zr. The analysis indicates that for both Zr and Mg, the frequency of twinning increases with SF, which is to be expected. However low SF twins are also activated. Figure 4c, d shows the distribution of twin variants as a function of twin SF for Mg and Zr, respectively. The frequency of each twin variant (1–6) is ~35.6%, 23.5%, 21.3%, 11.7%, 3.2%, and 4.6%, respectively, in Mg. Similar frequency in Zr is ~49.8%, 20.0%, 17.9%, 8.2%, 3.3%, and 0.7%. It is surprisingly common, among EBSD studies on twinned microstructures, to find that the twin variant selected is not the one with the highest Schmid factor or even the second highest Schmid factor. These low-rank SF twins have been referred to as "non-Schmid" twins. Activation of non-Schmid twins has also been reported in other HCP metal systems, like HCP Ti and AZ31 Mg alloy (Bieler et al. 2014; Kumar et al. 2018; Shi et al. 2015a, b; Wang et al. 2013c).


**Fig. 4** Effect of grain orientation, as measured by the Schmid factor associated with the twin system, on (**a**) twinning frequency and (**b**) average twin thickness of $\{10\bar{1}2\}$ tensile twins in deformed Mg (Beyerlein et al. 2010) and deformed Zr (Capolungo et al. 2009). (**c**) and (**d**) are the corresponding twin variant distributions in Mg and Zr, respectively

With all else being the same, twins with high geometric SF are expected to be thicker compared to twins with low SF. From the statistical data set, Fig. 4b shows the distribution of twin thickness as a function of SF for Mg and Zr. Evidently, twins with higher SF are thicker, presumably because they are better oriented for growth.

## 2.4    Statistical Analysis of Grain Size Effects

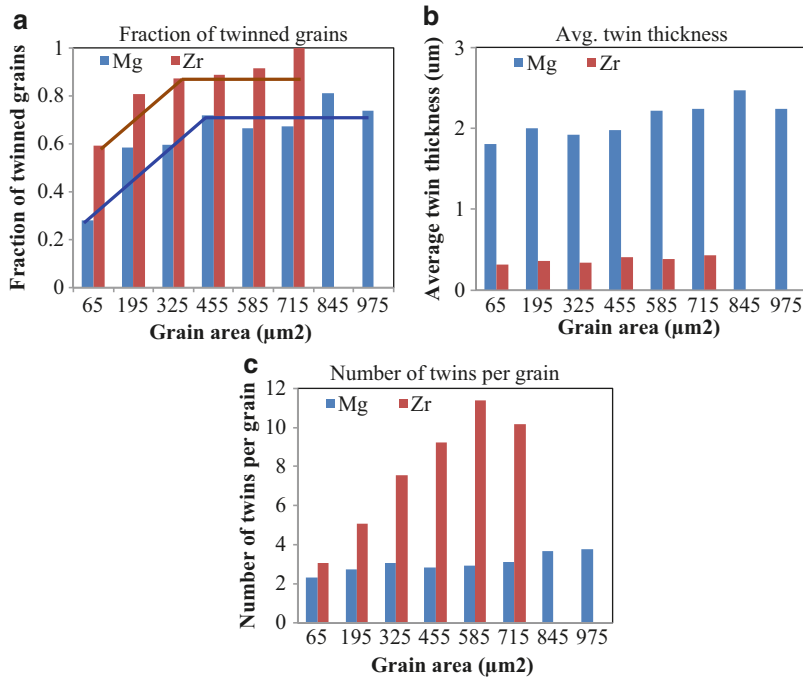
A common finding in many metals, not only those of HCP crystal structure, is that polycrystals with smaller average grain sizes develop lower twin volume fractions (Barnett et al. 2004, 2012; Beyerlein et al. 2010; Capolungo et al. 2009; Ecob and Ralph 1983; Ghaderi and Barnett 2011; Gutierrez-Urrutia and Raabe 2012; Jain et al. 2008; Juan et al. 2015; Kang et al. 2016; Kumar et al. 2016c, 2018; Lentz et al. 2014; Liu et al. 2015; Rahman et al. 2015; Stanford and Barnett 2008; Tsai and Chang 2013; Wongwiwat and Murr 1978). This frequent observation has motived the application of the Hall-Petch scaling law, originally used for slip, to twinning. This law was first used to explain the higher yield stresses or fracture strains with


**Fig. 5** Effect of grain size on (**a**) twinning frequency, (**b**) average twin thickness and (**c**) average number of twins per twinned grain of $\{10\bar{1}2\}$ tensile twins in Mg (Beyerlein et al. 2010) and Zr (Capolungo et al. 2009)

decreasing grain size. For twinning, it has been applied in a similar way, such as a twinning stress that increases according $1/\sqrt{D}$, where $D$ is grain size. In nearly all of these cases, the grain size refers to the diameter of the grain that has been cut in the 2D scan. In this section, the grain size dependence on twin frequency from statistically large EBSD data sets are discussed.

The variation in twinning tendency (defined as the number of twinned grains/total number of grains) with grain size for Mg and Zr is shown in Fig. 5a. Here the twinned grains refer to grains with at least one twin of any type. The analysis finds that for both material systems, the propensity for twin activation increases with increasing grain size. It is worth noting that the grain size dependence is not monotonic: the grain size dependence is more pronounced for smaller size grains and tends to saturate for larger grains (see Fig. 5a). The distribution of average twin thickness as a function of grain size is shown in Fig. 5b. The grain size plays a strong role on twin thickness in Mg, but not so in Zr. As another twinning metric, Fig. 5c shows the effect of grain size on the formation of multiple twins in HCP Mg and Zr. In both the materials, the number of twins per grain increases with increasing grain size, but it is particularly striking in Zr. Taking all the data into account, it appears that a grain of a given size in Zr accommodates more twins than grains of the same

size in Mg. Similar twinning statistics has been studied in other HCP metals and for other types of twins (Ghaderi and Barnett 2011; Juan et al. 2015; Lentz et al. 2015, 2016).

## 3 Computational Modeling Methods

### 3.1 Challenges in Modeling the Stochastic Twinning Process

In the foregoing section, statistical aspects of deformation twins were discussed. The substantial spatial variability in these features, across a deformed material grain structure, presents challenges in building both understanding and material models for several reasons. Firstly, twins appear to form randomly as the material is being deformed, and the origins of this stochastic behavior still need to be fully understood. Secondly, the discrete nature of twinning makes it inherently inhomogeneous, making the more commonly used and computationally efficient homogenization mean-field models not readily applicable to treat materials that undergo profuse deformation twinning. Thirdly, twin development is naturally a multiscale process. Twins initiate at the atomic scale, form embryos at the nanoscale, and grow to the submicron scale and can propagate across a grain and grain structure, manifesting at the micron scale and larger. Thus, it is not readily apparent how to apply coarse-graining modeling techniques to deformation twinning. Last, twins do not occur in isolation but concurrently with slip. The shear for HCP metals for the most common $\{10\bar{1}2\}$ tensile twin is 13% for Mg. Thus, even if the entire grain were to twin, slip would need to occur simultaneously in order to plastically strain the material. Twin-slip interactions are just as important or arguably more important for understanding the constitutive response of a material that deforms by slip and twinning. These interactions cannot be fully understood by studying slip and twinning separately.

### 3.2 Some Important Components for Models of Polycrystalline Materials That Deform by Slip and Twinning

Modeling the deformation of polycrystalline materials has been accomplished via a combination of crystal plasticity theory and polycrystal modeling schemes. Crystal plasticity (CP) theory is used to relate the distortion of a strained crystal to slip on crystallographic slip systems (Asaro 1983; Asaro and Lubarda 2006; Hosford 1993). Polycrystal plasticity models then link the individual grain response predicted by CP theory to the overall mechanical response of the polycrystalline aggregate (Asaro 1983; Canova et al. 1988; Kocks 1970; Kocks et al. 2000; Peirce et al. 1982; Roters et al. 2010; Tome et al. 1984). These polycrystal models appear in various levels of sophistication and computational efficiency as will be discussed shortly.

Implementing deformation twinning into a polycrystalline model would ideally seek to include the following elements: (1) the available twin modes, (2) a model

for activating a twin or a number of twins inside a grain, (3) a criterion for variant selection of the activated twins, (4) a scheme for reorienting and shearing the portion of the grain that is twinned, and (5) a criterion to grow the twin. Additional elements include accounting for twin-slip interactions and twin-twin interactions and twin transmission across grains. Not as many models exist that account for these other phenomena, in spite of the fact that they are common occurrences.

## 3.3   Two Categories of Computational Methods for Modeling Twins in Polycrystals

Computational crystal plasticity-based material models for the deformation of poly-crystalline materials can generally be broken down into two categories: mean-field models and full-field, spatially resolved models. The homogenized or mean-field response models, such as self-consistent models, take only a statistical description of the microstructure as input (e.g., crystallographic texture) and return a sample scale or effective response and microstructure evolution (Kocks et al. 2000). In this chapter, the visco-plastic self-consistent (VPSC) model is presented as an example for homogenized models (Lebensohn and Tome 1993).

Full-field micromechanical models, such as crystal plasticity finite element (CPFEM)- or crystal plasticity fast Fourier transform (CPFFT)-based approaches, require as input an explicit spatially resolved description of the material structure (e.g., grain orientation map) and return the spatially resolved material response and local structural evolution (Abdolvand and Daymond 2013b; Abdolvand et al. 2011; Ardeljan et al. 2016; Bronkhorst et al. 1992; Delannay et al. 2006; Eisenlohr et al. 2013; Idiart et al. 2006; Kalidindi 1998; Kanjarla et al. 2012b; Knezevic et al. 2016; Lebensohn 2001; Lebensohn et al. 2008, 2011a, b, 2012; Liu et al. 2010; Masson et al. 2000; Michel et al. 2000, 2001; Mika and Dawson 1999; Moulinec and Suquet 1994, 1998; Shanthraj et al. 2015; Zecevic and Knezevic 2017; Zhao et al. 2007). The term "full-field" indicates that both long-range and short-range grain interactions are considered, and the micromechanical fields are resolved on a discrete grid.

## 3.4   Homogenized VPSC Model Framework

VPSC model describes the polycrystal as a collection of orientations (grains) each with associated volume fraction. Each grain is regarded as a visco-plastic inclusion embedded in, and interacting with, a "homogeneous effective medium" (HEM), which has the average properties of the polycrystalline aggregate. The macroscopic response of the polycrystal results from the contribution of each grain. The visco-plastic compliance of the HEM is given by a self-consistent condition applied on the grain averages. At the single crystal level, the strain rate is given by the individual shear contributions of all active slip and twinning systems in the grain, as:

$$\dot{\varepsilon}_{ij}^g = \sum_s m_{ij}^s \dot{\gamma}^s = \dot{\gamma}_0 \sum_s m_{ij}^s \left( \frac{m_{kl}^s \sigma_{kl}^g}{\tau^s} \right)^n \tag{1}$$

Here, $\boldsymbol{m}^s$ is the symmetric Schmid tensor and $\dot{\gamma}^s$ is the shear rate on system $s$, $\dot{\gamma}_0$ is a normalized shear rate, $n$ is the inverse strain-rate sensitivity, and $\tau^s$ is the threshold or critical resolved shear stress required to activate system $s$. The latter is evolved using a thermally activated dislocation density-based hardening law (Beyerlein and Tome 2008). In order to avoid the further strain-rate dependence associated with the power $n$ in Eq. (1), $\dot{\gamma}_0$ is chosen equal to the norm of the macroscopic strain rate $\left\| \dot{\bar{\varepsilon}}_{ij} \right\|$. The constitutive laws relating strain-rate and stress for a single crystal and for the aggregate are written in a linearized form as:

$$\begin{aligned} \dot{\varepsilon}^g &= M^g : \sigma^g + \dot{\varepsilon}_0^g \\ \dot{\bar{\varepsilon}} &= \overline{M} : \overline{\sigma} + \dot{\bar{\varepsilon}}_0 \end{aligned} \tag{2}$$

where $M^g$ and $\overline{M}$ are the grain and the macroscopic visco-plastic compliance tensors. The tensors $\dot{\varepsilon}_0^g$ and $\dot{\bar{\varepsilon}}_0$ are the back-extrapolated terms for the grain and aggregate, respectively. These variables result from the linearization of Eq. (1). The effect of the linearization scheme on individual grain and polycrystal responses, thus, emerges only through these two variables.

The inclusion formalism couples stress and strain-rate in the grain $(\sigma^g, \dot{\varepsilon}^g)$ with the average stress and strain-rate in the effective medium $(\overline{\sigma}, \dot{\bar{\varepsilon}})$ through an interaction equation:

$$\left( \dot{\varepsilon}^g - \dot{\bar{\varepsilon}} \right) = -\tilde{M} : \left( \sigma^g - \overline{\sigma} \right) \tag{3}$$

where

$$\tilde{M} = n^{\text{eff}} (I - E)^{-1} : E : \overline{M}^{\text{secant}} \tag{4}$$

and $E$ is the visco-plastic Eshelby tensor, $\overline{M}^{\text{secant}}$ is the macroscopic visco-plastic compliance tensor for the secant interaction $(\dot{\bar{\varepsilon}}_0 = 0)$, and the parameter $n^{\text{eff}}$ "tunes" the stiffness of the inclusion-matrix interaction: $n^{\text{eff}} = 0$ for a Taylor case and $n^{\text{eff}} = 1$ for the stiff secant case.

## 3.5    Twinning in SC Approach: CG Model

An aspect of twinning that needs to be incorporated into the models is the fact that twins are finite domains that reorient the lattice and shear portions of the grain (usually taking on a lamellar morphology) and introduce a twin boundary. Over the years, a number of methods have been introduced for treating the
**Fig. 6** Schematic of the composite-grain (CG) model for modeling twin reorientations within the VPSC framework. Un-twinned grain is represented as an ellipsoidal inclusion within a homogenous effective medium (HEM). For twinned grains, which may be comprised of one twin variant type or multiple variants, the matrix and each twin variant is represented as separate inclusions. As an example, "Twin-1" corresponds to two twins of the same variant, and "Twin-2" corresponds to another twin variant, all within the same grain. Here the HEM represents the average response of the polycrystal except the chosen grain and/or twin

reorientation that accompanies twinning: (i) predominant twin reorientation (PTR) method (Lebensohn and Tome 1993; Tome et al. 1991) and composite-grain (CG) method (Proust et al. 2009; Proust et al. 2007), for instance. In these schemes, the twin phase replaces some fraction of the matrix phase, and as the volume of the twin phase increases with strain, the volume of the matrix phase shrinks accordingly. They generally involve splitting the original orientation (grain) into two parts, one part that is twinned and another part that is the matrix, while preserving the original volume fraction of the grain. For instance, in the CG method, the newly twinned grain is split into two inclusions, a twin inclusion with the twinned volume fraction and the remaining parent inclusion with the remaining fraction. The newly formed twin inclusions are treated as new ellipsoidal inclusions and added to the total number of grains in the polycrystal. As grains in these models are represented as ellipsoidal inclusions, the new twin inclusions can be made initially flat ellipsoids with their short axis perpendicular to the twinning plane, to reflect the lamellar shape of newly formed twins (see Fig. 6). The twinned inclusion adopts a mirror orientation with respect to the orientation of the parent grain, that is, characteristic of the type of twin (Yoo 1981; Yoo and Lee 1991).

Later, a modified CG model was developed, which allows for multiple twin types and variants to form in the same grain (Niezgoda et al. 2014). In the modified CG model, the twin and matrix grains are treated as two noninteracting inclusions (grains) embedded in the homogeneous effective medium. It is schematically shown

in Fig. 6. In the figure, a grain with two types of twin variants is shown, and in this case, un-twinned matrix grain, twin of variant 1, and twin of variant 2 are considered separate inclusions in the effective medium. The two twins are initially given a flat ellipsoid shape. The shortest axis of the ellipsoid is parallel to the twinning plane normal and another of the ellipsoid axes is parallel to the twinning direction. A similarly oriented ellipsoid is created to represent the un-twinned region of the grain. The aspect ratios of both ellipsoids evolve with deformation. These twin and matrix grains are characterized by independent secant compliances $M^{\mathrm{sec}}$, and consequently no explicit twin-matrix interaction is considered when solving the self-consistent equations. The relative fraction of each phase is updated incrementally with deformation as the grain twins.

Once a twin has formed inside a grain, growth of this twin is determined in a more traditional deterministic fashion within the modified CG framework. During deformation, the twin shear rate $\dot{\gamma}^{v}$ is calculated for the nucleated twin or variant $v$ in each grain by:

$$\dot{\gamma}^{v} = \dot{\gamma}_0 \left( \frac{\tau^{v}}{\tau_{c}^{\mathrm{twin}}} \right)^{n} \tag{5}$$

Here $\tau^{v}$ and $\tau_{c}^{\mathrm{twin}}$ are the resolved shear stress on twin variant v, and critical resolved shear stress for twin domain expansion (after nucleation).

## 3.6    Full-Field CPFFT Model Framework

The FFT-based crystal plasticity-based models provide spatially resolved micromechanical fields in the individual crystals within polycrystals. The formulation provides an exact solution of the governing equations of equilibrium and compatibility, in such a way that the final (converged) equilibrated stress and compatible strain fields fulfill the constitutive relationship at every discrete material point.

The original FFT formulation was developed to study the local and effective mechanical response of linear elastic (Moulinec and Suquet 1994), nonlinear elastoplastic (Moulinec and Suquet 1994, 1998), and visco-plastic (Michel et al. 2000, 2001) composite materials. The FFT formulation was later adapted for polycrystalline materials and permitted the study of the effective and local responses associated with the heterogeneity in the spatial distribution of crystallography and directional dependence of mechanical properties (Lebensohn 2001). In recent years, this FFT formulation has been extended to different deformation regimes like elasticity (Brenner et al. 2009), incompressible visco-plasticity (Lebensohn 2001; Lebensohn et al. 2008), dilatational visco-plasticity (Lebensohn et al. 2011b), infinitesimal elasto-visco-plasticity (Kanjarla et al. 2012b; Lebensohn et al. 2012) and finite elasto-visco-plasticity (Eisenlohr et al. 2013). Below the CPFFT model that allows for the crystals to deform by infinitesimal elasto-visco-plasticity (EVP) is briefly described and applied in later examples to study stress fluctuations in a deformed polycrystal and local stress states generated around discrete twins.

In the CPFFT method, the solution of an EVP problem involves the adoption of an appropriate time discretization scheme. Using an Euler implicit time discretization and Hooke's law, the expression for the stress in material point $x$ at $t + \Delta t$ is given by:

$$\boldsymbol{\sigma}^{t+\Delta t}(x) = \mathbf{C}(x) : \boldsymbol{\varepsilon}^{e,t+\Delta t}(x) = \mathbf{C}(x) : \left(\boldsymbol{\varepsilon}^{t+\Delta t}(x) - \boldsymbol{\varepsilon}^{p,t}(x) - \dot{\boldsymbol{\varepsilon}}^{p,t+\Delta t}(x)\,\Delta t\right)$$

(6)

where $\sigma(x)$ is the Cauchy stress tensor; $\mathbf{C}(x)$ is the elastic stiffness tensor; $\varepsilon(x)$, $\varepsilon^e(x)$, and $\varepsilon^p(x)$ are the total, elastic, and plastic strain tensors; and $\dot{\varepsilon}^p(x)$ is the plastic strain-rate tensor given in Eq. (1). The CPFFT model solves the equilibrium equation along with the above constitutive equation by iteratively adjusting the compatible strain field at every material point. The spatially resolved local response is calculated using the convolution integral between the Green's function associated with the displacement field of a linear reference homogeneous medium and a polarization field in which the heterogeneity and nonlinearity of the problem is specified. Application of Fourier transforms reduces the convolution integrals of the equilibrium equation in real space into simple products in Fourier space. Specifically the FFT algorithm transforms the polarization fields of the periodic microstructures, which are functions of the unknown strain field, into Fourier space, to obtain the micromechanical responses in real space.

## 3.7 Twinning Model in CPFFT Framework

Up to now, advancing CP models for discrete twins with a 3D microstructure has been hindered by the lack of 3D microstructural representation codes. Very recently, a few full-field, spatially resolved polycrystal models, such as CPFFT and CPFEM, have been advanced to include discrete twin domains within individual grains (Abdolvand and Daymond 2013a, b; Abdolvand et al. 2011, 2015b; Abdolvand and Wilkinson 2016; Ardeljan et al. 2015). To model the twin domain, the boundary of the domain, the twinning orientation, and the characteristic twin shear needs to be imposed homogeneously throughout the domain. A few examples of the local stress fields calculated around twins in Zr and uranium (U) with these techniques are shown in Fig. 7 (Abdolvand and Wilkinson 2016; Ardeljan et al. 2015). An important aspect captured is the heterogeneous stress field within crystals that result from the twin. The character, intensity, and extent of these fields depend sensitively on the elastic and plastic properties of the material. Recently a series of studies were undertaken to understand how response of the surrounding crystal could impact the mesoscopic processes of twinning (Abdolvand et al. 2018; Kumar et al. 2015, 2016a, b, c, 2017b).

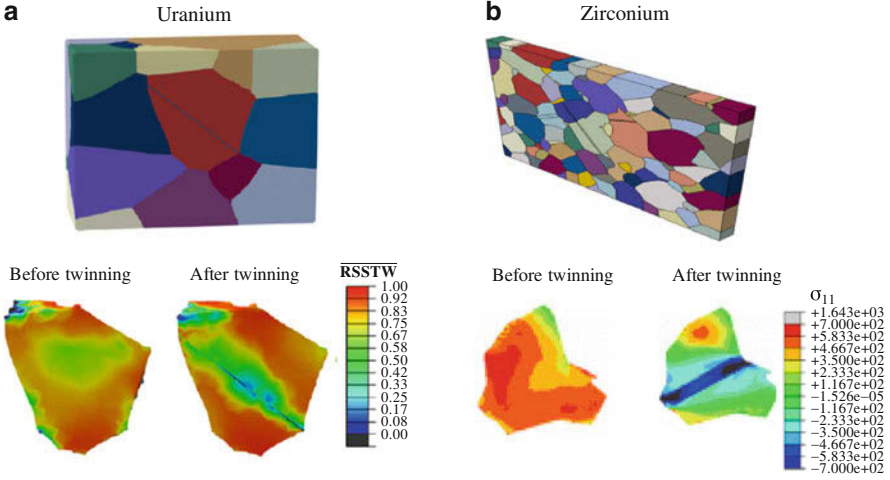
In this section, the recent extension of the CPFFT formulation to account for the reorientation and twinning shear transformation in discrete regions within a crystal is described. In this model, deformation twinning is treated as a shear transformation


**Fig. 7** Examples of recent modeling efforts in which discrete twin lamellae have been included within a full-field spatially resolved technique. The two shown are crystal plasticity finite element (CPFEM) models for (**a**) uranium (Ardeljan et al. 2015) and (**b**) zirconium (Abdolvand and Wilkinson 2016)

process. Accordingly the constitutive behavior of an elastic-visco-plastic material under an infinitesimal strain approximation with shear transformation becomes:

$$\boldsymbol{\sigma}^{t+\Delta t}(x) = \mathbf{C}(x) : \left(\boldsymbol{\varepsilon}^{t+\Delta t}(x) - \boldsymbol{\varepsilon}^{p,t}(x) - \dot{\boldsymbol{\varepsilon}}^{p,t+\Delta t}(x)\,\Delta t - \boldsymbol{\varepsilon}^{tr,t}(x) - \Delta\boldsymbol{\varepsilon}^{tr,t+\Delta t}(x)\right) \tag{7}$$

where $\boldsymbol{\varepsilon}^{tr}$ is the transformation strain. During the buildup of the twinning transformation, successive shear increments are imposed in the twin domain and the system relaxed. The associated strain increments have the following relationship with the local twin variant at point x:

$$\Delta\boldsymbol{\varepsilon}^{tr}(x) = \mathbf{m}^{tw}(x)\,\Delta\gamma^{tw}(x) \tag{8}$$

For material points lying outside the twin domain, $\Delta\varepsilon^{tr}(x)$ is zero. The tensor $\mathbf{m}^{tw} = \frac{1}{2}\left(\mathbf{b}^{tw} \otimes \mathbf{n}^{tw} + \mathbf{n}^{tw} \otimes \mathbf{b}^{tw}\right)$ is the Schmid tensor associated with the twinning system, where $\mathbf{b}^{tw}$ and $\mathbf{n}^{tw}$ are unit vectors along the twinning direction and twin plane normal, respectively. The twinning transformation builds up in increments, until reaching the characteristic twin shear, $s^{tw}$:

$$\Delta\gamma^{tw}(x) = \frac{s^{tw}}{N^{twincr}} \tag{9}$$

The time increment $\Delta t$ and the number of increments to achieve the twin transformation $N^{twincr}$ are set sufficiently low and high, respectively, to ensure convergence.

# 4       Stochastic Twin Nucleation Model

## 4.1      Probability Model for Critical Stresses for Twin Formation

In a few recent works (Beyerlein et al. 2011; Beyerlein and Tome 2010; Niezgoda et al. 2014), an approach was developed to include grain boundary-induced twin nucleation into constitutive laws for application into the mean-field crystal plasticity models, like VPSC with a twin reorientation scheme. Unlike conventional polycrystal models to date, the model they used for twin nucleation is not deterministic but probabilistic, dictated by the likelihood of forming a twin embryo in the grain boundaries. The approach involves incorporating two aspects of the grain boundaries in a bulk average probabilistic sense. One aspect is a probability model for the nucleation of twins when some numbers of grain boundary defects undergo stress-driven transformations, which then coalesce into a single stable nucleus. It assumes that the time scale of the transformation and subsequent coalescence is instantaneous compared to the applied deformation and introduces a characteristic length scale, within which a critical number of transformations occur to produce a propagating twin. The stochastic model gives an explicit form for the probability distribution for the critical stress values required for twin nucleation that could be used in the VPSC model for activating twinning.

The other aspect concerns the stresses that activate twinning. These stresses are those that are generated at grain boundaries, and these tend to deviate significantly from the average stresses calculated in VPSC for each grain. To tackle this, distributions of grain boundary stresses were obtained from separate full-field CP calculations. Taken together the VPSC model simulations of deformation were advanced to activate twinning when randomly sampled critical twin stresses were exceeded by randomly sampled grain boundary stresses.

In this section, the model is briefly reviewed. Consider a grain within a polycrystal as illustrated in Fig. 8. It has $n_f$ nearest neighbors and is joined to each neighbor k (k = 1, ... $n_f$) by a common grain boundary facet of area $A_k$. Connecting these facets is a network of triple lines and quadruple points, which generally have an atomic structure distinct from those of the facets.

A grain boundary area $A_k$ contains defects, or grain boundary dislocations (GBDs), varying spatially and temporally in defect content (e.g., size of the Burgers vector). When provided a sufficiently high stress for a GBD of a given size, GBDs can transform into a twin embryo, a process observed in atomistic simulation to involve the reshuffling of the atoms into the twinned structure (Wang et al. 2013b). Neighboring smaller twin nuclei can coalesce into a larger twin embryo. If the embryo reaches a critical size, it will propagate into the crystal (Beyerlein and Tome 2010).

According to this physical picture, forming an embryonic twin relies on the right stress fluctuation simultaneously hitting the right-sized defect. This confluence of events is more likely to occur in the grain boundaries, where local stress states and defect content are high. It is usually the case that the spatial distribution of GBDs and stresses are heterogeneous, a GBD-to-twin nucleus transformation is a

statistically occurring event, and the number of such events $N$ is a random variable. The number $N$ is expected to increase as the area $A_k$ of the facet and the magnitude of the stresses acting on the boundary increase.

In the model, a stochastic counting process is proposed for $N$, i.e., $\{N(A_k), A_k \geq 0\}$, where $N(A_k)$ is the number of transformation events that occurred in an area $A_k$. If each event is independent and identically distributed (i.i.d.), and the number of events in nonoverlapping elements is independent (stationary increments), then the Poisson process emerges as an appropriate model. Accordingly, the probability that $N = m$ defects will be transformed into a twin nucleus within a given area $A_k = a$ follows a Poisson distribution:

$$P\,(N = m, a) = \frac{(\lambda a)^m}{m!} \exp\,(-\lambda a) \tag{10}$$

where $\lambda$ is the rate of the process. The parameter $\lambda$ also corresponds to the expected number of transformation events per unit area. Another consequence of the Poisson model is that the events are uniformly distributed over area $a$, and spatial separation between transformation events is exponentially distributed. As the process is driven by stress, the Poisson rate $\lambda$ is assumed a monotonically increasing function of the resolved shear stress ($\tau$) on a twin system $s$. For convenience, the following power law formulation is introduced:

$$\lambda\,(\tau) = \frac{1}{a_0} \left( \frac{\tau}{\tau_0} \right)^{\alpha} \tag{11}$$

where $a_0$ is a material parameter assumed to be constant, and $\tau_0$ is a characteristic scalar stress value, which is interpreted as the stress required to dissociate, on average, one grain boundary dislocation on area $a_0$. Parameters $a_0$ and $\tau_0$ are, in

principle, functions of the defect content of the grain boundary. Therefore, they may vary from boundary to boundary and differ, for instance, for a coherent boundary versus an incoherent one.

To implement the above model into a computational mechanics code, the discrete counting of the number of transformation events needs to be linked to a continuous probability of forming a twin nucleus. To this end, a characteristic area $a_c$ is introduced as the minimum area that can produce one twin, i.e., one characteristic area $a_c$ produces one crystalline twin, which may have resulted from the coalescence of $n$ tinier twin nuclei created by $n$ transformation events. Suppose that at least $m^*$ distinct conversion events need to occur within $a_c$ in order to form one twin, then the probability that at least $m^*$ events occur in $a_c$ is:

$$P\big(N \geq m^*, a_c\big) = 1 - \sum_{m=1}^{m*-1} P(N = m, a_c) \tag{12}$$

Further, we assume that $m^* = 1$, that is, at least one defect must be activated within $a_c$, which yields the following Weibull distribution.

$$P(S < \tau) = P(N \geq 1, a_c) = 1 - \exp\left(-\left(\frac{\tau}{\tau_c}\right)^{\alpha}\right) \tag{13}$$

Using Eqs. (12) and (13), we can redefine P($S < \tau$) as the probability that the critical stress to nucleate a twin is less than or equal to $\tau$. Here $S$ is a random variable that quantifies the critical nucleation strength or equivalently the stress required to transform an appropriate number of grain boundary dislocations into twinning dislocations.

The area $a_c$ is an important model length scale, where in all dissociation events in $a_c$ lead to one twin. Accordingly, it sets the minimum twin spacing and the maximum number of twin lamellae that can form from a grain boundary of area $A_k$ as $n^* = A_k/a_c$. The material parameter $\alpha$ governs the dispersion in $S$ and is linked to the type of defects in the grain boundary.

## 4.2    Statistical Representations of Grain Structures

The above model applies to twinning from one-grain boundary facet of area $A_k$. Multiple grain neighbors in fact surround any given grain, and each neighbor shares just one of the many facets that comprise a grain's boundary.

Recall from Sect. 4.1 that in a given grain facet $A_k$, there are $n^*$ number of potential sites to form a twin. Correspondingly, following Eq. (13), there is a set of $n^*$ critical stresses $S_i$, $i = 1, \ldots n^*$, assumed to be independent and identically distributed. In order to assign the number of potential nucleation sites $n^*$ for each grain, the three-dimensional grain structure is needed. At a minimum, the microstructural parameters needed are (1) the number of neighbors ($n_k$) or

number of grain boundary facets of a grain and (2) the surface area of the grain boundary facets $A_k$ from which the twins will nucleate. These parameters depend on the grain size distribution and the morphology of the grains in the sample and can in principle be estimated from a combination of microscopy and some basic stereological principles.

When the computational model is a mean-field model, like VPSC, every grain is modeled as an ellipsoidal inclusion. Thus estimates are needed for the lattice orientation, effective radius (or equivalently volume), and the ratio between major and minor axes of the grains. For this purpose, the stochastic field model of Thorvaldsen (1993) is adopted. Using simple geometric arguments, this model develops an expression for the distribution of neighbors for a given grain and the distribution of facet areas depending on its size, $R$, and shape. According to this model, for a spherical grain with radius $R$, the expected number of grain neighbors $n_f$, $E(n_f)$, is related to the expected value of $R$, $E(R)$ according to:

$$E\left(n_f\right) = 4\left(1 + \frac{R}{E(R)}\right)^2 \tag{14}$$

Given a neighboring grain with radius $R_n$, the contact area, $A_k$, is given by (Thorvaldsen 1993):

$$\frac{1}{A_k} = \frac{1}{\pi}\left(\frac{1}{R_n} + \frac{1}{R}\right)^2 \tag{15}$$

To demonstrate, the mode is applied to high-purity HCP Zr. Figure 9 shows the distribution of grain size (Capolungo et al. 2009), the predicted distribution for the number of neighboring grains or facets, and the predicted distribution of grain facet areas for Zr. The equivalent circle radius exhibits an approximate Rayleigh distribution. Accordingly, the cross-sectional grain areas will be exponentially distributed. The expected number of neighbors for this grain size distribution is 17, indicating a wide range of grain sizes in the Zr aggregate being modeled.

## 4.3 Spatially Resolved Stress States in Deforming 3D Polycrystals

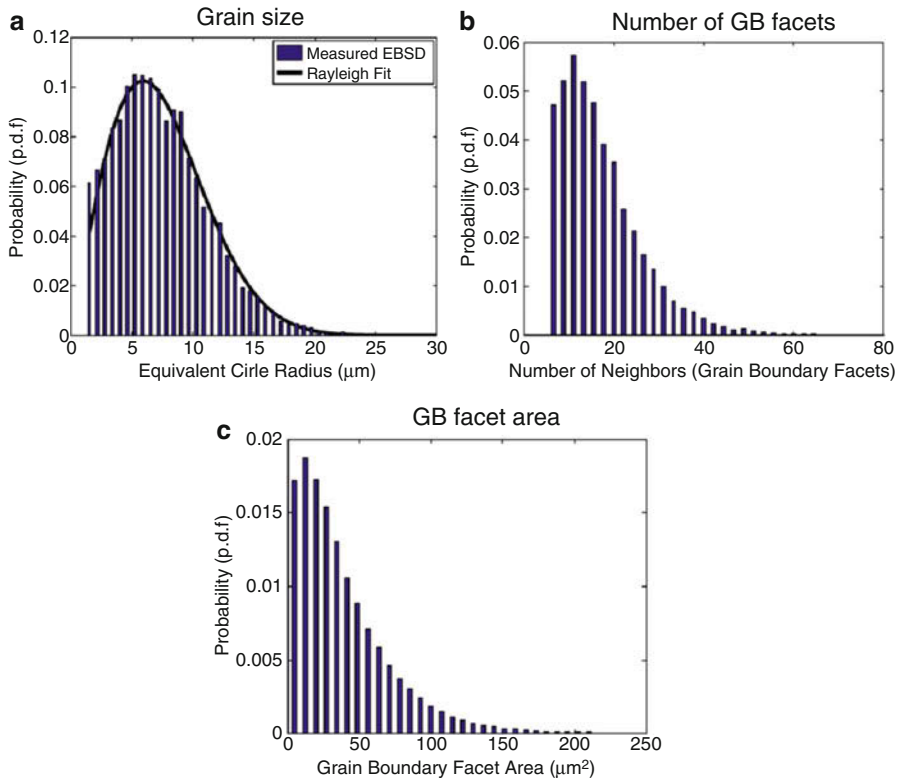
This critical stress $\tau_c$ can then be compared to the twin-plane resolved shear stress (TRSS) for the twin variant in question. If it exceeds the TRSS, then a twin embryo may nucleate, and if not, then the region remains un-twinned. For twinning, the local stress state in the region in question for twinning is desired. Self-consistent schemes can be used to calculate the local stress state in the grain. However the formulation does not allow for calculation of the stress state in the boundaries. Also by modeling each grain as an ellipsoid in a homogeneous medium, the scheme does not provide a way of defining the orientation of the grain boundary with respect to the loading direction. Full-field, spatially resolved techniques such as CPFFT or CPFE, however, are particularly well suited for calculating stress distributions


**Fig. 9** Microstructural variations considered in the stochastic twin nucleation model: (**a**) grain size, (**b**) number of grain boundary facets, and (**c**) grain boundary facet area (Niezgoda et al. 2014). These microstructural distributions are obtained from the EBSD-based statistical analysis of pure Zr (Capolungo et al. 2009)

within grains and in grain boundaries and triple and quadruple points. From this model, the stress fluctuation distributions, the deviation in stress from the average value, can be calculated and amenable for use in a mean-field technique.

Following this approach, CPFFT calculations are carried out on Zr. Several (100) realizations of 3D grain structures of representative Zr material volumes were performed to extract the stress fluctuations at grain boundaries (Kanjarla et al. 2012a; Niezgoda et al. 2013). The three-dimensional (3D) representative volume elements, RVEs, were created using DREAM-3D. Each RVE contained $500 \pm 50$ grains with $\sim 5 \times 10^5$ grain boundary voxels or elements per RVE. For each representative volume, simulations of multiple loading conditions were performed. The deviations from the grain-averaged stress at the grain boundaries were extracted for all representative volumes for each loading condition.

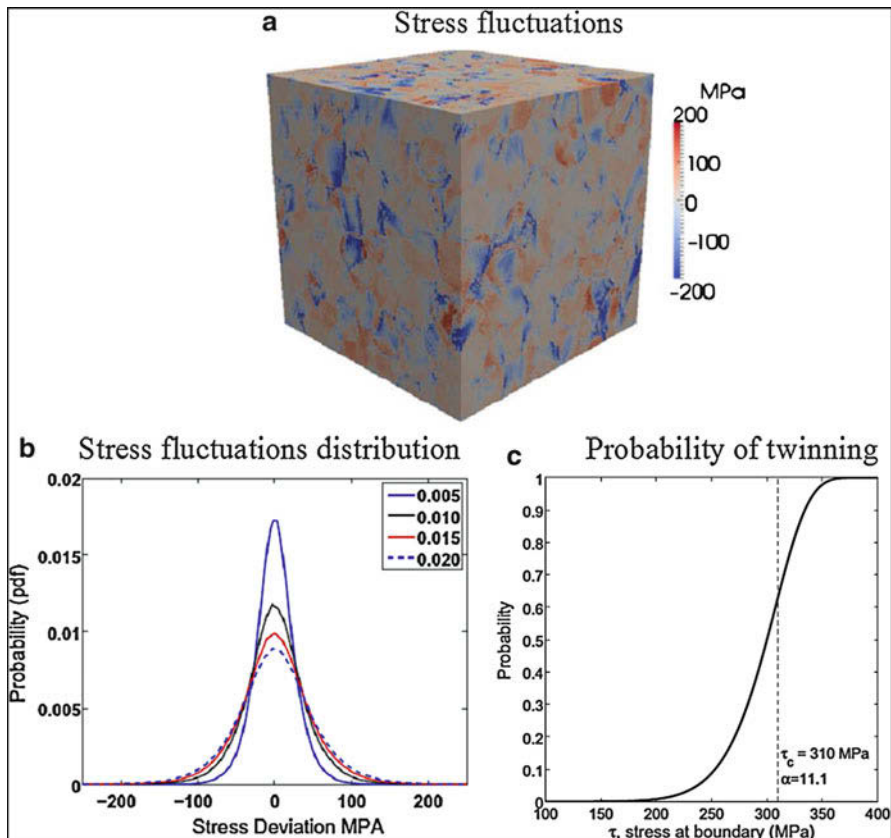
For one example RVE, Fig. 10a shows calculated stress fluctuations, defined as deviations in the Von-Mises effective stress from the grain average stress, at 2.5%


**Fig. 10** Mechanical stress fluctuations as calculated in the CPFFT model: (**a**) the deviations in the effective stress from the grain average stress. The FFT model contains 522 grains (Niezgoda et al. 2013). (**b**) Distribution of the CPFFT calculated stress fluctuations from 100 different representative volume elements like those in (**a**) (Niezgoda et al. 2013). (**c**) Separately, the probabilistic nucleation model provides the probability distribution for the critical stress to form a twin (Niezgoda et al. 2014)

applied strain. This result reveals significant deviations at the grain boundaries. It is not uncommon for single grains to have regions near their boundaries that deviate in both a highly compressive and tensile state from the grain average. Figure 10b presents the observed deviations in the normal stress components from the grain stress. By averaging over multiple loading conditions, the fluctuations on all three normal components had approximately the same distribution, as did the three shear stress components. As shown, the distributions are approximately Gaussian; however, the extreme tails of the distributions extend significantly farther than would be expected from a perfect Gaussian. For VPSC deformation simulations, a six-dimensional Gaussian with a zero mean vector was used to reasonably represent the CPFFT calculations.

## 4.4     Incorporation of Statistical Stress and Strength Distributions in Homogenization Models

Carrying out the simulation with the probability model for twinning added, the VPSC model needs as input the distribution for the twin nucleation stresses and stress fluctuations. Figure 10c shows the former, the twin nucleation stress distribution for $a_c = 0.01$ μm$^2$, $\alpha = 11.1$, and $\tau_c = 310$ MPa. The latter stress fluctuations, just described in the prior section, are provided in Fig. 10b. In an actual polycrystal, grain boundary misorientations are distributed, and their defect states vary, and in deformation, both can vary in time. However, for simplicity, the same Gaussian representation for the stress fluctuation distribution is applied for all grain boundaries at all times during deformation.

The procedure used is described as follows. The calculation begins with a description of the microstructure. The input texture for VPSC is constructed by sampling 8500 grains from the EBSD maps produced by Capolungo et al. (2009). The equivalent circle diameter from the EBSD is used to assign the weight or grain size for each grain (Fig. 9a). For each grain, Eq. (14) is used to determine the number of neighbors. The neighbors are randomly sampled from the input texture, and Eq. (15) is used to assign facet areas $A_k$. Each facet is then divided into $n^*$ areas of size $a_c$. Each of these areas is a potential nucleation site for a twin of variant $v$. For each site, at each strain increment, Eq. (13) is used to test for the nucleation of twin variant $v$, which requires knowing the resolved shear stress $\tau(v)$ projected on the twin variant $v$. To calculate $\tau(v)$, a stress fluctuation $\Delta\sigma$ is randomly sampled from the characteristic distribution (Fig. 10) for each variant and is added to the grain stress calculated at that strain increment. The sum is then projected onto the twin system to compute $\tau(v)$. This procedure for nucleation is then repeated for every twin variant at each site. In the case that multiple twin variants could nucleate from the same site, a single variant is selected at random to propagate. Each nucleation site is tested independently for nucleation, with no correlation with the neighboring sites. Although nucleation could occur on more than one facet belonging to a grain, in these example calculations, one facet for each grain is randomly chosen as the one from which twins are allowed to grow. Using the above procedure, any variant could nucleate, not just the one with the highest $\tau(v)$. Once a grain forms twins, no further nucleation is allowed. Twin growth follows a deterministic stress-based criterion, Eq. (5).

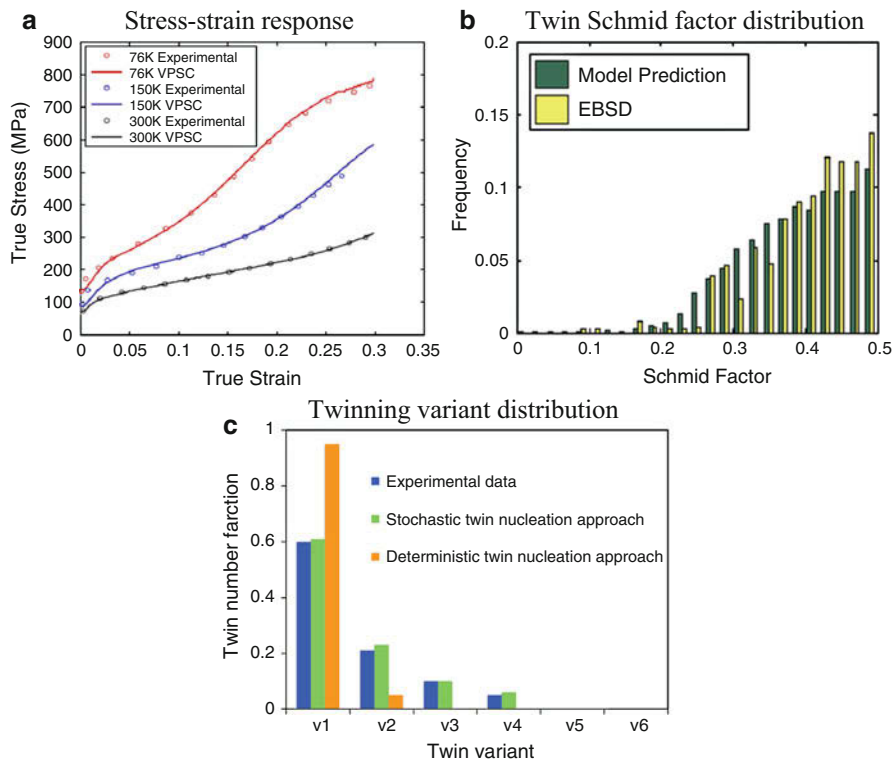
Using the above model, the deformation response of HCP Zr at three different temperatures, liquid nitrogen (77 K), 150 K, and room temperature (300 K) is simulated. In this calculation plastic deformation of Zr is accommodated by prismatic <a> slip and pyramidal <c + a> slip and $\{10\bar{1}2\}$ tensile and $\{11\bar{2}2\}$ compression twins. The evolution of the critical resolved shear stresses for only the slip modes follows the dislocation density-based hardening model developed in Beyerlein and Tome (2008). The same twin nucleation stress distribution is used at all temperatures, while the effect of temperature is included in the initial CRSS and the dislocation density evolution rate for slip. Figure 11a compares the model-predicted stress-strain curves at 76 K, 150 K, and 300 K under in-plane


**Fig. 11** Comparison of results from the VPSC model, with the twin nucleation model incorporated, for the (**a**) stress-strain response, (**b**) twinning frequency as a function of Schmid factor, and (**c**) twin number fraction for different twin variants at 10% compression. In (**c**), the frequency of twin variants formed as predicted from the polycrystal VPSC model with and without the stochastic twin model are compared. Without it, the criterion for forming a twin is deterministic. As shown, better agreement with the EBSD data is achieved with stochastic twin formation implemented (Niezgoda et al. 2014)

compression with the experimental curves for Zr. As shown, good agreement in the calculated flow stresses and hardening rates for all temperatures tested is achieved. Although not shown, the model also predicts well the experimentally observed texture evolution (Fig. 6 of Niezgoda et al. 2014)) and twin volume fraction evolution (Fig. 8 of (Niezgoda et al. 2014)). For completeness, the calculated twin volume fraction at 5% and 10% compression for 76 K temperature loading is 4% and 16%, respectively, which agrees well with the measured fraction from EBSD images is 5% and 16%, respectively.

The importance of the stochastic twin nucleation model cannot be fully appreciated from analyzing average responses. The model results can also be compared to local, microstructure data distributions of twinning. Figure 11b compares the calculated number fraction of twins with a given Schmid factor after 10% compression at

76 K with the experimentally measured number distribution of the observed twins at the same strain from EBSD. Like the measurement, the calculated frequency is also broad, including twins with high Schmid factors and with low Schmid factors (m < 0.3). Figure 11c compares the model predicted frequency distribution of each twin variants with that from EBSD. The model finds that the twin variant selected is most likely (but not always) the one with the highest geometric Schmid factor and that the grains that twin are most often (but not always) well oriented for twinning, again, in agreement with the measurement. EBSD analysis indicates that only 50–60% of the twins correspond to the twin variant with the highest SF, i.e., v-1, and 20% to the second highest SF variant, v-2. Remaining ∼20% of twins are the third and fourth highest SF variants.

The model overall predicts well the macroscopic deformation response because it predicts at the mesoscopic scale the formation of a broad range of twin variants over a broad straining period. In contrast, the model employing a deterministic twin nucleation approach, using a constant CRSS for all twins, predicts that ∼95% of the twins activated are v-1 and the remaining ∼5% are v-2. Lower ranked SF twin variants are not activated. The combined analysis of experiment and model results provides evidence that twin formation in polycrystalline materials is stochastic.

## 5   Stochastic Twin Growth Model

The earlier sections in this chapter discussed twin formation, as being derived from reactions involving intense localized stress and dissociations of individual or groups of discrete dislocations. The remaining sections of this chapter focus on the thickening of the twin band. In this stage, the dimensions of the twin domain lie above the atomic scale, being approximately submicron or micron and closer to the dimensions of the parent grain. The stress fields surrounding twin domains of this size range develop as a result of elastic and plastic deformation. The latter is carried by the collective glide of dislocations and can be adequately modeled at this scale by crystallographic slip. Accordingly, to study the effects of slip and crystal orientation on these two stages of deformation twinning, we employ a full-field, spatially resolved technique, the CPFFT model, which permits calculation of the mechanical fields (stress, strain, strain rate) in the presence of discrete twin domains within crystals. In the examples that follow, the model is applied to $\{10\bar{1}2\}$ tensile twins in HCP Mg and Zr metals. The anisotropic elastic constants (in GPa) for Mg at room temperature are 59.75, 23.24, 21.70, 61.70, and 16.39 (Hearmon 1946; Simmons and Wang 1971) and for Zr at 77 K are 143.50, 72.50, 65.40, 164.90, and 32.10 (Fisher and Renken 1964; Simmons and Wang 1971). Plastic deformation is accommodated by basal <a>, prismatic <a>, and pyramidal <c + a> slip for both HCP Mg and Zr metals. The critical resolved shear stress (CRSS) for basal, prismatic, and pyramidal slip systems (in MPa) are 3.3, 35.7, and 86.2, respectively, for Mg at room temperature (Beyerlein et al. 2011), and 700.0, 20.0, and 160.0, respectively, for Zr at 77 K (Knezevic et al. 2015).

## 5.1    Local Twin Boundary Stresses to Expand Twin

As mentioned earlier, twins most often nucleate at a grain boundary and propagate across the grain until they are stopped at the opposing grain boundary. They thicken further after having terminated at grain boundaries. Both the surrounding parent and neighboring grains deform in order to accommodate the shear strains resulting from the growing twin. To investigate the driving forces for twin growth, it is important to understand the local stresses generated around the twin band. To this end, consider a tri-crystal of three neighboring grains embedded in a polycrystal, as shown in Fig. 12. The central grain contains the deformation twin, which spans the width and intersects with the two neighboring crystals. The parent grain orientation is (0°,0°,0°), (Bunge convention), which corresponds to alignment of its c-axis with the Z-direction.

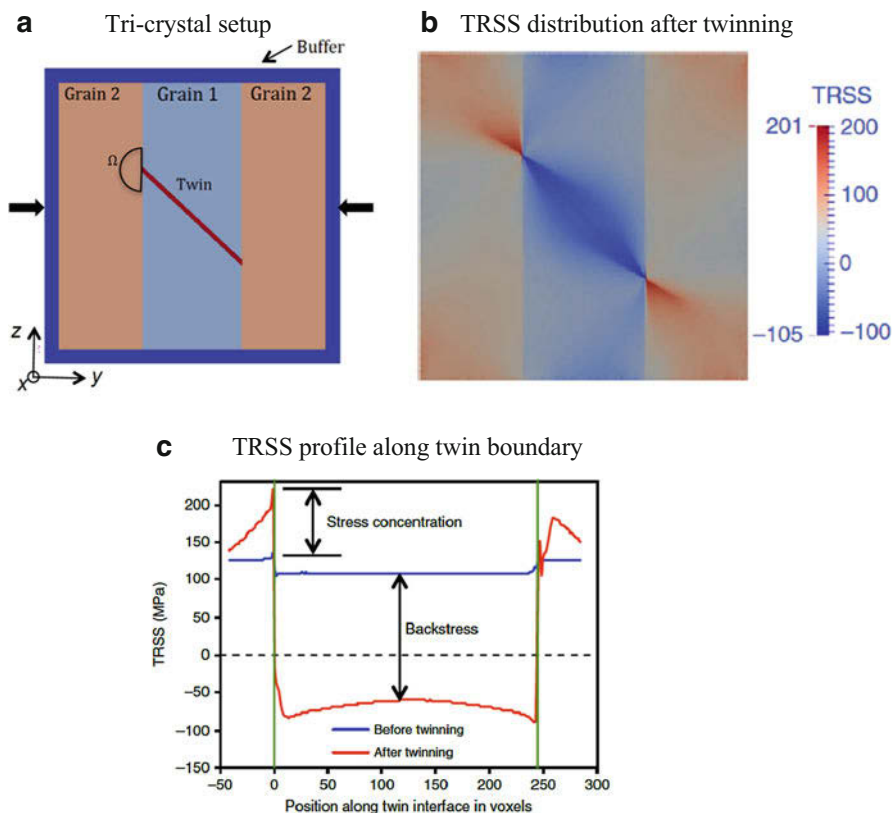

**Fig. 12** CPFFT calculated twin stress distributions generated by a twin lamella in Zr (Kumar et al. 2016a). (**a**) Tri-crystal setup consisting of a central grain "grain-1" containing a twin and two neighboring grains, with the same orientation on each side. Orientations of grain-1 and grain-2 are (0°, 0°, 0°) and (0°,30°,0°), respectively. (**b**) The twin-plane resolved shear stress (TRSS) distribution after twinning and (**c**) TRSS profile along twin boundary before and after twinning

Using CPFFT model, the stress and elastic and plastic strain tensorial fields are calculated, and for analysis, the TRSS field is presented in Fig. 12b after twinning. In this example, the neighboring grain orientation is (0°, 30°,0°) and the material is Zr. The stress inside the twin domain and along the lateral sides of the twins is negative, and in the neighboring grains, it is positive. Note that before the twin was present, the stress state was nearly uniform in the crystal, but when the twin is present, the stress state remains homogeneous in the twin domain but has become nonuniform, particularly in the matrix region immediately bordering twin. For more details, the TRSS distribution along the twin after twinning is given in Fig. 12c. The TRSS along the lateral interface of the twin band is negative, signifying that the negative TRSS along the twin boundary acts in the anti-twinning direction and thus serves as a resistance to further twinning. More quantitatively, a *twin backstress* field can be defined as the difference in the TRSS before and after twinning. The backstress is highest in value at each end, where the twin shear and reaction from the neighboring grain is the greatest and decays toward the middle of the twin. The backstress is the least at the middle of the twin. To migrate the boundaries, the applied load would need to be increased further such that the local TRSS along the twin becomes positive and exceeds a threshold value associated with boundary migration.

The amount of twin backstress observed here depends on the ability of the neighboring grain to accommodate the shear imposed by the twin. These grains deform elastically and plastically, and in the latter case, the plastic accommodation generally involves slip on multiple slip systems. For an HCP material, the activation barriers for slip depend on the mode of slip and typically include basal <a> slip, prismatic <a> slip, and pyramidal <c + a> slip. In the case of Mg, the easiest basal <a> slip (∼3 MPa) only provides two independent slip systems. Thus, basal slip alone would be insufficient to accommodate a general stress state, and in general the next easiest prismatic <a> slip and/or hardest pyramidal <c + a> slip would also have to be activated at the twin/grain boundary junction. A neighboring grain well oriented to accommodate the shearing action of the twin mostly with its easy slip system would be considered a "plastically soft" neighbor. Less backstress would result in the twin domain, particularly along the twin boundary. In contrast, a neighboring grain that is oriented poorly for easy slip must activate relatively large amounts of the harder slip modes in order to accommodate the shearing of the twin. It would constitute a "plastically hard" neighbor. A higher backstress in the twin would result and more applied load would be required to grow the twin. The grain neighbor orientation effect could be one explanation for why in a polycrystal some grains twin and others do not, despite being of similar size and orientation (Beyerlein et al. 2010; Capolungo et al. 2009; Kumar et al. 2018).

## 5.2    Grain Neighborhood Effects on Stresses to Expand the Twin

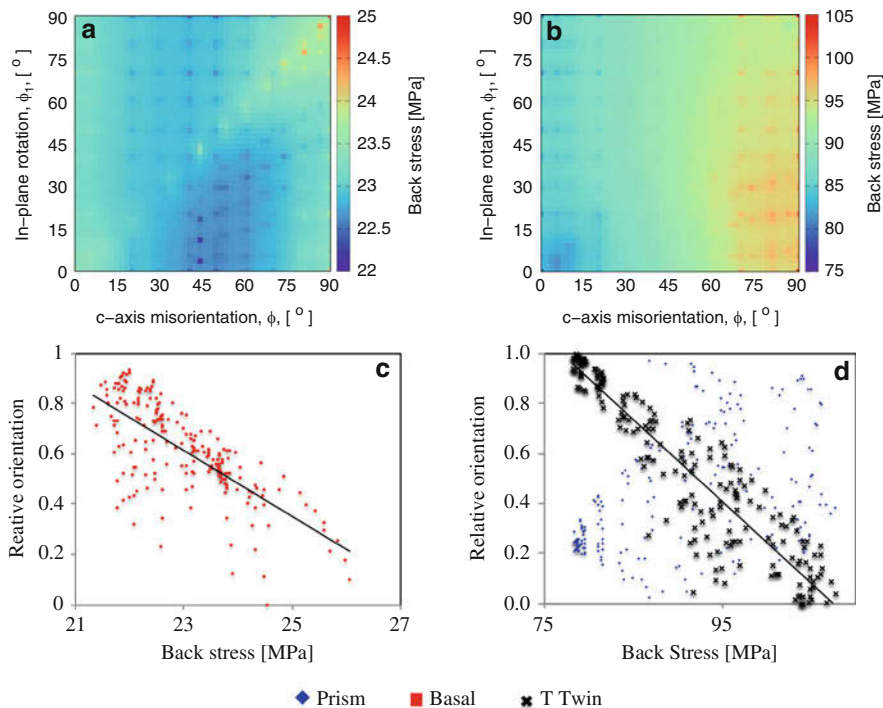
In this section, we study the effect of neighboring grain orientation on the twin backstress and twin expansion. The EVP-FFT-based twinning simulations are performed


**Fig. 13** Effect of neighboring grain orientation on twin backstress (Kumar et al. 2017b). Distribution of twin backstress in the neighboring grain orientation space in (**a**) Mg and (**b**) Zr. The correlation between the twin backstress and the relative orientation of primary slip system in (**c**) Mg and (**d**) Zr. In the calculations, easy basal slip systems in Mg and easy prismatic slip and tensile twin systems in Zr are shown, and the less active systems are not shown

for 221 different grain orientations that represent the entire orientation space of neighboring grains for a fixed parent grain orientation and twin type and variant. The neighboring grain orientation space is represented in the $\phi$ versus $\phi_1$ plot, the two angles denoting the in-plane rotation and c-axis misorientation, respectively (Kumar et al. 2017b). Maps for Mg and Zr are given in Fig. 13a, b. The landscapes are very different for these two materials. The magnitudes and anisotropy in the backstress are much higher for Zr than Mg. In the case of Mg, the backstress is particularly low ($\sim$22 MPa) for the neighboring grain when the c-axis misorientation ranges from $0°$ to $\sim$25$°$ and from $\sim$65$°$ to 90$°$, but slightly higher ($\sim$25 MPa) for the c-axis misorientation range from $\sim$25$°$ to $\sim$65$°$. In the case of Zr, the backstress is lower ($\sim$75 MPa) for the c-axis misorientation range from $0°$ to $\sim$45$°$ and substantially higher ($\sim$105 MPa) for the c-axis misorientation range from $\sim$45$°$ to 90$°$.

Whether a grain neighbor is plastically hard and non-accommodating, leading to a high backstress, or vice versa, plastically soft, leading to a low one depends on the crystal's ability to activate its easiest slip mode. For Zr, the easier modes

are prismatic slip and tensile twinning, and these require higher CRSS values than, say, Mg, for which the easiest one is basal slip and the CRSS value to activate it is comparatively low. The backstress can be correlated to grain neighbor orientation through its ability to activate its easiest slip or twin mode. A simple metric that quantifies alignment between the twin in the parent and a given slip mode in the neighbor is:

$$m_{rel} = \max\left((\mathbf{b_T}.\mathbf{b_s})\,(\mathbf{n_T}.\mathbf{n_s})\right) \tag{16}$$

where $\mathbf{b_T}$ and $\mathbf{n_T}$ are the Burgers vector and plane normal unit vector of the twin and $\mathbf{b_s}$ and $\mathbf{n_s}$ are the Burgers vector and plane normal unit vector of different slip systems of neighboring grain.

This relative neighboring grain orientation factor $m_{rel}$ ranges from 0 to 1 and can be set as the maximum value calculated among the systems belonging to the slip family. A high $m_{rel}$ means that the particular deformation mode is well aligned with the twin and the likely one accommodating the twin shear. Similar measures have been defined to quantify crystallographic alignment across boundaries but for different purposes, such as slip-slip transmission (Clark et al. 1992), slip-twin transmission (Wang et al. 2010b), and twin-twin transmissions (Kumar et al. 2016a, 2017a, c) across grain boundaries.

The relationships between $m_{rel}$ for the different deformation modes and the calculated twin backstress from the CPFFT are obtained for both Mg and Zr. For pure Mg, the relationship is studied between the twin in the parent and the predominant basal slip mode in the neighbor. For Zr, the relationship is examined for both prismatic slip and the tensile twin modes. It was found that the other deformation modes are not strongly correlated with the backstress. Figure 13c shows that for Mg, the twin backstress $\tau_B$ increases as $m_{rel}$ for basal slip decreases. In the case of Zr, in Fig. 13d, the tensile twin mode exhibits the stronger correlation with $\tau_B$ than prismatic slip. In particular, the correlation between $\tau_B$ and relative orientation of neighboring grain tensile twin $m_{TTwin}$ is nearly linear following (see the line in Fig. 13d):

$$\tau_B = -26.63\,m_{TTwin} + 105.26 \tag{17}$$

This relationship although simple can be used in mean-field polycrystal models to indirectly account for neighborhood effects.

## 5.3 Incorporation of Neighborhood Effects in Homogenization Models

To simulate the role of random neighboring grain orientations on the growth of twin lamellae, the relationship expressed in Eq. (17) is incorporated into a larger scale, mean-field visco-plastic self-consistent (VPSC) model. In this hybrid VPSC model
**Fig. 14** Effect of the twin backstress effect when incorporated into the VPSC model (Kumar et al. 2017b). Calculated twin area distribution from the deformation of pure Zr. Including the backstress from neighboring grains reduces twinning in the high Schmid factor region and increases it in the low Schmid factor region, aligning it better with the data than the mode without the effect of the backstress

(Kumar et al. 2017b), the twin shear rate is related to the TRSS by a power-law flow rule, which introduces a resistance to twinning:

$$\dot{\gamma}^v = \dot{\gamma}_o \left( \frac{\tau^v}{\tau_c^{\text{twin}} + \tau_B} \right)^n \tag{18}$$

where $n = 20$, $\dot{\gamma}_o$ is the reference shear rate, $\tau^v$ is the TRSS of twin variant $v$ calculated in VPSC without a neighbor effect, and $\tau_B$ is the contribution of the neighboring constraint to the resistance, the backstress we analyzed earlier with the CPFFT model.

This hybrid model is applied to polycrystalline Zr. In the simulation, for every grain, a neighboring grain orientation is randomly selected from the initial texture. Provided the grain forms a twin, its pre-assigned neighbor orientation is used to calculate the backstress on the twin using Eq. (17). Studies of the twin thickness distribution can be used to observe the effects of the neighbor on the backstress. Figure 14 compares the distribution of twin area fraction per twinned grain as a function of twin Schmid factor with the experimental measurement (see (Capolungo et al. 2009)). The model including grain neighborhood effects on twin growth reduces twinning in the high Schmid factor region yet increases it in the low Schmid factor region, providing overall better alignment with the data than the model without the effect of backstress. We find in the model that including the backstress neighbor effect lowers the growth rate *for all twins*, which is to be expected. However, in order to form the same twin fraction to accommodate the

applied strain as in the model without the backstress, the lower Schmid factor twins grew to a larger volume, an interesting consequence that again, places the hybrid model calculations in better alignment with the volume fraction of these low-rank twins.

# 6      Conclusions and Outlook

Decades of reports from experimental analyses of deformed HCP materials have undeniably demonstrated that deformation twinning is a highly heterogeneous deformation mechanism, exhibiting significant temporal and spatial variability across the crystalline microstructures. Yet to date the fundamental understanding of the mechanistic origins of the statistical and stochastic nature of these types of twins is still in development. Considering both the growing interest in HCP materials for structural applications and the profound influence of twinning on structural response, adopting a stochastic perspective in the studies of deformation twinning during mechanical deformation is sensible. In attempt to evaluate progress toward this end, this chapter reviews recent experimental analyses and modeling efforts to describe some statistical aspects of deformation twins, correlate the more statistically variable features of twins with parent microstructure, and propose the mechanisms that explain the observed microstructure/twin relationships. The contribution of grain neighborhoods to the statistical variability, as quantified by combining experimental and modeling methods, is highlighted. In addition, recent developments of stochastic twin nucleation and growth models are presented, with the aim to determine how these stochastic aspects of twinning impact mechanical behavior. The general finding is that substantial variation in twin formation, variant selection, and size significantly impacts mechanical response, from yield and hardening to ultimate strength. These strongly suggest that future pursuits for stochastic approaches to understanding the mechanical response of HCP materials that deform via twinning are worthwhile.

There are many other very important aspects of twinning that still require study from a stochastic perspective that were not covered in this chapter. Commonly seen in HCP materials, which twin profusely, are intragranular three-dimensional networks of twins. Understanding on how these twin-twin junctions form and the variation in the types of junctions that manifest would benefit from approaches that adopt statistical descriptions and stochastic models incorporated in simulation. It should also be noted that the mechanical properties reviewed in this work pertained to responses obtained in simple loading states. Twinning microstructures are, however, sensitive to deformation temperatures and imposed strain rates and deformation histories. For instance, cyclic loading can induce phenomenon such as detwinning, or changes in strain path can cause secondary twinning. There is still much opportunity for investigating the stochastic aspects of these frequently occurring twinning events.

Kurt Kremer

## Contents

**Abstract**

This collection of papers gives an introduction and overview of recent developments in polymer/soft matter simulations. The variety of the contributions reflects the fact that soft matter not only is based on a fast-growing body of elementary chemical structures but even more so on the way these structures are organized and interact with each other resulting in their specific structure/morphology and function.

## 1    Materials Properties and Link to Statistical Mechanics

A comprehensive polymer or – better – soft materials modeling, preferentially based on a thorough theoretical understanding of the underlying physical principles and chemical structure, requires to consider properties and processes originating from many connected length and time scales. Ideally that would mean a seamless modeling strategy from quantum chemical methods all the way to macroscopic continuum-based methodologies. Furthermore almost all experimentally available systems are the result of a specific preparation procedure, meaning that their state

K. Kremer (✉)
Max Planck Institute for Polymer Research, Mainz, Germany
e-mail: kremer@mpip-mainz.mpg.de; theoryoffice@mpip-mainz.mpg.de

is history dependent and thus not in thermodynamic equilibrium (in terms of the physical definition). Systems are "stuck" in a local free energy minimum. This requires a modified view away from the traditional structure property relationship (SPR) toward a structure-*process*-property relationship (SPPR), based on insight into processes on a molecular level. This holds even more so for all biological systems.

Polymer/soft matter physics flourished with the development of universality and scaling relationships for polymers in the last century by de Gennes, Edwards, and many others (de Gennes 1979; Doi and Edwards 1986; Rubinstein and Colby 2003; Doi 2013). That connected soft matter to the most modern statistical physics at that time. Polymers were not only materials with interesting physical properties, but they also became means to study modern physics. Scaling laws provided a generic understanding of whole classes of materials and allowed a systematic theoretical treatment. In parallel computer simulations, which focused on such generic models, began to become more widely possible. At the same time, chemistry similarly advanced and provided a huge wealth of new materials with rather different properties. Mechanical, chemical, and electronic properties and functionality can vary dramatically for different chemical species while the generic laws still hold. A rather trivial example may illustrate this. The viscosity $\eta$ of a polymer melt follows the law $\eta = f(T, \dots) N^{3.4}$, N being the polymerization index of the chains and f being a function of temperature, local chemistry, etc.. Doubling N increases the viscosity by roughly a factor of 10. This holds for all polymers, i.e., it is universally valid. However by, e.g., changing the temperature by a few degrees close to the glass transition temperature, $\eta$ also easily changes by a factor of 10 or more. Thus the prefactor f and the power law allow the adjustment of materials properties to the same degree, however by different means. It is this extreme versatility based on a combination of chemistry-specific aspects and generic power laws that makes soft matter an ubiquitously demanded class of materials (Potestio et al. 2014). Modern materials modeling has to take these two adjusting screws properly into account. Needless to say, that despite all the progress over the last years, many old and new challenges are tackled by the community.

## 2    Contributions

The collection of articles in this chapter provides an overview of recent developments in different areas of computational physics and materials science of soft matter. It covers topics from classical polymer solutions and melt materials simulations all the way to modern data-driven approaches. While such a collection cannot be complete, it should provide insight and guidance to further literature.

▶ Chapter 61, "Polymer Solutions" by B. Dünweg builds upon scaling relationships for statics and dynamics. It introduces the intuitive blob picture and the crossover scaling concept. While being especially of interest in the context of theoretical physics, polymer solutions play an important role in many areas of

technology, e.g., as viscosity modifiers. After introducing the theoretical concepts, the power of modern advanced simulation approaches is illustrated. This includes a short discussion of the difference between simulations including explicit versus implicit solvent. While less relevant for actual materials science problems, concepts and technologies developed in the context of solutions form a starting point for many applications presented in the subsequent chapters.

A special class of polymers with ample applications in science and technology ranging from chemical industry through health care and food science, not to speak of their biological relevance, are polyelectrolytes. In ▶ Chap. 62, "From the Atomistic to the Macromolecular Scale: Distinct Simulation Approaches for Polyelectrolyte Solutions," J. Smiatek and Ch. Holm cover the range of simulations from systems with atomistic details to more coarse generic models allowing to study structure formation and aggregation. Polyelectrolytes are charged macromolecules, where charges are dissociated from (some of) the beads. They can, depending on chemistry, either be anionic or cationic. In some special cases, one can have both types of charges within one macromolecule. Strong polyelectrolytes are completely ionized, while weak polyelectrolytes are only partially ionized. The degree of ionization, e.g., depends not only on pH but also on the properties of the uncharged parts of the molecule in between. Material properties equally depend on the long-range properties of the electrostatic interaction, i.e., screening due to salt, etc., as well as local chemistry-dependent aspects like poor solvent collapse or aggregation and ion dissociation.

At the other end of classical polymer materials problems are long chain polymer melts. ▶ Chapter 63, "Resolving Properties of Entangled Polymers Melts Through Atomistic Derived Coarse-Grained Models" by G. S. Grest and coworkers explain in detail how to obtain quantitative information for the dynamics in polymer melts by particle-based multiscale simulations. As an example, the most abundant commodity polymer polyethylene (PE) is chosen. This is the most simple polymer – a chain of $CH_2$ groups – which, however, displays all the characteristics and complications of conventional polymer melts. Thus it provides a perfect demonstration case as, on the one hand, local energy barriers and interactions are well known, making it possible to connect simulations to experiment without any free parameter. On the other hand, very precise experiments are available. The authors in detail explain how different levels of coarse graining affect the dynamics of the coarse-grained model in comparison to the underlying all-atom model. While the mapping of length scales is trivially given by the mapping procedure between all-atom and coarse-grained beads, this is not at all the case for dynamics. Actually mapping dynamics properties between different models is not at all trivial and still poses one of the central questions to be solved. This is a currently highly active research topic at the interface between applied mathematics and materials modeling. However, it would be beyond the scope of this chapter to cover such still rather preliminary research at this point.

So far, the chapters mentioned above described the classical approach of a bottom-up ansatz. Starting from a detailed, eventually all-atom description, systematically coarse-grained models are developed and studied. A complementary way of

incorporating specific materials properties into coarse models is given in the ▶ Chap. 64, "Top-Down Hybrid Models of Polymers" by K. Daoulas. Within these models, particles interact with their surrounding not in a particle-particle fashion but with an averaged field formed by all the other surrounding particles. This can speed up simulations dramatically; however the methodology includes several complications, which have to be addressed carefully. In this chapter, the theoretical framework is discussed in detail, and a solid basis for practical work is provided. Including specific materials parameters into these rather coarse models also requires special care. Recently these methods have found ample applications in block copolymer systems and polymer systems with locally anisotropic morphology, such as dense conjugated polymers studied for organics electronics.

When dealing with polymer electronics, all the above-discussed methodologies come into play as is described in ▶ Chap. 65, "Multiscale Concepts in Simulations of Organic Semiconductors," by D. Andrienko. Organic electronics, and more specifically polymer-based electronics, play an increasingly important role in several areas of technology and research such as in the study of organic solar cells, organic light-emitting diodes (OLEDs), or field-effect transistors. The idea is that using soft matter, eventually printable electronics can be developed. For this conjugated organic compounds have to be developed, which not only provide the appropriate intramolecular electronic properties but also form morphologies (amorphous, liquid crystalline, or crystalline), which foster charge transport along the backbones but equally important also between different molecules. Like for inorganic semiconductors, doping is needed as well. Here processing becomes especially important. For these complicated systems, a rational has to be developed to relate device properties to chemical structure and processing history. This cannot be accomplished by simulations alone but requires a close interaction with experiment. The chapter explains the workflow of methodologies to be applied and illustrates this for several examples.

So far examples have been presented, where multiscale modeling is employed in a sequential way, i.e., full systems are studied on different levels of resolution. There are however situations where this is not advisable. In many cases, local chemical detail is needed in some region of space, e.g., docking of a ligand to a protein, while further away details are not needed, and a more coarse description is sufficient to account for, e.g., thermal fluctuations. L. Delle Site and coworkers describe the ▶ Chap. 66, "Adaptive Resolution Molecular Dynamics Technique" which allows the simultaneous treatment of different resolutions in a liquid within a single simulation setup. The class of closely related methods, named AdResS (adaptive resolution simulation) methods, allows the simultaneous simulation of a system on an all-atom, coarse-grained, and continuum level, while the exchange of molecules between different regions of space is not at all restricted. The scheme allows to couple rather different system, e.g., also the coupling of all-atom simulations to an ideal gas, which makes true grand canonical MD simulations easily possible. After describing the general theoretical framework, a few specific examples are given, which illustrate how local chemistry-specific aspects and more global properties influence each other.

So far techniques and concepts have been discussed, which are based on physical concepts and chemical information about the systems. In parallel computer science over the years has developed (deep) learning methods, which are entirely based on available data, i.e., so-called training sets. These methods turn out to be quite successful in many areas, when it comes to the identification/description of general properties. However the inverse design question, namely, to derive a potential energy function from data or to design new chemicals based on "big data" remains a formidable problem. At this point in recent years, a combination of data-driven approaches together with physical/chemical insight has been developed, which leads to a new area of materials simulation and materials discovery. Especially for soft matter, this connection to simulation runs is needed, as entropy is as relevant as energy, unlike for hard matter. T. Bereau introduces these new methodologies in ▶ Chap. 67, "Data-Driven Methods in Multiscale Modeling of Soft Matter." There he also illustrates alternative approaches of sampling in chemical space rather than being confined to physical space of only one kind of system.

All the above chapters deal with soft materials, where thermal fluctuations lead to spatial and temporal averaging or where the response to external driving forces is studied. System evolution beyond thermal fluctuations is triggered by well-defined external sources. There is, however, a rather huge class of soft matter, whose behavior is governed by internal activity, such as bacteria, sperm, colloidal microswimmers, and so on. They consume energy, which can be supplied by various means and develop very interesting motion and structure patterns, especially of interest in biological context. From a modeling point of view, this poses special challenges as one is dealing low Reynolds number hydrodynamics of active systems, which only rather recently also got into the focus of experiment. R.G. Winkler and G. Gompper tackle this problem in their contribution (▶ Chap. 68, "Hydrodynamics in Motile Active Matter"), where several advanced methods to include hydrodynamics effects in dissipative systems are introduced and applied to different classes of microswimmers. The applications range from the study of individual active microswimmers to collective behavior of larger flocks of swimmers.

## 3    Summary/Outlook

The contributions of this general chapter provide an introduction into the very wide field of multiscale polymer/soft matter simulations and should guide to more special and extensive literature (see, e.g., following reviews and books: Frenkel and Smit 2001; Voth 2008; Peter and Kremer 2009; Noid 2013; Potestio et al. 2014; Schiller et al. 2018). Studies of large biomolecular systems as proteins or assemblies of proteins are not covered but are closely connected. The same holds for field-based approaches used in an (mainly commercial) engineering context, such as finite element-related methods (Zheng et al. 2008; Meijer and Govaert 2003). I am sure that the described materials simulations in connection with new advanced data-driven method as well as with links to biomolecular simulations and quantum chemistry on one side and engineering with molecular insight on

the other side will significantly grow and become even more important. Advanced simulation methodologies in general and for soft matter in particular are at a point of transition from reproducing and supporting experiment and theory under well-defined and thus controlled conditions toward true predictive power for materials properties and guidance of experiments. This can lead to new molecular systems, as suggested by advanced sampling in chemical space or to new materials based on molecular insight into specific processing conditions, which only can be acquired by modern simulations approaches. Thus materials discovery by advanced multiscale modeling seems in reach. This software-based development will be further seconded by increasingly available high-performance computing (HPC) power.

### Abstract

The chapter provides a brief general introduction into the concepts of scaling, universality, and crossover scaling, plus the blob concept that provides an intuitive picture of crossover phenomena. We present the most important static and dynamic scaling laws for unentangled uncharged polymer solutions, together with their test and refinement by careful computer simulations. A hoard of simulation methods has been developed for these systems, and these will be briefly discussed as well.

## 1 Introduction

Polymers exist in a variety of states and situations. They may appear as bulk systems or in confined geometries (like films), and they may be solid (semicrystalline,

B. Dünweg (✉)

e-mail: duenweg@mpip-mainz.mpg.de

rubbery, or glassy) or liquid. In the liquid state, the macromolecules may form a dense melt, or they are dissolved in a solvent of good or poor quality. Finally, for a solution, it makes a huge difference if the molecules are charged or not; in the former case, one has a polyelectrolyte system.

Theoretical physics is mainly interested in the *universal* properties of polymer systems, i.e., those properties that do not depend on the details of the chemistry that defines the monomer. Lots of insight has been gained by deliberately discarding these details and rather focusing on the effects that result from the physics of macromolecules as such. The most important aspects here are (i) connectivity, i.e., the macromolecular architecture, which may be linear chains, rings, stars, combs, networks, etc. (in other words, the topology arising from bonded interactions), (ii) nonbonded interactions (here in particular the excluded-volume interaction, solvent quality effects, and possibly long-range electrostatics), (iii) (possibly) geometric restrictions, and (iv) (for solutions) the dynamic coupling between the motion of macromolecules and the flow of the surrounding solvent (the so-called "hydrodynamic interaction"). This is altogether the huge field of theoretical polymer physics, for which excellent textbooks (De Gennes 1979; Doi and Edwards 1988; Grosberg and Khokhlov 1994; Rubinstein and Colby 2003) exist. Even though the complicated chemistry has been replaced by simplified or coarse-grained models, understanding the physics is still a challenging and complicated problem, which one cannot simply "solve" by straightforward pencil-and-paper analytical theory. Rather, one has to rely on a combination of intuitive insight, theoretical approximations, experiments in the laboratory, as well as careful numerical studies of well-defined models.

The most successful computer models in the "universal" regime of phenomena are (i) simple lattice models and (ii) bead-spring models in the continuum. Both types of models can faithfully model connectivity and interactions (aspects (i) and (ii) of the previous paragraph); however, they have different strengths and weaknesses when it comes to further aspects. Lattice models are particularly well-suited for Monte Carlo studies of static properties, while bead-spring models are particularly amenable for studying the dynamics of systems with hydrodynamic interactions and for applying molecular dynamics and similar methods, which are much easier to parallelize than Monte Carlo algorithms.

The present chapter attempts to provide some overview of the physics (statics and Brownian dynamics) of *neutral* polymer solutions in the *bulk* and computer simulations that have provided confirmation and/or refinement of the underlying ideas. For polyelectrolyte solutions and dense melts, please see the contributions by C. Holm and G. S. Grest in this volume, respectively.

## 2    Scaling Laws

A good deal of theoretical polymer physics is concerned with so-called "scaling laws." This is a very general concept, which has proven extremely useful not only for polymers but also, e.g., in the theory of critical phenomena or the study of

turbulence. From an abstract point of view, scaling laws are nothing but a special
case of the general observation that the mathematical structure of a physical theory is
strongly restricted or perhaps even fully determined by the underlying symmetries.
Here we deal with a special symmetry, which is the invariance under the rescaling of
parameters. Suppose we consider a certain physical quantity $Q$ and we are interested
in its dependence on another physical quantity $P$. As an example, let us think about
the dependence of the average size $R$ of a polymer coil on the contour length $L$
of the (linear) molecule. Let us further assume that we pick a certain value of $P$,
$P = p$, as the basic unit for $P$. Let $q$ be the value of $Q$ for this particular $P$ value.
Then we may write the relation in dimensionless form:

$$\frac{Q}{q} = F\left(\frac{P}{p}\right), \tag{1}$$

where $F$ is a dimensionless function with $F(1) = 1$. Of course, we could also
use a different unit system, by picking a different value $p'$ for the $P$ units and the
corresponding value $q'$ for the $Q$ units, such that we also have

$$\frac{Q}{q'} = \frac{Q}{\lambda q} = G\left(\frac{P}{p'}\right), \tag{2}$$

with (in general) another function $G$, $G(1) = 1$, where the rescaling factor is given
by $\lambda = q'/q$. On the right-hand side, we can similarly introduce $\phi = p'/p$.
Obviously $\phi$ will depend on $\lambda$, $\phi = \phi(\lambda)$. Now, the system is *scale invariant* if
$\phi$ depends *only* on $\lambda$ but not on the point from where the rescaling started (i.e., not
on $p$, $q$) and if also $G = F$. In other words, scale-invariant systems are those that
are characterized by a *lack* of intrinsic scale or those where the physics does *not*
provide some most natural unit system. In our polymer coil example, this means
that it does not matter how long the subchains are into which the full molecule is
decomposed (as long as these subchains are long compared to the size of a chemical
monomer and short compared to the overall contour length). Since we can combine
two rescaling transformations with factors $\lambda$ and $\mu$ into a single one with factor $\lambda\mu$,
we have, for scale-invariant systems,

$$\phi(\lambda\mu) = \phi(\lambda)\phi(\mu) \tag{3}$$

and of course $\phi(1) = 1$. By mapping this relation onto a differential equation, it is
trivial to show that its solution is a power law:

$$\phi(\lambda) = \lambda^{1/\alpha}, \tag{4}$$

with an undetermined exponent $\alpha$. Insertion into Eq. 2 yields

$$\frac{Q}{\lambda q} = F\left(\frac{P}{\lambda^{1/\alpha} p}\right), \tag{5}$$

or, with $x = P/p$,

$$F(x) = \lambda F(\lambda^{-1/\alpha} x). \tag{6}$$

By picking the special value $\lambda = x^{\alpha}$, we see that $F$ is also a power law:

$$F(x) = x^{\alpha}. \tag{7}$$

In other words, scale invariance automatically gives rise to power laws. For our polymer coil example, this means

$$\frac{R}{R_0} = \left(\frac{L}{L_0}\right)^{\nu}, \tag{8}$$

where $R_0$ is the coil size for contour length $L = L_0$ and the Flory exponent $\nu$ depends on the physical situation. For flexible (i.e., sufficiently long) polymers in three dimensions, $\nu$ takes the value $1/2$ for random-walk (RW) statistics, while it is roughly 0.59 for self-avoiding walk (SAW) statistics, which applies in good solvent conditions. Finally, for a chain that forms a collapsed globule due to attractive interactions, $\nu = 1/3$.

It is important to realize that the exponents of scaling laws are typically *universal* (and this is certainly true for $\nu$). This is so because scale invariance means that the system "looks the same" after proper rescaling. Now, the idea of the renormalization group for polymers (Des Cloizeaux and Jannink 1991; Schäfer 1999) is that one should start from an original system and then subject it to a coarse-graining procedure, where several original monomers are lumped into new effective monomers. Iterating this, the chain more and more "forgets" its chemical details, while only the asymptotic scale-invariant structure remains – and this is the same for all original systems within a so-called "universality class." For polymers, all chains with relevant excluded-volume interactions belong to the universality class of SAWs while those with turned-off excluded volume to the RW universality class. For simulations, the concept of universality implies that any model can in principle be used, as long as it falls into the universality class that one wishes to study. This in turn means that the construction of models is mainly guided by considerations of conceptual simplicity, computational efficiency, and convenience in general.

Further important universal quantities are amplitude ratios and crossover scaling functions. The latter will be discussed in the next section; the former are simply the ratios of prefactors of scaling laws in dimensionless form. For example, one can study various measures of the size of a polymer coil, i.e., the end-to-end-distance $R_E \equiv \langle R_E^2 \rangle^{1/2}$, the gyration radius $R_G \equiv \langle R_G^2 \rangle^{1/2}$, and the hydrodynamic radius $R_H \equiv \langle R_H^{-1} \rangle^{-1}$, with

$$R_G^2 = N^{-1} \sum_i (\mathbf{r}_i - \mathbf{R}_{CM})^2, \tag{9}$$

$$\mathbf{R}_{CM} = N^{-1} \sum_i \mathbf{r}_i, \tag{10}$$

$$\mathbf{R}_E = \mathbf{r}_N - \mathbf{r}_1, \tag{11}$$

$$R_H^{-1} = N^{-2} \sum_{i \neq j} |\mathbf{r}_i - \mathbf{r}_j|^{-1}. \tag{12}$$

Here $N$ is the number of monomers of the chain, whose coordinates are denoted with $\mathbf{r}_i$. In the asymptotic long-chain limit, the ratios $R_E/R_G$ and $R_G/R_H$ are universal numbers, taking the values $\sqrt{6}$ and $8/(3\sqrt{\pi})$ for three-dimensional RWs.

## 3    Crossover Scaling

There are many situations where one needs to consider the dependence of a quantity on more than a single variable. For example, in polymer solutions, one is interested in the dependence of the coil size on degree of polymerization $N$, concentration $c$ (total number of monomers per unit volume), and solvent quality. In such a situation, scale invariance is expressed by a straightforward generalization of Eq. 6:

$$F(x_1, x_2, \ldots) = \lambda F(\lambda^{-1/\alpha_1} x_1, \lambda^{-1/\alpha_2} x_2, \ldots). \tag{13}$$

A particularly important case occurs if there are just two arguments, in which case we have

$$F(x_1, x_2) = x_1^{\alpha_1} F(1, x_1^{-\alpha_1/\alpha_2} x_2), \tag{14}$$

such that apart from the power law $x_1^{\alpha_1}$, we also have a dependence on the "crossover scaling variable" $x_c \equiv x_1^{-\alpha_1/\alpha_2} x_2$, while $F(1, x_1^{-\alpha_1/\alpha_2} x_2)$ is then called a "crossover scaling function." Typically the behavior becomes simple in the asymptotic limits $x_c \gg 1$, $x_c \ll 1$, where simple power laws $F \propto x_1^{\beta_>}$, $F \propto x_1^{\beta_<}$ are recovered. In such a case, the crossover scaling function must itself asymptotically behave like an appropriate power law. Finally, if $F$ describes the behavior of a universal ratio, it must itself be universal in the limit of long chains.

## 4    Blobs

Crossover phenomena in polymer solutions can conveniently be described in terms of so-called "blobs." A blob is a portion of the polymer chain that is composed of $g$ monomers and has a typical extension (the "blob size") $\xi$. This length scale marks

the crossover between two different behaviors, and typically an energy of $k_B T$ (thermal energy) is associated with it. The blob concept provides a nice pictorial description of crossover phenomena and is hence a very useful tool for deriving crossover scaling laws. The most important crossovers in the statics of polymer solutions are those between RW and SAW behavior, driven by (i) attractive effective interactions and (ii) concentration.

For a single isolated chain, the quality of solvent can be measured in terms of an effective interaction energy $\epsilon(T)$, which measures the temperature-dependent degree of attraction between two monomers. At the temperature of the theta transition (Lifshitz et al. 1978; Schäfer 1999) ($T = \Theta$), the repulsive and attractive parts of the interaction cancel out, such that effectively the chain behaves as a RW. In the vicinity of $T = \Theta$, we may write $\epsilon(T) = \epsilon_0(1 - \Theta/T)$, which gives rise to a dimensionless interaction parameter $z^\star = (k_B T)^{-1}\epsilon_0(1 - \Theta/T)$. For any $z^\star > 0$, the chain structure is asymptotically a SAW. However, if $z^\star$ is small, the amount of repulsion is too small to disturb the RW statistics on small length scales. This gives rise to a thermal blob size $\xi_T$ corresponding to $g_T$ monomers, of which each has a size $b$, such that $\xi_T \sim b g_T^{1/2}$. The number of monomer-monomer contacts within the blob is estimated as $g_T^{1/2}$. The blob size is found by equating the total energy in the blob with $k_B T$, i.e., $g_T^{1/2}z^\star \sim 1$, or $\xi_T \sim b/z^\star$. Visualizing a very long chain as a SAW composed of RW blobs, one finds $R \sim \xi_T (N/g_T)^\nu$ or

$$R \sim bN^{1/2} \left(N^{1/2}z^\star\right)^{2\nu-1},\tag{15}$$

from which the relevant crossover scaling variable $z = N^{1/2}z^\star$ is read off. For chains that violate the condition $N \gg g_T$, Eq. 15 is generalized to

$$R \sim bN^{1/2}f(z),\tag{16}$$

where the crossover scaling function $f(z)$ behaves like $f(z) \sim z^{2\nu-1}$ for $z \gg 1$ while $f(z) \sim 1$ for $z \ll 1$.

Next, let us consider the concentration-driven crossover from SAW to RW behavior in perfectly good solvent, as a result of Flory screening of excluded-volume interactions (De Gennes 1979; Rubinstein and Colby 2003). The overlap concentration $c^\star$ is the concentration where an arrangement of perfectly swollen chains is just space-filling, i.e., $c^\star \sim N/R^3 \sim b^{-3}N^{-(3\nu-1)}$. At concentrations $c$ that significantly exceed $c^\star$, the chains overlap. This gives rise to concentration blobs of size $\xi_c$, containing $g_c$ monomers. Since on length scales below $\xi_c$ there is no overlap, the SAW structure is unperturbed in this regime. Conversely, on scales above $\xi_c$, we have RW behavior. Therefore, $\xi_c \sim b g_c^\nu$ and $c \sim b^{-3}g_c^{-(3\nu-1)}$ or $\xi_c \sim b(b^3c)^{-\nu/(3\nu-1)}$. A long chain is then a RW composed of SAW blobs, $R \sim \xi_c(N/g_c)^{1/2}$ or

$$R \sim bN^{\nu} \left( \frac{c}{c^{\star}} \right)^{-\frac{\nu-1/2}{3\nu-1}} , \qquad (17)$$

from which the natural crossover scaling variable $c/c^{\star}$ is read off. The generalization in terms of a crossover scaling function is $R \sim bN^{\nu} f(c/c^{\star})$, where now $f(c/c^{\star}) \sim 1$ for $c/c^{\star} \ll 1$, while for $c/c^{\star} \gg 1$ the power law Eq. 17 is recovered. A solution whose monomer concentration is small but whose chains are so long that there is nevertheless a strong overlap is called "semidilute." The semidilute regime ends at a concentration $c^{\star\star}$ where the blob size has shrunken to the monomer size, such that no SAW regime is left.

In the general case, the structure is determined by the interplay between concentration and solvent quality effects or the competition between $\xi_T$ and $\xi_c$. For the ideal picture of a semidilute solution, we have $b \ll \xi_T \ll \xi_c \ll R$. On length scales below $\xi_T$ and above $\xi_c$, we have RW behavior. This is due to attraction on the small scales and due to Flory screening on the large scales. For length scales between $\xi_T$ and $\xi_c$, we have SAW behavior; this regime shrinks more and more upon deteriorating the solvent quality or upon increasing the concentration. This picture gives rise to the generic phase diagram shown in Fig. 1. For more details on the derivation, see the textbook literature or the supplemental material of Jain et al. (2012a). It is important to note that all universal ratios can, in the asymptotic limit of infinite chain length, be expressed in terms of just the two crossover scaling variables $z$ and $c/c^{\star}$.

## 5    Dynamic Scaling

Polymer statics provides us with two important length scales, the monomer size $b$ and the coil size $R$. In case the system needs to be described in terms of a blob picture, there may be a blob size, or possibly even more blob sizes, as additional important length scales. In a dense melt of long chains, there may also be entanglements, which give rise to a "tube diameter" as yet another important length scale. In the present chapter, we will only consider non-entangled systems, where the chains are either too short or too dilute to develop entanglements.

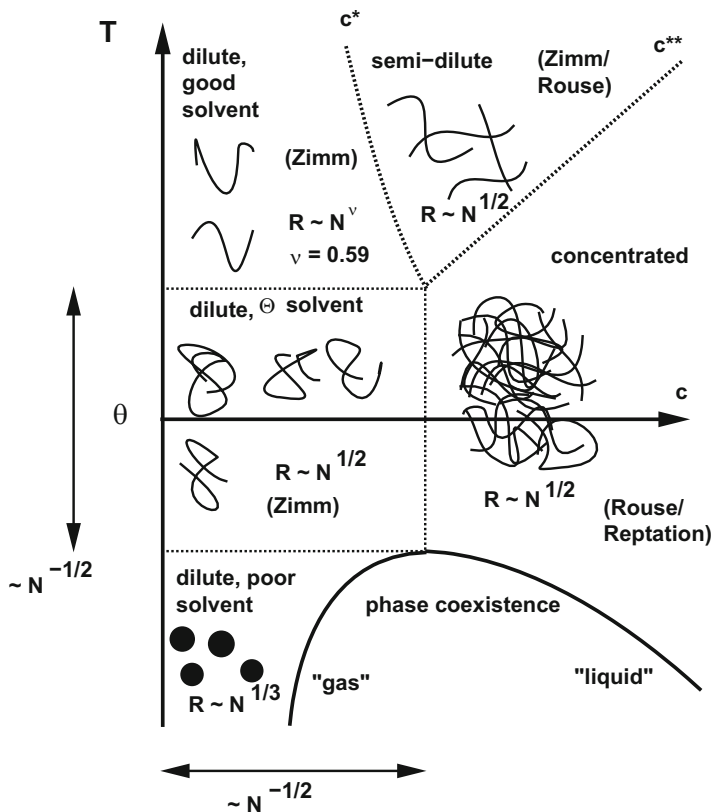
The idea of dynamic scaling for the Brownian motion of polymers may then be understood as follows: For each length $l$, there is an associated time $\tau(l)$. This time may be viewed as the time that a subchain of extension $l$ (in real space, *not* along the contour) needs to move diffusively by its own size. Alternatively, we may also pick a single monomer and study the time dependence of its root mean square displacement, $\langle (\Delta \mathbf{r})^2 \rangle^{1/2}$. The time $\tau(l)$ would then be given by the time that passes until $\langle (\Delta \mathbf{r})^2 \rangle^{1/2} = l$. The underlying concept is here that the single-monomer motion must be consistent with the motion of the object as a whole. Now suppose we consider $l$ values that are well within a regime that is bounded by two of the important scales mentioned in the previous paragraph, with no further important


**Fig. 1** Generic phase diagram of a polymer solution

scale in between. Then we again have a lack of a naturally provided unit system, and this applies not only to lengths but also to times. Therefore, the dynamics in such a regime must be described by a power law

$$\tau(l) \propto l^z, \tag{18}$$

which defines the *dynamic exponent z* (not to be confused with the crossover scaling variable of the previous section!), applicable to the regime under consideration.

Let us first consider a system where no blobs occur. This can either be a dilute solution ($c \ll c^\star$) or a dense melt ($c \gg c^{\star\star}$). The longest relaxation time $\tau_R$ is associated with the coil size:

$$\tau_R \propto R^z. \tag{19}$$

Dynamic scaling then implies that the mean square displacement for times $t$ with $\tau(b) \ll t \ll \tau_R$ must obey

$$\left\langle (\Delta \mathbf{r})^2 \right\rangle \propto t^{2/z}. \tag{20}$$

Furthermore, if $D$ denotes the center-of-mass diffusion constant of the chain as a whole, we have $D\tau_R \sim R^2$ or $D \propto R^{-(z-2)}$.

For an isolated chain in solvent (dilute limit), the intra-chain hydrodynamic interaction (i.e., the strong coupling of the monomer motion to the flow of the surrounding solvent) gives rise to so-called Zimm dynamics (Doi and Edwards 1988). A characteristic feature of Zimm dynamics is that the diffusive behavior of the chain is essentially that of a Stokes sphere, $D \sim (k_B T)/(\eta R)$, where $\eta$ is the solvent viscosity. More precisely, the approximate Kirkwood theory (Doi and Edwards 1988) predicts $D = (k_B T)/(6\pi \eta R_H)$. From this, one reads off $z = 3$.

In case the chain is in a dense melt, the hydrodynamic interactions are screened (more about this below). Therefore there are no hydrodynamic correlations in the monomer displacements, and if entanglements play no role (which is the case if the chains are not too long), then the relevant theory for the dynamics is the Rouse model (Doi and Edwards 1988). Here one simply assumes a homogeneous viscous background, and each monomer has a friction constant $\zeta$. The friction coefficients of these monomers simply add up to yield the total friction coefficient of the chain. Therefore $D = (k_B T)/(N\zeta)$. Since $R \sim bN^{1/2}$ (in a dense melt, we have RW statistics), $D \propto R^{-2}$ or $z = 4$.

In a semidilute solution, the length scale that governs the crossover from Zimm to Rouse dynamics is again the blob size $\xi_c$. Up to this length scale, one has unscreened excluded-volume and hydrodynamic interactions, i.e., SAW statistics and Zimm dynamics. The corresponding time scale is the blob relaxation time $\tau_\xi \sim \eta \xi_c^3/(k_B T)$. The blob as a whole has a Stokes friction coefficient $\sim \eta \xi_c$. Computer simulations (Ahlrichs et al. 2001) have shown that hydrodynamic interactions are unscreened as long as the *time* scale is significantly below $\tau_\xi$, regardless of length scales. This is reasonable, since on these short time scales, all monomers just move with the flow, such that correlations exist even on length scales significantly beyond $\xi_c$. Conversely, for times significantly above $\tau_\xi$, the blobs "feel" that they are not free to move (or that chain-chain collisions occur). Therefore, the blobs then dampen the hydrodynamic flow velocity $\mathbf{u}$ with a friction force per unit volume of (De Gennes 1976) $\sim \eta \xi_c \xi_c^{-3}\mathbf{u}$, which is a term that should be added to the Stokes equation for $\mathbf{u}$. For such a situation, the flow field generated by a point force does no longer decay like $1/r$ ($r$: distance from the point force) but rather like $\exp(-r/\xi_H)/r$, where the hydrodynamic screening length $\xi_H \sim \xi_c$. Hydrodynamic screening is thus understood as a randomization of hydrodynamic correlations, induced in essence by chain-chain collisions.

It should also be mentioned that melts do not exhibit strict Rouse dynamics in the dense limit, even if the chains are quite short. The reason is dynamic coupling of the chain motion to the viscoelastic modes of the "matrix," which gives rise to subtle corrections (Farago et al. 2012a, b). Similarly, there are also subtle corrections to the RW statistics of polymer chains in a melt (Wittmer et al. 2004). Both results have been obtained by careful computer simulations.

# 6    Simulations I: Statics

To study universal static single-chain properties, the method of choice is clearly
Monte Carlo (MC) of lattice models, where chains are simply walks on a lattice.
Mostly simple cubic lattices are studied, but other lattice structures are permitted
as well. The so-called pivot algorithm (Madras and Sokal 1988) is presently the
most efficient method known. Here one randomly selects a subchain and rotates
it by a random angle around a random axis. This is an MC trial move, which
is accepted or rejected by the standard Metropolis criterion. Presently the fastest
known implementation is that by N. Clisby (2010), where the information about
the chain conformation is stored in a somewhat unconventional manner: Firstly, one
defines a bounding box about the chain as a whole. Associated with it are global
properties like number of monomers, end-to-end vector, gyration radius, and center-
of-mass coordinate. Then one subdivides the chain into two subchains, for each of
which the analogous information is stored. This is done recursively all the way to
the monomer level, such that one obtains a binary tree. The coordinates of each
box and its contents are stored *relative* to the coordinates of the coarser level. This
makes it possible to move one such "container" as a whole without the need to ever
touch the data of the finer levels that it contains. Similarly, overlap checks are done
by checking the overlap between bounding boxes: If they do not overlap, then their
contents will surely not overlap either. With such tricks, it is possible to reduce the
computational complexity of one pivot move to $\ln N$, such that very long chains are
accessible. A recent study (Clisby and Dünweg 2016) has thus been able to find
for three-dimensional SAWs: $\nu = 0.58759700(40)$, $R_G/R_H = 1.5803940(45)$, and
$R_E^2/R_G^2 = 6.253531(10)$.

Similarly, accurate MC calculations have been able to study the $\Theta$ transition
in three dimensions (Grassberger 1997) and in particular investigate the subtle
logarithmic corrections to scaling that occur there. For this study, the so-called
"PERM" (prune-enriched Rosenbluth method) algorithm was used, where chains
are grown step by step and statistical criteria decide at each step if a chain is
terminated, continued, or even branched to generate yet another chain. In this way,
unbiased samples of long chains may be generated. Universal crossover scaling
functions for the $\Theta$ transition were studied as well (Kumar and Prakash 2003),
using the methodology of Brownian dynamics (BD; we will discuss this method
briefly below). This study emphasized the importance of appropriate extrapolation
procedures: In order to find the crossover scaling function, one should work at a
constant value of the crossover scaling variable (here $z = N^{1/2} z^\star$) and study the
residual dependence of a universal ratio (like $R_G(T)/R_G(T = \Theta)$) on the chain
length. This residual dependence is a correction to scaling; therefore the asymptotic
universal behavior is obtained after extrapolation $N \to \infty$.

The crossover scaling for Flory screening in good solvent was studied utilizing a
lattice model and MC simulation (Paul et al. 1991). However, here the model was the
so-called bond fluctuation model (Carmesin and Kremer 1988), where monomers do
not occupy single sites but rather elementary cubes, while the connecting bonds may
vary within limits. This allows to implement an MC dynamics that involves simply

a random displacement of an elementary cube on the lattice. Indeed it was found that a crossover from SAW to RW statistics occurs, with a crossover length scale $\xi_c$ that exhibits the concentration dependence predicted by blob theory. Later, the same model was also used to reveal the corrections to purely Gaussian behavior in a melt (Wittmer et al. 2004).

Finally, the double crossover that results from the competition between the theta blobs and the Flory screening blobs has recently been studied by BD (Jain et al. 2012a). The internal blob structure could not be resolved, for lack of sufficiently long chains; however the dependence of total chain properties like the coil size on concentration and solvent quality was in perfect agreement with blob theory. The same was true for dynamic properties like the diffusion constant.

# 7   Simulations II: Dynamics

For studies of dynamics, one needs algorithms that faithfully reproduce the motion of the monomers, at least on the (typically long) time scales that one is interested in. Obviously, brute-force molecular dynamics (MD) will satisfy this condition, if it involves all particles in the system. This approach has been highly successful for the studies of melts (see contribution by G. S. Grest in this volume) and can in principle also be applied to the dynamics of solutions, where the hydrodynamic interactions are taken into account by explicit solvent particles. Zimm dynamics for a single chain could thus be successfully established (Pierleoni and Ryckaert 1992; Dünweg and Kremer 1993). For such studies of a single macromolecule in a simulation box, one has to take into account that the latter is typically not much larger than the chain itself. Therefore, one has to deal with strong finite-size effects, which scale as $R_G/L$, where $L$ is the linear box size. This is a direct consequence of the long-range nature of the hydrodynamic interactions: Since the flow field generated by a point force decays like $1/r$ ($r$: distance from the force center), the correlations between the stochastic displacements of two distinct monomers are proportional to the inverse interparticle distance. The theory thus provides detailed quantitative predictions about the magnitude of such finite-size effects, and this in turn makes it possible to quantitatively check Zimm theory even in a finite-box situation.

However, for solutions MD is nearly always unnecessarily expensive and can rather be replaced by cheaper algorithms that simulate the solvent degrees of freedom in a simplified fashion. The only situations where this is not true are either fairly concentrated solutions, where the solvent contribution to the computational effort is only moderate, or investigations of local atomistic dynamics, where local packing and similar phenomena are of specific interest. In all other cases, the effect of the solvent can be summarized by (i) its quality, which may be modeled by just a suitable effective monomer-monomer interaction, and (ii) the hydrodynamic interactions, which give rise to dynamic correlations between monomers as a result of momentum transport through the solvent. The crucial observation is here that the solute-solvent system is characterized by a large separation of time scales: The slowest degree of freedom in the solvent is diffusive momentum transport,

characterized by the "kinematic viscosity" $\eta_{kin} = \eta/\rho$, i.e., the ratio between shear viscosity and mass density, which has the dimension of a diffusion constant. The dimensionless "Schmidt number" $Sc = \eta_{kin}/D$ then relates this to the diffusion constant $D$ of an immersed particle or, more generally, to the diffusion constant of some immersed soft-matter object of size $R$. Typically, in dense fluids $Sc \gg 1$ even for solvent particles, due to a sizeable viscosity value-note $\eta_{kin} \propto \eta$ but $D \propto 1/\eta$. For large (isolated) macromolecules, the corresponding Schmidt number is yet much larger, as $Sc \propto 1/D \propto R$. For these reasons, we may *either* replace the solvent by some sort of "generalized hydrodynamics solver," i.e., a set of more or less artificial degrees of freedom that exhibit the correct hydrodynamic behavior on large length and time scales, *or* dispose of the solvent altogether, by assuming that the flow field follows the configuration of monomers instantaneously, such that it becomes completely enslaved to the latter and thus no longer appears as an explicit degree of freedom.

Let us begin with the latter approach. This is the realm of *Brownian dynamics* (Öttinger 1995). Here one solves a discretized stochastic differential equation for the monomer coordinates $\mathbf{r}_i$, using a finite time step $h$. The update rule can then be written as

$$r_{i\alpha}(t + h) = r_{i\alpha}(t) + h \sum_j \mu_{i\alpha, j\beta} F_{j\beta} + k_B T h \sum_j \partial \mu_{i\alpha, j\beta}/\partial r_{j\beta}$$

$$+ \sqrt{2k_B T h} \sum_j \sigma_{i\alpha, j\beta} q_{j\beta}. \tag{21}$$

Here Greek letters indicate Cartesian indexes with Einstein summation convention. $\mathbf{F}_j$ is the force acting on particle $j$, while $\overset{\leftrightarrow}{\mu}_{ij}$ is the mobility tensor that describes the hydrodynamic correlations between the monomers $i$ and $j$. Typically, the Rotne-Prager tensor (Öttinger 1995) is used. In case one is not interested in correct solution dynamics, one may simply turn the hydrodynamic interactions off and replace $\overset{\leftrightarrow}{\mu}_{ij}$ with a multiple of the unit tensor. In this case, the method will produce Rouse-like dynamics for a single-chain simulation. The last term of Eq. 21 denotes the stochastic displacements, where $q_{i\alpha}$ are random variables with

$$\langle q_{i\alpha} \rangle = 0 \tag{22}$$

$$\langle q_{i\alpha} q_{j\beta} \rangle = \delta_{ij} \delta_{\alpha\beta}, \tag{23}$$

while the matrix $\sigma_{i\alpha, j\beta}$ satisfies

$$\sum_k \sigma_{i\alpha, k\gamma} \sigma_{j\beta, k\gamma} = \mu_{i\alpha, j\beta}. \tag{24}$$

This approach was pioneered by a seminal paper nearly 40 years ago (Ermak and McCammon 1978) and has seen many refinements since then. The main

difficulties are the evaluation of the mobility tensor, which couples all monomers in the system, and the calculation of a suitable square root. These problems have remained a computational challenge for decades. Standard Ewald sums for multichain systems (Jain et al. 2012b) have met moderate success, but only recently has a method been published (Fiore et al. 2017) whose computational effort scales strictly *linearly* with the number of involved monomers.

The generalized hydrodynamics solvers are technically much easier and also much more easy to parallelize. They also scale linearly with the number of monomers, however at the expense of an additional large set of explicit solvent degrees of freedom. These solvers all include thermal fluctuations in some way or another. This is necessary because in soft-matter physics, we are dealing with length and time scales that are so small that fluctuations play a role. Obviously, Brownian motion of polymer chains could not be studied if fluctuations were absent. Therefore such methods are not fully macroscopic but are rather frequently called "mesoscale" methods.

One can distinguish two classes of mesoscale methods, depending on the way how thermal fluctuations are treated. The first class, which one may call "MD-like," are particle methods where the amount of thermal fluctuations per degree of freedom is similar to what one would get in an MD simulation. Peculiar to these methods is the impossibility to adjust the degree of thermal fluctuations *independently* of the macroscopic fluid properties that are relevant for hydrodynamics. Conversely, in the second class, which one may call "hydrodynamics-like," the degree of thermal fluctuations *can* be adjusted independently of the macroscopic properties. The degree of thermal fluctuations is here a reflection of the degree of coarse-graining: The more atomistic particles are lumped into one mesoscale degree of freedom, the smaller is the amount of thermal fluctuations per mesoscale degree of freedom – simply as a result of Gaussian statistics and the law of large numbers.

As this aspect is typically underemphasized in the literature, let us illustrate this by a very simple example, a one-dimensional ideal gas, which we simulate by MD, augmented by a Lowe-Andersen thermostat (Lowe 1999) to bring the system to thermal equilibrium. This thermostat simply picks, from time to time, a pair of nearby particles at random. The center-of-mass velocity of that pair then remains unchanged, while the relative velocity is chosen at random, using the appropriate equilibrium Maxwell-Boltzmann distribution, such that the total momentum is conserved. The thermal (root mean square) velocity of a particle is then $(k_B T/m)^{1/2}$, where $m$ is its mass. This has macroscopic relevance, since this is also the speed of sound. Now let us assume that we lump $M$ adjacent particles into a new mesoscale particle. The new system is then again an ideal gas, which we wish to simulate with the same method. We then have two choices concerning the question of the mass of the mesoscale particles: Either we can assign the value $Mm$, which is naively the correct choice, since the bigger particle should indeed exhibit more inertia. Moreover, the thermal velocity (i.e., the amount of thermal fluctuations) is indeed correctly reduced by the factor $M^{-1/2}$. However, this comes at the price of also reducing the speed of sound by the same factor – and this is a value that we would prefer to keep constant, in order to maintain

the time-scale separation between immersed soft-matter objects and the sound waves. Therefore one typically chooses the value $m$, thus keeping the macroscopic properties intact but overestimating the degree of thermal fluctuations. In other words, MD-like methods are typically too restrictive to permit a fully consistent coarse-graining. This dilemma is solved by the hydrodynamics-like methods, where thermal fluctuations are an add-on with adjustable strength to a method that would also work in the strict macroscopic limit with no fluctuations whatsoever.

Dissipative particle dynamics (DPD) (Espanol and Warren 1995) is directly derived from MD, which is just augmented by a momentum-conserving Langevin thermostat. Similarly to the Lowe-Andersen method, DPD is based upon pairs of nearby particles, which are however not chosen at random but rather considered in their totality, at every single time step. The projection of the relative velocity onto the interparticle axis is dampened by a Langevin friction. This is compensated by stochastic Langevin forces on the two particles that also act along the interparticle axis and add up to zero. The total momentum is conserved, and the fluctuation-dissipation theorem (FDT) is satisfied. A generalized version also thermalizes the velocity components perpendicular to the axis (Junghans et al. 2008); however, it is presently not yet fully understood what effects the implied violation of angular-momentum conservation has on the hydrodynamics.

Quite often, DPD simulations are run with particles that have fairly soft interaction potentials. This is done in the spirit of coarse-graining, which in general leads to such softening of interactions. It also has a practical implication, since softer potentials also allow to use a larger time step. The most radical implementation of that idea is to simply run DPD of an ideal gas as a solvent for soft-matter objects (Smiatek et al. 2008). Using an ideal gas has a huge advantage: The solvent degrees of freedom are reduced to their prime function, which is to transmit momentum through the system, and the equilibrium structure of the immersed objects is unaltered compared to immersion in vacuum. The viscosity can nevertheless be adjusted to reflect dense-fluid conditions, by choosing a sufficiently strong friction.

A yet simpler variant is multiparticle collision dynamics (MPCD) (Gompper et al. 2009). Here the ideal-gas particles are sorted into cubic cells. In each cell, the algorithm determines its local center-of-mass velocity and the relative velocities of the particles with respect to it. The latter are then subjected to a random rotation. This "collision step," which conserves both the momentum and the kinetic energy, serves to thermalize the ideal gas and is followed by a standard MD "streaming step."

Both DPD and MPCD are "MD-like," with a coupling of the monomers to the solvent that arises naturally from the setup of the respective algorithms. We will now turn to the "hydrodynamics-like" methods.

Smoothed dissipative particle dynamics (SDPD) (Espanol and Revenga 2003) has been developed to cure the abovementioned deficiencies of DPD. The name suggests a closer proximity to DPD than the method actually exhibits. While DPD comes in spirit from MD, as essentially a bottom-up approach, SDPD rather is a top-down method: Here the starting point is smoothed particle hydrodynamics

(SPH) (Monaghan 2005), which is nothing but a discretization of the Navier-Stokes equations in terms of particles. This looks deceptively similar to MD but is fundamentally different: Firstly, in MD both the equation of state and also the transport coefficients like the viscosity are an output of the atomistic model and must be determined by simulation. Conversely, in SPH they are input parameters. Secondly, MD particles have as only properties their coordinates and momenta (and possibly their orientations and angular momenta). SPH particles, on the other hand, have additional properties "on board" that one could not even *define* for MD particles because their nature is genuinely *thermodynamic* – volume and entropy, which both change in the course of time as a result of the dynamics. SDPD adds Langevin noise to the SPH equations of motion such that the FDT is satisfied. Although the SDPD particles are thermodynamic objects, it is nevertheless possible to simply connect a set of them via springs and thus obtain an immersed polymer chain with the correct large-scale properties (Litvinov et al. 2008). The polymer-solvent coupling is therefore as straightforward as for DPD and MPCD.

Instead of discretizing the Navier-Stokes equations in terms of particles, one may also discretize them via a lattice. One therefore arrives at standard finite-difference or finite-volume schemes (Donev et al. 2010; Balboa-Usabiaga et al. 2012). Again, one may add thermal fluctuations to the equations to satisfy the FDT.

Finally, one may also simulate hydrodynamics via the Lattice Boltzmann (LB) (Dünweg and Ladd 2009) method. Here one solves a linearized and fully discretized version of the Boltzmann equation known from the kinetic theory of gases. Space and time are discretized in terms of a lattice spacing $a$ and time step $h$, respectively. Velocity space is also discretized and reduced to a small discrete set of velocities $\mathbf{c}_i$. Each lattice site contains a set of real-valued positive variables $n_i$, which are interpreted as the mass density corresponding to velocity $\mathbf{c}_i$. The mass density $\rho$ and the momentum density $\mathbf{j}$ are then obtained as zeroth and first velocity moment of the populations:

$$\rho = \sum_i n_i, \tag{25}$$

$$\mathbf{j} = \sum_i n_i \mathbf{c}_i. \tag{26}$$

The procedure then begins with a collision step, i.e., a rearrangement of the populations on the site such that mass and momentum are conserved:

$$n_i \to n_i^{\star} = n_i + \Delta_i, \tag{27}$$

where the "collision operator" $\Delta_i$ satisfies

$$\sum_i \Delta_i = 0, \tag{28}$$

$$\sum_i \Delta_i \mathbf{c}_i = 0. \tag{29}$$

This is followed by a streaming to the adjacent lattice sites, such that the total procedure can be written in terms of the Lattice Boltzmann equation (LBE):

$$n_i(\mathbf{r} + \mathbf{c}_i h, t + h) = n_i(\mathbf{r}, t) + \Delta_i(\mathbf{r}, t). \tag{30}$$

This implies that the discrete velocities must be chosen commensurate with the lattice. For example, the popular D3Q19 model (Dünweg and Ladd 2009), which lives on the three-dimensional simple cubic lattice, involves 19 velocities, which correspond to the 6 nearest and 12 next-nearest neighbors, plus the zero velocity.

The method involves lots of adjustable parameters, like the set of velocity shells, associated weight coefficients, and various details of the collision operator. All of these are tuned in order to obtain the correct Navier-Stokes behavior in the continuum limit, which is found from the algorithm by subjecting the LBE to an asymptotic (Chapman-Enskog) analysis. The LBE can therefore be used as a Navier-Stokes equation solver in its own right. Thermal fluctuations are introduced by adding a suitably chosen stochastic collision operator to $\Delta_i$. For further details, see Dünweg and Ladd (2009).

It should be emphasized that in all of the abovementioned "hydrodynamics-like" methods, it is very important to make sure that the FDT is not only satisfied in the asymptotic continuum limit but rather for the algorithm as such. Substantial effort has gone into the development of methods that do satisfy this condition.

In contrast to particle methods, hybrid methods that involve MD for the polymer chains and a lattice algorithm for the solvent need special care for the fluid-particle coupling. A particularly simple approach is a frictional coupling (Dünweg and Ladd 2009), where each monomer is assigned a Stokes friction coefficient. Therefore each monomer is not only subject to the conservative forces coming from other monomers (and possibly yet other sources) but also to a friction force and a Langevin stochastic force. The former dampens the *relative* velocity of the particle with respect to the local flow field, which is obtained via interpolation from adjacent lattice sites. The latter is just standard Langevin noise that is needed to satisfy the FDT. Back coupling is obtained by interpolating the thus-resulting momentum transfer back to the lattice and enforcing momentum conservation. Another possibility is to enforce a stick boundary condition, either on the surface of an extended particle  (Dünweg and Ladd 2009) or based upon a point-particle picture (Usabiaga et al. 2013).

At the end of this section, we briefly wish to mention a few studies that have focused on polymer solution dynamics. Zimm dynamics of a single chain has been studied by BD by many authors, e.g., Fixman (1986), Liu and Dünweg (2003), and Sunthar and Prakash (2006), where the last study also investigated the solvent quality-driven crossover behavior. Single-chain Zimm dynamics was also studied by LB/MD (Ahlrichs and Dünweg 1999), MPCD (Mussawisade et al. 2005), and

SDPD (Litvinov et al. 2008). Not surprisingly, all these studies yield essentially the same results, and it is even possible to quantitatively map them onto each other – this has explicitly been done for LB/MD vs. pure MD (Ahlrichs and Dünweg 1999) as well as for LB/MD vs. BD (Pham et al. 2009).

   Detailed studies of the concentration-driven crossover from Zimm to Rouse dynamics have been done by both LB/MD (Ahlrichs et al. 2001) and MPCD (Huang et al. 2010). Both confirmed the picture of hydrodynamic screening as outlined in Sect. 5, and the latter paper went even beyond to also study non-equilibrium behavior.

## 8    Summary

Polymer solution statics and dynamics are beautiful pieces of physics where progress has been made by analytical theory (in particular scaling considerations), experiments, and computer simulations. Improved physical and mathematical insight led to the development of computer simulation methods that went from simple and fairly brute force to more and more sophisticated and problem-oriented, focusing on the essence of the phenomena one wishes to study. The author hopes that the present contribution has given the reader a glimpse on how fruitfully theory and simulations have worked together in this field. For reasons of both space and also expertise of the author, the present chapter has only focused on the most basic equilibrium phenomena and completely left out the highly important field of non-equilibrium physics, i.e., nonlinear polymer solution rheology, which would be worth yet another chapter in this series.

# From the Atomistic to the Macromolecular Scale: Distinct Simulation Approaches for Polyelectrolyte Solutions

# 62

## Jens Smiatek and Christian Holm

## Contents

## Abstract

Polyelectrolytes reveal interesting properties in solution. At short length scales, the dissociation of counterions is heavily affected by the chemical structure of the polyelectrolyte, the properties of the solution, and specific ion effects. At larger length scales, the structure of polyelectrolyte solutions is dominated by long-range interactions. In the special case of dissolved polyanions and polycations, polyelectrolyte complexes or multilayers can form. In this review we present distinct simulation approaches to study the corresponding effects at different

length scales in more detail. Whereas at short length scales, atomistic molecular dynamics simulation is often the method of choice, semi-coarse-grained and coarse-grained models with a lower level of details reveal their benefits at larger length scales.

# 1    Introduction

In accordance with the IUPAC definition, polyelectrolytes are charged macro-molecules, in which a substantial portion of the constitutional units contains ionic or ionizable groups, or both (McNaught and Wilkinson 1997). Strong polyelectrolytes like DNA are completely ionized, whereas weak polyelectrolytes like polyacrylic acid show an incomplete and pH-dependent dissociation behavior. Consequently, the properties of polyelectrolytes are dominated by a combination of electrostatic and molecular interactions, which heavily affect the occurring conformations and the resulting ion dissociation behavior. In contrast to uncharged polymers, the long-range decay of electrostatic interactions between the ionic groups impedes the derivation of scaling relations in terms of simple mean-field approaches (de Gennes 1979; Doi and Edwards 1988; Dobrynin and Rubinstein 2005; Dobrynin 2008). Thus, the complex interplay between the polyelectrolyte, the ions in the solution, and the solvent reveals many interesting phenomena at different length scales, which can be studied in more detail with the help of distinct molecular dynamics (MD) simulation approaches in combination with appropriate models for the considered species.

At short length scales, previous atomistic MD simulations demonstrated that the molecular solvation behavior significantly influences the amount of ionized groups and thus the corresponding conformation with regard to counterion condensation effects and repulsive electrostatic interactions along the polyelectrolyte backbone (Smiatek et al. 2014). Vice versa, the behavior of the surrounding solvent molecules is also modified by the presence of ionic groups, which is reflected by local varia-tions concerning the dielectric permittivity and the solvation of ions (Fahrenberger et al. 2015a; Mukhopadhyay et al. 2012). In contrast to these local interactions, the aggregation of polyelectrolytes becomes important at larger length scales, such that polycations and polyanions form polyelectrolyte complexes and multilayers, whose stability significantly depends on enthalpic and entropic contributions and the properties of the embedded solvent molecules (Cerdà et al. 2009; Qiao et al. 2011, 2012). Also in bulk solution, molecular properties determine the configurational behavior of the polyelectrolyte, as can be seen by the formation of polyelectrolyte micelles, pearl-necklace structures, or the onset of microphase separation processes between polar and apolar regions (Limbach and Holm 2003; Limbach et al. 2004; Dormidontova et al. 1994). Thus, appropriate models with a sufficient degree of detail are needed for reliable simulations of polyelectrolyte solutions in order to elucidate the properties of interest.

In this chapter, we introduce several well-established approaches for the simu-lation of polyelectrolyte systems at different length and time scales. The benefits

and drawbacks of atomistic, semi-coarse-grained and simple coarse-grained models are discussed, and we will present representative examples for various applications. In the last section, we summarize the main points and address current limitations concerning the general applicability of the methods.

## 2    Simulation Approaches for Polyelectrolyte Solutions at Different Length Scales

The discussion of methods in this section follows a bottom-up approach, which means that we start with atomistic models and the description of molecular force fields. Hereafter, we decrease the level of resolution in terms of semi- and simple coarse-grained approaches, which are best suited for the simulation of processes at large length and long time scales. All models rely on the consideration of explicit particles in combination with molecular dynamics or Monte Carlo time integration schemes. It has to be noted that other continuum or self-consistent field approaches can also be used, for instance, as described in Schmid (1998). Over the last years, multiscale simulation approaches were also developed, which rely on a combined consideration of the following methods in terms of matching and adaptive resolution schemes. The reader is referred to Fritz et al. (2011) and Praprotnik et al. (2008) for more details and for other contributions to this volume.

### 2.1    Atomistic Models: Importance of Chemical and Molecular Details

Due to the massive increase of computational power over the last years, it is nowadays possible to study the properties of short polyelectrolyte chains, the so-called oligoelectrolytes, for hundreds of nanoseconds via atomistic MD simulations in combination with accurate molecular force fields. In terms of modern force fields, molecular properties are dictated by bonded and nonbonded interactions, which are represented by classical potential functions in order to avoid an extremely expensive evaluation of the electronic behavior. In more detail, standard atomistic force fields like OPLS/AA (Jorgensen et al. 1996) include parameters for bonded, angular, and dihedral potentials in addition to nonbonded interactions, which are usually represented by Coulomb and Lennard-Jones contributions. In combination with advanced electrostatics algorithms (Deserno and Holm 1998; Arnold et al. 2013) and the sophisticated use of graphics processing units (GPUs), the properties of polyelectrolyte solutions with a dimension up to several nanometers can be studied for hundreds of nanoseconds by standard atomistic MD approaches. Hence, detailed information on the molecular interactions, the solvent behavior, and the corresponding distribution functions are accessible.

As an illustrative example, the stable conformations for a sulfonated oligosulfonic acid with sodium counterions in water and chloroform are displayed in Fig. 1, where more details of this system can be found in Smiatek et al. (2014). It can
**Fig. 1** Sulfonated oligosulfonic acid with nine monomers according to $N_p = 9$ and an equivalent number of sodium counterions (blue spheres) in water (left side) and chloroform (right side). The solvent molecules are not shown for reasons of clarity, and the chemical structure of one monomer is depicted in the middle

be clearly seen that the oligoelectrolyte reveals a swollen conformation in polar solvents like water when compared with chloroform. This finding can be related to molecular solvation effects and standard polymer theories, which distinguish between good, poor, and theta solvents (de Gennes 1979). Thus, the average size of the polyelectrolyte with $N_p$ monomers can be described by a power-law behavior according to $R \sim N_p^\nu$ with the excluded-volume parameter $\nu$, which is usually $\nu = 0.588$ for uncharged polymers in good solvents (Doi and Edwards 1988). Depending on the actual value of the excluded-volume parameter, good and poor solvents are defined by $\nu > 1/2$ and $\nu < 1/2$, respectively, whereas a theta solvent is characterized by $\nu = 1/2$. A polyelectrolyte chain at infinite dilution should scale with $\nu = 1$. Hence, the molecular properties of the polyelectrolyte adapt directly to the polarity of the solvent, which is reflected by an increase or a decrease of the solvent-accessible surface area and the size.

Interestingly, further analysis concerning atomistic models for polyelectrolytes revealed that the counterion behavior differs significantly from standard theoretical descriptions (Manning 1969, 1996; Deserno et al. 2000; Deserno and Holm 2001), which highlights the benefits of atomistic MD approaches in order to verify molecular theories and to study the corresponding deviations. As a result of these simulations (Lund et al. 2008; Heyda and Dzubiella 2012; Smiatek et al. 2014; Batys et al. 2017), it was found that the counterion distribution around the polyelectrolyte can deviate from standard mean-field predictions in terms of the Poisson-Boltzmann theory (Andelman 1995), which can be attributed to specific solvation effects and molecular interactions (Smiatek et al. 2014). Furthermore, it was also observed that specific ion effects (Marcus 2009; Kunz 2010; Lo Nostro and Ninham 2012) and conformational properties of polyelectrolytes (Wohlfarth et al. 2015) influence the corresponding counterion distribution and yield results in good agreement with experimental data. To summarize, also atomistic simulations reveal short-range deviations from simple mean-field theories; however, Poisson-Boltzmann theory

and its generalizations often agree surprisingly well for global observables like the osmotic pressure or effects that are dominated by the Coulomb interactions (Deserno et al. 2001; Antypov et al. 2005; Antypov and Holm 2006; Lu et al. 2008).

## 2.2    Semi-Coarse-Grained Approaches: MARTINI Force Fields and Refined Models

Atomistic MD simulations mainly intend to study the properties of short oligoelectrolyte chains and their molecular interactions with counterions and other components of the solution. Although also larger systems were studied, for instance, polyelectrolyte complexes and multilayers (Farhat et al. 1999; Micciulla et al. 2014), it has to be mentioned that these simulations are very CPU-time demanding and usually restricted to several tens of nanoseconds, such that even a reasonable equilibration of these complex solutions is hard to achieve. In order to introduce efficient but still accurate models for these larger systems, the use of semi-coarse-grained approaches is highly beneficial. In general, coarse-grained approaches intend to reduce the degrees of freedom when compared with atomistic simulations, which results in a significant acceleration of the computation times and the possibility of using larger time steps (Winger et al. 2009; Marrink et al. 2010). Standard coarse-grained frameworks for polyelectrolytes and polymers include the introduction of simple bead-spring models (Doi and Edwards 1988). Hence, several atoms of a monomer are represented by one interaction site, the so-called bead, while the individual beads are connected with springs, which are usually modeled by classic harmonic or modified Finitely Extensible Nonlinear Elastic (FENE) potentials. In contrast to the most simple coarse-grained methods, semi-coarse-grained approaches like the MARTINI force field (Marrink and Tieleman 2013) refine these very generic models by consideration of important chemical details. For instance, the MARTINI force field usually relies on a 4:1 mapping scheme, such that four heavy atoms are combined into one interaction site (CG bead) with parameterized polarity values and hydrogen bond acceptor and donor abilities (Marrink et al. 2007). In more detail, the MARTINI CG beads can be divided into different particle-type classes (polar (P), nonpolar (N), apolar (C), and charged (Q) species). The subtypes within these classes are categorized due to their ability to form hydrogen bonds (donor (d), acceptor (a), both donor and acceptor (da), and none of them (0)) and with regard to their polarity (from 1 = low polarity to 5 = high polarity) (Marrink et al. 2007; Marrink and Tieleman 2013). Further subclasses were also defined to increase the local resolution (Marrink et al. 2007). All CG beads reveal different Lennard-Jones parameters and partial charges, which were parameterized according to partitioning coefficients for similar atomic groups in oil/water mixtures (Marrink et al. 2007; Marrink and Tieleman 2013).

Over the last years, several MARTINI models for polymers and polyelectrolytes were developed. Specific examples are DNA (Uusitalo et al. 2015), poly(styrene sulfonate) (PSS) and poly(diallyldimethylammonium) (PDADMA), which were both used for the study of polyelectrolyte complexes (Vögele et al. 2015a). The
**Fig. 2** Chemical structure of PSS (left side) and PDADMA (right side) with three monomers. The differently shaded regions denote spherical MARTINI CG beads with particle-type classes as defined in Marrink et al. (2007)

molecular topologies of PSS and PDADMA in terms of the MARTINI force field and the corresponding particle types according to Marrink et al. (2007) are shown in Fig. 2. In combination with refined polarizable water models (Yesylevskyy et al. 2010; Michalowsky et al. 2017), it was shown that MARTINI simulations are well suited to study the properties of highly charged systems at large length and time scales (Vögele et al. 2015a, b; Uusitalo et al. 2015).

The advantages of MARTINI models are mostly given by their flexibility and their transferability, but it has to be noted that solvent particles indeed have to be considered explicitly. In order to circumvent time-consuming calculations, the matching of potential of mean forces between atomistic and coarse-grained simulations provides a computationally efficient route in terms of tabulated potentials and thus an implicit solvent approach (Brini et al. 2013; Reith et al. 2002; Li et al. 2012; Lyubartsev and Laaksonen 1999; Savelyev and Papoian 2010; Hsu et al. 2012). Although this method, which is also often called iterative Boltzmann inversion technique (Reith et al. 2003), avoids time-consuming calculation of interactions between solvent particles and between solvent and polyelectrolyte groups, it has to be mentioned that the force-matching method is mostly applicable for homogeneous solutions without interfaces. More refined coarse-grained models for DNA and ionomer systems, based on the matching of ion mobilities, were published in Lu et al. (2014), Weik et al. (2016), and Rau et al. (2017). A semi-coarse-grained approach for the simulation of weak polyelectrolytes was recently introduced in Landsgesell et al. (2017a, b). Furthermore, the well-known decrease of the dielectric permittivity around charged objects and the corresponding consequences were recently studied in coarse-grained polyelectrolyte solution via a modification of the Maxwell equation molecular dynamics algorithm (Fahrenberger and Holm 2014; Fahrenberger et al. 2015a, b).

In summary, refined or semi-coarse-grained models can be used for the study of systems at intermediate length and time scales. Nevertheless, for the study of long time-scale processes like transport behavior or the influence of hydrodynamics on polyelectrolyte motion, the use of simple coarse-grained methods remains the most suitable choice.

## 2.3    Simple Coarse-Graining: Generic Bead-Spring Models with Explicit Charges

In general, all simple coarse-grained models are composed of single interaction sites, which have a lower resolution when compared with semi-coarse-grained approaches and thus usually correspond to individual monomers or the number of monomers within the corresponding persistence length (Doi and Edwards 1988). All adjacent beads are connected by springs in terms of simple harmonic or FENE potentials, which restrict the length of the bonds to the equilibrium distance in order to avoid entanglement effects in polymer melts (Kremer and Grest 1990; Stevens and Kremer 1993a, b). In contrast to semi-coarse-grained approaches, simple bead-spring models do not include angular or dihedral potentials per definition, and the corresponding nonbonded interactions are represented by simple Lennard-Jones (LJ) and Coulomb interactions. Most often, the WCA potential, a purely repulsive shifted and truncated version of the Lennard-Jones potential, is used to mimic hard spheres for beads and ions (Weeks et al. 1971). In contrast to MARTINI models, the solvent is often modeled implicitly by consideration of a global dielectric constant, which is thus inserted into the Coulomb potential. Furthermore, the model can be even more simplified by using a screened electrostatic potential or neglecting Coulomb interactions all together (Hickey et al. 2012; Szuttor et al. 2017; Roy et al. 2017). Specifically in solvents with high values of the dielectric constant, for instance, water, electrostatic interactions between charged groups and ions dominate only at short distances (Collins 2004). This can be mostly attributed to the low value of the Bjerrum length at room temperature $\lambda_B = e^2/4\pi\epsilon_0\epsilon_r k_B T$ with the elementary charge $e$, the vacuum permittivity $\epsilon_0$, the dielectric constant $\epsilon_r$, the temperature $T$, and the Boltzmann constant $k_B$. The Bjerrum length estimates the distance where the thermal energy dominates over the electrostatic energy and which is for water at 300 K around $\lambda_B \approx 0.7$ nm corresponding to two hydration shells (Collins 2004; Marcus and Hefter 2006). For larger and highly charged objects like polyelectrolytes or colloidal particles, also the salt concentration plays a significant role in order to induce a fast decay of electrostatic interactions. Hence, by a simple linearization of the Poisson-Boltzmann equation in terms of the Debye-Hückel approximation, the corresponding electrostatic screening length reads $\lambda_D = (\epsilon_r\epsilon_0 k_B T/(\sum_i 2z_i^2 e^2\rho_i))^{1/2}$ with the valency $z_i$ and the ion density $\rho_i$ (Andelman 1995). With regard to this relation, one usually obtains a screening length of $\lambda_D \approx 1$ nm for water at room temperature with a salt concentration of 0.1 mol/L, which implies that the monomers are only weakly affected by the electric field of the surrounding polyelectrolyte groups (Szuttor et al. 2017). Hence, for large objects like λ-DNA, it is often sufficient to neglect electrostatic interactions between the monomers, if the Debye and the Bjerrum length are significantly smaller than the size of the polyelectrolyte in accordance with $\lambda_D \approx \lambda_B \ll R$ (Szuttor et al. 2017; Roy et al. 2017).

Most of these simple coarse-grained models are used to study the dynamics of polyelectrolytes and other components in solution, often under the influence of

external forces in order to induce transport processes. Recent reviews highlighted the benefits of these models in combination with sophisticated mesoscopic simulation techniques for the study of transport processes and electrokinetic effects in microchannels (Slater et al. 2009; Pagonabarraga et al. 2010; Smiatek et al. 2012). In more detail, mesoscopic simulation approaches induce a stochastic motion of the solute species in the system, which is related to the behavior at long time scales. A simple but effective and thermodynamically consistent approach is represented by Langevin or Brownian dynamics (Kremer and Grest 1990). However, as it has been pointed out in Dünweg (1993), momentum is not conserved in Langevin dynamics, such that this approach cannot capture any hydrodynamical effects (Doi and Edwards 1988; Ober and Thomas 1997; Grass et al. 2008; Frank and Winkler 2009). Most often, one is indeed specifically interested in hydrodynamic effects, such that either the Langevin dynamics approach can be modified by introducing the Oseen tensor (Ermak and McCammon 1978) or efficient Navier-Stokes solvers have to be used. In terms of mesoscopic approaches, the most common techniques are dissipative particle dynamics (DPD) (Groot and Warren 1997; Smiatek et al. 2012), coupled lattice Boltzmann/molecular dynamics (LBMD) (Dünweg and Ladd 2009) or multiparticle collision dynamics (MPCD) (Gompper et al. 2008). Previous articles highlighted the good quantitative agreement between DPD and LBMD simulations (Smiatek et al. 2009) and their applicability to study transport processes in confined geometries (Smiatek and Schmid 2010, 2011; Smiatek et al. 2012; Weik et al. 2016). In general, the use of mesoscopic simulation methods can be nowadays regarded as a standard approach in order to study the influence of hydrodynamics in many different research fields.

Furthermore, simple coarse-grained models were often used to validate analytical mean-field approaches like counterion condensation theories (Deserno et al. 2000), stretching forces on tethered polymers (Szuttor et al. 2017), electrohydrodynamic screening effects (Grass et al. 2008), or the combined influence of electroosmotic and electrophoretic motion (Smiatek and Schmid 2010). Interestingly, also the influence of the solvent quality on the resulting conformations can be studied via the use of simple approaches. In terms of experimental and atomistic simulation results, it is known that poor solvents imply collapsed conformations, whereas good solvents lead to a swelling of the polyelectrolyte. Hence, these findings can be transferred to tunable attractive or repulsive interactions between the beads in order to correct for the presence of an implicit solvent. Hence, in combination with electrostatic interactions and attractive bead potentials, it was even possible to enforce the occurrence of pearl-necklace polyelectrolyte structures (Dobrynin et al. 1996; Micka et al. 1999; Limbach et al. 2002; Limbach and Holm 2003). Furthermore, also more complicated topologies like in polymeric ionic liquids (PILs) (Mecerreyes 2011; Yuan et al. 2013) can be modeled via simple coarse-grained approaches (Weyman et al. 2018). A simple example for a common alkylimidazolium-based PIL and a snapshot of a system conformation are shown in Fig. 3. As can be seen in the bottom, a simulation of 30 PIL chains with $N_p = 30$ reveals the occurrence of a microphase separation between polar and apolar beads. The aggregation of apolar beads was initiated by attractive LJ interactions, which initiate the formation

**Fig. 3** Chemical structure of a typical alkylimidazolium-based PIL with counterions X$^-$ (top left). The corresponding simple bead-spring model with $N_p = 4$ is shown at the upper right part. The charged terminal groups are shown as red spheres and the counterions as blue spheres. All neutral beads have a gray color. A snapshot of the simulation with 30 polymers with $N_p = 30$ in terms of the coarse-grained model is shown at the bottom. Neutral beads are colored in red, while charged beads and counterions are colored in green

of apolar and polar microphases for larger side chain lengths. In summary, simple coarse-grained polyelectrolyte models are computationally efficient and can be used for the study of different systems at larger scales. The consideration of further details can be simply achieved via effective generic or tunable potentials and provides reasonable results, if the specific molecular details and processes are of minor importance.

## 3   Summary and Conclusion

In this chapter, we described distinct approaches for the simulation of polyelectrolyte solutions at different length and time scales. For the study of fast processes and molecular interactions at short length scales, the use of atomistic models with regard to appropriate force fields is advised. In terms of larger length and longer time scales, semi- and simple coarse-grained models with different levels of detail can often be considered as the method of choice. A promising approach is the MARTINI force field, which provides a beneficial transferability between different systems without the need of a proper reparameterization for distinct models. Furthermore, also tabulated potential methods as well as refined coarse-grained models were also developed that can be interpreted as coarse-grained approaches with basic molecular

properties. For the simulation of transport processes and hydrodynamic effects, simple coarse-grained models in combination with mesoscopic simulation methods are highly beneficial, which can be rationalized by the fact that polymers show a universal scaling behavior at large scales, such that specific molecular details are of minor importance (de Gennes 1979; Doi and Edwards 1988).

In summary, the presented methods can be used for a broad range of systems at different time and length scales. However, which method is most appropriate will depend crucially on the question to be answered, and one cannot give any general advice. However, it has to be emphasized that all methods rely on crucial approximations, and thus, if possible, one should always verify the simulation results with experimental findings or theoretical predictions. A prominent example are specific ion effects, which are modeled explicitly only in few atomistic MD force fields (Fyta and Netz 2012). It is thus a challenging task to transfer this information to coarse-grained models. Moreover, the study of apolar organic solvents is significantly more complicated in comparison to polar solvents, due to the fact that the Debye and the Bjerrum lengths can easily exceed the simulation box size, which induces electrostatic correlation effects between the polyelectrolyte and its periodic images. These finite-size effects modify structural and dynamic properties of the solution and are thus a crucial problem in order to bring simulation outcomes in quantitative agreement with experimental results. Moreover, also non-ideal effects, as they are well known for higher component solutions (Krishnamoorthy et al. 2016), are often not correctly reproduced. In general, all considered methods rely on potential functions to mimic the electronic behavior. Hence, an accurate study of bond formation and cleavage processes in combination with varying pH values of the solution is often impossible. A promising new route is the introduction of reactive force fields (Senftle et al. 2016), which are, although time consuming, less computationally expensive than ab initio simulations. In accordance with the simplification of the electronic behavior, atomic polarization effects are also usually neglected, which have nowadays become an active field of research and model improvement (Lemkul et al. 2016; Bordin et al. 2016).

Despite their limitations, the presented methods and models are the most promising approaches for the reliable study of effects and processes in polyelectrolyte solutions. It can be expected that new and refined approaches in combination with longer simulation times will allow a more accurate study of these systems in the coming years.

# Resolving Properties of Entangled Polymers Melts Through Atomistic Derived Coarse-Grained Models

# 63

Gary S. Grest, K. Michael Salerno, Brandon L. Peters, Ting Ge, and Dvora Perahia

## Contents

### Abstract

Coupled length and time scales determine the dynamic behavior of polymers and polymer nanocomposites, thus causing their unique properties. To resolve the properties over large time and length scales it is imperative to develop coarse-grained models which retain atomistic specificity. Here we probe the degree of coarse graining required to access large length and time scales and simultaneously retain significant atomistic details. The degree of coarse graining

in turn sets the minimum length scale instrumental in defining polymer properties and dynamics. Using polyethylene as a model system, we probe how the scale of coarse graining affects the measured dynamics with different number of methylene groups per coarse-grained bead. Using these models, it is currently possible to simulate polyethylene melts for times of order 1 millisecond. This allows one to study a wide range of properties from chain mobility to viscoelastic response for well-entangled polymer melts while retaining atomistic detail.

# 1　　Introduction

Polymer properties depend on a wide range of coupled length and time scales, with unique viscoelastic properties stemming from interactions down to the atomistic level. The need to probe polymers across time and length scales to capture polymer behavior makes probing dynamics, and particularly computational modeling, inherently challenging. With increasing molecular weight, polymer melts become highly entangled, and the long-time diffusive regime becomes computationally inaccessible using atomistic simulations. While the largest length scales of polymer dynamics are controlled by entanglements, the shortest time and length scales required to resolve dynamic properties are not obvious. This knowledge is critical for developing models that can transpose atomistic details into the long-time scales needed to model long, entangled polymer chains.

One path to overcoming the computational challenge of large time and length scales in polymers and polymer nanocomposites is to coarse grain (CG) the polymer, reducing the number of degrees of freedom and increasing the fundamental time scale. The effectiveness of this process depends on retaining the smallest length scale essential to capturing the polymer dynamics. The process of coarse graining amounts to combining groups of atoms into pseudoatom beads and determining the bead interaction potentials. Simple models like the bead-spring model (Kremer and Grest 1990; Grest 2016) capture the main characteristics of polymers but disregard atomistic details. These models cannot quantitatively describe properties like structure, local dynamics, or densities. Numerous recent studies have worked to bridge the divide between atomistic and coarse models, developing new approaches to drive computational studies to larger length and time scales while maintaining relevant sub-nanometer details (Müller-Plathe 2002; Peter and Kremer 2009; Fritz et al. 2011; Li et al. 2013). The mapping scheme which defines which atoms are combined into a pseudoatom bead is not unique and depends on the specific system and the local properties one wants to retain. For polystyrene (PS), for example, there are at least seven different mapping schemes in which each PS monomer is represented by either one or two CG beads (Karimi-Varzabeh et al. 2012). For flexible polymers, such as polyethylene (Fukunaga et al. 2002; Padding and Briels 2002; Guerrault et al. 2004; Ashbaugh et al. 2005; Chen et al. 2006; Padding and Briels 2011), polybutadiene (Maurel et al. 2012), poly(dimethylsiloxane), and polyisobutylene (Maurel et al. 2015), multiple monomers are combined to form one CG bead. However, few of these studies have explored the effect of varying the

degree of coarse graining on the properties of polymer melts (Abrams and Kremer 2003; Harmandaris et al. 2007; Karimi-Varzabeh et al. 2012; Salerno et al. 2016a, b; Dallavalle and van der Vegt 2017; Peters et al. 2017).

Here, using linear polyethylene as a model system, we review how the degree of coarse graining affects the macromolecular structure and dynamics (Salerno et al. 2016a, b; Peters et al. 2017). The backbone of polyethylene (PE) consists of -$CH_2$– methylene groups, which are a natural coarse-graining unit. Probably the most well-known CG model for PE is the united atom (UA) model (Siepmann et al. 1993; Paul et al. 1995; Martin and Siepmann 1998; Nath et al. 1998), which combines each $CH_2$/$CH_3$ group into one pseudoatom. The UA interaction parameters are determined phenomenologically to reproduce physical properties such as densities and critical temperatures. Going beyond the UA model, PE has previously been studied using CG models with beads of $\lambda = 3$–$48$ methylene groups per CG bead (Padding and Briels 2001; Fukunaga et al. 2002; Padding and Briels 2002; Guerrault et al. 2004; Ashbaugh et al. 2005; Chen et al. 2006; Curcó and Alemán 2007; Padding and Briels 2011). However as most of these studies used a large degree of coarse graining ($\lambda \sim 20$) to study dynamics, an extra constraint is needed to prevent chains cutting through each other (Padding and Briels 2002). Here we focus on systems with fewer methylene groups per CG bead ($2 \leq \lambda \leq 6$) where we could largely (but not completely as discussed below) avoid including extra constraints to avoid chains cutting each other.

Figure 1 illustrates how the CG models with $\lambda = 2$–$6$ methylene groups per CG bead represent the underlying atomistic configuration. Though the chemical structure of PE is simple, it is a thermoplastic material useful in many applications, with tunable mechanical properties determined by the degree of branching. Using these CG models, we show here that one can capture polymer chain dynamics for long entangled polymers for time scales of order 1 ms using models that accurately represent atomistic detail. Accessing these large length and time scales, which are simply not accessible using fully atomistic models, allows one to measure a wide range of properties from the single-chain dynamics to the stress relaxation function and shear viscosity which depend on a hierarchy of length and time scales.

**Fig. 1** $C_{12}H_{24}$ segment of a PE chain represented with degree of coarse graining $\lambda = 2, 3, 4$, and 6 methylene groups per CG bead. The bead diameter corresponds to the position of the minimum in the nonbonded interaction for each CG model
## 2        Model and Methodology

Each of the CG potentials was derived from a fully atomistic molecular dynamics simulation of a melt of $C_nH_{2n+2}$ with n = 96 for $\lambda$ = 2, 3, 4, and 6 and n = 95 for $\lambda$ = 5 (Salerno et al. 2016a, b; Peters et al. 2017). The atomistic simulations used the all-atom optimized potentials for liquid simulations (OPLS-AA) potential (Jorgensen et al. 1984, 1996) with modified dihedral coefficients (Siu et al. 2012). These modified OPLS-AA parameters reproduce the experimental static and dynamic chain properties for long alkanes better than the original OPLS-AA parameters. Tabulated CG bond potentials $U_B(l)$ and angle potentials $U_A(\theta)$ were determined by Boltzmann inversion of the atomistic bond length and angle distributions:

$$U_B(l) = -k_B T \log \left[ \frac{P(l)}{l^2} \right]$$

$$U_A(\theta) = -k_B T \log \left[ \frac{P(\theta)}{\sin \theta} \right],$$

where $l$ is the bond length for CG beads overlaid on the atomistic reference configurations and $\theta$ is the angle between CG bead triplets from the atomistic reference configuration. These two potentials were determined at temperature T = 400 and 500 K and found to be independent of temperature (Peters et al. 2017).In the current study, dihedral interactions were not included. However, recently Salerno and Bernstein (2018) have shown that for differences in the end-to-end distance, $<R^2>$ of up to 40% can occur for CG models with no dihedral interaction. This error is a result of correlations inherent to the CG models that can be represented as a dihedral interaction. Including a dihedral interaction in CG models of PE can effectively correct this error in the chain stiffness.

Tabulated nonbonded potentials were calculated by a multistep iterative Boltzmann inversion process (Müller-Plathe 2002; Reith et al. 2003; Voth 2008). The intermolecular radial distribution function g(r) from the atomistic simulation was used as the target for iteration of the nonbonded potentials. The resulting potentials, while giving excellent agreement between the CG g(r) and the target g(r), always resulted in a pressure which was significantly larger than that of the atomistic system. A pressure correction (Milano and Müller-Plathe 2005; Sun and Faller 2005; Wang et al. 2009) was then applied to bring the pressure of the CG and atomistic systems into agreement. This resulted in a slight increase of the pair correlation function in the vicinity of the first peak for the CG model compared to the target, but this difference was found to have no effect on the chain mobility and viscoelastic response of the system (Salerno et al. 2016a, b; Peters et al. 2017). The resulting potentials for four values of $\lambda$ at 500 K are shown in Fig. 2. Unfortunately, these CG potentials are not necessarily transferable to other temperatures. For example, with $\lambda$ = 4 the attractive well for the CG potential developed at 500 K is

**Fig. 2** Potentials for nonbonded interactions for $\lambda = 2$ (red circle), 3 (purple square), 4 (green triangle), and 6 (blue diamond)
20% deeper compared with that developed at 400 K (Peters et al. 2017). Comparison of these potentials with the standard Lennard-Jones (LJ) 12:6 potential, which is often used in bead−spring models of polymers (Kremer and Grest 1990; Grest 2016), shows that these atomistically inspired CG potentials are softer with a much shallower attractive well than the LJ 12:6 potential (Peters et al. 2017). Since PE is locally stiff, as the degree of coarse graining increases, the methyl groups in each CG bead take up less of the volume. As a result, the nonbonded potentials become softer with increasing $\lambda$.

For large degrees of coarse graining, one must also include extra constraints so that the chains cannot cut through each other (Padding and Briels 2002). For polyethylene, even the $\lambda=6$ model has a surprisingly large equilibrium bond distance relative to the bead diameter which allows chains to occasionally cut through each other. Therefore, in our simulations, we added a modified soft segmental repulsive potential (Sirk et al. 2012) to CG beads to inhibit chain crossing for $\lambda = 6$. Complete details of the model and methodology are given in Salerno et al. (2016a, b).

One important advantage of CG models is that by eliminating the finest degrees of freedom, the time step in a molecular dynamics simulation is significantly larger than for fully atomistic models. We found that one can use a time step $\delta t = 20$ fs for $\lambda = 4$, 5, and 6 and 10 fs for $\lambda = 3$. However, for $\lambda = 2$, $\delta t$ is only 4 fs, comparable to that commonly used for atomistic (1 fs) and UA (1–2 fs) models. The reduction in the number of degrees of freedom in a system also creates a smoother free-energy landscape compared with fully atomistic or UA model simulations. While strong frictional and stochastic forces can be used to slow down the dynamics of the CG model to match those of the atomistic model (Salerno et al. 2016a, b), one can take advantage of this increase in the local dynamics of the CG model to simulate effectively much longer time scales (Harmandaris and Kremer 2009; Fritz et al. 2011).While the former approach may be useful for coarse graining small molecules, for entangled polymers which already have inherently slow dynamics, this additional speedup for CG models is very advantageous. Combining the

reduction in the number of atoms that one must simulate, the significant larger simulation time steps, and the increase in the dynamics from the smoother free-energy surface, the effective simulation time is effectively increased by at least three orders of magnitude for $\lambda = 4\text{--}6$, allowing one to reach times scales not accessible using fully atomistic simulations. Computationally for PE, $\lambda = 4$ and 5 are the most efficient since $\lambda = 6$ requires the addition of an extra bead between each CG bead to avoid chains cutting through each other. All of the simulations presented here were performed using the Large Atomic Molecular Massively Parallel Simulator (LAMMPS) molecular dynamics simulation code (Plimpton 1995), though any MD software package which allows tabulated forces for bond, angle, and nonbonded potentials could be used.

## 3    Results

In Salerno et al. (2016a, b), we probed the dynamics of polymers as the number of atoms included in a CG bead is varied from $\lambda = 2$ to 6. We found that independent of the degree of coarse graining, the static and dynamic properties are similar once the dynamic scaling factor $\alpha$ and non-crossing constraint for $\lambda = 6$ are included. Using these CG models, we have been able to reach times of order 1 ms, allowing us to measure several quantities which can be compared directly to experiments, including the stress relaxation function, plateau modulus, and shear viscosity. Here, some examples of our results are presented to illustrate the power of the coarse-graining methodology to sample times and length scales not accessible by atomistic simulations while retaining chemical specificity.

Coarse graining reduces the number of degrees of freedom in a system, creating a smoother free-energy landscape compared with fully atomistic simulations (Harmandaris and Kremer 2009; Fritz et al. 2011). This can be seen by measuring the mean squared displacement (MSD) for the atomistic model of PE with n = 96 and 480 carbons to the equivalent CG model as shown in Fig. 3a. The mobility of the chains in the CG models is clearly larger than in atomistic simulations. By scaling the time for each of the CG models, the results fall on a single collapsed curve for each chain length for the atomistic and CG models as shown in Fig. 3b. Notably, a single scaling factor $\alpha$ is required for each $\lambda$, independent of chain length. For T = 500 K, $\alpha$ varied from 6 to 9 for $\lambda = 2\text{--}6$ and increases with decreasing temperature (Peters et al. 2017). For $\lambda = 4$, $\alpha = 6.2$ for T = 500 K and increases to $\sim 12$ at 400 K. Combining the effects of fewer interaction sites, a larger time step, and the dynamic scaling factor $\alpha$, these CG models allow one to study well-entangled chains for long times.

Results for the MSD of the center of mass $g_3(t) = \langle (\mathbf{r}_{cm}(t) - \mathbf{r}_{cm}(0))^2 \rangle$ and motion of the center four beads $g_1(t) = \langle (\mathbf{r}_i(t) - \mathbf{r}_i(0))^2 \rangle$ for chain lengths n = 1920, 2560 and 4000 for $\lambda = 4$ at 500 K are shown in Fig. 4. The experimental entanglement length for PE is 1.1–1.2 kg/mol or n $\sim$ 80 (Fetters et al. 1999; Vega et al. 2004). For n = 1920 and 2560, the MSD has reached the diffusive regime where MSD $\sim t^1$. Over intermediate time scales for all three systems, the chains
**Fig. 3** (**a**) Mean squared displacement of the inner 24 -CH$_2$- groups of each polymer chain at 500 K for different levels of coarse graining compared to atomistic model for n = 96 and 480. (**b**) Coarse-grained MSD data scaled by dynamic rescaling factor α for n = 96–1920 compared to atomistic simulations

show the expected t$^{1/4}$ scaling predicted the tube model (de Gennes 1971; Doi and Edwards 1986). The diffusion constant D = g$_3$(t)/6t for t > τ$_d$ is shown in Fig. 5 as a function of n. For large n, D follows a power law decay D = D$_1$n$^{-2.18}$ where D$_1$ = 3.08 × 10$^{-6}$ m$^2$/s. The decay of D with a power law greater than 2 for large M is consistent with experimental results (Lodge 1999).

From the crossover time $t_e^*$ from the early time t$^{1/2}$ Rouse regime to t$^{1/4}$ reptation, one can extract the tube diameter d$_T$ and the entanglement time $\tau_e$. Assuming the distribution of segment displacement along the tube is Gaussian on the scale of the tube diameter $d_T$, then the entanglement time $\tau_e = \frac{9}{\pi} t_e^*$ (Hou 2017). From Fig. 4, this crossover time is $t_e^* \sim 14$ ns, which gives $\tau_e \sim 40$ ns. Note that in the

**Fig. 4** Mean squared displacement of the center of mass $g_3(t)$ (closed) and center four CG beads $g_1(t)$ (open) for n = 1920 (black circles), 2560 (red squares), and 4000 (green triangles) for $\lambda = 4$. The dashed lines represent the scaling predictions $t^1$ for the diffusive regime and $t^{1/4}$ for the reptation regime

**Fig. 5** Diffusion constant D versus n for $\lambda = 4$ at 500 K

literature, $\tau_e$ and $t_e^*$ are assumed to be the same. The MSD of the center monomers at $t_e^*$, $g_{1e}^* = \frac{2}{3\pi}d_T^2$ gives a tube $d_T \sim 4.9$ nm (Hou 2017). If one neglects the $\frac{2}{3\pi}$ prefactor between $g_{1e}^*$ and $d_T^2$, which is often done in the literature (Hsu and Kremer 2016), then $d_T \sim 2.3$ nm. The latter value is in good agreement with the assumption that $d_T^2 = 2 R_g^2 (N_e)$, which gives $d_T \sim 2.2$ nm. Neutron spin-echo experiments by Richter et al. (1992) and Schleger et al. (1998) estimate $\tau_e \sim 5$ ns and tube diameter $d = \sqrt{3}d_T \cong 4.35$ nm or $d_T \sim 2.5$ nm (Hsu and Kremer 2017). Thus the crossover times and distances of the CG model capture the essential aspect of the polymer motion, demonstrating that one can capture long-time and length scales with CG models while accounting for atomistic detail.

The stress response function after a small perturbation $G(t)$ is one of the most important experimental measurements for polymers. For long entangled polymers, at short times $G(t)$ decays as the chains locally relax in response to the perturbation like any fluid. However, for intermediate times, $G(t)$ plateaus at $G_N^o = \frac{4}{5}\rho RT/M_e$ where $M_e$ is the entanglement molecular weight. This plateau region in $G(t)$

**Fig. 6** Stress autocorrelation function $G(t)$ for $\lambda = 4$ at 500 K for n = 1920 (black) and 4000 (green). Solid lines are fit to the Likhtman-McLeish formula (Likhtman and McLeish 2002)
occurs for intermediate times where the chains are assumed to move in a tube due to entanglements from the other chains. Only after the chains have reached the diffusive regime, does $G(t)$ relax to zero. The relaxation modulus for each of our CG models was measured for different chain lengths via equilibrium stress autocorrelations. Figure 6 shows $G(t)$ for n = 1920 and 4000 for $\lambda = 4$, where time has been scaled by the dynamic rescaling factor $\alpha$. The solid lines in Fig. 4 are fit to the Likhtman-McLeish (LM) expression (Likhtman and McLeish 2002):

$$G(t) = \frac{k_B T}{nv} \left[ \frac{1}{5} \sum_{p=1}^{Z} \left( 4\mu(t)R(t) + e^{-tp^2/\tau_R} \right) + \sum_{p=Z+1}^{N} e^{-2tp^2/\tau_R} \right]$$

where

$$\mu(t) = \frac{8}{\pi^2} \sum_{q=1,odd}^{\infty} \frac{1}{q^2} \exp\left( -\frac{q^2 t}{\tau_d} \right)$$

is the Doi-Edwards reptation stress relaxation function (Doi and Edwards 1986) with terminal relaxation time $\tau_d$ and the double-reptation expression for constraint release $R(t) = \mu(t)$ is assumed (Marrucci 1985).The key quantity in this expression is the single-chain memory function $\mu(t)$ for the fraction of the primitive chain which has not escaped from its original tube after a time t. The fitting parameters are the number of entanglements per chain $Z$, the terminal relaxation time $\tau_d$, and the Rouse time $\tau_R$. The volume of a $CH_2$ monomer is $v = 0.031 nm^3$ for $\rho = 0.76 g/cm^3$. The best-fit results are $Z = 23 \pm 1$, $\tau_d = (1.49 \pm 0.04) \times 10^5 ns$, and $\tau_R = (2.60 \pm 0.16) \times 10^4 ns$ for n = 1920 and $Z = 40 \pm 1$, $\tau_d = (5.55 \pm 0.09) \times 10^5 ns$, and $\tau_R = (8.18 \pm 0.32) \times 10^4 ns$ for

$n = 4000$. Based on these results, the plateau modulus $G_e = 4Zk_BT/5nv = 2.3$MPa for $n = 1920$ and 1.8MPa for $n = 4000$; the entanglement time $\tau_e = \tau_R/Z^2 = 49.1$ ns for $n = 1920$ and 51.1 ns for $n = 4000$, consistent with the entanglement times extracted above from the MSD. The entanglement molecular weight $M_e = n/Z \times 14$g/mol $= 1.2$kg/mol for $n = 1920$ and 1.4kg/mol for $n = 4000$, which is consistent with experimental results for $M_e$ (Fetters et al. 1999; Vega et al. 2004). For comparison, the longest chain system we could study using fully atomistic simulations is n = 480, which is not long enough and cannot be simulated long enough to observe a plateau in *G(t)*.

Polymer entanglements can be directly determined by the primitive path analysis (PPA), an algorithm first developed by Everaers et al. (2004) In the PPA, the chain ends are fixed, and the intrachain excluded volume interactions are turned off while retaining the interchain excluded volume interactions. The energy of the system is then minimized by slowly cooling the system to T = 0. The entanglement molecular weight $M_e$ can then be obtained from the average contour length of the primitive path and the end-to-end distance of the chain (Everaers et al. 2004). In the standard PPA method (Everaers et al. 2004), the chains maintain the same diameter during the length minimization process. Alternatively one can introduce extra beads to reach the limit of zero thickness chains (Hoy and Grest 2007). These two methods are often referred to as thick- and thin-chain PPA, respectively. Although both methods can give good estimates of the entanglement length in a polymer melt, the effect of the bead size or CG level $\lambda$ should be considered. In this context, it is important to be able to represent a single reference configuration with various $\lambda$ and calculate the same primitive path length, independent of $\lambda$. We found that the thick-chain PPA method produces results that vary by 15–20% with $\lambda$. Hence, we adopt a procedure that is more like the thin-chain PPA method to reliably reproduce the primitive path length and entanglement length, independent of the coarse-graining level $\lambda$.

The primitive path contour length and the resulting entanglement length were estimated by inserting four (or nine) beads between each bead for $\lambda = 4$, setting the bead diameters to 1.3 Å (0.65 Å) and reducing the backbone bond length at constant tension. The primitive path contour length was computed for n = 480 for ten independent melt configurations. The primitive path length was estimated to be 19.8 nm, with lower and upper estimates of 24 and 31 CG beads for the entanglement length, based on the estimator proposed by Hoy et al. (2009). These thin-chain PPA values correspond to entanglement mass $M_e = 1.34$ and 1.74 kg/mol, somewhat higher than the estimate based on the plateau modulus.

Using non-equilibrium molecular dynamics simulations, we measured the shear viscosity $\eta$ as a function of shear rate over a wide range of shear rates from the shear-independent regime at low shear rates to the shear-thinning regime at high shear rates. Results for $\eta$ versus scaled shear rate for n = 96 to 1920 are presented in Salerno et al. (2016). Our results for the zero shear rate viscosity $\eta$ showed a crossover from a $n^1$ power law for small n to $n^{3.4}$ for large n at $n_c \sim 250$ or molecular weight $\sim 35$ kg/mol in excellent agreement with the experiment (Ferry 1980; Graessley and Edwards 1981).

While most studies of polymer melts model a homopolymer in which all the chains have the same length or at most a binary mixture of two lengths, experimental systems are never uniform. They are highly dispersed with a range of chain lengths. The standard way to characterize molar-mass dispersity is the dispersity index $Đ_M$ defined by $Đ_M = M_w/M_n$, where $M_w$ is the weight average molecular weight and $M_n$ is the number average molecular weight. $M_n$ is more sensitive to molecules of low molecular mass, while $M_w$ is more sensitive to molecules of high molecular mass. The best case experimentally for long polymers is $Đ_M \sim 1.02$ but in some cases $Đ_M > 2$. Even for $Đ_M \sim 1.02$, the ratio of the largest to shortest chain is larger than 2. How dispersity affects the chain mobility and viscoelastic response is difficult to predict theoretically, which makes testing theoretical models challenging due to the assumption that the system contains only uniform polymers.

Using our coarse-grained model with $\lambda = 4$, we (Peters et al. 2018) have recently initiated a study of the effect of polydispersity on polymer chain mobility and viscoelastic properties. We built dispersed systems of 2000 chains for $Đ_M = 1.02$, 1.04, and 1.08 and 4000 chains for $Đ_M = 1.16$ for highly entangled chains of molecular weight $M_w = 36$ kg/mol (n = 2650 $CH_2$ monomers or 640 CG beads). This chain length was chosen since it is long enough for the chains to be well entangled but short enough that the system fully relaxes on the time scales accessible to simulations ($\sim$600–800 μs). For short times, the monomers in the center of the chain diffuse the same independent of the degree of dispersity. However, for longer times, the MSD of the more dispersed samples moves faster. Unlike experiment, simulations can be used to extract more detailed information of how the various chain populations diffuse. For example, the average diffusion constant of all the chains as well as the shortest and longest can be readily determined as shown in Fig. 7. As $Đ_M$ increases, the spread in the diffusion constant increases very rapidly with $Đ_M$, while the average value of D increases by only a factor of 50% over this range.

**Fig. 7** Diffusion constant D as a function of molar-mass dispersity $Đ_M$ averaged over all the chains (black), for the shortest 5% of the chains (red), and longest 5% of the chains (blue) for n = 2560 for $\lambda = 4.5$
# 4    Conclusions

Here we probed the structure and dynamics of polymers with various numbers of atoms included in a coarse-grained bead. We have shown that for long, entangled polymers, independent of the degree of coarse graining, all static and dynamic properties are essentially the same once the dynamic scaling factor α and non-crossing constraint for λ = 6 are included. Due to the larger time step and reduced number of degrees of freedom of the coarse-grained model as well as the smoother free-energy surface, the coarse-grained simulations are effectively 3–4 orders of magnitude faster than the fully atomistic model, depending on the degree of coarse graining and the temperature. Of the five models studied, λ = 4 and 5 offer the optimum performance since larger degrees of coarse graining require an additional non-crossing constraint which negates the gain in effective speed due to free pairwise interactions. This translates to simulation times of hundreds to thousands of μs, which allows us to measure many quantities which can be compared directly to experiments, including the stress relaxation function, plateau modulus, and shear viscosity. With this speedup, one can readily extend the present study to longer chains as well as short- and long-chain branching in addition to the study of polydispersed systems.

# Top-Down Hybrid Models of Polymers

# 64

Kostas Ch. Daoulas

## Contents

**Abstract**

We review basic conceptual and methodological aspects of a special class
of hybrid models of polymeric materials. These particle-based models are
mesoscopic descriptions, where coarse-grained "force fields" are introduced
through functionals of local order parameters. These functionals bear similarities
to free-energy models in classical density functional theory and phase-field
simulations. Introducing interactions through free-energy-like functionals allows
one to develop top-down particle-based models with desired thermodynamic
behavior in a systematic and modular way. Hybrid models serve as a framework
for efficient simulations based on standard tools such as Monte Carlo sampling
and dynamical algorithms. Thanks to their special structure, hybrid models also
provide a basis for field-theoretical methods, such as numerical self-consistent
field theory.

# 1    Introduction

Investigating the mesoscopic behavior of polymeric materials with computer simulations requires special techniques. Considering that the involved length scales are at least on the order of 100 nm, these techniques must handle samples containing thousands of long polymer chains, while circumventing the slow polymer dynamics. Both requirements can be satisfied using drastically coarse-grained (CG) models, where large groups of building units of the actual polymer chains are represented by a single effective particle. Projecting a large number of microscopic states on a single CG configuration leads to strong entropic contributions to potentials acting between drastically CG particles. Therefore effective interactions have an explicit free-energy character, and their strength is comparable to the thermal energy, $kT$. Soft interactions and reduced amount of degrees of freedom allow for an efficient sampling of the configuration space.

The strong thermodynamic nature of interactions in drastically CG models justifies the implementation of computationally efficient soft potentials but complicates their determination. Systematic bottom-up methods, constructing the potentials such that the CG model reproduces physical quantities known from a more detailed description of the system (Kremer and Müller-Plathe 2002; Noid et al. 2008), are of limited use. Some of the reasons lie in representability and transferability problems (Peter and Kremer 2010; Noid et al. 2008) which are amplified by the prominent thermodynamic nature of drastically CG potentials. Tiny inaccuracies in bottom-up determination of interactions on the level of a single CG repeat unit change significantly phase behavior – due to chain connectivity, the impact of such inaccuracies increases proportionally to the degree of polymerization.

Top-down development of drastically CG models presents an alternative to bottom-up coarse-graining. Top-down approaches construct the CG model *postulatively*, building into the model "by hand" features that are necessary to reproduce a set of known structural, dynamic, and/or thermodynamic properties. The choice of postulated properties depends on the addressed questions, insights from fundamental physical principles, and/or experimental data. Top-down models first serve as a tool for qualitative understanding and prediction of unknown properties, based on existing limited knowledge about a system. Nevertheless, for certain classes of materials, top-down drastically CG models can provide quantitative predictions (Lodge 2003).

Comparing to bottom-up strategies, top-down coarse-graining is less formalized. Intriguingly, various structural, dynamic, and thermodynamic properties in polymers are frequently governed by universal laws (de Gennes 1979). These laws account for specific material chemistry through a few characteristic parameters, known as "invariants." Universality plays a central role in top-down modeling, enabling the study of polymer materials through very simple (minimal Müller et al. 2006) models, which reproduce the few required invariants. However, for many materials (especially those characterized by complex, heterogeneous structure),

finding universal laws is not straightforward. Moreover, universality may not be applicable altogether because the mesoscopic behavior remains coupled (possibly weakly) to microscopic features of molecular architecture and interactions. Therefore, it is necessary to develop systematic methods for constructing top-down models which are more complex compared to those based on simple universal laws. It is desirable that these top-down approaches are modular, allowing one to add to the model additional features to improve accuracy or expand the applicability range.

In this chapter, we will review the basics of top-down models developed through a systematic and modular strategy which is gaining popularity over the last years. The method constructs particle-based CG models in a hybrid manner, by introducing nonbonded interactions through a functional of a few local order parameters (collective coordinates). The functional is structurally similar to free energies in classical density functional theory (DFT) and phase-field models but differs conceptually, being a functional of *instantaneous* values of collective coordinates. Connecting instantaneous order parameters to individual coordinates of CG particles allows one to transform the functional into a law for nonbonded energies or forces and employ standard simulation techniques. The strength of the method is that the thermodynamic behavior of the model is modulated on the level of the functional used to "template" the nonbonded interactions. The choice of an appropriate functional is facilitated by a number of theoretical techniques including classical DFT and self-consistent field (SCF) theory.

## 1.1    Ingredients of Hybrid Top-Down Models

The first step of hybrid top-down coarse-graining is to specify a scheme for replacing groups of microscopic degrees of freedom by CG particles. The choice of the scheme depends on the features to be included into the model. The interactions between the CG particles are separated into bonded and nonbonded, defined by effective Hamiltonians $H_b$ and $H_{nb}$. Because the molecular structure is explicitly described on particle-based level, $H_b$ are functions of particle coordinates. Depending on the mapping scheme, $H_b$ is defined using either generic functions or chemistry-specific potentials, which can be derived, e.g. from standard bottom-up coarse-graining of single-chain atomistic configurations. By splitting the CG interactions into bonded and nonbonded contributions, hybrid top-down models follow the usual ansatz of coarse-graining (Peter and Kremer 2010) which assumes that intramolecular CG potentials do not depend on the environment of the molecules. Frequently, this assumption does not compromise the usefulness of top-down CG models for qualitative predictions. However, a posteriori refinement of parameters entering $H_b$ is usually necessary for quantitative studies.

After the mapping scheme and the bonded interactions are defined, $H_{nb}$ is introduced using a functional of collective coordinates. The concept is best clarified considering the formal statistical mechanics of hybrid models, where configurational partition functions take the form:

$$Z(n, V, T) =$$

$$\frac{1}{n!} \int d\mathbf{R} \exp \Big[ - \sum\nolimits_{i=1}^{n} \beta H_b(\mathbf{R}_i) - \underbrace{\int d\mathbf{r} f(\{\hat{\rho}_\lambda(\mathbf{r}; \mathbf{R}_1, \cdots, \mathbf{R}_n)\})}_{\beta H_{nb}} \Big] \quad (1)$$

Here, without loss of generality, we consider the canonical ensemble and assume that the polymer system contains $n$ identical chains (extending to several chain species, e.g., homopolymer blends, is straightforward). Nevertheless, the identical polymers can contain several monomer species. The coordinates of CG monomers comprising the $i$-th chain are denoted by $\mathbf{R}_i$, and $\int d\mathbf{R} \equiv \int \prod_{i=1}^{n} d\mathbf{R}_i$ indicates integration over all possible realizations of monomer coordinates. The argument of $H_b(\mathbf{R}_i)$ emphasizes the explicit particle-based description of molecular architecture. Expressing $H_{nb}$ through a functional of local order parameters makes Eq. 1 to appear different from the partition functions of standard CG models. For illustration purposes, we consider the simplest case, where the functional depends only on the set of local densities of the different monomer species, $\{\hat{\rho}_\lambda(\mathbf{r}; \mathbf{R}_1, \cdots, \mathbf{R}_n)\}$ (the index $\lambda$ spans the spectrum of species present in the system). The "hats" over the densities indicate that we are dealing with their *instantaneous* values and that they are not the fundamental degrees of freedom. They are operators transforming a configuration of coordinates $\mathbf{R}$ into instantaneous values of collective coordinates at point $\mathbf{r}$. To emphasize the role of $\hat{\rho}_\lambda$ as operators, we write explicitly their arguments $\mathbf{R}_1, \cdots, \mathbf{R}_n$. In the following, we will omit these arguments and use the compact notation $\hat{\rho}_\lambda(\mathbf{r})$. Through the operators, $H_{nb}$ depends implicitly on coordinates. Therefore (Edwards 1965; Fredrickson 2006) Eq. 1 still defines a particle-based partition function and is not a field-theoretical description.

Simulations based on models formalized through Eq. 1 require energies or forces which are functions of monomer coordinates $\mathbf{R}$. Therefore, the mathematical form of the functional and operators must facilitate the derivation of energies or forces from $H_{nb}$. The mathematical structure of these two ingredients determines the simulation techniques that can be applied to the given model.

## 1.2    Defining Functionals

An attractive idea for constructing $H_{nb}$ is to benefit from the classical DFT where free-energy functionals are playing a central role. Classical DFT is founded upon a theorem stating that for a system of particles (atoms or molecules) with defined interactions, the part of the Helmholtz free energy which does not explicitly depend on external fields (possibly acting on the system) is a unique functional of equilibrium local average densities, $\{\bar{\rho}_\lambda(\mathbf{r})\}$. This free-energy component, $F_{int}(\{\bar{\rho}_\lambda(\mathbf{r})\})$, is known as the "intrinsic Helmholtz free energy" and constitutes an inherent property of the system. The total free energy is obtained by adding to the intrinsic part trivial terms accounting for interactions with external fields. An analog of this theorem was first derived in quantum mechanics considering the density of

an interacting gas of electrons at ground state (Hohenberg and Kohn 1964) and thermal equilibrium ($k_B T \neq 0$) (Mermin 1965). For classical systems, detailed proofs are available in specialized reviews and textbooks; see Evans (1979), Hansen and McDonald (2006), and Plischke and Bergersen (1994). Although the functional of the intrinsic Helmholtz free energy formally exists, establishing this functional from a microscopic description is a formidable task. Developing strategies for obtaining approximate free-energy functionals is an active area of research in modern DFT (Wu and Li 2007; Löwen 2002).

The intrinsic Helmholtz free energy from DFT can be used to define nonbonded interactions in a hybrid model by setting $H_{nb}$ equal to $F_{int}(\hat{\rho}_\lambda(\mathbf{r}))$. However, there are important subtleties. First when $F_{int}(\{\hat{\rho}_\lambda(\mathbf{r})\})$ is used to define $H_{nb}$, density-dependent terms associated with translational and conformational entropy must be excluded because particle coordinates and molecular structure are explicitly present in the model. Otherwise, entropic contributions will be double counted. Second the intrinsic free energy of a system described by a model where $H_{nb}$ is determined by $F_{int}(\{\hat{\rho}_\lambda(\mathbf{r})\})$ differs from the original DFT free energy $F_{int}(\{\bar{\rho}_\lambda(\mathbf{r})\})$ (even when redundant entropic terms are omitted). The discrepancy stems from fluctuations captured by the partition function, Eq. 1. One consequence of the difference of the two free energies is that the top-down model reproduces the thermodynamic behavior corresponding to the DFT free energy only approximately.

To clarify better the origin of differences in the free energies, it is instructive to consider a system with $n$ interacting identical monomeric particles. Even in this simple example, the average local equilibrium density, $\bar{\rho}(\mathbf{r})$, can be inhomogeneous; coexisting liquid and vapor phases are an example. Assuming that for this system the DFT free energy is known, we define a hybrid toy model with a partition function:

$$Z(n, V, T) = \frac{1}{\Lambda^{3n} n!} \int d\mathbf{R}_1 \cdots d\mathbf{R}_n \exp\left[ -\beta F_{int(ex)}(\hat{\rho}(\mathbf{r})) \right] \tag{2}$$

$$= \frac{1}{\Lambda^3 n!} \int \mathscr{D}\rho(\mathbf{r}) \exp\left[ -\beta F_{int(ex)}(\rho(\mathbf{r})) \right] \int d\mathbf{R}_1 \cdots d\mathbf{R}_n \delta(\rho(\mathbf{r}) - \hat{\rho}(\mathbf{r})) \tag{3}$$

For clarity, we include the kinetic part of the partition function ($\Lambda$ is the thermal de Broglie wavelength). The definition of $H_{nb}$ is based on the excess DFT functional $\beta F_{int(ex)}(\hat{\rho}(\mathbf{r}))$, that is, the intrinsic free energy without the translational entropy term $\int d\mathbf{r}\hat{\rho}(\mathbf{r}) \left[ \ln(\hat{\rho}(\mathbf{r})\Lambda^3) - 1 \right]$. Equation 2 is transformed into an equivalent form by introducing an auxiliary integration in the functional space of all possible density distributions, as demonstrated in Eq. 3. The integration is denoted by $\int \mathscr{D}\rho(\mathbf{r})$ where $\delta(\rho(\mathbf{r}) - \hat{\rho}(\mathbf{r}))$ is a $\delta$-functional constraining the density field $\hat{\rho}(\mathbf{r})$. Because this density field is an implicit function of coordinates, the integral $\int d\mathbf{R}_1 \cdots d\mathbf{R}_n$, taken over the coordinates of the $n$ particles, quantifies the number of microstates with the same density pattern, $\rho(\mathbf{r})$. Hence, this conventional integration restores the translational entropy which was omitted from $F_{int(ex)}$. From Eq. 3, we obtain the free energy of our toy model as:

$$\beta F(n, V, T)$$

$$= -\ln\left(\int \mathcal{D}\rho(\mathbf{r})\exp\left[-\beta F_{\text{int(ex)}}(\rho(\mathbf{r}))\right]\underbrace{\int\frac{d\mathbf{R}_1\cdots d\mathbf{R}_n}{\Lambda^{3n}n!}\delta(\rho(\mathbf{r})-\hat{\rho}(\mathbf{r}))}_{=\exp(-\int d\mathbf{r}\rho(\mathbf{r})[\ln(\rho(\mathbf{r})\Lambda^3)-1])}\right)$$

$$(4)$$

Considering that the set of possible density distributions in $\int \mathcal{D}\rho(\mathbf{r})$ contains the pattern of the average density $\bar{\rho}(\mathbf{r})$, we conclude that:

$$\beta F(n, V, T) < \underbrace{\beta F_{\text{int(ex)}}(\bar{\rho}(\mathbf{r})) + \int d\mathbf{r}\bar{\rho}(\mathbf{r})\left[\ln\left(\bar{\rho}(\mathbf{r})\Lambda^3\right)-1\right]}_{\beta F_{\text{int}}(\bar{\rho}(\mathbf{r}))} \qquad (5)$$

The free energy of the toy model equals the DFT free energy only in the case of quenched fluctuations, where the instantaneous and the average density distributions are equal.

Frequently it is simpler to define $H_{\text{nb}}$ phenomenologically than to extract it through formal DFT derivations. For this purpose, one can benefit from generic relationships between the mathematical structure of the functional and thermodynamics. For example, defining $H_{\text{nb}}$ through a third-order density polynom is the simplest way to obtain models describing liquid-vapor coexistence (double-well free-energy landscape). This feature is important for systems where free polymer surfaces play an important role. Consequently, third-order functionals have been frequently applied for generic modeling of polymer brushes (Soga et al. 1995), films (Müller and Smith 2005) of melts and solutions, and amphiphilic membranes (Daoulas and Müller 2010). Although for some actual materials third-order functionals can approximately reproduce phase-equilibria properties (Binder et al. 2005), usually more complicated expressions are required. A simple empirical approach is to use higher-order polynomials, which are reminiscent of the Wohl's expansion (Wohl 1946; Prausnitz et al. 1999) of the excess Gibbs free energy.

Currently, most hybrid models for multicomponent polymer liquids employ $H_{\text{nb}}$ which are variants of the general form:

$$\beta H_{\text{nb}} = \frac{\kappa\rho_0}{2}\int d\mathbf{r}\,\left(\hat{\phi}_A(\mathbf{r}) + \hat{\phi}_B(\mathbf{r}) - 1\right)^2 + \chi\rho_0\int d\mathbf{r}\,\hat{\phi}_A(\mathbf{r})\hat{\phi}_B(\mathbf{r}) \qquad (6)$$

For simplicity, Eq. 6 refers to a system with only two types of monomers, A and B (extending to multiple components is straightforward). The operators $\hat{\phi}_\lambda(\mathbf{r}) = \hat{\rho}_\lambda(\mathbf{r})/\rho_0$ define the local volume fractions of the two monomer species ($\lambda = $ A,B). The average reference density is given by $\rho_0$.

The two-term structure of Eq. 6 illustrates the modularity of hybrid models. When A and B monomers are identical, the first term of $\beta H_{\text{nb}}$ describes a homopolymer melt, where a simple equation-of-state (EOS) penalizes deviations of

the instantaneous density from the reference value. The simple quadratic form can be motivated by a second-order expansion of the excess free energy of a positionally inhomogeneous homopolymer melt (Helfand 1975; Jiang et al. 2017) around a homogeneous reference state with density $\rho_0$. More sophisticated EOS can be integrated into the model replacing the first term by more complex functionals. The compressibility of the CG polymer liquid is set by the parameter $\kappa$. The second term of $\beta H_{nb}$ describes the incompatibility of the two components. The strength of the incompatibility is controlled by $\chi$. This standard description can be traced back to the lattice-based Flory-Huggins (FH) model, where the FH parameter $\chi$ is expressed through contact energies of monomers occupying neighboring lattice points. This expression can be also motivated assuming short-ranged pairwise interactions of monomers in continuum space (Doi and Edwards 1986; Matsen 2006; Müller 2006). From the standpoint of top-down modeling, the second term can be introduced as a simple penalty of contacts between unlike monomers, without considering any specific microscopic picture. The question of how one can determine $\chi$ to represent a given multicomponent polymer system has attracted significant attention (Wang 2002; Schweizer and Singh 1995; Müller 2006; Schmid 2011; Müller and Binder 1995; Morse and Chung 2009) and cannot be covered in this chapter. We mention briefly that determining $\chi$ from the "first principles" is a challenging task – being a coarse-grained interaction parameter, $\chi$ is in fact a free energy which depends on numerous subtle enthalpic and entropic effects present on the microscale. Within the spirit of top-down modeling, one usually follows the pragmatic approach where $\chi$ is considered as a phenomenological (black box) parameter, which is adjusted until selected mesoscopic observables reproduce their counterparts in experiments or simulations with more detailed models. Typical examples of these observables are intrinsic interfacial width, composition of coexisting phases, and structure factors.

It is instructive to compare $\beta H_{nb}$ from Eq. 6 with the standard Flory-Huggins-de-Gennes (de Gennes 1980) (FHG) density functional describing homopolymer blends. In the simplest case of a symmetric binary blend of $A$- and $B$-homopolymers, this functional takes the form:

$$\beta F(\{\phi_A\}) = \int d\mathbf{r} f(\phi_A(\mathbf{r})), \quad f(\phi_A(\mathbf{r})) = \sqrt{\bar{N}} \Big[ \phi_A(\mathbf{r}) \ln \phi_A(\mathbf{r})(1 - \phi_A(\mathbf{r}))$$

$$+ \ln(1 - \phi_A(\mathbf{r})) + \chi N \phi_A(\mathbf{r})(1 - \phi_A(\mathbf{r})) + \tilde{B}(\phi_A(\mathbf{r}))|\nabla \phi_A(\mathbf{r})|^2 \Big] \tag{7}$$

Eq. 7 assumes that the blend is incompressible with constant density $\rho_0$ so that the free-energy density, $f(\phi_A(\mathbf{r}))$, depends only on the concentration of one component, $\phi_A(\mathbf{r})$. All length scales are expressed in units of the root-mean-square end-to-end distance, $R_e$, of the homopolymer chains. The invariant degree of polymerization, $\bar{N}$, is defined such that $\sqrt{\bar{N}} \equiv n R_e^3 / V$, where $n/V$ is the number density of homopolymer chains. $\sqrt{\bar{N}}$ quantifies the amount of interacting chains threading through the volume of a test polymer coil and therefore sets the strength

of fluctuations. Comparing Eq. 6 with the FHG functional demonstrates that $\beta H_{nb}$ is missing the logarithmic terms which are associated with the translational entropy of the molecules. As discussed previously, omitting the logarithmic terms is consistent with the explicit presence of particle coordinates in the hybrid model. The nonlocal square-gradient term in the FHG functional penalizes the formation of interfaces and is, therefore, important for reproducing correct physics. Specifically the term accounts for the loss of conformational entropy (Lifshitz et al. 1978) of the chains at an $A/B$ interface. The precise form of $\tilde{B}(\phi_A)$ depends on the strength of segregation and is not essential for our discussion. Although the square-gradient term is missing from $\beta H_{nb}$, the hybrid model still captures the loss of conformational entropy at interfaces because the molecular architecture is explicitly described. However, introducing into $H_{nb}$ non-locality of interactions is important for modeling systems containing monomeric particles. Dilute films of polymer solutions are an example, where non-locality is required to describe a phase of liquid solvent exposed to vapor.

Simple symmetry arguments are useful when developing functional-based models for materials with complex order, such as polymer liquid crystals (LC). For uniaxial nematics, one can start from the Landau-de-Gennes expansion (de Gennes and Prost 1995) of the free energy with respect to the local alignment tensor, $\hat{\mathbf{Q}}(\mathbf{r})$:

$$\beta F = \int d\mathbf{r} \left[ \frac{A}{2} \hat{\mathbf{Q}}(\mathbf{r}){:}\hat{\mathbf{Q}}(\mathbf{r}) + \frac{B}{3} (\hat{\mathbf{Q}}(\mathbf{r}){\cdot}\hat{\mathbf{Q}}(\mathbf{r})){:}\hat{\mathbf{Q}}(\mathbf{r}) + \frac{C}{4} (\hat{\mathbf{Q}}(\mathbf{r}){:}\hat{\mathbf{Q}}(\mathbf{r}))^2 \right] \qquad (8)$$

The expansion in Eq. 2 includes terms justified by general symmetry arguments (de Gennes and Prost 1995) (rotational invariance of free energy). The constants $A$, $B$, and $C$ are unimportant for our discussion. Expressing the tensorial operators $\hat{\mathbf{Q}}(\mathbf{r})$ through coordinates and orientation vectors of CG units is straightforward. Therefore Eq. 8 can be used to generate particle-based LC models of polymer LC (Daoulas et al. 2012; Gemünden et al. 2013; Gemünden and Daoulas 2015). Retaining only the quadratic term of Eq. 8 delivers the class of Maier-Saupe models. The Landau-de-Gennes expansion can be generalized (Matteis et al. 2008) to include additional tensorial order parameters describing, e.g. biaxial order (Gemünden et al. 2013). We notice that the functional $\beta F$ is local without scalar combinations of gradients of $\hat{\mathbf{Q}}(\mathbf{r})$. These terms are necessary in a continuum description because they penalize inhomogeneities in ordering and are connected to Frank-Oseen elastic constants. However, Eq. 8 is sufficient for constructing particle-based models of polymer LC because non-locality is generated by explicit chain connectivity and using density distributions, which deliver potentials with finite range (see Sect. 1.5).

Continuum functional-based descriptions can address crystallization phenomena, which are one of the most complex cases of material structuring. Among these approaches, phase-field (PF) models (Boettinger et al. 2002; Bragard et al. 2002; Gránácy et al. 2013, 2014) have been successful in describing mesoscale morphologies during polymer crystallization, including dendrites and spherulites. Free-energy functionals in PF modeling can account for crystallization through (i) additional phenomenological order parameters expressing the local fraction of crystalline

phase or (ii) density-dependent terms. It remains to be explored whether some of the available PF formalisms can provide a framework for developing particle-based models describing polymer crystallization.

## 1.3    Defining Operators

Operators transforming a configuration of particle coordinates into an instantaneous field of local order parameters are an integral part of hybrid models. They can be defined through schemes which are either (i) particle-to-mesh (PM) or (ii) based on density distributions.

PM schemes discretize space through a lattice (usually cubic) with $N_{cell}$ nodes. Nevertheless, the coordinates of the CG particles are still distributed in the continuum space underlying the lattice. The operators, used to calculate at each grid point $\mathbf{c}_m$ instantaneous densities or orientation tensors, are defined as:

$$\hat{\rho}_\lambda(\mathbf{c}_m) = C \sum_{i=1}^{n} \sum_{s=1}^{N} \Pi(\mathbf{r}_i(s), \mathbf{c}_m) \gamma_\lambda(i, s) \qquad (9)$$

$$\hat{\mathbf{Q}}_\lambda(\mathbf{c}_m) = \tilde{C} \sum_{i=1}^{n} \sum_{s=1}^{N} \Pi(\mathbf{r}_i(s), \mathbf{c}_m) \mathbf{q}_i(s) \gamma_\lambda(i, s) \qquad (10)$$

Here we assume again for simplicity that the polymer system is comprised of $n$ identical chains which can contain several different monomer species. The chemical type of a CG monomer is defined through $\gamma_\lambda(i, s)$. Namely, $\gamma_\lambda(i, s) = 1$ if the $s$-th segment of the $i$-th chain is of type $\lambda$ and $\gamma_\lambda(i, s) = 0$ otherwise. The function $\Pi(\mathbf{r}_i(s), \mathbf{c}_m)$ defines the rule of how particles with coordinates $\mathbf{r}_i(s)$ are assigned to the grid points. The lattice spacing, $\Delta L$, and the function $\Pi(\mathbf{r}, \mathbf{c})$ are parts of the model definition. As in PM methods in electrostatics (Eastwood et al. 1980), $\Pi(\mathbf{r}_i(s), \mathbf{c}_m)$ is commonly defined (Laradji et al. 1994; Müller and Smith 2005; Daoulas and Müller 2006; Müller 2011; Detcheverry et al. 2008; Qi et al. 2013; Milano and Kawakatsu 2009) through polynomials of $d_\alpha$ ($\alpha = x, y, z$). Here $d_\alpha$ are distances along the three Cartesian directions between the grid point at $\mathbf{c}_m$ and the position of the CG particle. A popular approach is to employ zero-order assignment functions defined as: $\Pi_0 = 1$ if $|d_\alpha| \leq \Delta L/2$ and $\Pi_0 = 0$ otherwise. The normalization prefactors $C$ and $\tilde{C}$ depend on the system. Equation 10 demonstrates that specifying a tensorial operator requires tensors defined on segmental level. In particular, Eq. 10 defines a rule for calculating the local alignment tensor (cf. Eq. 8), where $\mathbf{q}_i(s) = [3\mathbf{u}_i(s) \otimes \mathbf{u}_i(s) - \mathbf{I}]/2$ is a symmetric traceless tensor quantifying the orientation of a characteristic unit vector $\mathbf{u}_i(s)$ assigned to the CG monomer. Instead of $\mathbf{q}_i(s)$ more complex tensors, e.g. biaxial (Gemünden et al. 2013), can be employed to define other tensorial operators. Linking to a coordinate-based representation is not straightforward for all order parameters; PF models describing crystallization are a typical example (Boettinger et al. 2002).

Schemes based on density distributions define operators in continuum. This definition retains translational invariance and isotropicity of space, which are violated in PM schemes because of the lattice. These schemes use the same rules (see Eqs. 9 and 10) as PM methods to express order parameters through particle coordinates, but now the set of node vectors $\mathbf{c}_m$ is replaced by vectors $\mathbf{r}$ defined in continuum space. Instead of $\Pi(\mathbf{r}_i(s), \mathbf{c}_m)$, each particle is assigned a density distribution $W(\mathbf{r}_i(s) - \mathbf{r})$. Frequently, one can give $W(\mathbf{r}_i(s) - \mathbf{r})$ a qualitative physical interpretation, assuming that this mathematical object characterizes the distribution in space of microscopic degrees of freedom that were coarse-grained out. Depending on the problem, the distributions $W(\mathbf{r}_i(s) - \mathbf{r})$ can be isotropic or anisotropic, and their definition is a compromise between physical insights, simplicity of implementation, and computational efficiency.

Two popular families of isotropic distributions are Gaussian (Laradji et al. 1994; Vettorel et al. 2010) and spherical (Müller 2011; Gemünden et al. 2013; Gemünden and Daoulas 2015) functions. The latter are defined as $W(\mathbf{r}) = 3/(4\pi\sigma^3)$ if $|\mathbf{r}| \leq \sigma$ and $W(\mathbf{r}) = 0$ otherwise. The characteristic size of the distribution, $\sigma$, can be chosen (i) empirically (for instance, to achieve a desired amount of interacting neighbors (Pike et al. 2009)) or (ii) to reproduce qualitatively (Vettorel et al. 2010; Gemünden et al. 2013) the dimensions of large groups of microscopic monomers represented by a single CG unit. Ellipsoidal distributions are frequently chosen (Berne and Pechukas 1972; Murat and Kremer 1998; Eurich and Maass 2001) to describe anisotropic CG objects.

## 1.4    Defining Functionals and Parameters: Insights from Mean Field

Field-theoretical approaches based on hybrid models are not the focus of this chapter. Still they deserve some discussion because they often provide the first estimates of how the form and the parameters of the functional affect the properties of the model.

Self-consistent field (SCF) theory is a standard (Edwards 1965; Helfand 1975; Matsen 2006; Müller 2006; Schmid 2011; Fredrickson 2006) method based on field theory. First, the partition function of $n$ interacting chains, Eq. 1, is transformed into a field-theoretical representation, formalized through an equivalent partition function of an ensemble of $n$ independent chains in *fluctuating* fields. This operation is accomplished via the Hubbard-Stratonovich transformation or a method based on insertion of $\delta$-functionals (cf. Eq. 3). Transforming the partition function into a field-theoretical representation shifts the problem of describing the statistical mechanics of mutually interacting molecules to an equally intractable problem of functional integration over fluctuating external fields. SCF theory makes progress by introducing a saddle point approximation for the functional integrals. This operation is equivalent to placing the $n$ independent chains in *average* fields defined through the functional derivative of $H_{nb}$ as:

$$W_\lambda(\mathbf{r}) = \left. \frac{\delta H_{\text{nb}}}{\delta \hat{\rho}_\lambda} \right|_{\hat{\rho}_\lambda(\mathbf{r}) = \bar{\rho}_\lambda(\mathbf{r})} \tag{11}$$

Here $\bar{\rho}_\lambda(\mathbf{r})$ are average densities. In their turn, these average densities are determined by the distribution of the $n$ independent chains in the background fields $W_\lambda(\mathbf{r})$, which closes the self-consistency loop.

Typically the SCF formalism is solved using iterative schemes. When the model of the chain architecture is complex, the average densities at each iteration are calculated over single-chain conformations generated by direct stochastic sampling (Marčelja 1974; Ben-Shaul et al. 1985; Avalos et al. 2004) in the background fields $W_\lambda(\mathbf{r})$. For certain molecular models, the chain statistics in background fields can be obtained more efficiently. For the Gaussian connectivity model, the statistics of chain conformations in $W_\lambda(\mathbf{r})$ is characterized through the probability $q(\mathbf{r}, s)$ of finding a monomer $s$ at point $\mathbf{r}$ of space. This probability is obtained by solving the Edwards diffusion equation (Edwards 1965; Doi and Edwards 1986). The average densities follow from $q(\mathbf{r}, s)$ through a simple integral relationship. For the Gaussian model, several efficient numerical techniques are available (Matsen 2006; Müller 2006; Schmid 2011; Fredrickson 2006) for solving the set of SCF theory equations (including the Edwards equation), such as spectral, pseudo-spectral, and real-space schemes. Over the last years, there has been significant progress (Song et al. 2009; Jiang and Chen 2013) in developing numerical methods for SCF theory based on the wormlike chain model. In this case, the statistics of chain conformations in mean fields follows from the Saito et al differential equation (Saito et al. 1966).

Within SCF theory, free energies can be directly obtained, and one can estimate the thermodynamic properties of a specific model. The accuracy of this estimate depends on the specifics of the system because it is subjected to various approximations inherent to the mean-field SCF theory, such as neglected fluctuations and correlations. Nevertheless, the thermodynamic properties extracted from SCF can assist top-down modeling providing guidelines for choosing parameters and adjusting functionals. SCF results provide the basis for techniques such as the random phase approximation (RPA) which, to some extent, takes into account fluctuations. Structure factors of composition fluctuations in the homogeneous phase derived from RPA are frequently employed in top-down identification of FH parameters (cf. Sect. 1.2).

Frequently, guidelines for top-down modeling are obtained from rudimentary mean-field approximations without engaging the complex machinery of SCF theory. As an illustration, we consider a mixture of homopolymers belonging to several chemical species. There are $n_\lambda$ chains of each homopolymer type comprised of $N_\lambda$ CG monomers. For homogeneous phases, where the composition is described by average densities $\bar{\rho}_\lambda$, a crude mean-field expression for the Helmholtz free energy per volume, $V$, is given by:

$$\frac{\beta F}{V} = \sum_{\lambda} \frac{\bar{\rho}_{\lambda}}{N_{\lambda}} \left[ \ln \left( \frac{\bar{\rho}_{\lambda}}{N_{\lambda} Z_{\lambda}} \right) - 1 \right] + f \left[ \bar{\rho}_{\lambda} \right] \tag{12}$$

The first term of Eq. 12 is the entropy, where $Z_{\lambda}$ stands for the single-molecule partition function of each component. In spirit of the classical FH model, this simple mean-field approximation assumes that $Z_{\lambda}$ do not depend on composition. Hence, only the translational entropy is present. The simple Helmholtz free energy can be employed to estimate observables such as pressure, chemical potential of molecules, and response functions, e.g. isothermal compressibility. Matching chemical potentials in top-down models and simple mean-field expressions obtained from FH-like free energies is often used to fix the degree of monomer incompatibility in the former.

## 1.5    Simulation Techniques for Hybrid Models

Many standard simulation techniques can be straightforwardly applied to hybrid models with PM-based definition of collective variables. In these applications, the grid introduced for the PM definition of the operators also serves to discretize the functional. For example, the partition function in Eq. 1 reads:

$$Z(n, V, T) = \frac{1}{n!} \int d\mathbf{R} \exp \left[ -\sum_{i=1}^{n} \beta H_b(\mathbf{R}_i) \right] \exp \left[ -\underbrace{\sum_{m=1}^{N_{\text{cell}}} f(\{\hat{\rho}_{\lambda}(\mathbf{c}_m)\}) \Delta L^3}_{\beta H_{nb}} \right] \tag{13}$$

where the operators $\hat{\rho}_{\lambda}(\mathbf{c}_m)$ are defined via Eq. 9. For quadratic functionals, the sum over grid cells defining $\beta H_{nb}$ can be rewritten (Daoulas and Müller 2006; Müller 2011) in terms of pairwise potentials between individual particles. These potentials are not invariant translationally. The formalism of pairwise potentials clearly demonstrates (Müller 2011) that the functional in Eq. 13 includes self-interactions.

Partition functions with $\beta H_{nb}$ discretized as in Eq. 13 provide a framework for MC simulations (Laradji et al. 1994; Daoulas and Müller 2006; Müller 2011; Detcheverry et al. 2008). Starting from an initial configuration, standard MC moves, including random segment displacement, slithering snake, chain translation, identity exchange, configuration bias, and chain rebridging algorithms, are used to propose a new configuration. Based on the proposed coordinates of the CG units affected by the MC move, new values of collective coordinates are obtained via the PM operators. The nonbonded energy of the proposed configuration is calculated with the discretized $\beta H_{nb}$. After taking into account the change in the bonded energy (through $\beta H_b$), it is straightforward to formulate a Metropolis criterion for accepting or rejecting the move.

Calculating the changes of collective coordinates during a MC move via a lattice "background" avoids computationally expensive neighbor lists used for nonbonded interactions defined in continuum space. The choice of the assignment function $\Pi(\mathbf{r}_i(s), \mathbf{c}_m)$ affects the computational cost of the MC simulation. Algorithms based on $\Pi_0$ functions are the most efficient and easy to develop, because each particle affects the values of collective coordinates at only one node. It has been demonstrated (Müller 2011) that self-interactions are one of the factors leading to nonuniform distribution of CG particles within one lattice cell. $\Pi_0$ is an exception because self-interactions contribute a constant energy shift which has no effect on the density distribution within a cell (Müller 2011). Formally, the spacing of the grid sets the smallest length scale that can be resolved by a PM model (Daoulas and Müller 2006). Hence, quantifying properties on scales smaller than $\Delta L$ is irrelevant for many applications. One can attempt (Detcheverry et al. 2008; Vogiatzis and Theodorou 2013) to mitigate the breaking of translational invariance by introducing during simulations random lattice displacements. When the displacements are subjected to a Metropolis acceptance criterion (Vogiatzis and Theodorou 2013), the sub-grid structure of the liquid can influence the acceptance rate. With higher-order assignment functions, a single particle contributes to the evaluation of collective coordinates at several grid points. This reduces artifacts related to space discretization, including pinning of interfaces in strongly segregated systems. Nevertheless, the implementation of assignment functions higher than first order is usually undesirable due to substantial increase in computations. One of the exceptions are models of high-molecular-weight polymer melts where molecules are described by chains of linked blobs. Each blob is represented by a Gaussian density cloud distributed over a large number of lattice nodes (Zhang et al. 2013, 2014), i.e., the period of the lattice $\Delta L$ is significantly smaller than the width of the Gaussian. Within this approach, lattice effects become negligible (Zhang et al. 2013) to an extent that one can perform MC simulations in the isobaric ensemble.

MC simulations offer an "exact" (within statistical errors) solution of the statistical mechanics formalized through the partition function in Eq. 13. At the same time, PM techniques provide the framework for approximate but significantly more efficient methods closely linked to field-theoretical approaches. For instance, the "quasi-instantaneous" field approximation presents a powerful concept realized using single-chain-in-mean-field (SCMF) simulations (Müller and Smith 2005; Daoulas and Müller 2006). In SCMF simulations, the instantaneous interactions of a CG monomer with its surroundings are *equivalently* represented through fields defined at each grid node as functional derivatives of $\beta H_{nb}$ with respect to the collective degrees of freedom. Within the "quasi-instantaneous" field approximation, the fields are *frequently* updated substituting the collective coordinates calculated from the coordinates of the CG monomers. Between the updates, the fields remain stationary, and the CG polymer chains evolve in them *independently* typically using local MC moves. The frequent recalculation of the fields recovers partially the correlations between monomers. In the limit where the fields follow instantaneously the configurations of the system, the SCMF simulations become equivalent to the MC simulations. An approach for estimating the accuracy of

the "quasi-instantaneous" field approximation has been elaborated in Daoulas and Müller (2006). PM methods combining particle-based representations with field-based descriptions of interactions have been also employed in context of dynamical algorithms, such as self-consistent Brownian dynamics (SCBD) simulations (Ganesan and Pryamitsyn 2003; Narayanan et al. 2004) and particle-field MD simulations (Milano and Kawakatsu 2009). In dynamical schemes based on hybrid models, forces acting on a particle can be calculated by expressing derivatives of $H_{nb}$ with respect to particle coordinates through the derivatives of the weighting function (Zhang et al. 2017). An alternative approach (Milano and Kawakatsu 2009) is to use stencil operators (Sevink 2015) acting on densities defined on the grid points.

With the help of operators defined through density distributions, nonbonded interactions defined through functionals can be converted into potentials or forces acting in continuum space. This strategy avoids the artifacts of PM schemes but is more demanding computationally, because the interactions must be treated as in standard simulations (including the implementation of cell lists). Quadratic functionals are transformed into pairwise interactions by substituting the definitions of the operators. Namely, scalar and tensorial terms can equivalently be rewritten as:

$$\frac{1}{2} \int d\mathbf{r} \hat{\rho}^2(\mathbf{r}) = \frac{C^2}{2} \sum_{i,s=1}^{n,N} \sum_{j,t=1}^{n,N} \underbrace{\left[ \int d\mathbf{r} W(\mathbf{r}_i(s) - \mathbf{r}) W(\mathbf{r}_j(t) - \mathbf{r}) \right]}_{U(\mathbf{r}_i(s) - \mathbf{r}_j(t))}$$

$$\frac{1}{2} \int d\mathbf{r} \hat{\mathbf{Q}}(\mathbf{r}) : \hat{\mathbf{Q}}(\mathbf{r}) = \frac{\tilde{C}^2}{2} \sum_{i,s=1}^{n,N} \sum_{j,t=1}^{n,N}$$
$$\times \left[ \int d\mathbf{r} W(\mathbf{r}_i(s) - \mathbf{r}) W(\mathbf{r}_j(t) - \mathbf{r}) \right] \mathbf{q}_i(s) : \mathbf{q}_j(t) \qquad (14)$$

For simplicity, we consider here the density of a single component (the subscript $\lambda$ is dropped off) and omit arithmetic as well as material-specific constant prefactors. Only the $1/2$ coefficient is retained to exclude double counting. The integral $U(\mathbf{r}_i(s) - \mathbf{r}_j(t))$ can be calculated analytically for suitable choices of $W(\mathbf{r}_i(s) - \mathbf{r})$ (e.g. the spherical density distribution (Müller 2011) from Sect. 1.3) to obtain explicit pairwise potentials. In simulations of soft matter, it is common to derive CG potentials from overlaps of density distributions, although this approach is not always explicitly linked to density functionals. The anisotropic potential derived analytically from the overlap of two Gaussian ellipsoid density distributions (Berne and Pechukas 1972) is an important example, serving as a basis for developing the standard Gay-Berne potential (Gay and Berne 1981). Models based on overlap of anisotropic objects have been also directly employed (Vink and Schilling 2005; Zong et al. 2012) to study liquid crystalline mesophases. In these models, the LC order is obtained mainly as a consequence of the excluded volume interaction. In contrast, Eq. 14 describes a class of potentials where effects of liquid packing, determined by $U(\mathbf{r}_i(s) - \mathbf{r}_j(t))$, are largely (but not entirely Greco et al. 2016) decoupled

from LC order generated by the tensorial term $\mathbf{q}_i(s){:}\mathbf{q}_j(t)$. This "factorization" offers an easier control over system thermodynamics.

With PM methods, it is straightforward to perform simulations using hybrid models based on functionals with higher order than quadratic (Soga et al. 1995; Daoulas and Müller 2010). However, in this case, it is challenging to use density distributions to derive potentials because high-order polynoms lead to multibody-overlap integrals which cannot be easily calculated analytically. This problem is circumvented in the method of multibody dissipative particle dynamics (DPD) (Pagonabarraga and Frenkel 2001; Warren 2001; Trofimov et al. 2002; Español and Warren 2017). To sketch the approach, we consider a simple system of $n$ identical monomeric particles. The functional of nonbonded interactions is approximately transformed into:

$$\beta H_{nb} = \int d\mathbf{r} f(\hat{\rho}(\mathbf{r})) \simeq \int d\mathbf{r} \sum_{i=1}^{n} \delta(\mathbf{r} - \mathbf{r}_i)\psi(\tilde{\rho}(\mathbf{r})) = \sum_{i=1}^{n} \psi(\tilde{\rho}(\mathbf{r}_i)) \qquad (15)$$

where $\psi(\tilde{\rho}(\mathbf{r}))$ has the meaning of a local free energy per particle (Pagonabarraga and Frenkel 2001). The function $\tilde{\rho}(\mathbf{r})$ is a "smeared-out" local density defined as:

$$\tilde{\rho}(\mathbf{r}) = \int d\mathbf{r}' \sum_{i=1}^{n} w_m(|\mathbf{r} - \mathbf{r}'|)\delta(\mathbf{r}' - \mathbf{r}_i) = \sum_{i=1}^{n} w_m(|\mathbf{r} - \mathbf{r}_i|) \qquad (16)$$

The definition of the "smeared-out" local density is based on the concept of density distributions. However, in multibody DPD, depending on the studied problem, different weighting functions $w_m$ are used to define the smeared-out densities entering the different parts of $\psi(\tilde{\rho}(\mathbf{r}))$. A typical example (Hömberg and Müller 2010) is free energies containing terms which account for short-range repulsions and long-range attractions in the liquid. Differentiating the RHS of Eq. 15 with respect to a particle coordinate, say $\mathbf{r}_i$, generates a force law of *pairwise* forces, which makes simulations straightforward. Obtaining the multibody DPD force law through a density functional presents a "potential-based" derivation. This feature avoids implications related to the "No-go theorem for multibody DPD" (Warren 2013).

## 1.6    Outlook

Modeling polymeric materials by combining particle-based and classical density-functional-based descriptions represents a broad field of research. By defining interaction laws between particles through a free-energy-like functional, these top-down methods enable one to develop systematically particle-based models with desired thermodynamic behavior. Materials described by hybrid models can be studied with standard simulation tools including Monte Carlo sampling and various dynamical methods. In addition to particle-based simulations, hybrid models provide the framework for powerful field-theoretical methods. Although hybrid

modeling has been successful in many fundamental and application-oriented studies of polymeric systems, the field is far from being mature.

One important methodological problem is that the properties of hybrid models cannot be a priori determined in an entirely knowledgeable way even though the interactions are linked to a density functional. The reason is that prior to performing particle-based simulations, the thermodynamic behavior of hybrid models is estimated using approximate mean-field methods. After an initial mean-field-based parameterization, simple hybrid models can be improved using elementary heuristic schemes. However, systematic strategies must be developed in order to refine complex models.

Soft interactions in hybrid models eliminate mechanisms which are crucial for studying polymer dynamics. Currently, there is significant interest in reintroducing the effects of these mechanisms in a top-down fashion. For example, recovering chain non-crossability is necessary to study rheological behavior. Two ideas explored for this purpose are (i) algorithmic detection and prevention of intersection events (Padding and Briels 2011) and (ii) phenomenological interactions (slip-links), temporarily constraining the motion of the chain backbone (Hua and Schieber 1998; Masubuchi et al. 2001; Likhtman 2005; Chappa et al. 2012).

Due to their specific structure, hybrid models have significant potential as platforms for methods where a polymeric system is simultaneously described on particle-based and field-based level. This potential of hybrid models has been already demonstrated through concurrent coupling (Müller 2009) of a continuum Landau-Ginzburg to a hybrid particle-based model. A popular idea is to use hybrid models for semi-discrete representations (Kawakatsu and Kawasaki 1990; Sides et al. 2006; Sevink et al. 2013). These approaches introduce a particle-based description only for some molecular species, while the remaining components are treated on a continuum level. With hybrid models, schemes can be developed (Qi et al. 2013) where the system simultaneously contains regions described on field- and particle-based level. These schemes are field-based analogs of adaptive resolution simulation (AdResS) strategies (Praprotnik et al. 2007; Potestio et al. 2013), which have become very popular in standard particle-based simulations.

Denis Andrienko

## Contents

**Abstract**

We critically review simulation approaches developed to study organic solar cells, light emitting diodes, and field effect transistors. Special attention is paid to multiscale techniques. In particular, we discuss how to parametrize coarse-grained models for morphology and charge transport simulations, to account for finite-size effects, and to treat long-range interactions in small systems.

## 1  Introduction

Organic semiconductors are conjugated molecular compounds constituted of by carbon and hydrogen atoms and heteroatoms such as nitrogen, sulfur, and oxygen. Examples of organic semiconducting molecules are shown in Fig. 1. Conjugation is the key feature of these materials: Connected $\pi$-orbitals with delocalized electrons can donate or accept electrons easily, thus facilitating charge transfer reactions. Efficient charge transfer enables charge transport on a mesoscale. In their pristine

Host and guest materials forming an active layer of a blue phosphorescent light emitting diode (May et al. 2012a). Self-assembling organic molecules with high charge mobilities measured in field effect transistors (Ebata et al. 2007; Abe et al. 2015)

state, however, organic semiconductors are insulators. They become semiconducting only upon charge injection – from electrodes, by doping, or by photoexcitation.

Besides charge carrier mobility, other relevant physical properties of organic semiconductors are their absorption and emission spectra, ionization potential and electron affinity, solubility, self-assembling abilities, and glass transition temperature. These quantities depend on the molecular arrangement in the solid state, which can vary from crystalline to liquid crystalline to completely amorphous. The prime task of material design is to relate these quantities to the chemical composition and processing conditions, hence helping to prescreen compounds prior to their synthesis. Computer simulations can assist in finding such relationships by providing information which is not accessible to experimental techniques.

In silico prediction of properties of organic semiconducting devices requires multiscale approaches. Indeed, solving the time-dependent Schroedinger or the relativistic Dirac equation is computationally infeasible for an entire device. Likewise, timescales of dynamic processes such as charge or energy transfer span several orders of magnitude. Hence, charge/exciton kinetics cannot be treated by numerical methods with a fixed time step. It is normally coarse-grained into a master equation, as illustrated in Fig. 2, with rates evaluated with the help of the Fermi's golden rule (Athanasopoulos et al. 2007; Kirkpatrick et al. 2007; Nelson et al. 2009; Rühle et al. 2011; Schrader et al. 2012a, b; May et al. 2012a, b; Poelking and Andrienko 2013; Poelking et al. 2013; Kordt et al. 2015a). Multiscaling is essential not only to electronic processes, but also when addressing material processing, since self-assembling properties of conjugated materials, especially polymers can only be studied using coarse-grained models.

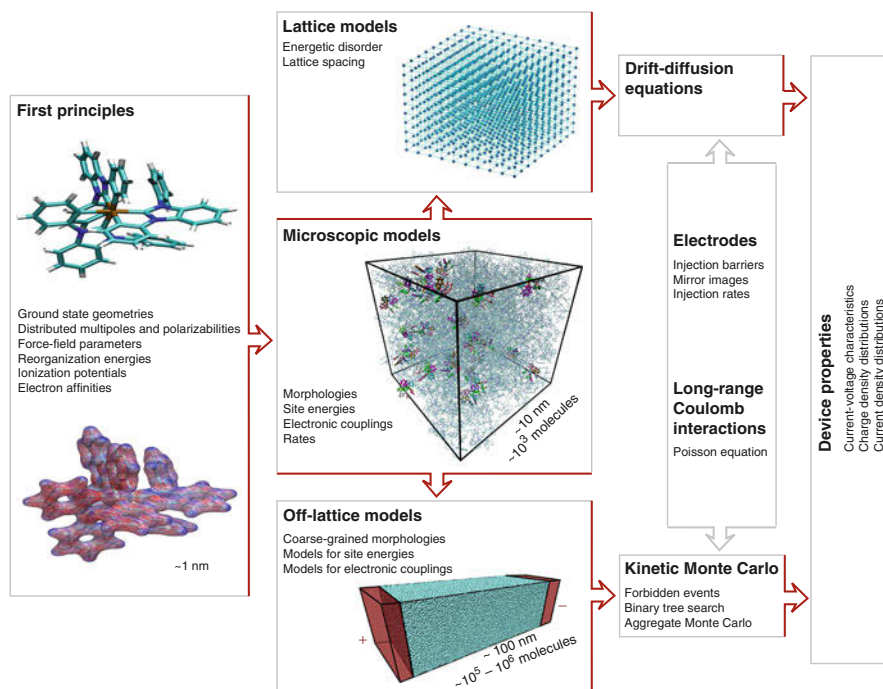
In spite of the implicit treatment of the electronic degrees of freedom, the approach based on the master equation is still computationally demanding. Indeed, electronic coupling elements must be evaluated for all pairs of neighboring molecules using first principles calculations. In addition, the evaluation of the self-consistent electrostatic and induction contributions to the free energy of localized charges requires large interaction cutoffs. To reduce the computational overhead,


**Fig. 2** Multiscale simulations of organic semiconductors. Polarizable force-fields and electronic properties of isolated molecules obtained from first principles are used to generate morphologies and evaluate charge transfer rates in small systems (microscopic models). Coarse-grained models are parametrized either by matching macroscopic observables, e.g., charge mobility, of the microscopic and coarse-grained (lattice) models. After incorporating long-range electrostatic effects and electrodes, the resulting analytical expressions for mobility are then used to solve drift-diffusion equations for the entire device. Alternatively, off-lattice models can be developed by matching distributions and correlations of site energies, electronic couplings, and positions of molecules. The master equations for this model can be solved using the kinetic Monte Carlo algorithm, yielding macroscopic characteristics of a device. (Reproduced with permission from Adv. Funct. Mater. 25, 1955–1971, 2015)

we can parametrize a lattice model using the solutions to the master equation and then apply this model to study charge/exciton dynamics in larger systems. We will discuss this approach and its pitfalls in Sect. 2.

We can also design a stochastic model, an algorithm which generates the morphologies and the rates of the master equation without computationally demanding evaluations of electronic couplings and site energies. Together with an efficient kinetic Monte Carlo solver, the stochastic model can be used to simulate an entire device. Alternatively, it can be employed as an intermediate model to parameterize the closures of drift-diffusion equations. We will review this approach in Sect. 3.

To further reduce computational costs, we can mimic a macroscopically large system by replicating a relatively small simulation box in two or three spatial

directions. The use of periodic boundary conditions might, however, truncate the tails of the density of states, smoothen the free energy landscape, and artificially increase the charge carrier mobility. These artifacts can be corrected by various extrapolations, which will be discussed in Sect. 4.

In addition, periodic boundary conditions complicate correct treatments of long-range Coulomb forces. To accurately evaluate the density of states, the algorithm should be able to treat charged systems. Unlike the neutral surrounding of the charge, the charge itself should not be periodically repeated. Approaches applicable to partially periodic systems will be discussed in Sect. 5.

## 2    Regular Lattices

From the computational point of view, the most efficient device modeling is based on the drift-diffusion equations (Knapp et al. 2010). Material properties enter these equations through closures, such as dependencies of diffusion constants and mobilities on charge density, temperature, and pressure. Closures provide a link to the chemical composition and material morphology and can be measured experimentally or computed using lower-resolution models. Lattice models are typical minimalist models required to compute such dependencies. In these models, a regular lattice represents material morphology, charge transfer rates decay exponentially with the intermolecular separation, and energy differences obey a Gaussian distribution. This approach was initiated by Bässler and has been used by several groups to understand the role of traps, finite charge carrier density, energetic disorder, and other mesoscopic parameters on charge mobility (Pasveer et al. 2005; Cottaar et al. 2011; van der Holst et al. 2011; Bässler 1993; Yimer et al. 2009; Novikov et al. 1998; Freire and Tonezer 2009).

Fits of phenomenological expressions for charge carrier mobility to the kinetic Monte Carlo simulations of lattice models are known as extended (correlated) Gaussian disorder models, EGDM, and ECDM. These expressions depend parametrically on the lattice constant $a$, the energetic disorder $\sigma$, and a prefactor $\mu_0$. In principle, $a$ and $\sigma$ can be evaluated in a relatively small system: $a$ as the mean distance between neighboring molecules and $\sigma$ as the width of the DOS that results from perturbative energy calculations. $\mu_0$ can be extracted from charge transport simulations performed at different temperatures. This approach, however, does not lead to reliable parameterizations (Kordt et al. 2014, 2015a). Indeed, a multidimensional fit of simulated mobilities to the EGDM or ECDM expressions yields a very different set of parameters: the EGDM underestimates the energetic disorder, while the ECDM overestimates it. In both cases spatial site energy correlations are responsible for this discrepancy. EGDM does not include correlations and compensates for higher mobility values by reducing the energetic disorder $\sigma$. ECDM overestimates spatial correlations and compensates this by reducing the lattice constant (Kordt and Andrienko 2016). The discrepancy between microscopic values and fits to EGDM and ECDM tells us that parameters of these models do not have a clear physical interpretation. Nevertheless, they still provide

reasonable parameterizations and can eventually be used in conjunction with drift-diffusion equations.

A more conceptual drawback of EGDM and ECDM resides in the approximations incorporated in the rates of the master equation of the underlying lattice model, which constrain the functional form of $\mu(\rho, \mathbf{F}, T)$. To avoid such constraints, we can simply tabulate the mobility in a wide range of charge densities, temperatures, and electric fields with the help of the microscopic model. The tabulated function can then be used in the drift-diffusion equations solver (Kordt et al. 2015b). Computationally, the tabulation is only feasible with the help of a stochastic model, which we will discuss in the next section.

## 3    Stochastic Models

In heterogeneous organic semiconducting devices, charges are nonuniformly distributed and charge density variations span several orders of magnitude. To cover the required density range in simulations, we need to simulate relatively large systems. This quickly becomes computationally demanding if all rates are evaluated from first principles (Kordt et al. 2015b). To remedy the situation, we can devise a phenomenological algorithm to parametrize the master equation (Baumeier et al. 2012; Stenzel et al. 2014; Brereton et al. 2014; Stenzel et al. 2014).

In case of morphologies, this algorithm reproduces given correlation functions, densities, and coordination numbers. For (approximately) spherically shaped molecules, the pair correlation function, or radial distribution function, $g(r)$, contains the most relevant structural information. To reproduce this function approximately, we can use a Poisson process (Baumeier et al. 2012; Kordt et al. 2014). More accurate coarse-graining techniques, such as iterative Boltzmann inversion (Tschoep et al. 1998; Reith et al. 2003) or inverse Monte Carlo (Lyubartsev and Laaksonen 1995; Soper 1996; Murtola et al. 2009), allow an exact reproduction of the radial distribution function (Kordt et al. 2015a). These methods optimize a pair interaction potential, $U(r)$, in a way that the corresponding $g(r)$ is reproduced. The approach can also be applied to non-spherical molecules, by using several interacting sites per molecule (Rühle et al. 2009).

The second ingredient of the stochastic model is the connectivity. In the atomistic model only molecules within a certain cutoff distance are used for calculating charge transfer rates, while the rest of the rates is set to zero. This is justified by the fact that electronic coupling elements decrease roughly exponentially with molecular separation (Kordt et al. 2015a). The distance that determines whether or not two molecules are connected is given by their two closest atoms. Since this information is not present in the coarse-grained model, the resulting probability of two sites being connected is given by the corresponding probability extracted from the atomistic system.

For charge transfer rates, a simple procedure can be developed by analyzing the distributions of parameters entering the charge transfer rate. For example, in an amorphous mesophase of the organic semiconductor $Alq_3$, the distribution

of electronic couplings at every particular intermolecular separation is Gaussian. The dependence of the width and the mean of this Gaussian on intermolecular separation can be determined from microscopic simulations. The spatial correlations of site energies can be introduced by using a moving-average procedure. In this approach, the site energies of the neighbors within a certain cutoff are mixed into initially independent Gaussian site-energy distribution (Kordt and Andrienko 2016). Electronic coupling elements can also be generated using appropriate distributions. These distributions are, however, separation-dependent: the logarithm of squared transfer integrals, $\log J^2$ (which is often Gaussian distributed) depends on molecular separation. In the stochastic model, transfer integrals are then drawn from the distant-dependent distributions.

Stochastic models developed for amorphous mesophases of Alq$_3$ and DCV4T could reproduce the mobility-field and mobility-density dependencies (Baumeier et al. 2012; Stenzel et al. 2014; Kordt et al. 2014). This indicates that they indeed can serve as an intermediate step between the completely microscopic descriptions and macroscopic, drift-diffusion-equation-based models. The current challenge is to extend such models to anisotropic and heterogeneous systems.

## 4 Finite-Size Effects

The dependence of macroscopic observables on the system size has been experimentally observed in organic semiconductors in systems with large energetic disorder or broad density of states. For example, time-of-flight measurements of mobility are impossible in thin organic films, where charge transport is dispersive and transients do not have a characteristic plateau used to determine the transient time (Scher and Montroll 1975; Borsenberger et al. 1991, 1992, 1993). Using thicker samples normally remedies the situation.

A similar effect is also observed in simulations of small systems. It turns out that replicating the simulation box still gives incorrect (higher) values of charge carrier mobility (Lukyanov and Andrienko 2010). Indeed, all duplicated boxes have exactly the same (and small) number of independent site energies. Statistical averages are performed over this small set of site energies, and charge carriers traverse the sample at a different (higher) temperature than in an infinitely large system. Surprisingly, an additional averaging over different, statistically uncorrelated, but still repeated snapshots does not help, since the origin of the problem lies in the limited number of available for every distinct Monte Carlo simulation sites.

This type of finite-size effects becomes much smaller at higher temperatures, since the relevant dimensionless parameter (at least in the Gaussian disorder model) is the width of the site energy distribution $\sigma$ divided by $k_B T$. In fact, an empirical expression, $(\sigma/k_B T_{ND})^2 = -5.7 + 1.05 \ln N$, can be used to estimate at what temperature the "transition" between the dispersive and non-dispersive transport occurs, where $N$ is the number of the hopping sites (molecules) in the system. This observation has been used to perform an empirical correction of finite-size effects (Lukyanov and Andrienko 2010): Nondispersive mobilities were calculated

for a set of temperatures above $T_{\mathrm{ND}}$. Then, an explicit temperature dependence was used to extrapolate the value of mobility to room temperature.

This method relies on an explicit knowledge of the temperature dependence of mobility. While the exact analytical expression of this dependence is available only for one-dimensional systems (Derrida 1983; Seki and Tachiya 2001),

$$\mu(T) = \frac{\mu_0}{T^{3/2}} \exp\left[ -\left(\frac{a}{T}\right)^2 - \left(\frac{b}{T}\right) \right],$$

it can still be used in a three-dimensional case in a rather broad temperature range, as was verified by performing simulations for systems of different sizes and at different temperatures (Lukyanov and Andrienko 2010).

An alternative method is to determine the mobility as a function of the box size. For one-dimensional systems and Gaussian DOS, the mobility is inversely proportional to the number of visited sites $N$ (Kordt et al. 2016),

$$\mu(N) = \mu_\infty \left(1 + \frac{c}{N}\right).$$

Using this relation, it is possible to extrapolate the finite-size mobilities to its macroscopic value $\mu_\infty$.

To illustrate the relevance of such extrapolation, charge transport in the amorphous mesophase of $Alq_3$ was simulated in systems of different sizes (Lukyanov and Andrienko 2010). In a system of 512 molecules, the simulated mobility was of the order of $10^{-6}\,\mathrm{cm^2/Vs}$, while in a box of 4096 molecules, an order of magnitude lower value was measured. Extrapolation procedure resulted in a mobility of $10^{-9}\,\mathrm{cm^2/Vs}$, which is three orders of magnitude lower than the one simulated in a small system. Note that the magnitude of the correction is very sensitive to the value of the energetic disorder $\sigma$. While in $Alq_3$ $\sigma = 0.14\,\mathrm{eV}$, in an amorphous DCV4T $\sigma = 0.25\,\mathrm{eV}$, the value of mobility can be overestimated by seven(!) orders of magnitude (Kordt et al. 2014).

## 5   Long-Range Interactions

An important ingredient of charge and energy transfer reactions is the free energy difference between the final and initial states or the driving force. In organic semiconductors this energy difference is often evaluated in a perturbative way, starting from an isolated molecule and then calculating the electrostatic and induction contributions of the environment. Coulomb interactions of partial charges or higher distributed multipoles are inherently long-range and require special summation techniques, e.g., Ewald summation, which is widely used in atomistic molecular dynamics simulations (Ewald 1921). In this approach, the Coulomb potential is split into two terms, one of which is converging fast in real and the other in reciprocal space. Induction contribution can also be incorporated in such a

scheme (Ren and Ponder 2003). While this method is well developed, it is designed for neutral systems, whereas for charge transport, our interest lies in energies of a localized charge interacting with the neutral environment. The presence of a charged excitation and its polarization cloud violates the periodicity of the system, which is essential for calculations in the reciprocal space.

A computationally more demanding solution is to evaluate electrostatic sums for spheres centered around the charged molecule (bulk) or cylinders (slab) of radius $R$. In both cases charge-quadrupole interactions scale as $1/R$, making it possible to extrapolate to $R \rightarrow \infty$ (D'Avino et al. 2016). A more elegant solution to this problem has been proposed by Poelking and Andrienko (2016). The nonperiodic (foreground) part of the system which incorporates the charged excitation and its induction cloud is superimposed onto a periodic, neutral background, which is computed using the Ewald summation method. The real-space interaction between these two regions is mediated by fields created by the background charge distribution, including induced moments. A modified shape term (Smith 1981) is added to account for the net charge and quadrupole of the simulation box. This term takes into account surface effects and depends on the summation geometry.

By applying this technique to organic/organic interfaces, it has been shown that a cutoff of $4-8$ nm is sufficient to converge the energy of a periodic three-dimensional system (Schwarze et al. 2016). For ordered interfaces, the convergence turns out to be significantly slower: for a 12 nm thick slab, the energy is far from converged even for the cutoff of 22 nm (Poelking and Andrienko 2016, 2015; Poelking et al. 2014). Hence, this method should be used for two-dimensional periodic systems or, in general, heterogeneous systems with a long-range molecular ordering. The differences between using simulations with a cutoff and without it are remarkable: the additional electrostatic/induction contribution can change from 0.5 eV (10 nm cutoff) to $-0.7$ eV (infinite system). The correct treatment of electrostatic can therefore *reverse* the role of donor and acceptor as conditioned by gas-phase energy levels and energy levels calculated with a seemingly ample cutoff. It also predicts that the energy profiles for electrons and holes are flat at the organic-organic interfaces, while cutoff-based calculations lead to a significant level bending. Finally, it allows to establish a relationship between structural coherence and state energetics: the structural coherence is probed up to a $\mu m$ scale, hence emphasizing the role of extended crystallites (and their alignment) at interfaces.

## 6    Outlook

There are still a few directions where substantial method development is required to achieve a parameter-free modeling of realistic devices. An important step is to explicitly include the many-body induction interactions to the solution of the master equation. This, however, requires the reevaluation of rates at every Monte Carlo

step and is computationally demanding. Another issue is the quantitative treatment of excited states embedded in a heterogeneous polarizable molecular environment, including descriptions of charge-exciton and exciton-exciton interactions. These advancements are absolutely vital for devising accurate structure-property relationships for organic semiconductors.

### Abstract

Soft matter systems display properties that span different time and length scales. In addition, scales' interplay is often the key to understand fundamental mechanisms to the aim of controlling and/or designing materials with properties on demand. On the other hand, computational soft matter is limited by computational power for both, size and time of simulation and analysis of large sets of

data. In this perspective, computational efficiency to treat large systems on long time scales becomes one of the main goals in constructing modern algorithms, together with the capability of designing theoretical schemes for data analysis capable of extracting the relevant information of interest above all the effects of scales' interplay. One common and recurrent feature, in such studies, is the need to include relevant chemical details in a specific region where an event of interest is taking place, while the environment plays simply the role of a macroscopic thermodynamic bath that can be treatable at a coarse-grained level. Thus, an efficient computational strategy consists in employing multiple resolution methods, which simultaneously consider models with different resolution in different regions. This chapter provides a basic introduction to the adaptive resolution simulation (AdResS) method and its recent extensions. This methodology is designed with the idea of efficient computation and analysis of multiple scales as envisaged above. We will report its basic principles and technical aspects for the various directions along which the original idea was developed. As it will emerge in the next sections, the basic idea of adaptive resolution, already highly efficient in its first implementation, has now reached a high level of theoretical solidity, being framed in different but complementary ways in physically rigorous principles. Finally, selected applications, relevant in the field of materials science, chemical physics, and biochemistry, are illustrated in order to show the advanced possibilities of application of the method.

# 1    Adaptive Resolution Simulations

AdResS (Praprotnik et al. 2005, 2008) is a multi-resolution simulation method that links two regions of a simulation box having different resolutions: region 1, atomistic (AT), and region 2, coarse-grained (CG). The innovative aspect of such a setup is that the boundary between such regions is open; thus, it allows the free exchange of particles/molecules between the two regions. This free exchange occurs through a coupling transition region (HY) where molecules have space-dependent hybrid atomistic/coarse-grained resolution or intermolecular interactions. In the original version (Praprotnik et al. 2005, 2008), the guiding principle employed was that the coupling between two regions must be smooth enough so that the dynamics of the atomistic and the dynamics of the coarse-grained region, through a hybrid resolution region, would not be perturbed in a sizable way, i.e., Newton's 3rd law should be fulfilled. This empirical principle corresponds to a straightforward molecular dynamics (MD) algorithm based on the interpolation of the atomistic and coarse-grained forces. The above requirement prevents the use of an interpolation based on a Hamiltonian (Delle Site 2007). While for most typical applications not of a serious concern and for some even advantageous, e.g., hydrodynamics, the desire to base such an interpolation scheme on a Hamiltonian description led to the development of H-AdResS (Potestio et al. 2013a, b). At the cost of a weak violation of Newton's 3rd law, the Hamiltonian description offers some advantages, including the option to perform adaptive Monte Carlo (MC) simulations. Recently,

AdResS has been also extended to simulate open molecular systems within the grand canonical ensemble by grand canonical AdResS (GC-AdResS) (Wang et al. 2012, 2013) and open boundary molecular dynamics (OBMD) (Delgado-Buscalioni et al. 2015; Sablić et al. 2016, 2017a, b). In the following, the different adaptive resolution approaches will be introduced, and some typical applications will be presented.

## 2 Adaptive Resolution Simulations: AdResS

The original concept is based on the idea that forces between particles/molecules should change upon variation of the molecular resolution and that this should, in principle, not affect the intermolecular dynamics. Thus, the explicit coupling is such that the force between two molecules $\alpha$ and $\beta$ is computed via a space-dependent interpolation formula and is written as

$$F_{\alpha\beta} = w(X_\alpha)w(X_\alpha)F_{\alpha\beta}^{AT} + [1 - w(X_\alpha)w(X_\alpha)]F_{\alpha\beta}^{CG} \tag{1}$$

here, $F_{\alpha\beta}^{AT}$ is the atomistic force between the particles and $F_{\alpha\beta}^{CG}$ is the coarse-grained force; $w(x)$ is the interpolating function and is defined as

$$\begin{Bmatrix} 1 & x < d_{AT} \\ cos^2[\pi/(2d_\Delta)(x - d_{AT})] & d_{AT} < x < d_{AT} + d_\Delta \\ 0 & d_{AT} + d_\Delta < x \end{Bmatrix}$$

where $d_{AT}$ and $d_\Delta$ are the linear dimension of the atomistic region and hybrid regions, respectively (see Fig. 1). The weighting function smoothly goes from 0 to 1 in the hybrid region and allows the coarse-grained particles to change their resolution into an atomistic molecule and vice versa. A local thermostat takes care of adsorbing and releasing the excess of heat produced by the change of resolution (see e.g., Poblete et al. 2010). This minimal ansatz has been shown to be already sufficient for performing accurate simulations in both the atomistic and coarse-grained regions (see e.g., Praprotnik et al. 2007b). Other more natural choices of coupling, e.g., through an energy, were not considered at this point. Provided that the dynamics should be governed by intermolecular forces only, it was shown that a spatial interpolation of any energy functional, instead of forces, leads to the mathematical nonexistence of a global physically consistent energy in the adaptive sense. As a consequence, any energy functional constructed on the basis of spatial interpolation would be artificial from the physical point of view (see Eqs. 14 and 15 in Delle Site 2007). Nevertheless, relaxing the constraint on the exact conservation of Newton's 3rd law, energy-based algorithms, which have the technical capability of conserving energy (a familiar concept for practitioners of MD and needed for MC) and enable more flexibility in the choice of the standard technical setups, can be devised. In both types of approach one needs to carefully consider the
**Fig. 1** (**a**) Cartoon of the AdResS setup with spherical regions modeled with different levels of resolution. In the center, there is the AT domain with the molecules surrounded by the HY and CG domains, respectively. (**b**) Multiscale system of a liquid composed of tetrahedral molecules. (Reprinted from Praprotnik et al. 2006)

meaning of global ensemble averages in order to identify realistic and artificial results. In the next sections, we will consider these two different options. From the basic technical point of view, they are actually more or less equivalent (Delle Site and Praprotnik 2017). As a final general remark, it must be underlined that AdResS, in any of its variations, turned out to be conceptually and computationally far more robust than other similar methods (Ensing et al. 2007; Heyden et al. 2007; Mones et al. 2015). In fact, beyond the basic coupling structure, several additional technical aspects were also implemented and tested; relevant examples are the design of a diffusing high-resolution region where the high resolution follows a solvated molecule in space (Praprotnik et al. 2007a) or the design of high-resolution regions of adjustable size (Kreis et al. 2016b), the use of the method for the calculation of potential of mean force for the solvation of relevant biomolecules (Fiorentini et al. 2017) or for the calculation of the chemical potential of liquids and mixtures (Agarwal et al. 2014).

## 3  Grand Canonical AdResS: GC-AdResS

Further methodological developments of the initial idea based on force interpolation led to the definition of a space-dependent thermodynamic force acting on to the centers of mass of molecules in the hybrid region. Such a force imposes a priori a proper thermodynamic equilibrium and a correct exchange of particles between the AT and CG region (Poblete et al. 2010; Fritsch et al. 2012a). Later on, it has been shown that the thermodynamic force and the work of the thermostat exactly

give the proper chemical potential of coupling even when coarse-grained models reproduce only density and temperature that is only macroscopic thermodynamics. Thus, AdResS was reframed within a grand canonical-like approach (Wang et al. 2012, 2013). Finally, the coupling of the atomistic region to the rest of the system has been rationalized in such a way that a rigorous formalization of a control error is employed to check whether or not the textbook definition of grand canonical system (see, e.g., the procedure in Huang 1987) is satisfied (GC-AdResS). The corresponding formula for the control of the error opened the gate to the conceptual embedding of GC-AdResS into the so-called Bergman-Lebowitz model of open systems (Lebowitz and Bergmann 1957; Bergmann and Lebowitz 1955) and hence to the definition of a Liouville equation for a system that exchanges particles with a reservoir. This led to the physically correct definition of ensemble average time correlation functions for open systems (Agarwal et al. 2015; Agarwal and Delle Site 2015, 2016). In this context, a surprising result of an unexpected locality in the IR spectra of water was found (Agarwal and Delle Site 2016), which is due to the interplay between local quantum effect and global structural properties for the solvation of hydrophobic molecules (Agarwal et al. 2017). Another success of GC-AdResS is its application to ionic liquids, due to the highly challenging role of electrostatics (Krekeler and Delle Site 2017). We could show that independently from the fact whether the coarse-grained model is charged or not, the AT region reproduces always the results of an equivalent subregion of a large full atomistic simulation. The absence of any atomistic degree of freedom outside the atomistic region allowed us to confirm and quantify the structure of the cage within which an ion rattles (Jabes et al. 2018). Here, it should be underlined that the fact that the method applied is force-based plays no more a role for the conceptual justification of the method, since the embedding of the algorithm into the grand canonical frame, and its correspondence to the Bergman-Lebowitz model of open system applies to any possible form of coupling between the AT region and the reservoir. Along such lines, recent theoretical progress has led to the construction of a numerical protocol for allowing the adaptive resolution simulation of molecules with electrons where physical consistency at statistical mechanics level is strictly assured by exact formulas of control of the approximations (Delle Site 2018). In general, AdResS can handle systems in equilibrium and beyond, and, in the next sections, the idea of system with open boundaries is moved even forward to a truly open systems such as coupling to continuum or an ideal gas.

## 4  AdResS and Its Coupling to Continuum: Open Boundary MD (OBMD)

Another extension of the force-based AdResS that allows for simulations of open molecular systems that exchange mass, momentum, and energy with their surroundings has been coined open boundary MD (OBMD) (Delgado-Buscalioni et al. 2015; Sablić et al. 2016, 2017a, b). The OBMD methodology, which is an offspring of two linear-momentum-preserving methods, i.e., open MD (Flekkoy et al. 2005;

Delgado-Buscalioni 2012) and AdResS, enables us to perform equilibrium MD simulations in the grand canonical ensemble as well as non-equilibrium fluid flow simulations. The flow is introduced via an external boundary condition, while the equations of motion for the bulk remain unaltered.

In the OBMD simulations, the MD domain is typically sandwiched in between two (auxiliary) buffer domains. The latter two act as mass reservoirs and hence enable the former to exchange particles, momentum, and energy with its surrounding. Thus, the OBMD system is opened, i.e., not periodic, in the coupling direction. Molecules freely move between the MD and buffer domains. Moreover, in the buffers, the molecules change their resolution from the fine- (close to the MD domain) to the coarse-grained resolution (at the outer boundaries of the simulation box). The underlying idea of the resolution change is that AdResS allows for the insertion of molecules of arbitrary size into the system. In the coarse-grained parts of the buffers, relatively large molecules can thus be easily inserted due to soft effective interactions among coarse-grained beads (Delgado-Buscalioni and Coveney 2003; De Fabritiis et al. 2004). Then, as the molecules move toward the MD domain, they gain the fine-grained details owing to AdResS used in the buffers. Molecules are deleted once they leave the outer boundary of a given buffer, and new molecules are inserted to achieve the mass balance, i.e., to have a desired average density in the system.

The OBMD setup can be further extended to computational fluid dynamics (CFD) description of a liquid, i.e., Navier-Stokes (NS) are used to describe the dynamics of the liquid on the continuum scale (going beyond the particle-based modeling of the liquid) (Delgado-Buscalioni et al. 2008, 2009). Such hybrid MD/CFD approaches are especially useful for simulations of the transport of nanoparticles through fluids. Simulations using MD can capture the atomistic details of the nanoparticle-liquid interface, but due to their computational cost, they cannot be extended, in the foreseeable future, to the macroscale regime of the full flow field. In turn, continuum descriptions, using the NS equations may capture the macroscale behavior of the flow, but they fail to represent accurately the flow field at the nanoparticle surface. The hybrid approaches, on the other hand, combine the powerful features of both descriptions, i.e., the ability to describe the macroscale behavior of the flow as well as accurate boundary conditions around nanoparticles (Walther et al. 2012).

While technically and (when considering the AT region as a grand ensemble) conceptually equivalent to the force-based approach, the energy-based approach (H-AdResS), presented in the next section, becomes particularly relevant if one wants to perform MC adaptive resolution simulations.

## 5　Hamiltonian-Based AdResS: H-AdResS

The AdResS method ensures that Newton's 3rd law is exactly satisfied everywhere within the simulation box. As a consequence, it is impossible to interpolate the potential energy using a position-dependent switching function and simultaneously

preserve Newton's 3rd Law. This, as shown in previous sections, proves not to be a major practical problem (Wang et al. 2013). However, without a global Hamiltonian, it is unfeasible to technically carry out NVE or MC simulations in a straightforward way. In the Hamiltonian AdResS (H-AdResS) method (Potestio et al. 2013a, b; Español et al. 2015), the constraint of global momentum conservation of momentum is relaxed in order to overcome the limitations of AdResS reported above. In H-AdResS, total energy of each molecule is expressed in terms of a position-dependent function:

$$H = \mathcal{K} + V^{int} + \sum_{\alpha} \left\{ \lambda_\alpha V_\alpha^{AT} + (1 - \lambda_\alpha) V_\alpha^{CG} \right\} \tag{2}$$

where $\mathcal{K}$ is the (all-atom) kinetic energy of the molecules, $V^{int}$ is the interaction internal to the molecules, and

$$\begin{cases} V_\alpha^{AT} \equiv \dfrac{1}{2} \sum_{\beta, \beta \neq \alpha}^{N} \sum_{ij} V^{AT}(|\mathbf{r}_{\alpha i} - \mathbf{r}_{\beta j}|) \\ V_\alpha^{CG} \equiv \dfrac{1}{2} \sum_{\beta, \beta \neq \alpha}^{N} V^{CG}(|\mathbf{R}_\alpha - \mathbf{R}_\beta|) \\ \lambda_\alpha = \lambda(\mathbf{R}_\alpha) \end{cases}$$

As in the AdResS scheme, the switching function $\lambda$ goes from 0 (purely CG) to 1 (purely AT). The force acting on atom $i$ in molecule $\alpha$ is obtained through differentiation of the Hamiltonian in Eq. 2. In particular, differently from standard AdResS in this case, one has a further term: $\left[ V_\alpha^{AT} - V_\alpha^{CG} \right] \nabla_{\alpha i} \lambda_\alpha$. This term is asymmetric and locally breaks Newton's 3rd law. This force, which is nonzero only in the hybrid region, is proportional to the difference between the potential energies of a molecule in the AT and the CG representation. The effect of this term is to push molecules into one of the two bulk regions, similar to AdResS, where the thermodynamic force has been introduced. Formally, the solution to this is to introduce a compensation term in such a way that

$$\left. \frac{d \Delta H(\lambda)}{d\lambda} \right|_{\lambda = \lambda_\alpha} = \left\langle \left[ V_\alpha^{AT} - V_\alpha^{CG} \right] \right\rangle_{\mathbf{R}_\alpha} \tag{3}$$

The subscript in the average indicates that the latter has to be performed constraining the CG site of molecule $\alpha$ in the position $\mathbf{R}_\alpha$. This correction leads to a position-dependent correction term in the hybrid zone:

$$\left\langle \left[ V_\alpha^{AT} - V_\alpha^{CG} \right] \right\rangle_{\mathbf{R}_\alpha} \simeq \frac{1}{N} \left\langle \left[ V^{AT} - V^{CG} \right] \right\rangle_{\lambda'} \tag{4}$$

where $\lambda' \equiv \lambda(\mathbf{R}_\alpha)$ is the same for all molecules.

Formally, this can be seen as a position-dependent compensation term to the change in the *Helmholtz free energy* difference between the AT and the CG system (Kirkwood 1935). Therefore, it is possible to calculate the compensating function needed to restore, on average, Newton's 3rd law by performing a Kirkwood thermodynamic integration and add it to the Hamiltonian, so that an effective global Hamiltonian for MD (Potestio et al. 2013a) and MC (Potestio et al. 2013b) approaches, resulting in

$$\Delta H(\lambda) \equiv \Delta\mu(\lambda) = \frac{\Delta F(\lambda)}{N} + \frac{\Delta p(\lambda)}{\rho^{\star}} \tag{5}$$

Practically, while the free energy difference between the AT and the CG description is correctly reproduced, details of the local shape of the compensations force are determined by a few iterations. This ensures perfectly flat density profiles. In general, for such methods global ensemble averages must be carefully considered, since the transition region always represents an artificial filter. Like for AdResS this has been done in very detail for H-AdResS in a recent publication (Español et al. 2015). The general Bergman and Lebowitz framework allows to include H-AdResS within an overall adaptive resolution framework. As for (GC-)AdResS (Poma and Delle Site 2010, 2011; Potestio and Delle Site 2012; Agarwal and Delle Site 2015, 2016; Agarwal et al. 2017) also H-AdResS can be employed to put the coarse-grained resolution in connection with a quantum path integral description of molecules (Kreis et al. 2016a, 2017). The technical advantage in this case is that the presence of a global Hamiltonian allows for a straightforward quantization of the Hamiltonian in the high-resolution region. Other examples are the appropriate treatment of electrostatic interactions in the AT and CG region (Heidari et al. 2016) or the connection to relative entropy coarse-graining methodologies (Kreis and Potestio 2016).

## 6    AdResS, GC-AdResS, and H-AdResS: Examples of Complementary Approaches in a Unified Framework

All AdResS versions are equivalent when considering the AT region as an open system embedded in a reservoir (Agarwal et al. 2015) and that they are equivalent regarding the technical efficiency. Moreover, recent works (Kreis et al. 2014; Zhu et al. 2016) show that a formal connection can be drawn between force-based methods for dual-resolution simulations, such as AdResS, and energy-based methods, such as H-AdResS. Specifically, in Kreis et al. (2014), it was shown that the force-based version of the H-AdResS scheme, i.e., without the drift force, has the same statistical properties of a H-AdResS simulation with a colored noise. Furthermore, mathematical analysis of the asymptotic properties of the force-based and Hamiltonian-based versions (Zhu et al. 2016) reveals that they are equivalent under the condition of large coarse-grained region compared to the atomistic region and (at the same time) large atomistic region compared to the hybrid region. Such

connections prove the mathematical and physical solidity of the AdResS idea in general, which accompanied to its computational efficiency makes the method a powerful tool of simulation and analysis to address the modern challenges in different fields of applied molecular science, as illustrated in the next section.

The AdResS development has meanwhile reached a mature stage at which we can readily apply the methodology to tackle interesting problems in life and material sciences. For instance, AdResS has been applied to study biomolecular systems such as solvated proteins (Fogarty et al. 2015; Kreis et al. 2016b; Fogarty et al. 2016; Tarenzi et al. 2017) and DNA molecules (Zavadlav et al. 2015a, 2017a; Netz et al. 2016). In those examples, we have used a 1-to-1 molecular mapping, in which one coarse-grained bead corresponds to one atomistic water molecule. The next stage of development has involved coupling of atomistic to supramolecular water models such as the widely used MARTINI force-field (Marrink et al. 2004; Marrink et al. 2007; Marrink and Tieleman 2013), where four water molecules are represented with one coarse-grained bead (4-to-1 molecular mapping). Here, water changes its resolution from four molecules to one coarse-grained particle and vice versa adaptively on-the-fly (Zavadlav et al. 2014a, b, 2015b, 2016a; Nagarajan et al. 2013); see Fig. 2. To this end, we have developed a dynamic clustering algorithm SWINGER that can concurrently assemble, disassemble, and reassemble water bundles, consisting of several water molecules (Zavadlav et al. 2016b). Thus, it allows for a seamless coupling between any standard atomistic and supramolecular water models, e.g., dissipative particle dynamics (DPD) (Hoogerbrugge and Koelman 1992; Español and Warren 1995), in adaptive resolution simulations (Zavadlav and Praprotnik 2017). This multiscale approach paves the way for efficient multiscale simulations of biomolecular systems without compromising the accuracy of atomistic water models (Zavadlav et al. 2017b).

**Fig. 2**  (**a**) AdResS simulation of an atomistic protein in MARTINI water. (**b**) AdResS simulation of an atomistic DNA molecule in MARTINI water. (Reprinted from Zavadlav et al. 2014a, 2016a)

A recent use of AdResS, in its GC-AdResS version, as a tool to investigate the structural locality of ionic liquids, has allowed to unambiguously conclude that specific atom-atom electrostatic interactions do not play a role in the formation of structures on spatial scales beyond the ion-ion distance. Such a conclusion is rather surprising because in current literature, it is actually postulated the opposite, although purely coarse-grained simulations (without explicit charges) had already put the postulate in discussion (Krekeler and Delle Site 2017; Jabes et al. 2018). The study allowed to draw a picture of the essential feature of the liquid structure for a relevant class of ionic liquids (see Fig. 3). Further on, a particularly promising direction to take full advantage of the coupling between models at different resolution is to employ in the CG region the most computationally inexpensive model available, relying on the fact that the compensating external field (thermodynamic force in AdResS, free energy compensation (FEC) in H-AdResS) guarantees that the AT region will reproduce the correct thermodynamics. The extreme case of a model with few, simple interactions is the ideal gas, to be interpreted as a collection of thermostatted noninteracting particles. In Kreis et al. (2015), this possibility was explored by simulating a water system where 6526 water molecules were modeled at the atomistic level in the high-resolution region, while in the CG region, they were subject to no interaction other than the Langevin thermostat. The results show that neither the structure nor the dynamics of the fluid in the AT region of the water-ideal gas hybrid system are compromised. This can be seen from the fully atomistic pair correlation functions and diffusion profiles of the H-AdResS simulation as reported in Fig. 4. These RDFs and diffusion profiles are fully consistent with those measured in completely atomistic reference simulations. Another application which goes beyond the previous examples is the triple-scale simulation of an enzyme in solution with a binding ligand (Fogarty et al. 2016). There the center part of the enzyme, the ligand, and the surrounding water are treated on an all-atom level, while

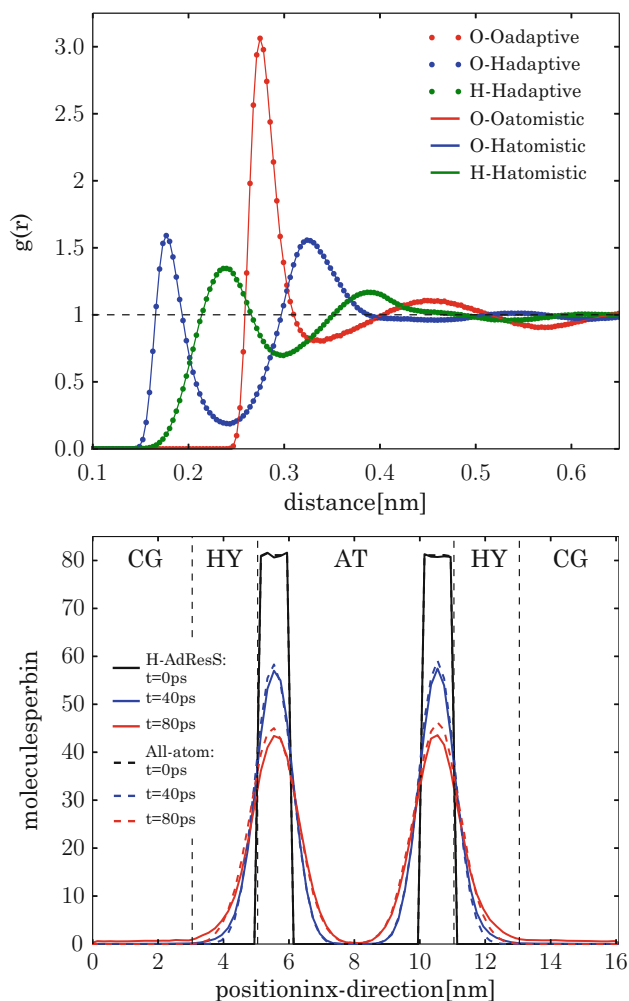
**Fig. 3** Cations and anions in imidazolium-based ionic liquids need only a first shell of neighboring ions to build typical structures of the liquid. Such atomistic islands are embedded in a thermodynamic bath without the need of explicit electrostatic interactions. This picture deviates from the intuitive argument put forward in many papers in the field that explicit electrostatic interactions play a key role in the formation of typical liquid structures, even at local level. (This figure is an adaptation from Jabes et al. 2018)


**Fig. 4** Top: RDFs for pure water and for the atomistic region of the H-AdResS water-ideal gas with Kirkwood TI-based Gibbs FEC. Since a rigid water model is employed, all RDFs consider only intermolecular atom pairs. Bottom: diffusion profiles in H-AdResS simulations of the water-ideal gas system and in fully atomistic reference simulations of SPC/E water: time evolution of the position of molecules initially located in a 1-nm-wide slab in the atomistic region, immediately adjacent to the HY region. The y-axis is the absolute number of these molecules whose center of mass $X$ coordinate is in a given bin at the given time. (Figures from Kreis et al. 2015)

the water molecules further away are treated on a coarse-grained level and the rest of the residues of the enzyme is considered on an elastic network level. Finally, on the practical side, it must be reported that all the various method start to be included in some of the most popular simulation codes used within the community. In particular, AdResS, H-AdResS, and OBMD are implemented in ESPResSo++

(Halverson et al. 2013; Guzman et al. 2017), AdResS, H-AdResS, and GC-AdResS are implemented in GROMACS (Abraham et al. 2015; Fritsch et al. 2012a), and H-AdResS is implemented also in LAMMPS (Plimpton 1995; Heidari et al. 2016).

# 7 Perspectives

By now, the general AdResS concept with its variants is well established and has been shown to be robustly applicable to a variety of important problems. Beyond that new developments, which require more or less effort of method development or code adjustment open the path to new applications and opportunities. In fact, the possibility of treating molecules with electrons would allow AdResS to become a tool that can span all the relevant scales of molecular science up to the fluid dynamics. In this perspective, H-AdResS has been connected to QM/MM approaches in which a small sub-domain of the system of interest is treated at the ab initio level, while the rest is described with a classical potential (Boereboom et al. 2016). Furthermore, as anticipated in the section dedicated to GC-AdResS, it has been proposed to go even beyond that and use AdResS (in any form GC-AdResS or H-AdResS) as a physical rigorous platform for a truly grand canonical method for molecules with electrons (Delle Site 2018). A resulting electronic quantum mechanical AdResS approach (el-QM-AdResS) would allow to treat local quantum events, such as conformational deformations of atomistic structures, chemical reactions, specific solvation, and atom-atom bonding effects, to name a few, while assuring the correct statistical mechanics electronic structure and macroscopic thermodynamics. The coupling of any region of resolution to an ideal gas allows the easy treatment of systems, which are driven by an external supply of matter, such as controlled growth or structure formation.

# Data-Driven Methods in Multiscale Modeling of Soft Matter

# 67

Tristan Bereau

## Contents

### Abstract

As in many other scientific fields, data-driven methods are rapidly impacting multiscale modeling. This chapter will illustrate some of the many ways advanced statistical models and a data-centric perspective help augmenting computer simulations in soft matter. A specific focus on force fields, sampling, and simulation analysis is presented, taking advantage of machine learning, high-throughput schemes, and Bayesian inference.

## 1　Introduction

Advanced statistical models are rapidly impregnating many technological and scientific fields, from the automobile industry to robotics to particle physics. Not only do novel data-driven methods offer new perspectives on approaching long-

T. Bereau (✉)
Theory Group, Max Planck Institute for Polymer Research, Mainz, Germany
e-mail: bereau@mpip-mainz.mpg.de

standing problems, they hold the promise of accelerating the pace of research. Materials science is one such field, where data is likely to accelerate computational rational design. The decisive impact of materials design in various aspects of our society has led to large-scale strategies – among others the Materials Genome Initiative (Jain et al. 2013). These recent efforts are already bearing fruit in various disciplines of hard condensed matter, inorganic chemistry, and also semiconductor physics (Curtarolo et al. 2013). Interestingly, little has happened in soft matter.

The slow development of computational materials design in soft matter likely precisely arises from what makes these systems unique: the prominent role of thermal fluctuations. Soft matter systems display weak characteristic energies on par with thermal energy, $k_B T$, leading to fascinating phenomena, such as self-assembly. On the other hand, thermal fluctuations obscure the link between the chemistry and materials properties, because of the complex interplay of a system with its environment. This makes computational materials discovery for soft matter all the more challenging (Bereau et al. 2016).

Modeling soft matter systems is traditionally approached using multiscale simulations. They bridge the relevant length and time scales of the system: from quantum, to classical atomistic, to coarse-grained (CG), and to continuum resolutions. These methods are all entrenched within certain physical laws and symmetries. They stand at odds with purely data-driven methods, which typically contain little physics a priori but are instead mostly empirical. Can we benefit by combining these two paradigms?

This chapter discusses recent examples that apply data-driven methods to *augment* multiscale modeling in soft matter. Here, I will emphasize how advanced statistical models can help improve existing methodologies or offer new perspectives. The chapter describes efforts in building better force fields, tackling sampling challenges, but also efficiently analyzing computer simulations. In each case, significant progress is achieved by a variety of methods, such as machine learning (ML), high-throughput schemes, and Bayesian inference. This chapter will assume prior exposure to computer simulations – it is intended to help the simulator better grasp the benefits of introducing data-driven methods in their research.

## 2 Force Fields

Force fields lie at the heart of classical particle-based modeling. When numerically integrating Newton's equations of motion, the force field dictates how particles interact over time. As such, the force field encodes all the physics and chemistry of the model, no less. Accuracy here is critical because it determines the aggregate behavior of the system after heaps of integration steps. Emergent complexity arises from countless evaluations of $\mathbf{F} = m\mathbf{a}$. In this sense, the force field links the system's chemical composition to its long-time properties, such as free energies or kinetic properties. The corollary to this critical role is the attention force fields have received in the last three to four decades (Maple et al. 1988; Halgren 1992; Halgren and Damm 2001; Wang et al. 2001; Ponder and Case 2003; Mackerell 2004).

Force fields map a particle configuration to interaction energies and forces, leading to the coveted *potential energy surface*. The mapping ought to hit an appropriate balance between accuracy and computational investment: the physics should be described appropriately at small numerical cost. For instance, a simple spring will capture the limited range of a covalent bond but will evidently fail to describe anharmonic effects. Identifying the sweet spot depends critically on the problem at hand. The other facet of a force field development project entails transferability: given a parametrization among certain configurations, compounds, and environments, to what extent can the resulting model extrapolate to scenarios absent from the training set? In the following, we highlight recent strategies where ML has helped improve force field accuracy and transferability.

## 2.1    Accuracy: Beyond Traditional Basis Sets

Traditionally, most of the functional forms commonly used in molecular mechanics have largely been constrained by computational considerations. Among others, a pairwise decomposition is an appealing treatment of intermolecular interactions but fails to capture some of the many-body physics, as found, for instance, when modeling dispersion (Tkatchenko et al. 2012). Mathematically, this is a basis set problem: the vector space used to construct the force field fails to accurately reproduce all aspects of the underlying potential energy surface.

A striking illustration of the basis set problem arises upon coarse-graining. Coarse-graining reduces the representation of a molecular system by grouping atoms into larger particles or beads. Structure-based coarse-graining aims at a systematic derivation of CG potentials from reference atomistic simulations (Voth 2008; Peter and Kremer 2010; Noid 2013). Several methods exist to derive CG potentials that aim at best reproducing the underlying forces or distribution functions. Examples of these strategies include force matching and iterative Boltzmann inversion. The averaging performed over the degrees of freedom that have been coarse-grained away effectively leads to a potential of mean force (PMF). This PMF is typically a many-body quantity. The many-body aspect holds even when the reference simulation only relies on pairwise interactions, because of correlations owing to the missing degrees of freedom (Rühle et al. 2009). This situation makes the pairwise assumption even more critical in CG models, limiting an accurate description of the structure and thermodynamics.

Unlike standard regression schemes, a machine learning (ML) algorithm does not aim at optimally fitting parameters on a predefined basis set. It instead looks for similarities between training points to interpolate the target property in a high-dimensional feature space. Because the interpolation can always improve with added training points, a specific attribute of ML is its ability to improve its accuracy with added data. We illustrate the concept with kernel ridge regression (Rasmussen and Williams 2006), though neural network-type architectures share a number of aspects (see Behler 2016). Consider the regression of property $p$ of sample $\mathbf{x}$. A kernel machine will consist of the prediction:

$$p(\mathbf{x}) = \sum_i \alpha_i K(\mathbf{x}_i, \mathbf{x}), \tag{1}$$

where the sum runs over training samples, $\alpha_i$ is the weight of sample $i$, and $K(\mathbf{x}, \mathbf{x}')$ is the kernel between samples $\mathbf{x}$ and $\mathbf{x}'$. The kernel consists of a similarity measure, or covariance function, between two samples:

$$K(\mathbf{x}, \mathbf{x}') = \langle \phi(\mathbf{x}), \phi(\mathbf{x}') \rangle = \exp\left(-\frac{||\mathbf{x} - \mathbf{x}'||^2}{2\sigma^2}\right), \tag{2}$$

where here we chose a Gaussian kernel with Euclidean distance as a measure between two samples. This metric implies that the distance is 1 and 0 for samples that are identical and very different, respectively. The middle part of the equation expresses the kernel as an inner product between the two samples. While the samples are expressed in their input space, also called "representations," the so-called *kernel trick* implicitly maps the samples via $\phi$ into an infinite-dimensional feature space, where the interpolation between samples takes place (Schiilkopf 2001). The optimization of the weights $\boldsymbol{\alpha}$ consists of solving Eq. 1 for the samples in the training set, adding a regularization term $\lambda$:

$$\boldsymbol{\alpha} = (K + \lambda \mathbb{K})^{-1} \mathbf{p}, \tag{3}$$

where $\lambda$ is set by the amount of noise in the reference data. Interestingly, while the basis set limits the possible accuracy of a regression problem, it is largely the relevance of the representation that determines the accuracy of an ML model (Huang and von Lilienfeld 2016).

There is a rapidly growing literature of studies applying machine learning to learning chemical properties, such as atomization energies (Rupp et al. 2012; Ramakrishnan and von Lilienfeld 2017). Adequate training can yield remarkably accurate predictions (Faber et al. 2017). Recent studies have aimed at using ML methods to help optimize a potential energy surface or force field (Li et al. 2017; Huan et al. 2017). When it comes to learning forces, the intrinsic orientation of the vector must be reproduced. Unlike scalar quantities, vectors contain three independent components. Different strategies have been devised to tackle this issue: the derivative of the kernel with respect to particle coordinates (Bartók et al. 2010; Chmiela et al. 2017), local axis systems (Bereau et al. 2015), or covariant kernels (Glielmo et al. 2017).

The use of ML potentials has mostly been applied to replace expensive ab initio MD simulations (Li et al. 2015; Morawietz et al. 2016; Deringer and Csányi 2017), where the computational cost difference between a single-point electronic structure calculation and ML prediction is significant. When aiming at predicting classical reference models however, the gain is smaller. Recent work on coarse-graining two benzene molecules in water indicates a better reproduction of the PMF compared to force matching (John 2016). The cost of the prediction remains significant compared to traditional pairwise potentials, but these results provide potential avenues to break the glass ceiling of pairwise interactions in CG potentials.

## 2.2     Transferability: Across Conformations, Phases, and Compositions

Molecular simulations often exhibit a complex relationship between model parameters and the resulting emergent properties. This obscures the role and impact of force field parameters. For instance, how does the tuning of a Lennard-Jones parameter affect a compound's hydration free energy or a folding timescale? This complex relationship can make force field parametrization a tedious, long, and rather unsystematic process. Systematically understanding the relationship between force field parameter and thermodynamic properties can help automate parametrization methods (Stroet et al. 2017). More often than not, coarser models tend to be more difficult to parametrize, because the missing physics require ad hoc compensations. For instance, most biomolecular atomistic models are additive – they do not explicitly model induction/polarization. Instead, mean-field polarization effects are incorporated effectively by tuning the other force field terms, most importantly Coulomb and Lennard-Jones. This typically comes at the cost of limited phase transferability: not only will they not transfer from the gas to the condensed phase, these models are typically state-point dependent. In other words, they are bound to a limited range of thermodynamic parameters, such as temperature and pressure.

Enhancing the phase transferability of these models is subject to ongoing research – a field where ML can help (Deringer and Csányi 2017) – but not the only strategy. The obscure link between model parameters and emergent properties leads to an unsystematic, largely empirical approach to force field parametrization – the craftsmanship of a biomolecular modeler. As such, developing more automated parametrization schemes offers extremely valuable perspectives: reduced parametrization efforts would speed up and enhance the pace of research in molecular simulations. In the following, two examples from atomistic and coarse-grained modeling illustrate this emerging trend. They both leverage the link between chemical properties and specific force field parameters.

High-resolution models offer a closer, more straightforward link from chemistry to force field parameters. This has motivated the development of force fields from first principles: Electronic structure calculations provide molecular and atomic properties, such as atomic polarizabilities or electrostatic coefficients, used as parameters for classical models (Van Vleet et al. 2016). This framework still requires reference calculations for every new compound considered. One can instead envision relying on the abovementioned use of ML to *predict* these chemical properties. Such a scheme was recently introduced (Bereau et al. 2018) to construct classical intermolecular potentials from atomic polarizabilities, multipole electrostatic coefficients (Bereau et al. 2015), and atomic density parameters. These parameters are fed into a physics-based model based on perturbation theory and an overlap model at long and short ranges, respectively. They lead to a remarkably small number of global parameters that only need tuning across organic compounds once and for all.

Switching to a coarse-grained resolution, the transferable Martini biomolecular force field offers a set of bead types, from which one constructs biomolecules, from proteins to lipids to sugars (Marrink and Tieleman 2013). Charged groups

interact through integer-charge Coulomb interactions. Otherwise, beads interact by means of Lennard-Jones interactions, with a predefined interaction matrix that determines the cross interactions between beads (Marrink et al. 2007). The model aims at capturing the essential thermodynamics of partitioning of chemical groups in different environments. In particular, it relies heavily on the water/octanol partitioning to assign a measure of hydrophobicity to the bead. Though not readily accessible, the water/octanol partitioning can also be predicted: ML models exist to do just that (Tetko et al. 2001). This enables a completely automated parametrization of Martini for small molecules, which both optimizes the mapping from atoms to beads and assigns the most appropriate bead type to every chemical group (Bereau and Kremer 2015). The parametrization scheme was applied to the calculation of solvation free energies for more than 1,000 compounds, clearly illustrating the potential benefits beyond manual parametrizations.

### 2.3    Example: Learning of Atomic Polarizabilities

As an illustrative example, we consider the learning of atomic polarizabilities across small organic molecules, following Bereau et al. (2018). Atomic polarizabilities are estimated using the Hirshfeld ratio, which consists of a spatial integral over the electron density of an atom in a molecule, compared to the corresponding free atom. Reference data consist of quantum chemistry calculations for thousands of isolated small molecules. We refer the interested reader to Bereau et al. (2018) for further technical details. The code to generate the data below can be found in a repository online (Bereau 2018).

   We build an ML model using kernel ridge regression (Eq. 1) and encode atomic environments – the representation – using the Coulomb matrix: a pairwise matrix of inverse distances scaled by the product of atomic numbers (Rupp et al. 2012). The dataset is split between training and test sets to ensure out-of-sample predictions, thereby limiting overfitting. Figure 1a shows a learning curve: the mean absolute error (MAE) as a function of the number of atoms incorporated in the training set. The error systematically decreases with added data. Note the power law behavior. Figure 1b displays the correlation between predicted and reference Hirshfeld ratios for the rightmost ML model shown in panel a. The color-coding distinguishes between chemical elements.

### 3    Sampling

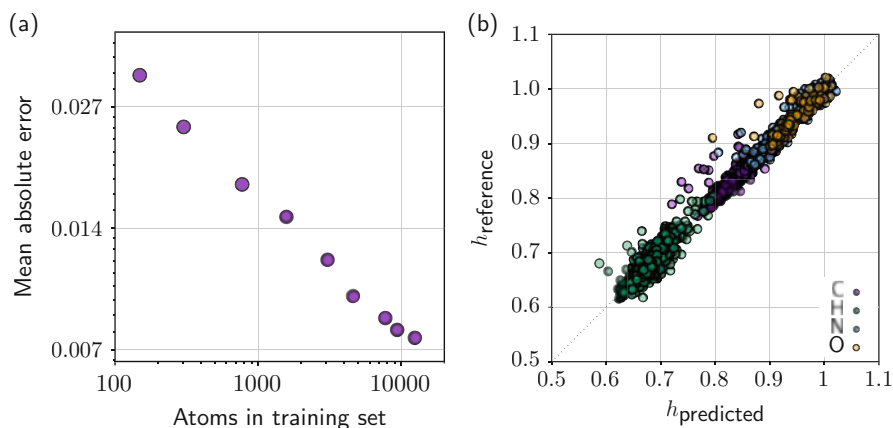
Sampling is the second corner stone of particle-based modeling in soft matter: teasing out a representative subset of conformational space is essential to extract reliable condensed-phase properties, from free energies to kinetics. The difficulty lies in assessing how much sampling is good enough. Umbrella sampling simulations are notoriously challenging, as they often hide slow conformational changes happening on degrees of freedom orthogonal to the reaction coordinate(s) (Neale et al. 2011).


**Fig. 1** (**a**) Saturation curve of the mean absolute error (MAE) as a function of training set size for Hirshfeld ratios. Note that both axes are on a log scale. (**b**) Correlation plot of out-of-sample predictions of the Hirshfeld ratio, $h$, for the ML model with largest training set size. The different chemical elements considered are color-coded

Unsupervised machine learning techniques may help systematically improve the sampling of conformational space within an umbrella sampling protocol (Ferguson et al. 2011).

The last decade has seen a significant leap forward in timescales accessible to computer simulations. Naively, reaching longer timescales means running ever-longer single trajectories. This bodes poorly with high-performance computer clusters, because one cannot parallelize a trajectory in time. A recent paradigm shift consisted in better leveraging the statistics contained in swarms of short trajectories covering the relevant parts of conformational space. For instance, Markov state models (MSMs) discretize the simulation trajectory in conformational space and in time to analyze its long-time kinetics (Noé 2008; Bowman et al. 2013). This framework has been shown to be extremely efficient in leveraging computational resources available – from distributed computing to high-performance clusters – even at a time when dedicated hardware has significantly pushed the state of the art for long trajectories (Shaw et al. 2014). The surge in high-throughput short simulations has helped approach the sampling problem more systematically: an adaptive sampling strategy spawns new simulations from poorly populated regions of conformational space, until convergence is found. Examples include protein-protein interactions (Plattner et al. 2017) and intrinsically disordered proteins (Kukharenko et al. 2016). These ideas rely on a simple concept: it is often easier to locally equilibrate highly diverse seed conformations than waiting for a single trajectory to cross all relevant barriers. This can be extended to a multiscale approach, in which relevant snapshots from computationally efficient CG trajectories are backmapped to provide these seed conformations at the atomistic level. This strategy can help cut down the computational investment of free-energy calculations

by more than tenfold (Menichetti et al. 2017b). Analogously, a more data-driven alternative has been proposed that tries to *extrapolate* possibly interesting new seed conformations from unsupervised machine learning techniques (Chiavazzo et al. 2017).

The discussion so far has focused on sampling conformational space. Recent developments in materials discovery are aiming at exploring chemical compound space – the diversity of chemical compounds – to extract thermodynamic properties. From a simulation perspective, this poses significant challenges due to the compounded issue of sampling both across conformational and chemical compound space. While unattainable at an atomistic resolution for the foreseeable future, coarse-graining can help address this: high-throughput coarse-grained simulations provide an ensemble study of the PMF for the insertion of solute molecules in a lipid bilayer. The study both predicted PMFs for more than 450,000 compounds and identified novel linear relationships between bulk measurements and features of the PMF (Menichetti et al. 2017a).

## 4 Analysis

Everything mentioned so far has focused on improving the quality of computer simulations by improving the force field or the sampling. This section instead consists of extracting insight or information from an *existing* simulation. Advanced data-driven and statistical methodologies have helped develop more robust methods to analyze computer simulations.

Some of the most interesting developments in the analysis of computer simulations have come from approaching the very concept of probability in a new way. The traditional approach to probability theory – the one taught most often at an elementary level – is so-called *frequentist*. It interprets probability from the frequency or propensity of an event to occur. Complementary to this is the Bayesian perspective: how can one infer a reasonable expectation given limited data and/or prior belief? It offers an elegant framework to evaluate the probability of a model $M$, when dealing with limited data $D$, as illustrated by Bayes' theorem:

$$P(M|D) = \frac{P(D|M)P(M)}{P(D)}, \tag{4}$$

where $P(M|D)$ and $P(D|M)$ are coined the posterior and the likelihood, respectively. Bayes' theorem has shown extremely useful because while the posterior is typically difficult to evaluate directly, the likelihood is often easier. In addition, it highlights the concept of prior information by means of $P(M)$, which encodes external information we may already hold on the validity of a model. For instance, physical laws and symmetries can naturally be enforced into the prior, effectively biasing the distribution of models to those that satisfy these constraints. Several examples illustrate the conceptual benefits of approaching a problem in a Bayesian framework:

- The weighted histogram method (WHAM) provides a minimum-variance estimator to best estimate the density of states of a system from different simulations (Ferrenberg and Swendsen 1989). These simulations provide complementary information to the system by encompassing a range of temperatures or different values of a collective variable in enhanced sampling. The likelihood incorporates the different Boltzmann distributions, while the prior ensures the normalization of probabilities. A derivation can be found elsewhere (Bereau et al. 2016; Ferguson 2017).
- MSMs build a discrete propagator for the time evolution of a simulation or single-molecule experiment (Noé 2008; Bowman et al. 2013). The simulation trajectory or experimental time series feeds into the likelihood, while the prior incorporates several constraints, most notably detailed balance.
- The MSM of a simulation trajectory can be further tuned to best incorporate external kinetic information. This is useful when a model is known to yield inconsistent kinetics, such as most coarse-grained models. So-called biased MSMs incorporate the coarse reference kinetic information (e.g., folding timescale or mean first passage time) as a prior, thereby selecting more consistent probabilistic models (Rudzinski et al. 2016). This conceptual framework was recently applied to incorporate experimental information to atomistic simulations (Olsson et al. 2017). More generally, the blending of physics-based models with experimental information has recently been subject to increasing interest (Perez et al. 2015, 2017).

Hidden Markov models (HMMs) add to MSMs the possibility of handling unobserved/hidden states (Rabiner and Juang 1986). While these states are not directly visible, the output, which is dependent on the state, is visible. One illustrative analogy consists of a hermit stuck inside a cave: he is attempting to forecast the weather but cannot see the sky outside. His best strategy is then to collect indirect evidence by analyzing the state of a seaweed – probabilistically related to the state of the weather – and thereby to *infer* the hidden state of the weather. HMMs can be thought as a nonlinear filtering process and have been shown to be useful in several studies, from the identification of liquid-ordered and liquid-disordered domains in lipid membrane simulations (Sodt et al. 2014) to the kinetics of protein-protein association (Plattner et al. 2017).

## 5    Outlook

Advanced data-driven methods and data-centric simulation protocols are rapidly impacting the field of soft matter and are here to stay: (i) Supervised machine learning techniques – primarily kernel methods and neural network – will likely contribute to more accurate and transferable force fields; (ii) high-throughput methods have already pushed the boundaries of conformational sampling and are likely to affect the systematic screening of compounds and materials; and (iii) Bayesian inference provides a conceptually appealing framework to combine

simulation data and physical laws and symmetries. Another notable method of interest is unsupervised machine learning, which looks for features/structure in "unlabeled" datasets, such as clustering or dimensionality reduction techniques (Fisher et al. 2014). The rapid ongoing developments of unsupervised machine learning are likely to significantly affect computer simulations in the years to come.

# Hydrodynamics in Motile Active Matter

# 68

Roland G. Winkler and Gerhard Gompper

## Contents

### Abstract

Hydrodynamic interactions determine the individual and collective behavior of nano- to micrometer size active objects such as swimming bacteria, sperm, algae, and synthetic colloidal microswimmers. Based on the Navier-Stokes equations of hydrodynamics, the major contributions to the flow field of a swimmer in a

Newtonian fluid are presented. The propulsion of beating and rotating filaments is shown to emerge as consequence of the distinct friction coefficients for parallel and perpendicular motion of the filament. Hydrodynamic interactions with a wall lead to a preferred alignment of a swimmer adjacent to a wall. Moreover, the rotational motion of a flagellar bundle of swimming bacteria combined with the counterrotation of the cell body leads to circular trajectories on a surface, where the handedness depends on the wall slip. Even more, the collective behavior of active matter is determined by hydrodynamic interactions, which is illustrated by cilia synchronization and the squirmer model for microswimmers.

# 1    Introduction

Active matter, whose agents consume internal energy or extract energy from the environment to propel themselves through a fluid, and are thus far from thermal equilibrium, is omnipresent in nature. Examples on the microscale range from an uncountable number of bacteria in soil or living in symbiosis with humans, spermatozoa in their attempt to fertilize an ovum, or algae harvesting sunlight in ponds and the ocean. Nowadays, synthetic active systems have been designed, which are powered by phoretic processes, e.g., thermophoresis or diffusiophoresis (Bechinger et al. 2016). In any case, the microswimmer is embedded in a fluid, and the fluid plays a decisive role for the propulsion itself as well as the collective behavior (Lauga and Powers 2009; Yeomans et al. 2014; Elgeti et al. 2015; Zöttl and Stark 2016; Winkler 2016). The physics ruling swimming on the micrometer scale is very different from that applying to swimming in the macro-world, although certain propulsion strategies are reminiscent of those on a macro-scale – bacteria, such as *Escherichia coli*, are propelled by rotating flagella, sperm perform a snakelike motion, and algae, such as *Chlamydomonas reinhardtii*, apply a breaststroke-type beating pattern. However, swimming at the micrometer scale is swimming at low-Reynolds numbers (Purcell 1977), where viscous damping by far dominates over inertia. Hence, swimming concepts of the high-Reynolds number macro-world are ineffective on small scales. In the evolutionary process, microorganisms acquired propulsion strategies, which successfully overcome and even exploit viscous drag.

Bacteria, sperm, or algae use flagella – filamentous structures protruding from their bodies – for their propulsion (cf. Fig. 1 for an illustration). In fact, eukaryotic flagella are very different from prokaryotic ones, which is manifested in the differing propulsion strategies (Elgeti et al. 2015). However, in any case, the thrust force emerges by the difference in the hydrodynamic friction of a (long) slender body parallel and perpendicular to the body major axis. Thereby, the flow field far from the swimmer is usually dominated by a "force dipole" and decays similarly with distance, independent of the propulsion mechanism, since a microswimmer is force- and torque-free. At walls, surface hydrodynamic interactions lead to a propulsion-dependent preferred alignment of a microswimmer (Spagnolie and Lauga 2012) or circular trajectories (Lauga et al. 2006; Di Leonardo et al. 2011; Hu et al. 2015a). Under shear flow, the hydrodynamic force-dipole flow field substantially affects
the overall viscosity (Saintillan 2010), and for suspensions of pushers, e.g., *E. coli* bacteria, "superfluidlike" behavior has been observed, where the viscous resistance to shear vanishes (López et al. 2015).

Active matter exhibits fascinating emergent collective phenomena. In nature, microswimmers can reach astonishing densities. Sperm cells are released by the millions to compete in the run for the egg, and biofilms are made up of billions of bacteria. Coordinated motion is exploited by spermatozoa of some species by self-assembling into unique train-like aggregates of hundreds or thousands of cells and thereby significantly increased sperm motility in a viscous environment (Sivinski 1984; Moore and Taggart 1995). Flagellated bacteria exhibit a particular mode of motion, where they migrate collectively over surfaces and are able to form stable aggregates, which can become highly motile (Heinrichsen 1978; Copeland and Weibel 2009; Kearns 2010). Here, cooperativity reaches a new level, and bacteria exhibit highly organized movements with remarkable large-scale patterns such as networks, complex vortices, or swarms (Copeland and Weibel 2009; Wensink et al. 2012). These type of patterns are remarkably similar to patterns appearing for other active matter systems such as schools of fish, flocks of birds, mammalian herds, or crowds of humans (Vicsek and Zafeiris 2012; Elgeti et al. 2015; Popkin 2016).

The various aspects touched above illustrate the fundamental importance of hydrodynamics for microscopic active matter ranging from swimming of individuals to large-scale collective migration. In the following, the low-Reynolds number aspects relevant for microswimmers will be briefly summarized, and various hydrodynamic phenomena will be presented.

## 2   Low-Reynolds Number Hydrodynamics

### 2.1   Equations of Motion

Typically, the dynamics of the (isothermal) incompressible fluid flow field surrounding a microswimmer is described by the Navier-Stokes equations

$$\rho \left( \frac{\partial}{\partial t} \boldsymbol{v} + (\boldsymbol{v} \cdot \nabla) \, \boldsymbol{v} \right) = -\nabla p + \eta \nabla^2 \boldsymbol{v} + \boldsymbol{f} \,, \qquad \nabla \cdot \boldsymbol{v} = 0, \qquad (1)$$

where $\boldsymbol{v}(\boldsymbol{r}, t)$, $p(\boldsymbol{r}, t)$, and $\boldsymbol{f}(\boldsymbol{r}, t)$ are the velocity, pressure, and volume-force density fields, respectively. At small Reynolds numbers $Re = \rho u L / \eta \ll 1$, where $\rho$ is the fluid mass density, $u$ the characteristic velocity, $L$ the size of the microswimmer, and $\eta$ the fluid viscosity, the inertia terms on the left-hand side of Eq. (1) can be neglected, and the equations reduce to the Stokes or creeping flow equations

$$\nabla p(\boldsymbol{r}) - \eta \nabla^2 \boldsymbol{v}(\boldsymbol{r}) = \boldsymbol{f}(\boldsymbol{r}) \,, \qquad \nabla \cdot \boldsymbol{v} = 0. \qquad (2)$$
