For illustration, the Reynolds number in water of a swimmer of length $L = 10 \, \mu\text{m}$, a velocity of $u = 50 \mu\text{m/s}$, and the kinematic viscosity $\nu = \eta / \rho = 10^{-6} \text{m}^2/\text{s}$ is $Re \approx 10^{-3}$. The Stokes equation (2) is linear and time independent. The consequences of this intrinsic symmetry under time reversal for microswimmers undergoing periodic shape changes were first expressed by Purcell (1977) and are now known as "scallop theorem", which can be stated as: if the shape changes displayed by a swimmer are identical when viewed in reverse order (time reversal symmetry), it will generate an oscillatory, but no directed motion (Purcell 1977; Lauga and Powers 2009; Yeomans et al. 2014; Elgeti et al. 2015). Thus, just by opening and closing its two shells, a mussel (scallop) cannot move forward at $Re \ll 1$. Microswimmers developed various strategies to beat the scallop theorem. Aside from many (elastic) degrees of freedom, they use specific propulsion mechanisms which are not time reversible – bacteria such as *E. coli* are propelled by rotating helical flagella bundles, sperm use sinusoidal bending waves propagating from head to tail, and algae, e.g., *Chlamydomonas*, use a nonreciprocal stroke pattern.

## 2.2 Solution of Stokes Equation

The linear Stokes equations (2) are easily solved analytically for an unbounded fluid. The respective fluid velocity field is

$$\boldsymbol{v}(\boldsymbol{r}) = \int \mathbf{Q}(\boldsymbol{r} - \boldsymbol{r}') \boldsymbol{f}(\boldsymbol{r}') \, d^3 r' \,, \qquad Q_{\alpha\alpha'}(\boldsymbol{r}) = \frac{1}{8\pi \eta r} \left[ \delta_{\alpha\alpha'} + \frac{r_\alpha r_{\alpha'}}{r^2} \right], \qquad (3)$$

where $\mathbf{Q}(\boldsymbol{r})$ is the well-known Oseen tensor, with the Cartesian components $Q_{\alpha\alpha'}$ ($\alpha, \alpha' \in \{x, y, z\}$) and $r = |\boldsymbol{r}|$ (Kim and Karrila 1991; Dhont 1996). The Oseen tensor, also denoted as Stokeslet, shows that hydrodynamic interactions are long ranged, with a $1/r$ decay like the Coulomb potential, and are anisotropic due to the incompressibility of the fluid. The Oseen tensor is the Green's function of the Stokes equation (2), which is evident, when the point force $\boldsymbol{f}(\boldsymbol{r}) = f_0 \delta(\boldsymbol{r}) \boldsymbol{e}$ in the direction $\boldsymbol{e}$ ($|\boldsymbol{e}| = 1$) is inserted. Then, Eq. (3) yields

$$v(r) = \frac{f_0}{8\pi\eta r}\left[e + \frac{(r\cdot e)r}{r^2}\right]. \tag{4}$$

The magnitude of the flow field is twice larger in the force direction than perpendicular to it.

## 2.3  Microswimmer Flow Field

Most microswimmers move autonomously, with no external force or torque applied, and hence the total force/torque of the swimmer on the fluid and *vice versa* vanishes. In the simplest case, which actually applies to many microswimmers like bacteria, spermatozoa, or algae, the far-field hydrodynamics (at distances from the swimmer much larger than its size) can well be described by a force dipole (Lauga and Powers 2009; Ishikawa 2009). This has been confirmed experimentally for *E. coli* (Drescher et al. 2010, 2011) and in simulations (Hu et al. 2015b). The flow field of *Chlamydomonas* is well reproduced by three Stokeslets (Drescher et al. 2010).

Mathematically, the flow field $v(r-r_0)$ of a hydrodynamic force dipole located at $r_0$ follows by a superposition of two Stokeslets (4) with opposite forces $f_0 = \pm f_0 e$ of equal magnitude at $r_0 \pm l/2$, where $l = le$ and $l$ is the distance between the Stokeslets. Taylor expansion to leading order in $|l|/|r - r_0|$ yields

$$v(r) = \frac{P}{8\pi\eta}v^{FD}(r)\,,\quad v^{FD}(r) = \frac{r}{r^3}\left[-1 + 3\frac{(r\cdot e)^2}{r^2}\right], \tag{5}$$

where $P = \pm f_0 l$ is the dipole strength. Note that the flow field of a force dipole decays as $1/r^2$ from the center of the dipole, faster than the force monopole or Stokeslet Eq. (3). The flow fields of hydrodynamic dipoles are shown in Fig. 2. In two dimensions, there are two inflow (left, right) and two outflow (top, bottom) regions, which are separated by the separatrices $z = \pm\sqrt{2}x$. In three dimensions, the outflow region is a cone.

Two classes of dipole swimmers can be distinguished. A swimmer with its "motor" in the back, and a passive body dragging along the surrounding fluid in front, creates a "pusher" flow field (cf. Fig. 2 (left)). Similarly, a swimmer with its "motor" in front, and the passive body dragging along the fluid behind, develops a "puller" flow field. This field follows by inversion of the arrows in Fig. 2 (left), i.e., the flow fields of pushers and pullers look similar but with opposite flow directions. This has important consequences for the interactions between swimmers and of swimmers with walls, as will be explained below.

The dipolar flow field and higher-order multipoles follow by a systematic expansion of the Oseen tensor in Eq. (3) (Kim and Karrila 1991; Pozrikidis 1992; Spagnolie and Lauga 2012). For a sphere of radius $R$, the swimmer far field up to order $\mathcal{O}(r^{-4})$ is dominated by the force dipole (FD) (Eq. (5)), source dipole (SD), force quadrupole (FQ), source quadrupole (SQ), and rotlet dipol (RD) contributions
**Fig. 2** (Left) Flow lines in the far-field of a hydrodynamic force dipole (5) and (Middle) a source dipole (7) oriented along the vertical direction. (Right) The flow field of the rotlet dipole (10) is rotational symmetric around the horizontal axis. The white crosses and bullets indicate the intersections of the flow lines with the plane

$$
\boldsymbol{v}(\boldsymbol{r}) = \kappa^{FD}\boldsymbol{v}^{FD}(\boldsymbol{r}) + \kappa^{SD}\boldsymbol{v}^{SD}(\boldsymbol{r}) + \kappa^{FQ}\boldsymbol{v}^{FQ}(\boldsymbol{r}) + \kappa^{SQ}\boldsymbol{v}^{SQ}(\boldsymbol{r})
$$
$$
+ \kappa^{RD}\boldsymbol{v}^{RD}(\boldsymbol{r}) + \mathcal{O}(r^{-4}), \tag{6}
$$

where

$$
\boldsymbol{v}^{SD}(\boldsymbol{r}) = -\frac{1}{r^3}\left(-\boldsymbol{e}_z + \frac{3z\boldsymbol{r}}{r^2}\right), \tag{7}
$$

$$
\boldsymbol{v}^{FQ}(\boldsymbol{r}) = \frac{1}{r^3}\left[\left(1 - \frac{3z^2}{r^2}\right)\boldsymbol{e}_z + \left(\frac{15z^3}{r^4} - 9\frac{z}{r^2}\right)\boldsymbol{r}\right], \tag{8}
$$

$$
\boldsymbol{v}^{SQ}(\boldsymbol{r}) = \frac{3}{r^4}\left(\frac{5z^2\boldsymbol{r}}{r^3} - \frac{2z\boldsymbol{e}_z + \boldsymbol{r}}{r}\right), \tag{9}
$$

$$
\boldsymbol{v}^{RD}(\boldsymbol{r}) = \frac{3z\boldsymbol{e}_z \times \boldsymbol{r}}{r^5}, \tag{10}
$$

which decay like $r^{-2}, r^{-3}, r^{-4}$, and $r^{-3}$, respectively (Spagnolie and Lauga 2012). Note that in Eq. (7) the swimming direction $\boldsymbol{e}$ points along the positive $z$-axis, i.e., $\boldsymbol{e} \equiv \boldsymbol{e}_z$. The various factors $\kappa$ account for the strength of the respective multipole, where $\kappa^{FD} = P/8\pi\eta$, $\kappa^{SD} = -v_0 R^3/2$, and $\kappa^{SQ} = 3PR^3/8\pi\eta$.

Aside from the force-dipole term, most relevant for microswimmer are the source-dipole term $(1/r^3)$ due to the volume of the swimmer and the rotlet-dipole term $(1/r^3)$, e.g., for *E. coli* bacteria by the opposite rotation of the cell body and the flagella bundle.

## 3 Swimming Due to Flagellar Motion

### 3.1 Friction of Slender Body

Many microorganisms are propelled in a fluid by beating or rotating a flagellum. Thereby, a swimmer exploits the viscous frictional properties of the fluid environment, specifically, the anisotropic friction of a slender body. The frictional anisotropy can be demonstrated for a long and thin rod of radius $R$ and length $L$. Considering the rod as composed of a sequence of beads with no-slip boundary conditions, the beat velocity is equal to the fluid velocity of Eq. (3). Under the influence of an external constant force $\boldsymbol{F} = F\boldsymbol{e}$, the average velocity of a rod aligned along the $z$-axis of the reference system is (Elgeti et al. 2015)

$$\boldsymbol{v}_{\text{rod}} = F\frac{\boldsymbol{e} + (\boldsymbol{e}_z \cdot \boldsymbol{e})\boldsymbol{e}_z}{4\pi\eta L^2} \int_{2R}^{L} \frac{L-s}{s} ds \qquad (11)$$

in the limit of a continuous rod. The lower cutoff of the integral excludes a region of the thickness of the rod. Because $(\boldsymbol{e}_z \cdot \boldsymbol{e})\boldsymbol{e}_z$ is 1 and 0 for parallel and perpendicular orientation of the force with the rod axis, respectively, evaluation of the integral and the relation $\boldsymbol{F} = \zeta_\parallel \boldsymbol{v}_\parallel + \zeta_\perp \boldsymbol{v}_\perp$ yields

$$\zeta_\perp = 2\zeta_\parallel, \qquad \zeta_\perp = \frac{4\pi\eta L}{\ln(L/2R)} \qquad (12)$$

in the asymptotic limit of a long rod. Hence, pulling a rod along its axis is easier than perpendicular to it. The logarithmic divergence is a result of the long-range nature of hydrodynamic interactions between different parts of the rod. Thus, hydrodynamic interactions reduce the friction coefficient compared to that of a rod of hydrodynamically noninteracting beads, where $\zeta_\perp = \zeta_\parallel \sim L$. Corrections of the friction coefficients for a more precise account of hydrodynamics for a cylinder have been calculated (Tirado et al. 1984).

### 3.2 Propulsion by Beating Flagella

The time-dependent shape of a sinusoidally beating flagellum with a planer beat ($xz$-plane) $z(x, t)$ and its local velocity $v_z(x, t)$ at the position $x$ along its contour are described by

$$z(x, t) = A\sin(kx - wt), \quad v_z(x, t) = \frac{\partial z}{\partial t} = -A\omega\cos(kx - \omega t), \qquad (13)$$

where $A$ is the amplitude, $\omega$ the frequency, and $k$ the wave number. Decomposing the velocity $\boldsymbol{v}(x, t) = (0, 0, v_z(x, t))^T$ into a component parallel $\boldsymbol{v}_\parallel = (\boldsymbol{v} \cdot \boldsymbol{t})\boldsymbol{t}$ and perpendicular $\boldsymbol{v}_\perp = \boldsymbol{v} - \boldsymbol{v}_\parallel$ to the local tangent vector $\boldsymbol{t} \sim (1, 0, Ak\cos(kx - \omega t))^T$ yields

$$\boldsymbol{v}_\parallel = -\frac{A^2\omega k \cos^2(kx - \omega t)}{1 + A^2 k^2 \cos^2(kx - \omega t)}\, \boldsymbol{t}. \tag{14}$$

The separation $\boldsymbol{F} = \zeta_\parallel \boldsymbol{v}_\parallel + \zeta_\perp \boldsymbol{v}_\perp$ gives the average force of the flagellum in the swimming direction

$$F_z = (\zeta_\parallel - \zeta_\perp)\frac{1}{L}\int \frac{A^2\omega k \cos^2(kx - \omega t)}{1 + A^2 k^2 \cos^2(kx - \omega t)}\, dx, \tag{15}$$

while the average force in the perpendicular direction vanishes. For small beating amplitudes, Eq. (15) can easily be integrated, which yields the average propulsion force

$$F_z = \frac{1}{2}(\zeta_\parallel - \zeta_\perp)A^2\omega k, \tag{16}$$

and the swimming velocity, $v_{\text{flag}} \approx F_z/\zeta_\parallel$, (Gray and Hancock 1955)

$$v_{\text{flag}} = -\frac{1}{2}\left(\frac{\zeta_\perp}{\zeta_\parallel} - 1\right)A^2\omega k\,. \tag{17}$$

This simplified calculation shows several important aspects of flagellar propulsion. First, swimming is only possible due to the frictional anisotropy, i.e., $\zeta_\parallel \neq \zeta_\perp$. Second, for a traveling wave in the positive $x$-direction, the flagellum moves in the negative $x$-direction, i.e., movement is opposite to the direction of the traveling wave. Third, the swimming velocity increases linearly with the beating frequency $\omega$ and the wave vector $k$ but quadratically with the beating amplitude $A$. And finally, the swimming velocity is independent of the fluid viscosity for a given beating amplitude.

### 3.3 Propulsion by Helical Flagella

Propulsion by rotation of helical flagella can also be illustrated by resistive force theory. Rotation of a rodlike segment in the direction $\boldsymbol{v}'$, where $v' = |\boldsymbol{v}'| = R_h\Omega$ (cf. Fig. 3), with $R_h$ the helix radius and $\Omega$ its rotation frequency, yields the thrust force contribution $F_T$ and the torque $M_z$ (Lauga and Powers 2009)

$$F_T = (\zeta_\parallel - \zeta_\perp)v' \cos\vartheta \sin\vartheta \approx (\zeta_\parallel - \zeta_\perp)\vartheta\, R_h\Omega, \quad M_z = \zeta_\perp R_h v' = \zeta_\perp R_h^2\Omega, \tag{18}$$

where $\vartheta \ll 1$ is assumed. Hence, the relation between force, torque, and translational and rotational velocity is
**Fig. 3** Helical segment moving in a viscous fluid. Only half of a helical pitch is shown. The drag-based thrust force $F_T$ appears by the rotation of the red rodlike segment in the direction $v'$. The orientation angle $\vartheta$ is related with the pitch angle by $\pi/2 - \vartheta$. (From Elgeti et al. 2015)

$$\begin{pmatrix} F_z \\ M_z \end{pmatrix} = \begin{pmatrix} \zeta_\parallel & -(\zeta_\perp - \zeta_\parallel)\vartheta R_h \\ -(\zeta_\perp - \zeta_\parallel)\vartheta R_h & \zeta_\perp R_h^2 \end{pmatrix} \begin{pmatrix} v_z \\ \Omega \end{pmatrix}, \tag{19}$$

with $F_z = \zeta_\parallel v_z$ in case of no helix rotation. For a spherical cell body of radius $R_b$ and with the assumption $R_b \ll L$, the frictional body force $F_b$ and the body torque $M_b$ are

$$F_b = \zeta_b v_z, \quad M_b = -\zeta_r^b \omega_b, \tag{20}$$

where $\zeta_b = 6\pi \eta R_b$ and $\zeta_r^b = 8\pi \eta R_b^3$ are the translation and rotational friction coefficients. The helix is driven by a rotary motor with the frequency $\Omega_m$ relative to the body. In response, the helix and body rotate with the frequencies $\Omega$ and $\Omega_b$. These frequencies are related by $\Omega + \Omega_b = \Omega_m$. Since the whole bacterium is force- and torque-free, i.e., $F_z + F_b = 0$ and $M_z + M_b = 0$, its swimming velocity is obtained as

$$v_z \approx \vartheta \left( \frac{\zeta_\perp}{\zeta_\parallel} - 1 \right) \frac{\zeta_r^b}{\zeta_\perp R_h} \Omega_m. \tag{21}$$

The friction coefficient $\zeta_b$ does not appear, since $\zeta_\parallel \gg \zeta_b$ ($L \gg R_b$) is assumed. Evidently, swimming is again – as in the sperm case – only possible due to frictional anisotropy. Moreover, $v_z$ depends linearly on the body rotational friction coefficient. Hence, without body, the bacterium could not swim. Due to the approximation $\vartheta \ll 1$, $v_z$ depends linearly on the orientation angle $\vartheta$. Changing the handedness of the helix leads to a change of the swimming direction.

Note that a helix driven by an external torque also moves forward; however, it is not torque-free, and therefore is not an autonomous swimmer.

## 3.4    Bacteria Swimming

A wide variety of bacteria exploits the propulsion strategy described in Sect. 3.3. Different species possess various numbers and differing arrangements of flagella. According to the arrangement, flagellated bacteria are classified as monotrichous bacteria with a single flagellum only, lophotrichous bacteria with multiple flagella located at a particular spot on their surface, amphitrichous bacteria with a single flagellum on each of the two opposite ends, and peritrichous bacteria which are covered by multiple flagella pointing in all directions. Prominent examples of peritrichous bacteria are *E. coli*, *Salmonella typhimurium*, *Rhizobium lupini*, or *Proteus mirabilis*, to name just a few. A flagellum is rotated by a motor complex, which consists of several proteins, and is anchored in the bacterial cell wall (Berg 2003). Bacteria like *E. coli* swim in a "run-and- tumble" motion (Berg 2003). In the "run" phase, the helical flagella are left-handed, and they rotate counterclockwise. The flagella form a bundle, and the bacterium moves forward in a direction determined by its long axis. At the beginning of the "tumble" phase, a flagellum rotational direction is reverted to clockwise. The flagellum leaves the bundle, which implies a random reorientation of the bacterium. The reversal of the rotational direction is accompanied by a change of the helical handedness from left-handed to right-handed, and the flagellum undergoes a polymorphic transition, i.e., assumes a different pitch and radius (Calladine 1975; Macnab 1977). At the end of the tumbling phase, all flagella start to rotate again in the same counterclockwise direction, the bundle reforms, and the bacterium returns to a directional motion. The flagella of bacteria like *Rhizobium meliloti* or *Rhizobium lupini* are only capable of limited polymorphic transitions, and their motors are unidirectional (Platzer et al. 1997). These bacteria modulate the rotation speed of individual motors to induce tumbling.

Since bacterial cells are force- and torque-free, the rotational motion of the flagellum bundle leads to a counterrotation of the cell body, i.e., swimming bacteria possess a rotlet dipole (cf. Eq. (10)). This has consequences for their hydrodynamic interactions, specifically with surfaces and interfaces.

The flow field of an *E. coli* bacterium obtained from experiment and simulations is presented in Fig. 4. In both cases, the far field is well described by the force-dipole field of Eq. (5) (Drescher et al. 2011; Hu et al. 2015b).

## 4    Surface Interaction

## 4.1    Dipole Swimmer Near a Wall: Swimming with an Image

The swimming behavior of microorganisms is typically altered by the presence of nearby obstacles or boundaries. In fact, most bacteria in nature live on surfaces, e.g., in biofilms (Copeland and Weibel 2009; Spagnolie and Lauga 2012). Correspondingly, attraction of such microorganisms to surfaces is of major importance
**Fig. 4** Flow field of *E. coli* bacteria from (left) experiment (Drescher et al. 2011) and (right) simulations (Hu et al. 2015b). In simulations, a system with periodic boundary conditions is considered, which yields closed flow lines in contrast to the flow lines of the experimental bulk system. The logarithmic color scheme (right) indicates the magnitude of the flow speed scaled by the bacterial swimming velocity. (From Drescher et al. 2011 and Hu et al. 2015b)

and determines their microbial activity. Part of the attraction originates from hydrodynamic interactions of the swimmer with the surface. This is easily illustrated by a force dipole in front of a (slip) surface. The flow field of such a dipole can be obtained by the image method known from electrostatics. Considering, for simplicity, a planar wall with slip boundary conditions (cf. Fig. 5), at $z = 0$, the velocity field $v_{w,z}^{FD}$ perpendicular to the surface vanishes identically, i.e., $v_{w,z}^{FD}(z = 0) \equiv 0$. The flow field is then given by

$$v_w^{FD}(r - r_0) = v^{FD}(r - \mathbf{r}_0; e) + v^{FD}(\mathbf{r} - r_0'; e'), \tag{22}$$

with $r_0 = (x_0, y_0, z_0)$, $r_0' = (x_0, y_0, -z_0)$, where $z_0 > 0$ and $e'$ the mirror image of $e$ with respect to the $z = 0$ plane. The dipole experiences a flow field and, hence, a force near the surface, which is determined by the hydrodynamic interactions between the dipole and its image. As a consequence, the dipole swimmer is moving toward the surface with the velocity

$$v_{w,z}^{FD}(z_0) = -\frac{P}{32\pi\eta z_0^2}\left[1 - 3(e \cdot e_z)^2\right], \tag{23}$$

because $(e' \cdot e_z)^2 = (e \cdot e_z)^2$. The result shows that the hydrodynamic force decays as a dipole flow field quadratic with the distance from the wall. The exact solution for a no-slip wall (Berke et al. 2008) yields the same functional dependence on the angle and the wall distance as Eq. (23), only the numerical prefactor in Eq. (23) is smaller by a factor 2/3.

The direction of the flow field depends on the dipole moment and its orientation. The hydrodynamic force is attractive to the wall for pusher ($P > 0$, sperm or
**Fig. 5** Schematic representation of a dipole swimmer (pusher) near a wall. An image dipole ensures the correct boundary conditions at the impenetrable slip wall

bacteria) as long as $\cos \vartheta = (e \cdot e_z) < 1/\sqrt{3}$. Hence, pushers aligned parallel to the surface experience an attractive force. However, for pullers ($P < 0$, *Chlamydomonas*) hydrodynamic interactions are repulsive when they swim parallel to the wall, but they are attractive, when their orientation is nearly perpendicular to the wall. Yet, the average of the wall-induced interaction over a population of randomly oriented microorganisms is exactly equal to zero in a 3D system, since $\int v_{w,z}^{FD}(z_0) \sin \vartheta \, d\vartheta = 0$. As a consequence, the surface-induced velocity (23) alone cannot explain surface accumulation for initially randomly oriented incoming swimming cells.

The surface-induced hydrodynamic flow field is inhomogeneous and, thus, exerts a torque on the cell, which leads to a preferred alignment. The corresponding rotation rate is given by (Berke et al. 2008):

$$\Omega_r(\vartheta, z) = -\frac{3P \cos \vartheta \sin \vartheta}{64\pi \eta z^3} \left( 1 + \frac{\gamma^2 - 1}{2(\gamma^2 + 1)} (1 + \cos^2 \vartheta) \right), \qquad (24)$$

where $\gamma$ is the aspect ratio of the anisotropic swimmer. Since $\gamma$ is typically larger than unity, the sign of $\Omega_r$ is determined by that of $P$ and the product $\cos \vartheta \sin \vartheta$. When $0 \leq \vartheta \leq \pi/2$ or $\pi \leq \vartheta \leq 3\pi/2$, for a pusher the product is positive, and the rotation is negative, leading to parallel alignment with the surface. For the other angles, the rotation is positive, which leads to alignment too. Consequently, all pushers are oriented parallel to a surface and are attracted by the flow field. Pullers ($P < 0$) align normal to the surface. As both pushers and pullers come closer to the surface, higher orders in the multipole expansion become important (Spagnolie and Lauga 2012).

## 4.2    Bacteria Swimming at Surfaces

As a consequence of the rotlet dipole of bacteria by counterrotation of cell body and flagella bundle, hydrodynamic interactions lead to circular trajectories of bacteria at surfaces (Lauga et al. 2006; Di Leonardo et al. 2011; Hu et al. 2015a). Thereby, clockwise and counterclockwise trajectories appear, governed by the respective no-slip or slip boundary condition (cf. Fig. 6) (Lauga et al. 2006; Di Leonardo et al. 2011; Hu et al. 2015a; Elgeti et al. 2015; Elgeti and Gompper 2016). Moreover, the slip length determines the curvature of the circle. In qualitative agreement with experiments and quantitative agreement with theory and simulations, the trajectory curvature can well be described by

$$\kappa = \kappa_\infty + \frac{\kappa_0 - \kappa_\infty}{1 + b/h} \qquad (25)$$

as function of the slip length $b$, where $\kappa_0 < 0$ and $\kappa_\infty > 0$ are the curvatures for the slip lengths $b = 0$ (no-slip) and $b = \infty$ (perfect slip), respectively, and $h$ is an effective gap size between of the cell body and the surface (Hu et al. 2015a).

As found experimentally, the radius of the circle depends on the size of the cell body and increases linearly with body size. This fact can be exploited to separate cells of different sizes. As suggested by Hu et al. (2015a), a patterned surface with alternating hydrophobic and hydrophilic stripes leads to a preferred diffusion parallel to the stripes for radii on the order of the stripe widths, whereas for larger radii isotropic diffusion is obtained.

**Fig. 6** (Left) Counterclockwise and clockwise circular trajectories from hydrodynamic simulations of an *E. coli*-type bacterium swimming near homogeneous surfaces with different slip lengths $b$ as indicated. (Right) Effective curvatures of cells of various lengths, $l_b$, as function of the slip length. (From Hu et al. 2015a)

# 5 Squirmer: A Generic Model of Hydrodynamic Microswimmers

Generic models, which capture the essential swimming aspects, are crucial in theoretical studies of microswimmers. On the one hand, they help to unravel the relevant interaction mechanisms and, on the other hand, allow for the study of sufficiently large number of swimmers. A prominent example is the squirmer model (Lighthill 1952; Blake 1971). Originally, it was intended as a model for ciliated microswimmers, such as Paramecia. Nowadays, it is considered as a generic model for a broad class of microswimmers, ranging from diffusiophoretic particles to biological cells and has been applied to study collective effects in bulk, at surfaces, and in narrow slits (Ishikawa et al. 2006; Llopis and Pagonabarraga 2010; Zöttl and Stark 2014; Theers et al. 2016).

In its simplest form, a squirmer is represented as a spherical rigid colloid with a prescribed surface velocity. Restricting the surface velocity to be tangential, the slip velocity on the sphere surface can be expressed in terms of derivatives of Legendre polynomials, where the spherical squirmer is typically characterized by two modes only accounting for its swimming velocity ($B_1$) and its force dipole ($B_2$) (Ishikawa et al. 2006; Llopis and Pagonabarraga 2010). Explicitly, the leading contributions yield the slip velocity on the colloid surface (Ishikawa et al. 2006; Llopis and Pagonabarraga 2010; Theers et al. 2016)

$$\boldsymbol{v}_{sq} = (B_1 \sin \vartheta + B_2 \sin \vartheta \cos \vartheta)\boldsymbol{e}_\vartheta = B_1(\sin \vartheta + \beta \sin \vartheta \cos \vartheta)\boldsymbol{e}_\vartheta. \qquad (26)$$

The parameter $B_1 = 2v_0/3$ is related to the swimming velocity, $v_0$, and $\beta = B_2/B_1$ accounts for the force dipole. The angle $\vartheta$ is measured with respect to the propulsion direction in a body-fixed reference frame. Higher-order terms can easily be taken into account (Elgeti et al. 2015; Llopis and Pagonabarraga 2010). The term with $B_2$ (or $\beta$) distinguishes various propulsion patterns, namely, pushers ($\beta < 0$), pullers ($\beta > 0$), and neutral squirmers ($\beta = 0$), corresponding, e.g., to *E. coli*, *Chlamydomonas*, or *Volvox*, respectively.

The far field of a squirmer is well described by the flow fields of a force dipole (FD), a source dipole (SD), and a source quadrupole (SQ)

$$\boldsymbol{v}(\boldsymbol{r}) = \kappa^{FD}\boldsymbol{v}^{FD}(\boldsymbol{r}) + \kappa^{SD}\boldsymbol{v}^{SD}(\boldsymbol{r}) + \kappa^{SQ}\boldsymbol{v}^{SQ}(\boldsymbol{r}) + \mathcal{O}(r^{-5}), \qquad (27)$$

where the various terms are given in Eq. (5), (7), and (9).

The assumption of a spherical shape is adequate for swimmers like, e.g., *Volvox*; however, the shapes of other microswimmers (*E. coli, Chlamydomonas, Paramecium*) are nonspherical. Here, an extension of the squirmer concept to spheroidal objects has been proposed (Keller and Wu 1977; Theers et al. 2016). Figure 7 depicts flow fields of a spheroidal squirmer with the aspect ratio of two for the various kinds of dipolar terms in the laboratory and body-fixed reference frame. The near-field modifications by the finite-size swimmer is clearly visible in
**Fig. 7** Flow streamlines of isolated spheroidal squirmers. The top row corresponds to the laboratory reference frame and the bottom row to the body-fixed reference frame. (Left) Flow field of a pusher ($\beta = -3$), (Middle) a neutral squirmer $\beta = 0$, and (Right) a puller ($\beta = 3$). The magnitude of the relative velocity $3v/2v_0$ is color coded logarithmically. (The puller figures are from Theers et al. 2016)

comparison with Fig. 2. Moreover, pusher and puller exhibit a stagnation point in front or back, respectively, in the body-fixed reference frame for $|\beta| > 1$.

## 6    Collective Phenomena

Collective phenomena governed by hydrodynamic interactions appear on the level of flagella or cilia as well as on the scale of the microswimmers themselves. Examples on the flagella scale are the synchronization of flagella rotation in the formation of bacteria bundles (Reichert and Stark 2005; Qian et al. 2009; Reigh et al. 2012) or the development of metachronal waves in arrays of beating cilia (Sleigh 1962; Elgeti and Gompper 2013).

The importance of hydrodynamic interactions on the collective dynamics of microswimmers is most easily demonstrated for squirmers. On the one hand, the effect of the force dipole (pusher, puller, neutral squirmer) is captured, and, on the other hand, both far- and near-field hydrodynamics is taken into account, and their relative importance can be elucidated. In accordance with bacteria in biofilms, the collective behavior of squirmers is either studied by strictly two-dimensional motion with three-dimensional hydrodynamic interactions or by swimmers confined in a narrow slit with a respective limitation of hydrodynamic interactions by the surfaces. In the latter case, the boundary interactions play a major role (Theers et al. 2018).

## 6.1    Cilia Synchronization: Metachronal Waves

Propulsion of unicellular and multicellular organisms by cilia is omnipresent. Thereby, fluid is pumped across their surface by anchored motile cilia (flagella) (Sleigh 1962). Moreover, in higher organisms and humans, cilia are involved in moving mucus in the lungs (Afzelius 1976), the emergence of the embryonic left-right asymmetry (Cartwright et al. 2004), and intercellular communication (Wang et al. 2006). Already in the 1960s, Sleigh (1962) observed that arrays of cilia beat neither randomly nor synchronously but in a wave pattern called a metachronal wave (MCW). Several theoretical models have been proposed to shed light onto the metachronal coordination by hydrodynamic interactions. A model of coupled rotating spheres placed near a no-slip wall proves useful in clarifying the diverse types of MCWs observed in nature (Brumley et al. 2012).

Deeper insight into coordinated beating is gained by simulations of anchored semiflexible filaments with a nonreciprocal beat, where a "trigger" mechanism switches between the power and recovery stroke. Simulations of an array of $60 \times 60$ cilia in a 3D explicit fluid yield metachronal waves emerging autonomously, despite the presence of significant noise (Elgeti and Gompper 2013). The beat pattern of an individual cilium can react to the surrounding fluid flow, because the model only imposes time-dependent curvature forces and employs geometric thresholds for the switch between power and recovery stroke, and vice versa. Figure 8 displays the beating pattern of an individual filament with an asymmetric power and recovery stroke. The hydrodynamically induced metachronal waves are visible in Fig. 8 (right).

## 6.2    Aggregation of Squirmers

The interactions between microswimmers depend on their relative orientation. Thereby, interactions of pushers and pullers in equivalent positions and orientations are equal in magnitude but opposite in sign, because of the opposite sign of their dipole strength $P$. Since swimmers typically meet at different relative positions and orientations and due to the stochastic motion of many interacting objects, scattering of microswimmers occurs, and cooperative swimming is the exception rather than
**Fig. 8** (Left) Top and side view of the beat pattern of the computational cilia model. Subsequent conformations are equally spaced in time. The fast, planar power stroke (frames 1−5) continues until a positive curvature threshold in the lower part of the cilium is reached. The cilium then switches to a slow, out-of-plane recovery stroke (frames 6−17), which ends when a negative curvature threshold is exceeded. (Right) Simulation snapshot of an array of $40 \times 40$ beating cilia. Cilia are placed on a square lattice. The metachronal wave is easily recognized by the lines of fully extended cilia during the power stroke. (From Elgeti and Gompper 2013)

the rule in dilute suspensions (Ishikawa et al. 2006; Llopis and Pagonabarraga 2010; Götze and Gompper 2010). This applies to spherical as well as spheroidal squirmers. However, hydrodynamic interactions with confining surfaces in a slit geometry stabilize the cooperative swimming of spheroidal pulling squirmers, which emphasizes the relevance of hydrodynamic interactions in confinement (Theers et al. 2016).

Self-propelled particles exhibit a strong tendency for clustering and phase separation. The origin of this behavior is the blockage of motion when several particles collide with each other (cf. Fig. 9). The particular (small) cluster would dissolve after a time corresponding to the reorientation time of a swimmer. Interactions and collisions with other particles are controlled by the density and propulsion velocity $v_0$. Hence, if other particles collide before the original cluster dissolved, the cluster grows. This behavior already occurs for active Brownian particles (Bialké et al. 2012; Buttinoni et al. 2013; Redner et al. 2013; Palacci et al. 2013; Marchetti et al. 2016; Bechinger et al. 2016), i.e., for self-propelled particles with steric but without hydrodynamic interactions. The separation into a dense solid (2D) (Bialké et al. 2012; Marchetti et al. 2016; Bechinger et al. 2016) or fluid (3D) (Wysocki et al. 2014) phase and a dilute gas phase is denoted as motility-induced phase separation (MIPS) (Cates and Tailleur 2015). Hydrodynamic interactions strongly modify the collective behavior.

The collective swimming patterns of spherical squirmers in 2D exhibit a strong dependence on the sign of the force dipole (far field). Moreover, hydrodynamic near-field effects play an important role. The phase behavior of neutral squirmers ($\beta = 0$) with only far-field interactions is similar to that of active Brownian particles without hydrodynamic interactions (Yoshinaga and Liverpool 2017). The additional contribution due to hydrodynamics is an enhanced reorientation of the squirmers, which suppresses phase separation. Squirmer ensembles in 2D without thermal motion exhibit clustering for pullers and pushers due to near-field hydrodynamic interactions. Neutral squirmers spontaneously develop polar order and collectively
**Fig. 9** (Left) Aggregation and cluster formation of squirmers by blockage. (Middle) Fluid phase of spherical squirmers and (Right) cluster of spheroidal squirmers confined in a slit at the two-dimensional packing fraction $\phi^{2D} = 0.5$ and the Péclet number $Pe = 12$. The Péclet number is defined as $Pe = v_0/2b_z D_R^\perp$, where $b_z$ is the longer spheroid semiaxis and $D_R^\perp$ the rotational diffusion coefficient around the minor axis

move in a preferred direction (Kyoya et al. 2015; Yoshinaga and Liverpool 2017). Yet polar order is destroyed by thermal fluctuations. With fluctuations, all spherical squirmers exhibit cluster formation, however, with distinct characteristics. Here, cluster formation is most pronounced for pullers (Alarcón et al. 2017).

The anisotropic shape of a spheroidal squirmer enhances cluster formation compared to spherical swimmers (cf. Fig. 9) (Ginelli et al. 2010; Abkenar et al. 2013). This applies to ABPs as well as hydrodynamically coupled swimmers. Thereby, hydrodynamic interactions suppress motility-induced phase separation for spheres, whereas for spheroids hydrodynamic interactions enhance cluster formation in a slit geometry (Theers et al. 2018).

# 7    Conclusions

Hydrodynamic interactions are essential for active matter, specifically biological microswimmers. They are not only fundamental for the propulsion of microswimmers but also determine their behavior next to surfaces as well as the emergent collective dynamics and structures. Hydrodynamic interactions imply a very rich dynamics, which depends on the detailed swimming mechanism. For a fundamental understanding of the fluid-mediated interactions, consideration of the dominant multipole terms might suffice. However, the detailed collective properties depend also on the actual near-field flow. Hence, the full flow field has to be taken into account for a quantitative understanding of the local features of microswimmer aggregates. As a general conclusion, hydrodynamic interactions have to be taken into account for a qualitative and quantitative understanding of the emerging properties of active matter.

**Abstract**

Chapters in this section introduce recent advances in computational models and numerical methods for establishing a physics-based understanding of crystal plasticity, starting from atomistic models of dislocations, to discrete models of dislocation line networks, to continuum descriptions of microstructure evolution.

## 1    Purpose of Physics-Based Modeling

The plastic deformation of crystalline materials (especially metals and alloys) is a fundamental process that has been critically important for the technologies of mankind for thousands of years. Understanding the process of crystal plasticity is an essential step for addressing many of today's technological needs, by enabling

precise control of the deformation process and design of new materials with tailored properties. The application areas where such an understanding has an impact include metal forming, machining, additive manufacturing, and material design for high-temperature components (such as turbine blades), to name a few. Crystal plasticity also plays an important role in other processes such as ductile fracture and fatigue.

Our initial understanding of crystal plasticity came from experiments (such as tensile and torsion tests) and phenomenological continuum theories (such as $J_2$ plasticity theory) that are consistent with observations and symmetry requirements. With the latest advances of experimental characterization techniques (e.g., accurate 3D representation of grain structure of a polycrystal) and computational tools (e.g., parallel processors, GPUs), physics-based models of crystal plasticity that account for granular, subgranular, and atomic-level processes are becoming ever more realistic and predictive. Bridges between such models at different scales are starting to be established. A well-connected multiscale framework for crystal plasticity may be established in the near future. Such a framework is needed to realize the full potential of physics-based predictive models in order to make an impact on application areas in manufacturing and materials design.

In this section, we present ten chapters that introduce recent advances on physics-based crystal plasticity models at different scales, starting from atomistic models of the dislocation core, to discrete models of dislocation line networks, to continuum descriptions of subgranular and intergranular microstructure evolution. In addition to providing new researchers entering this field an introduction to the modeling techniques they may want to learn, we hope that by looking at the latest advances at crystal plasticity models at all scales, this section also helps to identify the opportunities and the gaps in the multiscale framework that may also be useful to an experienced researcher.

## 2    Multiscale Challenge of Crystal Plasticity

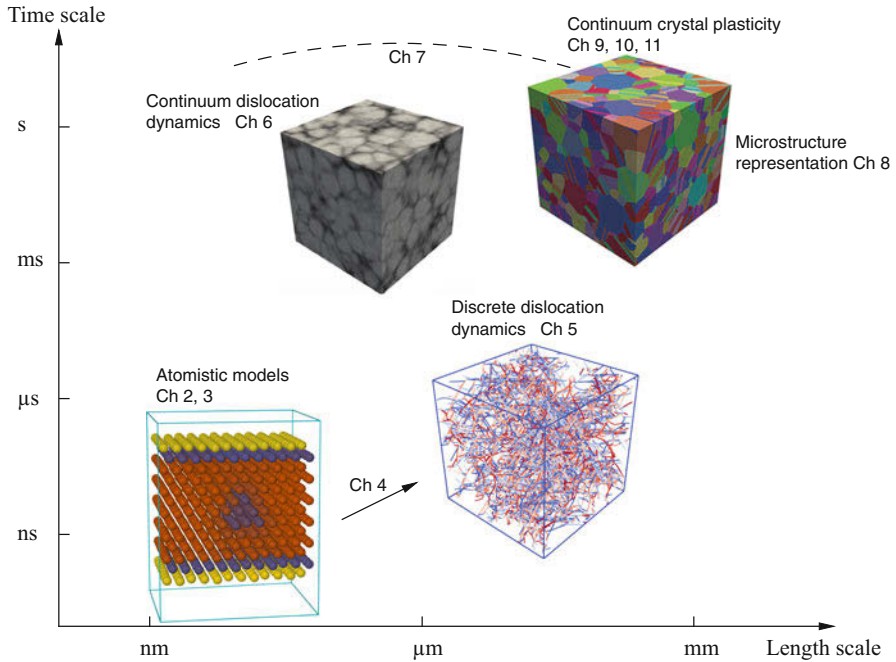
Under most conditions (e.g., temperature below $\sim 1/3$ of the melting point, strain rate below $\sim 10^5\,\text{s}^{-1}$), the plastic deformations of metals and alloys are predominantly carried out by the motion of dislocations, which are line defects in the crystal (Hull and Bacon 2011; Cai and Nix 2016; Anderson et al. 2017). This is why dislocations feature prominently in physics-based models of crystal plasticity. At the lower limit of the length scales of interest here, the electronic structure in the atomistic region around the dislocation core determines the energetics and mobility of the dislocation. At the upper limit of the length scale, engineering materials are usually available in the form of a polycrystal, consisting of many grains whose size and orientation distributions (i.e., texture) influence the overall response of the material. Establishing a quantitative understanding of crystal plasticity is challenging because of the wide range of length scales (and an even wider range of time scales) between these two limits, as shown in Fig. 1. No single theoretical/computational model can cover the entire range of the relevant length


**Fig. 1** Schematics of crystal plasticity models at different length and time scales and the relationship between different chapters in this section

and time scales, which is why different models have been developed and ultimately need to be connected to reach a comprehensive understanding of crystal plasticity.

The chapters in this section progress generally from smaller to larger length and time scales as shown in Fig. 1. In ▶ Chap. 70, "Ab Initio Models of Dislocations" (by E. Clouet), we start with ab initio models of the dislocation core. These are atomistic models that also account for the quantum mechanics of electrons based on the density functional theory. In the multiscale hierarchy here, these models are the most accurate and contain the fewest of empirical parameters, but their high computational cost limits them to very small material volumes typically containing at most a few hundred atoms. As a result, boundary conditions are important considerations for the successful applications of such models. A significant emphasis of Chap. 2 is on periodic boundary conditions (PBC). Chapter 2 discusses how key dislocation properties such as core structure, core energy, and Peierls stress (i.e., the critical stress required to move a dislocation at zero temperature) can be predicted by ab initio models under PBC. These properties can be used to construct functions that describe forces on and mobility of dislocations that can be used in higher-scale dislocation dynamics (DD) models (Chap. 4).

In ▶ Chap. 71, "Modeling the Thermally Activated Mobility of Dislocations at the Atomic Scale" (by L. Proville and D. Rodney), we introduce atomistic models of dislocations in which interatomic interactions are described by empirical

potentials. The simplification (i.e., removal of quantum mechanics of the electrons) allows such models to handle much larger material volumes, containing millions of atoms. This allows molecular dynamics (MD) simulations of the motion of fairly long dislocation lines (e.g., 100 Burgers vectors in length) over time scales of nanoseconds, so that mobility (a key input to DD models, Chap. 5) of fast moving dislocations (e.g., those in face-centered cubic metals) at finite temperature can be directly extracted. However, in materials with high Peierls stress (e.g., screw dislocations in body-centered cubic metals), dislocation motion can be thermally activated, and dislocation velocity would be too slow to be observable by direct MD simulations. Chapter 3 presents computational methods based on the transition state theory to determine the dislocation mobility in these circumstances. It also discusses how to incorporate quantum corrections (due to the zero-point motion of the nuclei) to the predicted dislocation mobility.

In ▶ Chap. 72, "Dislocation Analysis Tool for Atomistic Simulations" (by A. Stukowski), we introduce methods which convert atomistic descriptions of dislocations into line descriptions in the discrete dislocation dynamics (DDD) model (which is the subject of Chap. 5). Doing so leads to a tremendous reduction in the number of degrees of freedom, so that DDD models can deal with much larger material volumes, e.g., with sizes exceeding $10\,\mu$m. Chapter 3 introduces the dislocation extraction algorithm (DXA), which automatically identifies dislocations in an atomistic simulation snapshot and determines their Burgers vectors. This capability not only facilitates the visualization of atomistic simulations of crystal plasticity but also opens the exciting possibility of one-to-one comparisons between MD and DDD simulations of the same dislocation ensemble. This would allow higher-scale models (such as DDD) to be benchmarked against more fundamental, lower-scale models (such as MD), thus strengthening the multiscale hierarchy of crystal plasticity.

In ▶ Chap. 73, "Line Dislocation Dynamics Simulations with Complex Physics" (by R. B. Sills and S. Aubry), we present recent advances in discrete dislocation dynamics (DDD) models, which take core energy and mobility inputs from atomistic models and predict single crystal stress-strain relations that can be used in continuum plasticity models at even higher scales. Chapter 5 focuses on the recent developments of DDD models on the more "complex" physical aspects of dislocation processes relevant to crystal plasticity. These include, for example, elastic anisotropy, nonlinear mobility laws, and interactions with solutes, vacancies, precipitates, and grain boundaries.

While DDD models have the potential to link fundamental dislocation processes with plastic deformation behavior of single crystals and to predict spontaneous pattern formation in the dislocation microstructure, currently DDD models are still very much limited in the amount of strain they can reach (e.g., about a few percent) under work-hardening conditions. It is possible that directly connecting DDD models with continuum crystal plasticity models may still be impractical (or uneconomical) in the near future, and another model may be needed to bridge the two.

In ▶ Chap. 74, "Continuum Dislocation Dynamics: Classical Theory and Contemporary Models" (by A. El-Azab and G. Po), we present the continuum dislocation dynamics (CDD) model that is motivated by this need. The degrees of freedom in the CDD model are (smooth) fields (e.g., dislocation densities) represented on a volumetric grid. The grid sizes (e.g., 30 nm) are typically larger than minimum segment lengths in DDD models. The explicit network structure in the DDD model is "smeared out" and replaced by density variations in space, so that the CDD model can be considered as the result of "coarse-graining" the DDD model. The main challenge in CDD models is to decide which degrees of freedom (i.e., microstructural information beyond total density) should be kept after the coarse-graining and what their equations of motion should be. At present, multiple CDD formulations exist in the literature, and a number of them are discussed in Chap. 6. It is exciting to see that some of the 3D CDD formulations are already able to generate dislocation density patterns that are similar to experimental observations. Establishing a closer comparison between DDD and CDD models (e.g., through a systematic process of coarse-graining) appears to be a promising and important task for establishing a robust multiscale hierarchy of crystal plasticity models.

The next few chapters from 7 to 11 have a major focus on higher length scales, those corresponding to single and polycrystals in the microstructure. They propose alternative approaches for solving crystal plasticity problems in polycrystalline microstructures, overcoming some of the bottlenecks that jeopardize their use in complex applications. While a quantitative connection with the more fundamental, dislocation-based models is still lacking, impressive progress has been made over the last decade in crystal plasticity models in terms of numerical efficiency and the ability to model realistic microstructures.

In ▶ Chap. 75, "Connecting Lower and Higher Scales in Crystal Plasticity Modeling" (by D. L. McDowell) a generalized description of crystalline plasticity is proposed to encompass a spectrum of models that address various phenomena associated with dislocation evolution in crystals across a range of length and time scales. The evolution processes involve dislocation nucleation, generation, migration, interaction, trapping, and annihilation in crystals and polycrystals. Starting from coarse-grained atomistics, the models described include microscopic phase-field models, field dislocation models, discrete dislocation dynamics, statistical continuum dislocation models, mesoscale generalized continuum models categorized as gradients, micropolar or micromorphic types, all the way up to local continuum plasticity of polycrystalline aggregates. Furthermore the concepts of concurrent and hierarchical multiscale modeling in spatial and temporal domains are discussed. The chapter concludes with a summary of the challenging and long-standing gaps in hierarchical modeling of crystalline plasticity models, including quantification of coarse-graining and model reduction errors and uncertainty quantification of individual models, domain decomposition, as well as various two-scale transitions.

In ▶ Chap. 76, "Developing Virtual Microstructures and Statistically Equivalent Representative Volume Elements for Polycrystalline Materials" (by S. Ghosh and M. Groeber), the development of computational methods for simulating statistically

equivalent virtual microstructures of materials with complex heterogeneities is discussed. Specifically, the methods focus on polycrystalline metallic materials containing localized features such as annealing twins, particulates or precipitates, and subgrain-scale precipitates. The materials discussed include alloys of titanium, magnesium, and aluminum, as well as nickel-based superalloys. Data from image analysis and characterization are used to construct 3D statistical distribution and correlation functions. This serves as input to the virtual microstructure generation process. The methods accommodate computational approaches that infer 3D statistical descriptors and functions from 2D observations and surface data from stereology and other optimization-based projection techniques. The chapter introduces the software package DREAM.3D that is widely used for generating virtual microstructures of polycrystalline materials. A host of newly developed methods for incorporating twins, particles, and subgrain-scale phases in polycrystalline microstructures are further discussed. Finally the concept of the microstructure-based SERVE or M-SERVE, in which morphological and crystallographic characteristics of the microstructure are determinants of the statistically equivalent representative volume element, is introduced.

In ▸ Chap. 77, "Polycrystal Plasticity Models Based on Green's Functions: Mean-Field Self-Consistent and Full-Field Fast Fourier Transform Formulations" (by R. Lebensohn), two Green's function-based crystal plasticity methodologies for predicting microstructure-property relations in polycrystalline aggregates are discussed: The mean-field viscoplastic self-consistent (VPSC) method and the full-field viscoplastic fast Fourier transform method (VPFFT). These formulations are based on the Green's function solution of the PDEs governing the micromechanical response of polycrystals. The heterogeneity is related to the inherent directional properties of grains along different crystal directions and crystallographic orientations of each grain in the aggregate. The VPSC formulation uses a linearization assumption of the behavior of single crystals and utilizes Fourier transforms in an ellipsoidal domain of the Green's function for an infinite medium with homogenous properties. The VPFFT method evaluates convolution integrals over periodic unit cells using the Green's function for a periodic medium and a polarization term containing all the information on the heterogeneity and nonlinearity of the crystalline material behavior. The chapter delineates the similarities and differences of both the crystal plasticity formulations and cross-validates their predictions.

In ▸ Chap. 78, "Computationally Efficient Crystal Plasticity Simulations Using Spectral Databases" (by S. R. Kalidindi, A. Gupta and E. Popova), a spectral approach to crystal plasticity solutions is presented. The spectral database approach is able to significantly enhance the computational efficiency of the crystal plasticity framework. Important variables from crystal plasticity computations are accessed directly from precomputed spectral databases based on discrete Fourier transform (DFT). The chapter discusses the DFT database generation process for deviatoric stresses, lattice spins, and strain-hardening rates using Taylor-type crystal plasticity models. Studies are performed on Taylor-type simulations for FCC and BCC materials, yield surface evaluation, property closures, as well as forming limit diagrams. They show considerable computational speedup due to reduced level of

computing with this approach. The extension of the spectral database framework to crystal plasticity FEM simulations is also discussed. The advantages of using the spectral crystal plasticity method with graphics processing unit (GPU) computing are predicted.

In ▶ Chap. 79, "Advances in Computational Mechanics to Address Challenges in Crystal Plasticity FEM" (by S. Ghosh), novel methods and algorithms in computational mechanics are discussed for facilitating robust and efficient crystal plasticity finite element (CPFE) modeling of deformation and failure in metals and alloys. Image-based CPFE models incorporate characteristic microstructural features, as well as underlying physical mechanisms. A number of challenges arise when using CPFE models for modeling deformation mechanisms in complex microstructures, especially those involving phenomena like localization, twinning, crack propagation, fatigue, etc. This chapter examines three challenges that commonly persist with conventional CPFEM and offers remedies for overcoming them. The three problems include element stabilization to overcome plastic incompressibility due to volumetric locking of tetrahedral elements in CPFE analyses, time-domain subcycling to account for disparate deformation rates in modeling localization phenomena like discrete twin evolution in CPFEM, and wavelet-induced adaptive hierarchical CPFEM for enhanced efficiency. The chapter ends with a discussion of multi-time scaling issues in fatigue problems.

**Abstract**

This chapter reviews the different methodological aspects of the ab initio modeling of dislocations. Such simulations are now frequently used to study the dislocation core, i.e., the region in the immediate vicinity of the line defect where the crystal is so strongly distorted that an atomic description is needed. This core region controls some dislocation fundamental properties, like their ability to glide in different crystallographic planes. Ab initio calculations based on the density functional theory offer a predictive way to model this core region. Because

dislocations break the periodicity of the crystal and induce long-range elastic fields, several specific approaches relying on different boundary conditions have been developed to allow for the atomistic modeling of these defects in simulation cells having a size compatible with ab initio calculations. We describe these different approaches which can be used to study dislocations with ab initio calculations and introduce the different analyses which are currently performed to characterize the core structure, before discussing how meaningful energy properties can be extracted from such simulations.

# 1    Introduction

Dislocations are line defects which control the development of the plastic deformation in crystals. These defects induce a long-range stress field, which is well described by elasticity, and dislocation elasticity theory offers a powerful framework to model dislocations and their interaction with their surrounding environment (Hirth and Lothe 1982; Bacon et al. 1980). But some of their fundamental properties, like their glide plane and their mobility, highly depend on their core, i.e., the region in the immediate vicinity of the defect where the perturbation of the crystal is too important to be described by elasticity. The modeling of this core region necessitates an atomic description, and atomistic simulations have thus become a valuable tool to study dislocation properties. Among such simulations, ab initio calculations based on the density functional theory (DFT), as they rely on an electronic description of the atomic bonding, appear as the most accurate and predictive. But as these calculations are still limited in the size of the system they can handle, typically at most a few hundred atoms, the ab initio modeling of dislocations need special attention. Specific methodologies have been therefore developed to study dislocation core properties with ab initio calculations. The purpose of this chapter is to review the different modeling approaches for the ab initio study of dislocations, starting from a quick overview of DFT formalism, before describing more thoroughly boundary conditions specific to dislocation models, then the analysis of the atomic structure in the dislocation core and finally the extraction of meaningful energy properties. Beyond the examples illustrated in this chapter, results which have been obtained from such ab initio studies for the dislocation core properties in different metals and semiconductors can be found in the recent review of Rodney et al. (2017).

# 2    Ab Initio Calculations

Ab initio calculations describe the bonding between atoms, thanks to the resolutions of the Schrödinger equation for the electrons of the system. These are first-principles approaches as they do not use any experimental data and allows the modeling of atomic interaction only from the atomic number and other fundamental quantities. Compared to empirical interatomic potentials, such approaches are completely

transferable, without any parameterization depending on the environment under study, but at the expense of a much higher CPU time. Although ab initio in nature and usually very accurate, these approaches nevertheless rely on different approximations, the validity of which needs generally to be assessed.

The most fundamental approximation is the Born-Oppenheimer approximation. As atom nuclei have a much higher mass than electrons, one can assume that the electrons are always equilibrated with respect to the positions of the nuclei which are considered as immobile. The resolution of the Schrödinger equation for the electrons therefore leads to the energy of the system as a function of the atomic positions. Knowing this function and also its first derivatives, i.e., the atomic forces, standard algorithms of atomic simulations can then be used. For the ab initio modeling of dislocations, this is usually restricted to molecular statics, including energy barrier calculations, because of the high CPU burden of the energy and force calculation.

Most ab initio calculations of dislocations are relying on the density functional theory (DFT). This makes use of the Hohenberg and Kohn (1964) theorem showing that the ground-state energy is the minimum of a functional depending only on the electronic density. This dramatically simplifies the problem as the electronic density depends only on the position, whereas the many-electron wave function entering Schrödinger equation is a function depending on the $3N$ electron coordinates, with $N$ the number of electrons in the system. The Kohn and Sham (1965) approach allows then a practical implementation, where the Schrödinger equation is solved for an equivalent system of noninteracting electrons. This necessitates the definition of an unknown contribution to the Hamiltonian, the exchange and correlation potential. Most of dislocation calculations are performed with the local density (LDA) or the generalized gradient (GGA) approximations, assuming that this contribution depends only locally on the electronic density or also its gradient.

For dislocation calculations, it is enough to consider that only the electrons of the outer shells participate to the atomic bonding. Electrons of the inner shells are not sensitive to the atom environment and can be assumed to have the same ground state as for the isolated atom. Kohn-Sham equations are then solved only for valence electrons. One can further reduce the CPU overhead by replacing with a pseudopotential the interaction potential of the valence electrons with the ionic core. This pseudopotential aims to reduce the strong oscillations of the electronic wave functions close to the dislocation core, because the description of these oscillations necessitates a large basis set, while still leading to the correct wave functions outside this core region. Different pseudoization schemes, norm-conserving or ultrasoft pseudopotentials as well as the projected augmented wave (PAW) method, are available.

Ab initio codes used for dislocations are relying on Born-von Karman periodic boundary conditions to model the solid, whatever the boundary conditions used to incorporate a dislocation in the simulation cell (Sect. 3). Electronic wave functions are thus a superposition of Bloch waves with wavevectors spanning the first Brillouin zone. Integration in the reciprocal space is performed on a regular grid sampling the first Brillouin zone, using smearing functions to broaden the electronic

density of states. Different basis sets can be used to describe the Bloch waves, with plane waves being the most popular choice for dislocations.

Ab initio approaches devoted to the study of dislocations are thus not specific: they are making use of standard DFT implementations which are now current modeling tools in solid-state physics. Feature specific to dislocation modeling, as described in the next section, is the necessity to use a supercell large enough to let the dislocation core adopt its fully relaxed configuration, with boundary conditions compatible with the long-range distortion induced by the defect. A high accuracy is also generally needed for such calculations as the energy variations involved by the dislocation core are usually small. For instance, the Peierls energy barrier opposing the glide of $1/2 \langle 111 \rangle$ screw dislocations in BCC transition metals does not exceed $100 \, \text{meV}/b$, where $b$, the norm of the Burgers vector, corresponds to the height of the simulation cell necessary to model such a dislocation.

## 3    Boundary Conditions

The ab initio modeling of dislocations needs special care in the way the boundary conditions are handled. First, a dislocation creates a long-range elastic field which needs to be taken into account. Second, it is not possible to include a single dislocation in a simulation box with full periodic boundary conditions which usually constitute the paradigm in the modeling of bulk materials: the dislocation opens a displacement discontinuity, and another defect is needed to close the discontinuity and allow for periodicity. As a result, different boundary conditions compatible with ab initio calculations have been developed to model dislocations.

All approaches enforce periodicity in the direction of the dislocation line. In pure metals, one usually uses the shortest periodicity vector to define the dimension of the simulation cell in this direction, thus modeling an infinite straight dislocation. But this size needs to be increased if one wants to introduce a solute atom on the dislocation line, so as to minimize the interaction of the solute atom with its periodic images and truly study the interaction of the dislocation with a single foreign atom. A larger size is also needed to model a kinked dislocation. This is usually possible only in covalent crystals where the atomic bonds are highly directional, leading to abrupt kinks experiencing a non-negligible energy barrier when migrating along the dislocation line. In metallic systems with less directional atomic bonding, kinks are usually spread over a larger distance and are highly mobile, making it hard to stabilize them in a simulation cell whose size is compatible with ab initio calculations.

### 3.1    Cluster Approach

The easiest way to model a dislocation is to use an infinite cylinder whose axis coincides with the dislocation line. Periodicity is enforced only along the dislocation line. The dislocation is created by displacing all atoms according to the Volterra

**Fig. 1** Boundary conditions used to model an isolated straight dislocation in the cluster approach. The outer boundary is either (**a**) rigid or (**b**) flexible and controlled by lattice Green's functions or by coupling with an empirical potential
solution given by anisotropic elasticity theory for the dislocation displacement field (Stroh 1958, 1962). Atoms at the cylinder surface (region 2 in Fig. 1a) are kept fixed in their initial positions, and only atoms inside the cylinder are relaxed. One thus models an isolated dislocation in an infinite continuum.

But this modeling approach has severe drawbacks. The elastic solution used to fix the atoms at the boundary is only approximate as it relies on linear elasticity, thus neglecting crystal anharmonicity which can be strong close to the dislocation line. Moreover, the Volterra elastic solution, used to fix the atoms at the boundary, only corresponds to the long-range elastic field of the dislocation. Close to the dislocation line some additional contributions, the dislocation core field, need to be accounted for (Eshelby et al. 1953). A spreading of the dislocation core can be the reason for the existence of such a core field, but even dislocations with a compact core, like ⟨111⟩ screw dislocations in BCC metals, possess a non-negligible core field. Although this core field decays more rapidly than the Volterra elastic field, the size of the simulation boxes that can be handled by ab initio calculations is never large enough to neglect it. The rigid boundary conditions do not allow the correct development of this core field and thus perturb the relaxation of the dislocation core.

The fixed atomic positions imposed at the boundary also prevent use of this method to determine the lattice friction opposing dislocation motion. If the dislocation moves during the simulation, this boundary condition will not be compatible anymore with the new dislocation position. This induces indeed a back-stress opposing the dislocation motion. As a result, any simulation relying on this boundary condition will overestimate the dislocation Peierls stress, which is the minimum stress necessary to move the dislocation at 0 K.

## 3.2    Flexible Boundary Conditions

To remove the artifacts induced by the rigid boundary conditions, dislocation modeling with flexible boundary conditions has been developed. The proposed method relies either on the use of the lattice Green's function (Sinclair et al. 1978; Woodward 2005) or on the coupling with an empirical potential (Liu et al. 2007; Chen et al. 2008).

The lattice Green's function $G_{ij}(\mathbf{r})$ expresses, in the crystal harmonic approximation, the displacement $\mathbf{u}$ induced on an atom in position $\mathbf{r}$ by a force $\mathbf{F}$ acting on an atom at origin (We use the Einstein implicit summation convention on repeated indexes appearing in all expressions.):

$$u_i(\mathbf{r}) = G_{ij}(\mathbf{r})F_j. \tag{1}$$

This lattice Green's function can be obtained by inversion of the force-constant matrices of the perfect crystal (Yasi et al. 2012; Tan and Trinkle 2016) or can be tabulated from direct calculations in a perfect lattice (Sinclair et al. 1978; Rao et al. 1998). In the long-range limit, $G_{ij}(\mathbf{r})$ converges to the elastic Green's function given by anisotropic elasticity theory.

Flexible boundary conditions based on lattice Green's functions still make use of a cylinder geometry to model a single dislocation, but three zones are now defined (Fig. 1b). Atoms in the inner zone (1) are relaxed with the ab initio code until the forces acting on them are smaller than a fixed threshold, while atoms in zones (2) and (3) are kept fixed. At the end of this step, atomic forces have appeared in zone (2), because the dislocation elastic field deviates from the Volterra solution used as an initial guess. The lattice Green's function is then used to displace atoms in all three zones according to Eq. 1 using all atomic forces in zone (2). This leads to the cancelation of forces in zone (2) but makes new forces appear in zone (1). The procedure is thus iterated until all forces in zones (1) and (2) are null. This self-consistent cycle is necessary because the lattice Green's function of the perfect crystal only approximates the linear response of the dislocated crystal. Atoms in zone (3) serve as a buffer to prevent any perturbation by the external boundary of forces building in zone (2). As shown by Segall et al. (2003), this buffer region may need to be quite large in metals to obtain negligible perturbations in the inner regions. This can be minimized by removing the surfaces delineating zone (3) and using periodic boundary conditions in all directions. Interface defects are then present at the boundary between two periodic simulations cells. But these defects lead to a smaller perturbation of the electronic density than the vacuum layer of the surfaces (Woodward 2005). One thus perfectly models an isolated dislocation in an infinite crystal taking full account of the dislocation core field. It is possible to study dislocation cores with a reduced number of atoms in the simulation cell, a size usually compatible with ab initio calculations.

A similar approach relies on the coupling of the ab initio calculations with an empirical potential (Liu et al. 2007; Chen et al. 2008). The simulation cell is still divided in three regions (Fig. 1b). Ab initio calculations are performed only for a smaller simulation cell corresponding to regions (1) and (2). Atoms in regions (2) and (3) are relaxed according to the forces calculated with the empirical potential, whereas atoms in region (1) are relaxed according to ab initio forces plus a correction to withdraw the perturbation caused by the external boundary of the ab initio box. The buffer region (2) has been added to the original approach (Choly et al. 2005) to minimize this correction by protecting atoms from the external boundary. To operate, this method needs therefore an empirical potential which

perfectly reproduces the lattice parameters given by ab initio calculations, which can generally be done by rescaling the distances. Besides, the potential has also to match as best as possible the ab initio linear response, i.e., at least the elastic constants and, ideally, the whole phonon spectrum.

As it will be discussed in the last section, the main drawback of this ab initio dislocation model using flexible boundaries arises from the difficulty of extracting dislocation energy. The problem may be actually less sensitive with the second approach relying on a coupling with an empirical potential where an energy formulation exists. In this case, one can obtain a reasonable estimation of the dislocation energy provided the potential gives an accurate description of the boundary energy compared to the ab initio calculations. While these flexible boundaries truly allow the modeling of an isolated dislocation, thus predicting its core structure and its evolution under an applied stress without any a priori artifact induced by the small size of the simulation cell inherent to ab initio calculations, the approach is still under active development to also provide information on the dislocation energy.

## 3.3    Periodic Boundary Conditions

To get rid of the external boundary and to use periodic boundary conditions in all three directions without the introduction of a defective interface, one needs to introduce in the simulation cell a dislocation dipole, i.e., two dislocations with opposite Burgers vectors. One thus models a 2D periodic array of dislocations (Fig. 2).

Several arrangements of dislocation arrays can be though off, but they are not all equivalent. Among all of them, the ones which are quadrupolar display strong advantages. A periodic array is quadrupolar, if the vector $\mathbf{d}$ linking the two dislocations of opposite signs is equal to $1/2$ $(\mathbf{u}_1 + \mathbf{u}_2)$, where $\mathbf{u}_1$ and $\mathbf{u}_2$ are the periodicity vectors of the simulation cell (Fig. 2). This ensures that every dislocation is a symmetry center of the array: fixing, as a convention, the origin at a dislocation center, if a dislocation $\mathbf{b}$ is located at the position $\mathbf{r}$, there will also be a dislocation $\mathbf{b}$ in $-\mathbf{r}$. The stress created by these two dislocations will cancel to first order at the origin, thanks to the symmetry property of the Volterra elastic field. ($\sigma_V(-\mathbf{r}) = -\sigma_V(\mathbf{r})$ with $\sigma_V$ the Volterra stress field of a single dislocation.) As a consequence, this quadrupolar periodic array minimizes the elastic interaction between the dislocations and hence the Peach-Koehler force acting on each dislocation because of the image dislocations associated with periodic boundaries. It is the best-suited periodic array to extract dislocation core properties from ab initio calculations.

Linear elasticity is still used to build the initial configuration, displacing all atoms according to the superposition of the displacement fields created by each dislocation composing the periodic array. The summation on periodic images can be either performed in reciprocal space (Daw 2006) or in direct space after regularization of the conditionally convergent sums (Cai et al. 2003). The crystal orientation used in such elastic calculations should be chosen so as to fix the displacement
**Fig. 2** Simulation of a dislocation dipole with periodic boundary conditions, using a quadrupolar arrangement. The dipole is defined by its Burgers vector **b**, the dipole vector **d** joining the two dislocation centers, and the cut vector **A**, with the corresponding discontinuity surface indicated by a double black line. $\mathbf{u}_1$ and $\mathbf{u}_2$ are the periodicity vectors of the simulation cell perpendicular to the dislocation line. The example on the right corresponds to the simulation cell used for the modeling of the $1/2 \langle 111 \rangle$ screw dislocation in bcc iron. The dislocation core structures are shown through their differential displacement maps and their density (cf. Fig. 3a for a details)

discontinuity exactly in between the two dislocations composing the dipole, thus preventing the propagation of this discontinuity to infinity. The cut vector **A** defining this discontinuity (Fig. 2) is therefore given by $\mathbf{A} = \mathbf{l} \times \mathbf{d}$, where **l** is the line vector of the dislocations and **d** the vector joining the centers of the $+\mathbf{b}$ dislocation to the $-\mathbf{b}$ one. If the scalar product **A.b** is non-null, i.e., if the dislocation dipole has an edge component and the displacement discontinuity does not coincide with the dislocation glide plane, it is also necessary to insert atoms into or delete them from the original lattice at the discontinuity location, thus following the Volterra operation.

A homogeneous strain needs also to be applied to accommodate the plastic strain created by the dipole (Daw 2006; Cai et al. 2003) and ensure that the average stress in the simulation cell is null. This can be easily demonstrated by considering the variation of the elastic energy when a homogeneous strain $\varepsilon_{ij}$ is applied to a simulation cell containing a dislocation dipole defined by its Burgers vector **b** and its cut vector **A**

$$\Delta E(\varepsilon) = \frac{1}{2} S\, C_{ijkl}\, \varepsilon_{ij}\, \varepsilon_{kl} + C_{ijkl}\, b_i\, A_j\, \varepsilon_{kl},$$

where energies are defined per dislocation unit length and have been thus normalized by the height of the simulation cell in the direction of the dislocation line. $S$ is the area of the simulation cell perpendicular to this direction and $C_{ijkl}$ are the elastic constants. The average stress existing in the simulation cell is then given by

$$\sigma_{ij} = \frac{1}{S} \frac{\partial \Delta E}{\partial \varepsilon_{ij}} = C_{ijkl} \left( \varepsilon_{kl} - \varepsilon_{kl}^0 \right), \tag{2}$$

with the plastic strain defined by

$$\varepsilon_{kl}^0 = -\frac{b_i A_j + b_j A_i}{2S}. \tag{3}$$

One thus sees that the stress given by Eq. 2 is null when the applied strain $\varepsilon_{ij}$ is equal to the plastic strain $\varepsilon_{ij}^0$. When this applied strain is different, a Peach-Koehler force acting on the dislocations may exist. This allows studying properties of the dislocation core under an applied stress, to determine its Peierls stress, for instance. Finally, when a stress variation is observed in ab initio calculations, Eq. 2 allows to deduce the plastic strain from this stress, and thus the dislocations' relative positions via the cut vector **A** (Eq. 3). For instance, the trajectories of the screw dislocations gliding between two neighboring Peierls valleys have been determined, thanks to this method in HCP Zr (Chaari et al. 2014) and in BCC transition metals (Dezerald et al. 2016).

With these periodic boundary conditions, all the excess energy contained in the simulation cell is due to the dislocations. As it will be shown in the last section, elasticity theory can be used to isolate the contribution of a single dislocation. These periodic boundary conditions offer thus a convenient way to extract dislocation energy from ab initio calculations. But the dislocation core structure, and hence the associated excess energy, can be perturbed by the presence of the periodic images. In practice, one will therefore need to check how sensitive are the obtained dislocation properties with the size of the simulation cell.

## 4  Dislocation Core Structures

Different representations can be used to image and analyze the relaxed dislocation core structure obtained by atomic simulations. This allows, for instance, highlighting a spreading of or a dissociation of the dislocation.

### 4.1  Differential Displacement Maps

Differential displacement maps were introduced by Vitek et al. (1970). Two examples are shown in Fig. 3 for a screw dislocation in a body-centered cubic (bcc) crystal and a hexagonal close-packed (hcp) crystal. In these maps, the crystal

is projected in the plane perpendicular to the dislocation line, using for atomic columns the positions in the perfect crystal. The differential displacement caused by the dislocation is calculated by considering the difference between the vector connecting two neighbor atoms in the relaxed dislocated crystal and the same connecting vector in the perfect crystal. One then plots the projection of this differential displacement along the direction of the Burgers vector with an arrow pointing from one atomic column to the other, centered in the middle of the two columns and with an amplitude proportional to the differential displacement. As the arrows are proportional to the displacement difference, they are a representation of the discrete derivative of the displacement field, i.e., of the strain created by the dislocation.

The differential displacement map of the $1/2 \langle 111 \rangle$ screw dislocation in bcc Fe shown in Fig. 3a highlights the compactness and the threefold symmetry of the core. Arrows have been normalized so that an arrow linking the centers of two atomic columns corresponds to a differential displacement of $b/3$. One can thus draw Burgers circuits on this map and obtain the norm of the Burgers vector of the enclosed dislocation by summing arrows. The only non-null Burgers vector is obtained for circuits containing the dislocation center indicated by a cross, in particular for the triangle connecting the three central [111] atomic rows, with a norm equal to $b$. The dislocation is thus well localized.

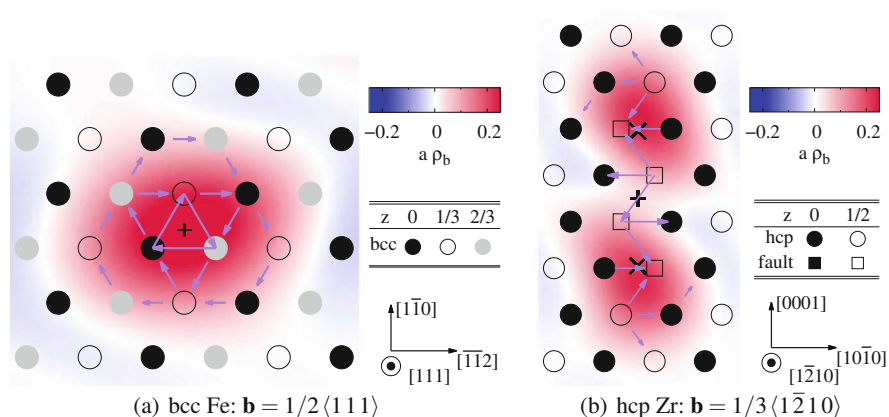
(a) bcc Fe: $\mathbf{b} = 1/2 \langle 1\,1\,1 \rangle$           (b) hcp Zr: $\mathbf{b} = 1/3 \langle 1\,\overline{2}\,1\,0 \rangle$


**Fig. 3** Core structure of a $\mathbf{b}$ screw dislocation (**a**) in bcc iron (Dezerald et al. 2016) and (**b**) in hcp zirconium (Clouet et al. 2015). In these projections perpendicular to the dislocation line, atoms are sketched by symbols with a colour depending on their (**a**) (111) and (**b**) ($1\overline{2}10$) plane in the original perfect crystal. In (**b**), different symbols are used for atoms depending on their neighbourhood in the dislocated crystal, i.e. close to the perfect hcp crystal (circles) or to the unrelaxed prismatic stacking fault (squares). The arrows between atomic columns are proportional to the differential displacement created by the dislocation in the direction of the Burgers vector. The colour map show the dislocation density $\rho_b$ normalized by the lattice parameter (Nye tensor). The center of the dislocation is indicated by a + cross. The × crosses in (**b**) correspond to the positions of the partial dislocations deduced from the disregistry in Fig. 4

The picture is quite different for the $1/3\langle 1\bar{2}10\rangle$ screw dislocation in hcp Zr shown in Fig. 3b. The differential displacement map shows a non-isotropic distribution with a spreading of the dislocation core in the $(10\bar{1}0)$ prismatic plane. The normalization here ensures that the maximal arrows correspond to a $b/2$ differential displacement. The presence of a ribbon with arrows having almost the same length therefore corresponds to a $b/2$ prismatic stacking fault which is known to be stable in this transition metal. The differential displacement map thus clearly evidences the dissociation of the screw dislocation in two $1/6\langle 1\bar{2}10\rangle$ partial dislocations separated by a prismatic stacking fault.

## 4.2    Dislocation Density

Another visualization method proposed by Hartley and Mishin (2005) consists of extracting the Nye tensor from the relaxed atomic structure, thus giving a measure of the dislocation density. The component $\alpha_{jk}$ of the Nye tensor corresponds to the density of dislocations with a line direction along $\mathbf{e}_k$ and a Burgers vector along $\mathbf{e}_j$. If $A$ is a surface element of normal $\mathbf{n}$, the dislocation content of line defects along $\mathbf{n}$ intersecting $A$ is given by the surface integral

$$\mathbf{b} = \int_A \alpha \cdot \mathbf{n}\, dS.$$

We only give here the salient points of the method to extract the Nye tensor from atomic simulations, and the reader is referred to the original publication for the practical implementation.

The first step is to define the elastic distortion, i.e., the gradient of the elastic displacement, at each atomic position. Note that this differs from the gradient of the total displacement. One cannot simply compare the atomic positions after and before the introduction of the dislocation to obtain this elastic distortion, but one needs to find for each position the closest undistorted environment corresponding to a zero-stress state. This is performed by comparing, for each atom, the positions of its nearest neighbors in the dislocated relaxed crystal with the ones in a perfect crystal. Knowing the two sets of neighbor positions, each bond in the dislocated crystal, defined by its vector $\mathbf{P}^{(\gamma)}$, is identified with the corresponding $\mathbf{Q}^{(\beta)}$ bond in the perfect crystal, which is the perfect bond leading to the smallest angle $\Phi^{(\gamma\beta)}$ between the vectors $\mathbf{P}^{(\gamma)}$ and $\mathbf{Q}^{(\beta)}$. Only the bonds which are not too much distorted and for which the angle $\Phi^{(\gamma\beta)}$ is smaller than a chosen threshold are kept. The elastic distortion $F^{\mathrm{e}}$ is then locally defined through the relation $P_i^{(\gamma)} = F_{ij}^{\mathrm{e}} Q_j^{(\beta)}$. This cannot be satisfied for each set of associated bond $(\gamma\,\beta)$ as the system of equations is overdetermined and the matrix $F^{\mathrm{e}}$ is obtained by the pseudo-inverse method, i.e., a least-square fitting. The Nye tensor $\alpha$ is then defined through the curl of the inverse transpose of the distortion, $\alpha = -\nabla \times (^+F^{\mathrm{e}})^{-1}$, using finite differences between neighbor atoms for derivation. This defines the Nye tensor on a set of discrete points,

generally atomic positions, which can be then interpolated with cubic splines or Fourier series, or smeared with Gaussian-like spreading functions.

The dislocation density obtained for the $1/2 \langle 111 \rangle$ screw dislocation in bcc Fe (Fig. 3a) illustrates the compactness of the core: the distribution has only one peak. On the other hand, the dislocation distribution for the $1/3 \langle 1\bar{2}10 \rangle$ screw dislocation in hcp Zr (Fig. 3b) shows two well-separated peaks which correspond to the two partial dislocations. To obtain the Nye tensor in this latter case, the neighborhood of each atom in the dislocated crystal is compared not only to the two different neighborhoods existing in the perfect hcp crystal but also to the ones of the unrelaxed prismatic stacking fault, to identify the closer reference from which the elastic distortion is calculated.

## 4.3    Disregistry

The extraction of the disregistry offers another way to characterize the dislocation core structure, particularly convenient when the core is planar. The disregistry is the difference of displacement induced by the dislocation between the plane just above and the one just below the dislocation glide plane. It is thus obtained from the relaxed configuration through

$$\mathbf{D}(x) = \mathbf{u}^{+}(x) - \mathbf{u}^{-}(x),$$

where $\mathbf{u}^{+}(x)$ and $\mathbf{u}^{-}(x)$ are the displacements of the atoms belonging, respectively, to the upper and lower planes and located at the position $x$ in the direction perpendicular to the dislocation line. This disregistry varies from $\mathbf{0}$ for $x \to -\infty$ to $\mathbf{b}$ for $x \to \infty$, thus corresponding to the dislocation glide plane being locally sheared by one Burgers vector $\mathbf{b}$. The dislocation center $x_{\mathrm{D}}$ is defined by $\mathbf{D}(x_{\mathrm{D}}) = \mathbf{b}/2$. The disregistry derivative, $\boldsymbol{\rho}(x) = \partial \mathbf{D}(x)/\partial x$, corresponds to the dislocation density in the glide plane. If the cut plane used to introduce the dislocation in the simulation cell does not correspond to its glide plane, it is necessary to define the atomic displacement in the $\mathbf{0}$ to $\mathbf{b}$ interval. This can be done as the Burgers vector $\mathbf{b}$ of a perfect dislocation is a periodicity vector of the lattice and adding a displacement $n\mathbf{b}$ ($n \in \mathbb{Z}$) to an atom does not change the configuration.

Peierls and Nabarro built a model that leads to a simple analytical expression of the disregistry (Lu 2005). According to this model, the disregistry is given by

$$D(x) = \frac{b}{\pi} \left[ \arctan \left( \frac{x - x_{\mathrm{D}}}{\zeta} \right) + \frac{\pi}{2} \right],$$

where $x_{\mathrm{D}}$ is the dislocation position and $\zeta$ its spreading in the glide plane. For simplicity, we consider scalar quantities by projecting the displacement in the direction of the Burgers vector. Fitting of these two parameters to the data extracted from the atomistic simulations allows thus defining the dislocation position and characterizing the spreading of its core.

For dissociated dislocations, the disregistry is the sum of the contributions of the two partial dislocations, i.e.,, assuming that each partial dislocation has the same Burgers vector $\mathbf{b}/2$ and the same spreading $\zeta$:

$$D(x) = \frac{b}{2\pi} \left[ \arctan\left( \frac{x - x_D - d/2}{\zeta} \right) + \arctan\left( \frac{x - x_D + d/2}{\zeta} \right) + \pi \right],$$

where $d$ is the dissociation distance. As shown in Fig. 4 for the $1/3 \langle 1\bar{2}10 \rangle$ screw dislocation in hcp Zr, such an analytical expression generally perfectly describes the disregistry extracted from the atomic simulations. One can also notice that the positions in the glide plane of the partial dislocations deduced from the disregistry agree which what can be inferred from the differential displacement and the Nye tensor maps (Fig. 3b). Some consequences of the periodic boundary conditions used to model this dislocation are visible on these disregistry plots. The dislocation density slightly depends, through the dissociation distance $d$ and the partial spreading $\zeta$, on the simulation cell, not only its size but also its shape. One also sees that the density of the periodic dislocation arrays (solid line in Fig. 4), obtained by summation of the contributions of the periodic images in the glide plane, slightly differs from the one of the isolated dislocation (dashed line in

**Fig. 4** Disregistry $D(x)$ created by a $1/3 \langle 1\bar{2}10 \rangle$ screw dislocation in its $(10\bar{1}0)$ prismatic glide plane in hcp Zr, and corresponding dislocation density $\rho(x) = \partial D(x)/\partial x$. Symbols correspond to ab initio calculations and lines to the fit of the Peierls-Nabarro model, considering periodicity or not (straight and dashed lines respectively). Results are shown for different $n \times m$ periodic arrangements corresponding to the periodicity vectors $\mathbf{u}_1 = n/2 \,[10\bar{1}0]$ and $\mathbf{u}_2 = m \,[0001]$ (see Clouet 2012 for details). For clarity, disregistries $D(x)$ have been shifted by 0.2 between different data sets. The obtained dissociation distance $d$ and spreading $\zeta$ of the partial dislocations are indicated for the $6 \times 8$ periodic array whose core structure is shown in Fig. 3b

Fig. 4), especially in the distribution tail. Flexible boundary conditions, as discussed in Sect. 3.2, have been developed to solve such limitations of periodic boundary conditions.

## 5    Dislocation Energy

Ab initio calculations give access to the dislocation core energy and its variations. This core energy is the part of the dislocation excess energy which arises from the strong perturbation of the atomic interactions in the immediate vicinity of the dislocation line and which cannot be described by linear elasticity. Contrary to the dislocation elastic energy, this is an intrinsic property which only depends on the dislocation and not on the surrounding environment. When several configurations exist for the same dislocation, this core energy controls their relative stability. Its variations with the position of the dislocation in the crystal lattice is at the origin of the lattice friction opposing dislocation glide.

### 5.1    Core Energy

Among the different boundary conditions introduced in Sect. 3 to model a dislocation at an atomic scale, only periodic boundary conditions allow for an unambiguous determination of the dislocation core energy with ab initio calculations. This is a consequence of the energy formulation inherent to ab initio calculations. Because of the non-locality of the electronic energy, which contains a contribution which needs to be evaluated in reciprocal space, one cannot easily partition the excess energy of the simulation cell between the dislocation and the external boundary contributions when a defective boundary has been introduced like in cluster approaches using either fixed (Sect. 3.1) or flexible boundaries (Sect. 3.2). Ab initio methods to project the energy on atoms have been proposed: they theoretically allow for such a partition but the application to the calculation of a dislocation core energy still remains to be done. Even if the absolute value of the core energy appears difficult to determine with cluster approaches, methods to estimate its variation are nevertheless possible. One can, for instance, calculate the difference of core energy between two configurations of the same dislocations by simply considering the difference of ab initio total energies. But such an approach assumes that the contribution of the external boundary will cancel in the difference, an assumption which may be hard to validate. Variation of the dislocation energy with its position in the crystal lattice can also be estimated by considering the work of the atomic forces during the motion (Swinburne and Kermode 2017).

On the other hand, with periodic boundary conditions, all the excess energy arises from the dislocations. This excess energy $\Delta E$ is defined as the energy difference per unit of height between the supercell with and without the dislocation dipole. If atoms have been removed or inserted during the creation of the dipole, the energy of the perfect supercell needs to be normalized by the correct number of atoms. It is given

by the sum of the core energy $E^{\text{core}}$ of the two dislocations, of the elastic energy $E^{\text{elas}}_{\text{dipole}}$ of the dipole contained in the supercell and of its elastic interaction with its periodic images:

$$\Delta E = 2\, E^{\text{core}} + E^{\text{elas}}_{\text{dipole}} + \frac{1}{2} \sum_{n,m} E^{\text{elas}}_{\text{inter}} (n\, \mathbf{u}_1 + m\, \mathbf{u}_2). \tag{4}$$

The factor $1/2$ appears in front of this last contribution as only one half of the interaction is attributed to each interacting dipole. When partitioning the excess energy into a core and an elastic contribution, it is necessary to introduce a cutoff distance to isolate the dislocation cores. Close to the dislocation lines, strains are much too high to be described by linear elasticity. As a consequence, elastic fields diverge at the origin, and one needs to exclude the core region from the elastic description. The elastic contribution to the excess energy is thus obtained by integrating the elastic energy density on the whole supercell except two cylinders of radius $r_{\text{c}}$ which isolate this elastic divergence. The core energy corresponds to the excess energy contained in these cylinders. The total excess energy $\Delta E$ does not depend on the choice for this core radius, but the partition between a core and an elastic contribution depends on $r_{\text{c}}$.

The elastic energy of the dipole and its interaction with its periodic images can be computed by considering the Volterra elastic field created by the dislocations. This calculation can be performed either in reciprocal space (Daw 2006) or in direct space using classical results of dislocation elastic theory (Bacon et al. 1980). In this last case, one uses the decomposition of Eq. (4), with the contribution of the dipole contained in the supercell and its interaction with the periodic images calculated separately. The dipole elastic energy is obtained by the volume integral:

$$E^{\text{elas}}_{\text{dipole}} = \frac{1}{2} \iiint_V \left( \sigma^{(1)}_{ij} + \sigma^{(2)}_{ij} \right) \left( \varepsilon^{(1)}_{ij} + \varepsilon^{(2)}_{ij} \right) dV,$$

where $\sigma^{(n)}$ and $\varepsilon^{(n)}$ are the stress and strain created by the dislocation $n$. This is transformed into a surface integral, thanks to Gauss' theorem:

$$E^{\text{elas}}_{\text{dipole}} = \frac{1}{2} \iint_S \left( \sigma^{(1)}_{ij} + \sigma^{(2)}_{ij} \right) \left( u^{(1)}_i + u^{(2)}_i \right) dS_j,$$

with $\mathbf{u}^{(n)}$ the displacement field associated with dislocation $n$. The integration surface is composed of the two cylinders $S^{(1)}_{\text{c}}$ and $S^{(2)}_{\text{c}}$ of radii $r_{\text{c}}$ removing the elastic divergence at the dislocation cores, and of the two surfaces $S_{0-}$ and $S_{0+}$ removing the displacement discontinuity along the dislocation cut (Fig. 5). The integration on both core cylinders leads to the same contribution

$$E^{\text{elas}}_{\text{c}}(\phi) = \frac{1}{2} \iint_{S^{(1)}_{\text{c}}} \sigma^{(1)}_{ij} u^{(1)}_i dS_j = \frac{1}{2} \iint_{S^{(2)}_{\text{c}}} \sigma^{(2)}_{ij} u^{(2)}_i dS_j. \tag{5}$$

**Fig. 5** Definition of the contour surface used to calculate the elastic energy of a dislocation dipole

This contributions of the core tractions to the elastic energy (Clouet 2009) should not be forgotten as it ensures that the elastic energy is a state variable compatible with the work of the Peach-Koehler forces. Besides, in ab initio calculations where the distance $d$ between the two dipole dislocations is small, this can lead to a non-negligible contribution compared to the one associated with the integral along the cut surface, even for a screw orientation. The elastic energy of the dislocation dipole is then

$$E_{\text{dipole}}^{\text{elas}} = 2E_{\text{c}}^{\text{elas}}(\phi) + b_i K_{ij}^0 b_j \ln\left(\frac{d}{r_{\text{c}}}\right), \tag{6}$$

where the tensor $\mathbf{K}^0$ defined by Stroh (1958, 1962) only depends on the elastic constants. The total elastic energy is finally obtained by adding the interaction of the dipole with its periodic images. But, one should realize that the summation on periodic images appearing in Eq. (4) is only conditionally convergent: it can be regularized with the method of Cai et al. (2003).

As shown in Fig. 6 for the $1/2 \langle 111 \rangle$ screw dislocation in bcc iron, once this elastic energy is subtracted from the dislocation excess energy given by ab initio calculations, one obtains a constant core energy which does not depend on the size of the supercell. Some slight variations of the core energy are nevertheless still observed with the type of periodic arrangement used for the atomic simulations. These variations arise because only the Volerra elastic field has been considered in the calculation of the elastic energy. Dislocations also cause a core elastic field, which decays more rapidly than the Volterra elastic field. Because of the small size of the supercell used in ab initio calculations, this core field may also lead to an elastic interaction between the different dislocations composing the periodic array. This contribution to the elastic energy can be computed to improve the convergence of core energies (Clouet et al. 2009). A quadrupolar periodic arrangement minimizes this contribution of the core field. This is why such an arrangement is preferred when periodic boundary conditions are used. The neglect of anharmonic effects in the calculation of the elastic energy can also be a reason for the variation of the core energy with the supercell. Knowing higher-order elastic constants, one can

**Fig. 6** Decomposition of the excess energy $\Delta E$ of a $1/2 \langle 111 \rangle$ screw dislocation dipole in bcc Fe in an elastic contribution $E^{\text{elas}}$ and a core energy $E^{\text{core}}$, using a core radius $r_c = b/2$. Different symbols correspond to different periodic arrangements (see Clouet et al. 2009 for details)

use nonlinear elasticity theory in principle to calculate more precisely this elastic contribution (Teodosiu 1982). But this leads to much cumbersome calculations. In practice, as anharmonicity is important only close to the dislocation core, the consideration of the dislocation core field offers a way to incorporate anharmonic effects while still relying on linear elasticity.

## 5.2   Peierls Energy Barrier

The Peierls energy is the energy barrier opposing dislocation glide. It corresponds to a variation of the dislocation core energy as the elastic energy is not dependent upon the dislocation position in the crystal lattice. It can be calculated by finding the minimum energy path linking two neighboring stable positions of the dislocation using either constrained minimization or nudged elastic band (NEB) calculations (Henkelman et al. 2000).

With periodic boundary conditions, the Peierls energy is directly obtained by considering a path where both dislocations composing the dipole are displaced by one Peierls valley in the same direction. If the two dislocations are moved simultaneously along the path, their separation distance does not vary, and the elastic energy is constant. This ensures that the energy variation given by the constrained minimization or the NEB calculations directly corresponds to the Peierls energy. However, this is possible only if crystal symmetry ensures that the path is symmetrical as the two dislocations are traversing their Peierls barriers in the opposite direction. This is the case, for instance, for the $1/2 \langle 111 \rangle$ screw dislocation in a bcc lattice gliding in a $\{110\}$ plane (Fig. 7a).

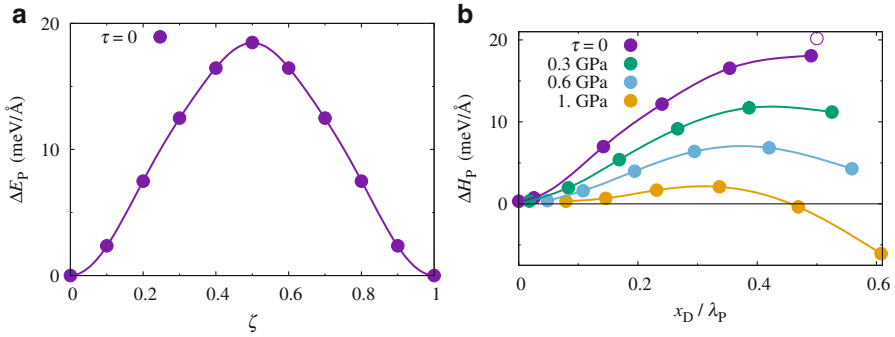
If the path is not symmetrical, either because of the lack of crystal symmetries or because of an applied stress, it is not possible anymore to move both dislocations simultaneously in the same direction. One needs either to move them in opposite directions or to keep one dislocation fixed when the second one is moving. As


**Fig. 7** Peierls barrier of a $1/2 \langle 111 \rangle$ screw dislocation in bcc Mo. (**a**) The energy variation $\Delta E$ is shown as a function of the reaction coordinate $\zeta$, and (**b**) the enthalpy variation $\Delta H$ as a function of the dislocation position $x_{\mathrm{D}}$ normalized by the distance $\lambda_{\mathrm{P}}$ between two Peierls valleys (see Dezerald et al. 2014, 2016 for details). For the Peierls barriers under stress (**b**), only one half of the barrier has been computed, with one dislocation of the dipole being displaced while the second one remains fixed. The open symbol is the enthalpy variation in the middle of the pathway ($x_{\mathrm{D}}/\lambda_{\mathrm{P}} = 1/2$) before correcting for the variation of the elastic interaction energy for the $\tau = 0$ calculation

a consequence, the separation distance, and thus the elastic interaction energy, is varying along the path. One can calculate this variation of the elastic energy and subtract it from the excess energy in order to obtain the Peierls energy. To be able to perform this elastic calculation, one needs first to determine the exact dislocation position $x_{\mathrm{D}}$ for each reaction coordinate $\zeta$ along the path. This can be done using the dislocation disregistry (cf. Sect. 4.3) if the motion is planar or by fitting the atomic displacements with the Volterra elastic solution. As the stress is directly linked to the applied strain and the dislocation positions (Eqs. 2 and 3), one can also use the stress variation observed along the dislocation path to determine the dislocations position. The example of Fig. 7b shows that, with this correction for the variation of the elastic energy, the same Peierls energy is obtained under zero applied stress when one dislocation is fixed or when both dislocations are moved (Fig. 7a).

## 5.3    Peierls Stress

The Peierls stress is the applied resolved shear stress necessary to cancel the Peierls barrier so that the dislocations can glide freely without the need of thermal activation, i.e., the stress necessary to move the dislocation at 0 K. For an applied stress $\tau$, the Peierls barrier is given by the enthalpy variation

$$\Delta H_{\mathrm{P}}(x_{\mathrm{D}}, \tau) = \Delta E_{\mathrm{P}}(x_{\mathrm{D}}) - \tau b x_{\mathrm{D}},$$

which corresponds to the Peierls energy barrier plus the work of the applied stress when the dislocation has glided a distance $x_{\mathrm{D}}$. The Peierls stress is thus

the maximum applied stress $\tau$ for which the function $\Delta H_P(x_D, \tau)$ goes through a maximum in the range $0 \leq x_D \leq \lambda_P$. If one assumes that the energy barrier $\Delta E_P(x_D)$ does not depend on the applied stress $\tau$, it is given by

$$\tau_P = \frac{1}{b}\text{Max}\left(\frac{\partial \Delta E_P}{\partial x_D}\right). \tag{7}$$

The Peierls stress can thus be theoretically obtained from the calculation of the Peierls energy barrier under zero applied stress. But, the evaluation of the derivative in Eq. 7 requires to know the variation of the energy as a function of the dislocation position and not only of the reaction coordinate. In practice, the obtained value for $\tau_P$ will sensitively vary with the method chosen to estimate the dislocation position along the path.

One can also directly calculate with ab initio calculations the Peierls barrier under an applied stress so as to estimate at which stress the barrier cancels (Fig. 7). In such calculations, one does not really apply a stress but a strain corresponding to the target stress (Eq. 2). With periodic boundary conditions, as the distance between the two dislocation is varying, the applied stress is also varying along the path. Equations (2) and (3) show that the stress variation is directly proportional to the dislocation displacement and to the inverse of the surface $S$ of the simulation cell perpendicular to the dislocation line. If only one dislocation is moving along the path, this stress variation therefore does not exceed

$$\delta\tau = \mu\frac{b\lambda_P}{S},$$

where $\mu$ is the shear modulus in the dislocation glide plane.

If one is only interested in the calculation of the Peierls stress and not in the variation of the Peierls barrier with the applied stress, one can simply perform static relaxation of a dislocation under an applied stress to see at which applied stress the dislocation glides by at least one Peierls valley. With periodic boundary conditions one still needs to take into account the variation of the elastic interaction and of the applied stress when the dislocation is moving to interpret the results. On the other hand, no such artifact exists with a cluster approach using flexible boundary conditions which truly models a single isolated dislocation under an applied stress. Straining homogeneously the simulation cell to obtain the targeted applied stress, the Peierls stress is defined as the stress for which the dislocation cannot be stabilized anymore and escapes from the cluster. If one is only interested in the evolution of the dislocation core structure under an applied stress and on the determination of the Peierls stress, this cluster approach therefore appears as the method of choice. Nevertheless, whatever the boundary conditions, determination of the Peierls stress by such an instability condition of the dislocation core under an applied stress necessitates a strict threshold criterion on the atomic forces to obtain a meaningful value.

# 6    Conclusions

Dislocation core properties can now be routinely studied with ab initio calculations, thanks to the different methodological developments summarized in this chapter. This usually necessitates a coupling between atomistic model and elasticity theory, for which different already available tools can be used: see, for instance, D. R. Trinkle website (http://dtrinkle.matse.illinois.edu) for an implementation of the lattice Greens functions or the Babel package (http://emmanuel.clouet.free.fr/Programs/Babel) for handling dislocations in atomistic simulation cells and elastic energy calculations. Useful information on the dislocation core structure are thus obtained. Such calculations can, for instance, characterize possible dissociation or spreading of the core, or evidence the existence of several stable configurations for the same dislocation. One gets access to the different energy barriers opposing the dislocation motion and to their variation with the applied stress. It is also possible to study how these core properties are altered by the interaction with solute atoms.

Because of the limited size that can be handled by ab initio calculations, such studies are usually limited to the study of straight dislocation, and only few ab initio calculations have considered until now the presence of kinks on the dislocation lines. Upscaling modeling approaches, relying, for instance, to the line tension approximation to describe kink nucleation, are therefore needed to go from these fundamental core properties determined at $0\,\mathrm{K}$ with ab initio calculations to dislocation mobility laws at finite temperature. Larger atomistic simulations are also possible using empirical potentials to describe atomic interactions. These simulations allow studying more complex situations and simulating different dislocation mechanisms, like glide, cross-slip and interaction with other elements of the microstructure, without assuming a priori the elementary mechanism. In such a context, ab initio calculations are useful to validate and also help the development of empirical potentials which correctly reproduce dislocation fundamental properties.

# Modeling the Thermally Activated Mobility of Dislocations at the Atomic Scale

# 71

Laurent Proville and David Rodney

## Contents

**Abstract**

We review in this chapter how to model the mobility of isolated dislocations at the atomic scale when glide requires to overcome energy barriers and is thermally activated, as is typically the case in body-centered cubic metals. We first recall the boundary and loading conditions used to model an isolated dislocation. We then detail a static approach based on the Transition State Theory parameterized on atomistic calculations to predict dislocation mobility. Finally, we address the low-temperature regime and explain how to include quantum corrections to the dislocation mobility law.

# 1    Introduction

Dislocations are set in motion under the action of an applied resolved shear stress. In absence of obstacles, that is, if the crystal is locally free of crystalline defects such as other dislocations, precipitates, or grain boundaries, the dislocation may reach a steady-state velocity if the applied stress is constant. In this stationary state, the work of the applied stress, which drives dislocation motion, is balanced by the energy lost to the surrounding crystal as heat (Leibfried 1950; Nadgornyi 1988). The mobility law, i.e., the relation between the applied resolved shear stress and the steady-state velocity, is one of the most fundamental ingredients of all dislocation dynamics theory (Suzuki et al. 1991; Cai and Bulatov 2004; Bulatov and Cai 2006). This relation has been measured experimentally (Johnston and Gilman 1959; Caillard 2010; Nosenko et al. 2011), but there is also an intense research activity to predict the mobility law from elementary dislocation properties (Koizumi et al. 2002). Such models must necessarily include the atomic structure of the dislocation core because the velocity reached by a dislocation at a given stress is intimately related to how its core interacts with the surrounding crystal. In the present chapter, we will discuss how to measure and predict a dislocation mobility law using atomic-scale simulations.

The mobility law concerns the motion of isolated dislocations gliding freely between obstacles. It should not be confused with the long timescale average velocity $v_d$, as estimated from Orowan's law $\dot{\varepsilon}_p = \rho_m b v_d$, where $\dot{\varepsilon}_p$ is the applied strain rate, $\rho_m$ the density of mobile dislocations, and $b$ the Burgers vector. Indeed, a dislocation meets numerous obstacles during its glide in a crystal and undergoes a stop-and-go motion, spending long periods of time immobile in contact with obstacles before unpinning and traveling rapidly to the next obstacle. The average velocity $v_d = \dot{\varepsilon}_p / \rho_m b$, which includes both the pinned and unpinned regimes, can therefore be significantly smaller than the unpinned velocity between obstacles, which is the object of the mobility law. Predicting the average dislocation velocity requires large-scale models, such as discrete dislocation dynamics simulations, to account for the collective interactions between dislocations and between dislocations and the other elements of the microstructure (Bulatov and Cai 2006; Kubin 2013). In contrast, in the present chapter, we consider the kinematic response of an isolated dislocation, which can be studied in simulation cells compatible with the size limit inherent to atomic-scale calculations.

The dislocation mobility has two very distinct regimes, depending on whether the applied stress is below or above the Peierls stress, the intrinsic resistance of the crystal against dislocation motion. If the applied stress is below the Peierls stress, the dislocation cannot glide without the help of thermal fluctuations and jumps between equilibrium positions by a thermally activated process (Caillard and Martin 2003). The resulting dislocation velocity is then thermally activated and depends exponentially on the temperature and the applied stress. As a result, the dislocation kinetics is too slow to be modeled by direct molecular dynamics (MD) simulations, except at high applied stresses close to the Peierls stress or high temperatures (Marian et al. 2004; Chaussidon et al. 2006; Gilbert et al. 2011). It can however

be approximated using the transition state theory (TST) parameterized on atomistic static calculations. This is typically the case of $a/2\langle 111 \rangle$ screw dislocations in body-centered cubic (BCC) metals, like Mo, Ta, or W, which will be discussed in the present chapter.

In the second regime, the applied stress is larger than the Peierls stress. This is typically the case of face-centered cubic (FCC) metals, like Al, Cu, and Ni, where the Peierls stress of the conventional $a/2\langle 110 \rangle$ dislocations is very small, a few tens of MPa at most. In any practical condition of deformation at finite strain rates, the applied stress is then much larger than the Peierls stress. In this stress regime, the dislocation velocity is large enough to be measured directly by MD simulations (Gumbsch and Gao 1999; Rodney and Martin 2000; Bhate et al. 2002; Olmsted et al. 2005; Mordehai et al. 2003; Oren et al. 2017). At stresses slightly greater than the Peierls stress, the dislocation velocity is limited by the rate at which atomic and electronic vibrations can dissipate the heat produced by the work of the applied stress. In MD simulations where only atomic vibrations are accounted for, the velocity increases linearly with the ratio $\tau/T$ where $\tau$ is the applied stress and $T$ the temperature, as expected from theoretical analysis of phonon damping (Leibfried 1950; Alshits 1992). At higher stresses, the dislocation velocity enters a relativistic regime and approaches asymptotically the shear wave speed. Finally, supersonic and transonic velocities may be reached at even higher stresses in conditions akin to shocks. We will not discuss these results further, but rather refer the reader, for example, to the recent work of Oren et al. (2017) and references therein for more details.

In the present chapter, we present how to predict the dislocation velocity using atomistic simulations in the thermally activated regime where the applied stress is below the Peierls stress. Because of the requirements in terms of space scale of these simulations, we will use atomistic simulations based on empirical potentials of the embedded atom method (EAM) type. In Sect. 2, we present how to set up a simulation cell to model an isolated dislocation. In Sects. 3, 4, and 5, we use BCC metals to illustrate how dislocation mobility can be modeled using the transition state theory, both in the high-temperature regime of classical dynamics and at lower temperatures where quantum zero-point energy vibrations can affect the motion of dislocations.

## 2 Construction of the Simulation Cell

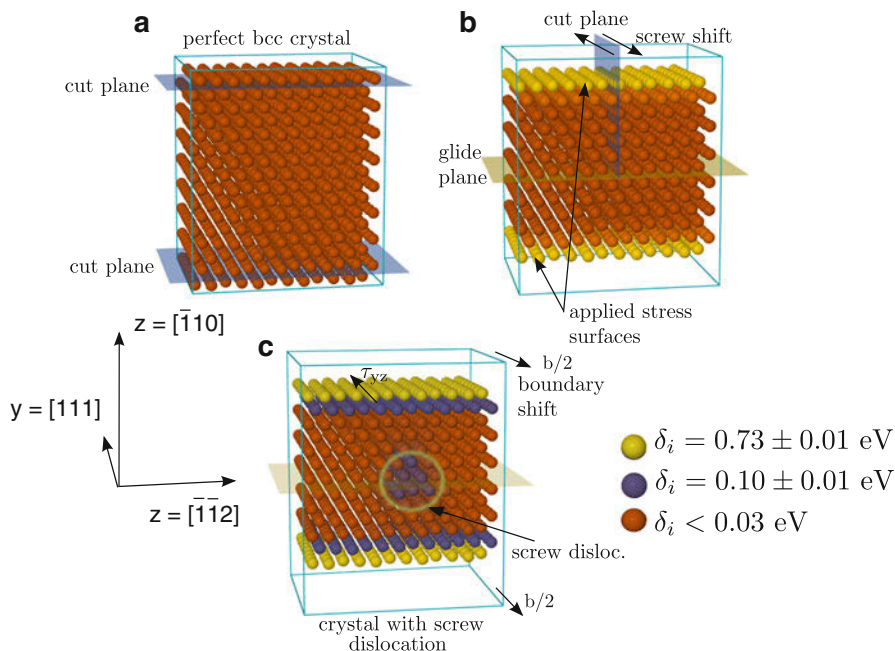
There are two main types of boundary conditions adapted to the study of dislocation mobility: periodic or slab conditions. In the former case, a dipole of dislocations of opposite Burgers vectors is introduced in the cell to produce a zero global Burgers vector, which is the condition to apply periodic boundary conditions in all three directions of space. The dislocations of the dipole interact with one another, as well as with their periodic images. The elastic part of these interactions can be corrected, as detailed in Chapter **AB - initio models of dislocations**, yielding well-defined dislocation core energies even in small simulation cells. Periodic boundary


**Fig. 1** Simulation cell construction for a $a/2[111](\bar{1}10)$ screw dislocation in a BCC crystal: (**a**) Perfect crystal simulation cell. conditions have been used to study dislocation glide in FCC crystals above the Peierls stress (Mordehai et al. 2003; Oren et al. 2017). One difficulty is that under the action of an applied shear stress, the two dislocations of the dipole move in opposite directions. Their relative distance and mutual interactions vary with time. As a consequence, the velocity of the dislocations vary periodically as they cross the simulation cell (Oren et al. 2017).

The second option is to use a slab geometry with a single dislocation in the cell. An example is shown in Fig. 1 for a screw dislocation in a BCC crystal and in Fig. 2 for an edge dislocation in a FCC crystal. The detailed methodology to construct a slab geometry is described in earlier works (Rodney and Martin 2000; Patinet and Proville 2008; Bacon et al. 2008; Rodney and Proville 2009). The simulation cell is oriented such that the dislocation glide plane is horizontal. In case of a BCC crystal, the crystal orientation is $[\bar{1}\bar{1}2]$ along the $X$ axis, $[111]$ along the $Y$ axis, and $[\bar{1}10]$ along the $Z$ axis. In case of a FCC crystal, we have $[1\bar{1}\bar{2}]$ along the $X$ axis, $[110]$ along the $Y$ axis, and $[1\bar{1}1]$ along the $Z$ axis. The Burgers vector $b = \frac{a}{2}[110]$ in the BCC crystal and $b = \frac{a}{2}[111]$ in the FCC crystal corresponds either to the line direction of the screw dislocation or the glide direction of the edge dislocation. Here, $a$ is the lattice parameter of the perfect lattice.

Starting from a perfect crystal, two free surfaces are created in the direction perpendicular to the glide plane. A dislocation is then introduced by displacing all atoms according to the corresponding isotropic elastic solution (Hirth and Lothe 1982). The anisotropic solution can also be used but is not necessary because the energy in the cell is relaxed after introduction of the dislocation and this relaxation recovers the anisotropy. In order to model an infinite glide plane, periodic boundary conditions are imposed along both the $X$ and $Y$ directions. When a screw dislocation is considered (Fig. 1), an additional shift of half a Burgers vector is introduced in the $Y$ direction (Rodney 2004; Bacon et al. 2008) in order to account for the plastic strain associated with the dislocation and to reconnect the left- and right-$Y$ surfaces. The simulation cell is therefore not rectangular. In the case of an edge dislocation, a half crystal plane orthogonal to the $Y$ direction is added to form a step, as shown in Fig. 2. This step is pushed in the simulation cell when the elastic displacements are applied to form the extra half plane of the edge dislocation. The size of the simulation cell is then increased by half a Burgers vector in the $Y$ direction, again in order to account for the plastic strain of the dislocation (Rodney and Martin 2000; Bacon et al. 2008).

Because of the non-zero Burgers vector in the cell, periodic boundary conditions cannot be applied in the $Z$ direction. Instead, two surfaces are created, forming a slab as shown in Figs. 1 and 2. The simplest solution is to consider free surfaces in this direction, but there are other possibilities, such as fully or semirigid

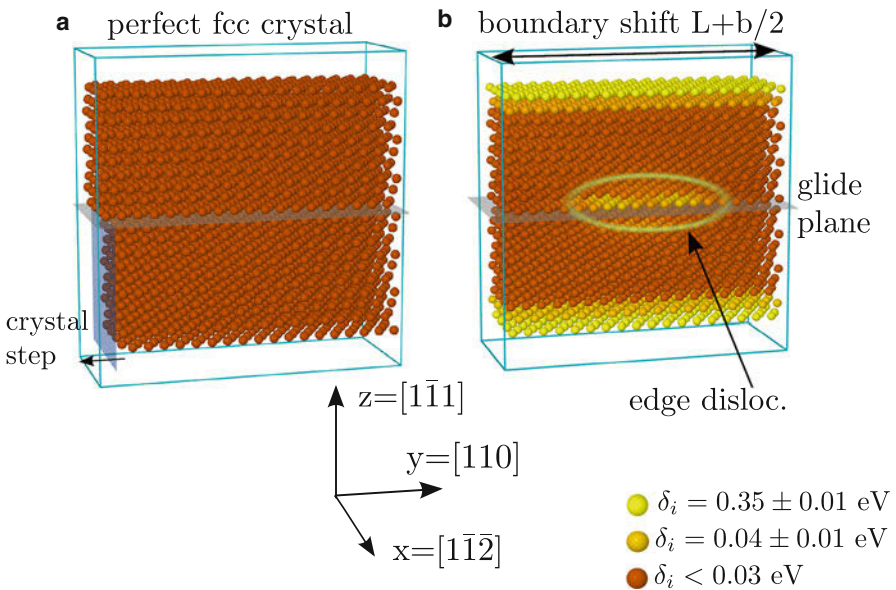

**Fig. 2** Simulation cell construction for a $a/2[110](1\bar{1}1)$ edge dislocation in a FCC crystal: (**a**) Perfect crystal simulation cell with one half plane removed (not relaxed). (**b**) Relaxed simulation cell after the introduction of an edge dislocation. Atomic colors are fixed according to the potential energy deviations from the perfect crystal cohesive energy

boundary conditions, as well as two-dimensional dynamics (Rodney and Martin 2000; Osetsky and Bacon 2003; Bacon et al. 2008). In case of free surfaces, a constant external shear stress $\tau_{xz}$ for the edge dislocation and $\tau_{yz}$ for the screw dislocation may be applied by adding external forces to the atoms near the top and bottom surfaces (usually within the cut-off radius of the interatomic potential). The external force is $\pm S\tau/N_{surf}$ where $N_{surf}$ is the number of atoms in the surface of area $S$, so that the total applied force is balanced between the upper and lower surfaces. We note that in case of an edge dislocation, the number of atoms in the top and bottom surfaces is not the same because of the extra half plane of the dislocation. Combinations of surface tractions parallel and perpendicular to the surfaces can be used to produce more complex stress tensors, including for instance, non-resolved components (Barvinschi et al. 2014).

After application of the initial displacement field, the atomic positions are relaxed through standard energy minimization algorithms, such as the conjugate gradient or damped dynamics, until typically the maximum atomic force component is below $10^{-4}$ eV/Å. As expected for FCC crystals, because of the existence of a stable stacking fault, the dislocation core splits in two partial dislocations separated by a stacking fault, the width of which depends on the stacking fault energy, the elastic constants, and the lattice parameter (Hirth and Lothe 1982). This is clearly seen in Fig. 2, where the atoms are colored according to their potential energy deviation from the cohesive energy of the perfect crystal. If the atom index is noted $i$ and $E_i^0$ is the reference energy, then with $E_i$ the potential energy of atom $i$ in the deformed cell, the potential energy deviation is $\Delta_i = E_i - E_i^0$. In the case where no impurity is present in the crystal, $E_i^0$ is simply the crystal cohesive energy per atom, $E_{coh}$.

In order to avoid spurious interactions with the periodic images, the dimension along the glide direction must be large enough (Proville and Patinet 2010). By increasing gradually the applied stress and relaxing the atomic positions, the dislocation starts to glide when the stress reaches a threshold, which corresponds to the dislocation Peierls stress. In the case where an impurity is situated close to the glide plane of the dislocation (as shown in Fig. 3), the stress threshold is larger than the Peierls stress, which is representative of solid solution hardening (Proville and Patinet 2010).

## 3 Kink-Pair Mechanism

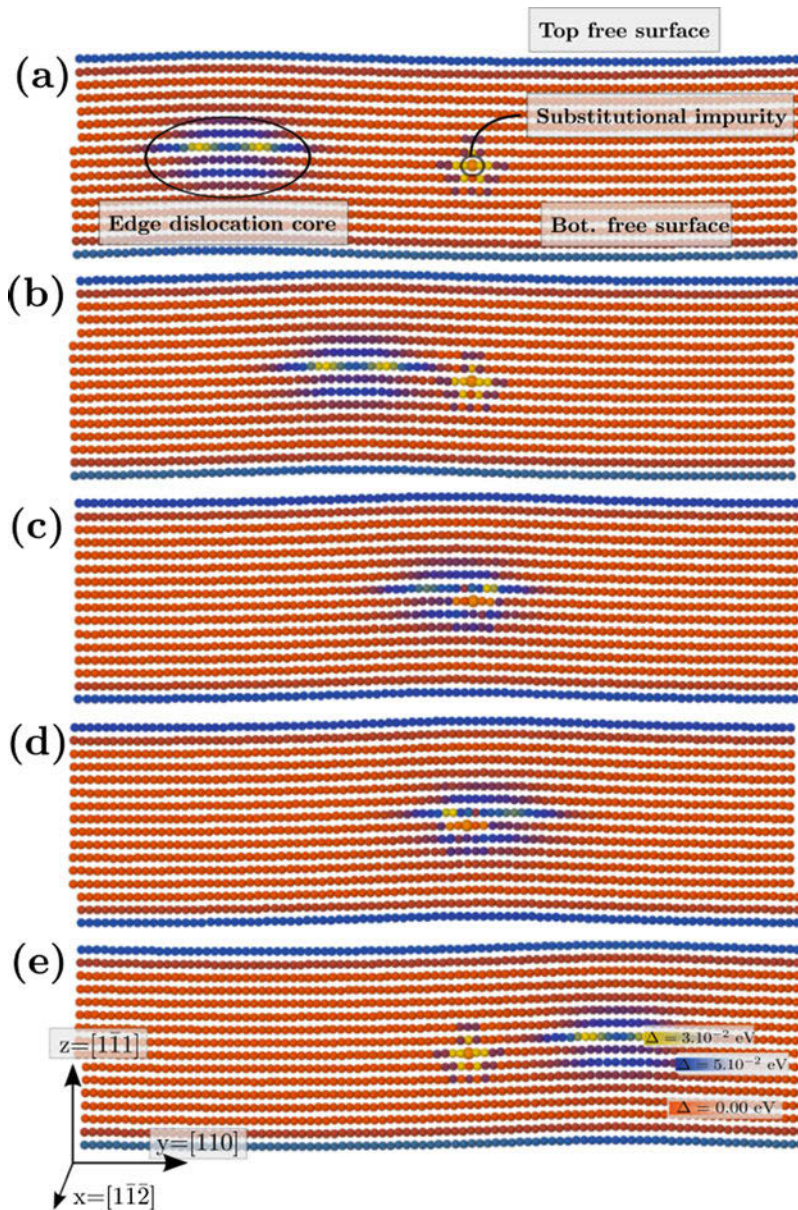
When the applied resolved shear stress is below the Peierls stress, the dislocation has stable positions in its glide plane and moves at low temperature from one stable position to the next by a thermally activated process. The stable positions, called Peierls valleys, usually correspond to the dislocation aligned along a low-index crystallographic direction. The archetype is the screw dislocation in BCC metals (Dorn and Rajnak 1964; Guyot and Dorn 1967; Caillard and Martin 2003), where the dislocation line aligns with the dense $\langle 111 \rangle$ direction of its Burgers vector. The dislocation is then in a minimum-energy configuration separated from the next


**Fig. 3** Snapshots of the crossing process for an $a/2[110](1\bar{1}1)$ edge dislocation in a FCC Al crystal with a single substitutional Mg impurity situated in the first crystal plane beneath the dislocation glide plane. Atomic colors are fixed according to the potential energy deviations from the perfect crystal cohesive energy
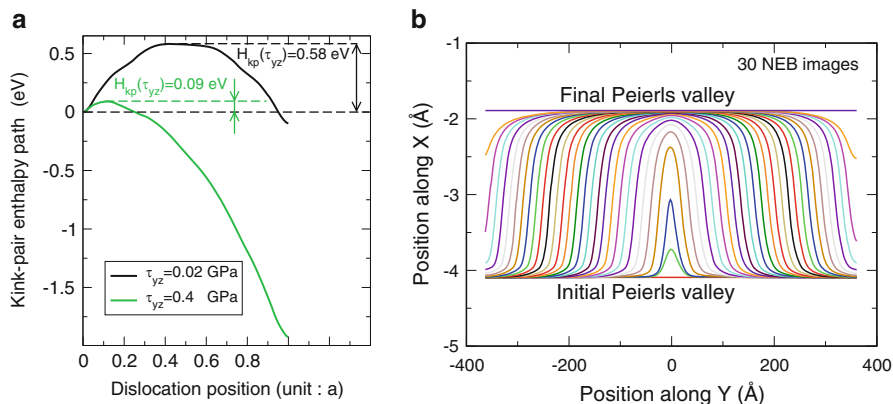

**Fig. 4** (**a**) Activation enthalpy for kink-pair formation on a screw dislocation in an EAM model of BCC $\alpha$-iron (Gordon et al. 2011) computed with nudged elastic band (NEB) method (Henkelman et al. 2000). (**b**) Profile of the dislocation in different NEB images showing the nucleation and expansion of a kink pair

equilibrium configuration by an energy barrier, called the Peierls barrier. To glide, the dislocation needs to jump to the next Peierls valley by a thermally activated process, which involves the nucleation of a short and localized segment in the next Peierls valley. This segment is bordered by two kinks, i.e., short dislocation segments that connect the dislocation between Peierls valleys. Once nucleated, this kink pair expands under the effect of the external stress, thereby progressively transferring the rest of the dislocation in the new Peierls valley.

This process can be computed at the atomic scale as illustrated in Fig. 4. Two configurations are generated with the dislocation in successive Peierls valleys. The nudged elastic band (NEB) method (Henkelman et al. 2000) is then used to identify the minimum energy path (MEP) between these configurations. The NEB method requires an initial path which must break the translational symmetry along the dislocation line to relax toward a MEP that reproduces the nucleation and propagation of a kink pair. Otherwise, the NEB method will converge to a high-energy path where the dislocation remains straight during the transition between Peierls valleys. To construct the intermediate states along the initial NEB path, atomic coordinates from the initial and final configurations are combined along the dislocation line. More precisely, the atomic coordinates are taken from the initial configuration except in a central region, whose width increases with the NEB image index. In this central region, the atomic coordinates are taken from the final state. A large number of NEB images allows to determine precisely the MEP. Examples under two different applied stresses are shown in Fig. 4a for a screw dislocation in a BCC iron model. The successive NEB images correspond to dislocation profiles, which are presented in Fig. 4b. As can be seen, the dislocation changes Peierls valley by the expected kink-pair mechanism. These dislocation profiles were obtained from the atomistic configurations by weighting the atomic positions with the atomic potential energy deviations, $\Delta_i$:

$$X_D = \frac{1}{\sum_i \Delta_i} \sum_i x_i \Delta_i \qquad (1)$$

$$Y_D = \frac{1}{\sum_i \Delta_i} \sum_i y_i \Delta_i$$

$$Z_D = \frac{1}{\sum_i \Delta_i} \sum_i z_i \Delta_i .$$

For a screw dislocation with a Burgers vector along Y axis, the dislocation position along the $X$ and $Z$ axis is expressed by $(X_D, Z_D)$, while for an edge dislocation with same Burgers vector, the position along the $Y$ and $Z$ axis is expressed by $(Y_D, Z_D)$. Then to determine the position of a dislocation segment, the computation of the position is performed within slices of crystal perpendicular to the dislocation line (see Landeiro Dos Reis et al. (2017) for more details). The dislocation position can be obtained from other considerations detailed in the literature (see, for instance, (Gröger and Vitek 2015; Dezerald et al. 2016) and Refs. therein), but the main advantages of the above definition are the following: (i) its simplicity when interatomic potentials are used and (ii) it can be generalized to other crystal defects, such as vacancies and interstitial atoms, using all three equations above to fully determine the defect position in the three dimensions of space. In the case of a long dislocation as in Fig. 4, the dislocation profile was obtained by computing the dislocation position in slices in direction $Y$ (the dislocation line direction) of width equal to the Burgers vector.

In case of a BCC screw dislocation, the migration barrier of the kinks along the dislocation line (called secondary Peierls barrier) is negligible, and the kink motion under stress is not thermally activated. The controlling process is then the nucleation of the initial unstable kink pair. The situation is different for instance in semiconductors, where the secondary Peierls valley is large and the diffusion of the kinks along the dislocation may be the controlling process (Hirth and Lothe 1982), depending on the temperature and the applied stress. We will however consider here only the case of BCC screw dislocations. At higher temperatures, in the so-called athermal regime, the thermal energy becomes large enough that dislocation motion is no longer thermally activated and resembles that observed in FCC metals.

As seen in Fig. 4a, the enthalpy barrier against kink-pair formation decreases with increasing applied shear stress due to the contribution of the work of the applied stress, which tilts the potential energy landscape. The stress at which the barrier disappears corresponds to the Peierls stress, above which dislocation motion is no longer thermally activated. This stress is obviously the same as the critical stress above which a stress-controlled enthalpy minimization does not find an equilibrium configuration but glides continuously in the simulation cell during the enthalpy minimization.

It has long been recognized that measurements of the Peierls stress from atomistic models systematically overestimate experimental data. This discrepancy was first reported by Basinski et al. (1971) in their early calculations in BCC

sodium modeled with an interatomic pair potential. But the same effect has since been repeatedly reported in BCC metals using more advanced energetic models, including EAM potentials (Wen and Ngan 2000; Chaussidon et al. 2006; Gordon et al. 2010), bond-order potentials (Gröger and Vitek 2008; Mrovec et al. 2011; Chen et al. 2013), and even ab initio density functional theory (DFT) (Woodward and Rao 2002; Ventelon and Willaime 2007; Ventelon et al. 2013; Weinberger et al. 2013). It was shown (Proville et al. 2012; Barvinschi et al. 2014) that the difference between experimental and simulated Peierls stresses is in part due to a quantum effect arising from the zero-point motion of the atoms near the dislocation core. This macroscopic quantum effect had so far been systematically discarded in atomistic simulations. However, such effect is expected even in heavy metals like Fe, because the Debye temperature, below which quantum effects in the vibrational modes of the system appear, is high (470 K in Fe) and the experiments to measure the Peierls stress were performed at very low temperatures, 4 K or less (Kuramoto et al. 1979; Brunner and Diehl 1992), well below the Debye temperature.

In contrast with glide above the Peierls stress, the thermally activated glide of dislocations below the Peierls stress cannot be studied using MD because the rate of kink-pair nucleation decreases exponentially rapidly when the stress decreases below the Peierls stress and the dislocation becomes immobile on MD timescales. On the other hand, the thermally activated nucleation of kink pairs can be modeled using the harmonic transition state theory (TST) (Benderskii et al. 1994). Moreover, this theory, which is the subject of the next section, can be written in a quantum form which allows to include zero-point energy corrections at low temperatures (Proville et al. 2012). Unlike in classical mechanics, quantum systems constantly fluctuate around their lowest energy state due to the Heisenberg uncertainty principle. The existence of non-zero minimum energy for a particle in a potential well $V(x) = m\omega_0^2/2x^2$ which is zero at the minimum position $x = 0$ can be demonstrated as follows. The Heisenberg uncertainty imposes that the fluctuations of the momentum $\delta p > \hbar/2\delta x$ which leads to a total energy $E = p^2/2m + V(x) > [(\hbar/2\delta x)^2/2m + V(\delta x)]$ which once minimized against $\delta x$ yields $\delta x^2 = \hbar/2m\omega_0$ and therefore $E > \hbar\omega_0/2$. Even though in a classical scheme the total energy is zero when both $x = 0$ and $p = 0$, the quantum fluctuations impose that the total energy cannot be less than $\hbar\omega_0/2$ which is called the zero-point energy. Within Einstein's model of crystals (Ashcroft and Mermin 1976), $\omega_0$ represents the Debye frequency, of the order of $\omega_0 \approx 60$ THz in Fe. This yields a zero-point energy per atom of 227 K, below which quantum fluctuations cannot be ignored.

## 4    Harmonic Transition State Theory

We consider a BCC crystal at low temperature where dislocation glide is thermally activated. Assuming that the plastic deformation is controlled by the glide of screw dislocations and not by their interactions with the microstructure, the mobility law equals the average velocity, and the plastic strain rate is given by Orowan law:

$$\dot{\varepsilon}_p = \rho_m b v_d \qquad (2)$$

where $\rho_m$ is the density of mobile screw dislocations, $b$ the Burgers vector, and $v_d$ the screw dislocation mobility law. Dislocation glide being controlled by the formation of kink pairs between nearest Peierls valleys, the dislocation velocity is expressed as $v_d = d\Gamma$ where $d$ is the distance between Peierls valleys and $\Gamma$ the kink-pair nucleation rate. According to the classical TST (Miller 1975), the rate $\Gamma$ for a three-dimensional system made of $N$ atoms of equal mass $m$ is expressed as an integral over phase space:

$$\Gamma = Z_r^{-1} \int \prod_{i=1}^{3N} \frac{dX_i dP_i}{h^{3N}} \delta((\mathbf{X} - \mathbf{X}_s).\mathbf{d}_s) \frac{|\mathbf{P}.\mathbf{d}_s|}{m} \theta(\mathbf{P}.\mathbf{d}_s) \exp\{[-\beta \mathscr{H}(\mathbf{P}, \mathbf{X})]\}, \qquad (3)$$

where thick symbols stand for 3N-dimensional vectors, $\beta \equiv 1/k_B T$, and $h$ is Planck's constant. $\mathbf{X}$ is the configuration position with $\mathbf{X}_s$ the transition state, i.e., the unstable dislocation configuration between Peierls valleys. $\mathbf{d}_s$ is the corresponding unstable eigenmode, i.e., the direction in configuration space from $\mathbf{X}_s$ where the energy has a negative curvature. This direction is perpendicular to the dividing surface, which separates at $\mathbf{X}_s$ the basins of attraction of the initial and final configurations, i.e., the dislocation in two successive Peierls valleys. The Dirac function term, $\delta((\mathbf{X} - \mathbf{X}_s).\mathbf{d}_s)$, therefore limits the configuration integral to the dividing surface. $\mathbf{P}$ is the momentum, and the Heaviside function term $\theta(\mathbf{P}.\mathbf{d}_s)$ ensures that the integration in momentum space is performed in the half-space toward the product, i.e., the dislocation in the next Peierls valley. $\mathscr{H}(\mathbf{P}, \mathbf{X})$ is the Hamiltonian of the system to which the work of applied stress is properly substracted. Finally, $Z_r$ is the reactant partition function, that is, the harmonic partition function of the crystal with the dislocation at the bottom in its Peierls valley. The three free translational modes of the system have no contribution to the rate $\Gamma$ since they equally contribute to $Z_r$ and to the numerator in Eq. 3. They are omitted in the following.

To introduce the harmonic approximation, we use a normal mode representation $(\mathbf{q}, \mathbf{p})$ computed at the saddle state, instead of the cartesian coordinates $(\mathbf{X}, \mathbf{P})$. The unstable mode is placed at the end of the mode list, i.e., $s = 3N - 3$. If we note $\lambda_\nu$ the eigenvalue of mode $\nu$, the kink-pair nucleation rate is then written as

$$\Gamma = Z_r^{-1} \int \frac{dq_s dp_s}{h} \frac{p_s}{m} \theta(p_s)\delta(q_s) \prod_{\nu=1}^{3N-4} \frac{dq_\nu dp_\nu}{h^{3N-4}}$$

$$\exp\left\{\left[-\beta\left(H_{kp} + \sum_{\nu=1}^{3N-3}[\frac{p_\nu^2}{2m} + \lambda_\nu \frac{q_\nu^2}{2}]\right)\right]\right\}, \qquad (4)$$

where $H_{kp}$ is the activation enthalpy for kink-pair formation (the enthalpy difference between saddle and initial states), function of the applied shear stress $\tau_{yz}$.

In BCC crystals, in the stress regime considered here, the secondary Peierls barrier is absent. As a result, there is no resistance for kink motion along the dislocation line, resulting in a Goldstone mode of zero eigenvalue. The latter, assumed to correspond to $\nu = 1$, can be integrated out (it corresponds to the Gaussian integration of a kinetic energy term $1/h \int dq dp \exp(-\beta p^2/2m) = L_d \sqrt{2\pi mkT}/h$), yielding:

$$\Gamma = \frac{L_d \sqrt{2\pi mkT}}{h Z_r} \int \frac{dq_s dp_s}{h} \frac{p_s}{m} \theta(p_s)\delta(q_s) \prod_{\nu=2}^{3N-4} \frac{dq_\nu dp_\nu}{h^{3N-5}}$$

$$\exp\left\{\left[-\beta\left(H_{kp} + \sum_{\nu=2}^{3N-4}[\frac{p_\nu^2}{2m} + \lambda_\nu \frac{q_\nu^2}{2}]\right)\right]\right\}. \tag{5}$$

Note that the dislocation length $L_d$ now appears explicitly in the nucleation rate as a result of the integration of the Goldstone mode. This length dependence of the dislocation velocity has been measured experimentally by in situ TEM (Caillard 2010).

At low temperature, quantum mechanics must be accounted for. Since the normal modes are independent of one another, each stable mode (for $\nu = 2$ to $3N-4$) yields in Eq. 5 the partition function of a quantum harmonic oscillator $[2\sinh\left(\frac{\hbar\beta}{2}\omega_\nu\right)]^{-1}$, where $\omega_\nu = \sqrt{\lambda_\nu/m}$ is the angular frequency of mode $\nu$. Similarly, the partition function in the stable reactant state $Z_r$ can be treated harmonically, yielding $Z_r = \prod_{\mu=1}^{3N-3}[2\sinh\left(\frac{\hbar\beta}{2}\Omega_\mu\right)]^{-1}$, with $\{\Omega_\mu\}$ the angular frequencies associated with the reactant state. The nucleation rate is then expressed as

$$\Gamma = \frac{L_d\sqrt{2\pi mkT} \prod_{\mu=1}^{3N-3}[2\sinh\left(\frac{\hbar\beta}{2}\Omega_\mu\right)]}{h \prod_{\nu=2}^{3N-4}[2\sinh\left(\frac{\hbar\beta}{2}\omega_\nu\right)]} I, \tag{6}$$

where the integral $I$ is defined by

$$I = \int \frac{dq_s dp_s}{h} \frac{p_s}{m} \theta(p_s)\delta(q_s) \exp\left\{\left[-\beta\left(\frac{p_s^2}{2m} + H_{kp} + \lambda_s \frac{q_s^2}{2}\right)\right]\right\}. \tag{7}$$

This integral over the $q_s$ coordinate of the unstable mode is replaced (Benderskii et al. 1994) by the crossing rate of the parabolic barrier $H_{kp} + \lambda_s \frac{q_s^2}{2}$, which yields

$$I = \frac{1}{h} \int dE \; W(E) \exp\{(-\beta E)\}, \tag{8}$$

where $W$ the transmission coefficient for a parabolic barrier (Landau and Lifshitz 1981), given by $W(E) = [1 + \exp\{(2\pi(H_{kp} - E)/\hbar\omega_s)\}]^{-1}$ and $\omega_s = \sqrt{-\lambda_s/m}$.

After simplication, the integral becomes:

$$I = \frac{kT}{h} \frac{\hbar\beta\omega_s/2}{\sin(\hbar\beta\omega_s/2)} e^{-\beta H_{kp}}. \tag{9}$$

Within the harmonic TST, the rate of kink-pair formation is therefore expressed as

$$\Gamma = L_d \sqrt{\frac{2\pi m}{kT}} \frac{\hbar\beta\omega_s/2}{\sin(\hbar\beta\omega_s/2)} \left(\frac{kT}{h}\right)^2 \frac{\prod_{\mu=1}^{3N-3}[2\sinh\left(\frac{\hbar\beta}{2}\Omega_\mu\right)]}{\prod_{\nu=2}^{3N-4}[2\sinh\left(\frac{\hbar\beta}{2}\omega_\nu\right)]} e^{-\beta H_{kp}}. \tag{10}$$

Combining this equation with Eq. 2, we can therefore express the plastic strain rate as a quantum thermally activated Orowan law. We note that at high temperature when $\beta = 1/k_B T \to 0$, the sin and sinh terms become equivalent to their arguments and Eq. 2 can be simplified. The well-known TST expression characteristic of the classical regime is then recovered (Vineyard 1957):

$$\Gamma_C = L_d \sqrt{\frac{2\pi m}{kT}} \frac{\prod_{\mu=1}^{3N-3} \Omega_\mu}{\prod_{\nu=2}^{3N-4} \omega_\nu} e^{-\beta H_{kp}}, \tag{11}$$

where the pre-exponential factor involves the Goldstone mode and the ratio of the product of the eigenfrequencies in the initial and activated states. In experimental conditions, the plastic strain rate $\dot{\varepsilon}_p$ is constant and so is the density of mobile dislocations, $\rho_d$, at least to a first-order approximation. For a given temperature, Orowan equation (Eq. 2) is therefore solved self-consistently, finding the appropriate applied stress $\tau_{yz}$, which sets the saddle state and thus sets $H_{kp}$, $\omega_s$, $\{\omega_\nu\}$ and $\{\Omega_\mu\}$, and produces the kink-pair nucleation rate, which satisfies Orowan's equation.

It is well-known (Benderskii et al. 1994; Gillan 1987) that Eq. 9 diverges at a critical temperature $T_{\text{tun}} = \hbar\omega_s/2\pi k$, which marks the onset of deep quantum tunneling. The above harmonic theory is thus valid only above $T_{\text{tun}}$, but for iron, this temperature is small, typically below 10 K. Below $T_{\text{tun}}$, nonlinear effects must be accounted for, which is the subject of the instanton theory developed by Miller (1975). The most important contribution of quantum mechanics comes from the crystal partition functions that appear in the pre-exponential factor in Eq. 10. This quantum correction has some similarities with the heat capacity deviation from the Dulong-Petit law (see textbooks as Ashcroft and Mermin 1976).

## 5    Numerical Implementation

Computing Eq. 10 requires to evaluate the eigenfrequencies of the system and therefore requires to diagonalize the Hessian matrix. The latter can be obtained analytically if the interatomic potential is itself analytical. Otherwise, the Hessian

matrix coefficients are obtained through the calculation of the first derivative of the forces under a finite displacement of each atom in the three directions of space. When atom $i$ is displaced in direction $d_i$, the force field must be computed for each neighbor $j$, in each direction $d_j$. Denoting by $F_{d_j,j}$, the force exerted on atom $j$ in direction $d_j$, and by $X_{d_i,i}$, the displacement of atom $i$ in direction $d_i$, the coefficient of the Hessian matrix situated at row $i + N_{at}(d_i - 1)$ and column $j + N_{at}(d_j - 1)$ is given by

$$\mathcal{H}_{i+N_{at}(d_i-1),\, j+N_{at}(d_j-1)} = -\frac{1}{\sqrt{m_i m_j}} \frac{\delta F_{d_j,j}}{\delta X_{d_i,i}}, \tag{12}$$

where $m_i$ and $m_j$ are the masses of atoms $i$ and $j$, respectively. Displacements $X_{d_i,i}$ are typically one hundredth of an Angström. The exact diagonalization of the matrix $\mathcal{H}$ can be performed using the linear algebra package LAPACK (Anderson et al. 1999). Different diagonalization methods can be used for small simulation cells, with a number of atoms typically $N_{at} < 10,000$. However treating larger systems requires the use of a distributed memory algorithm because the Hessian matrix size overpasses the capabilities of serial processors. In this case, we employed ScaLAPACK parallel routines.

The result of the calculations is shown in Fig. 5 for two EAM models of $\alpha$-iron. We compare here the quantum (Eq. 10) and classical (Eq. 11) TST expressions. We see that in both cases, the classical expression strongly overestimates experimental

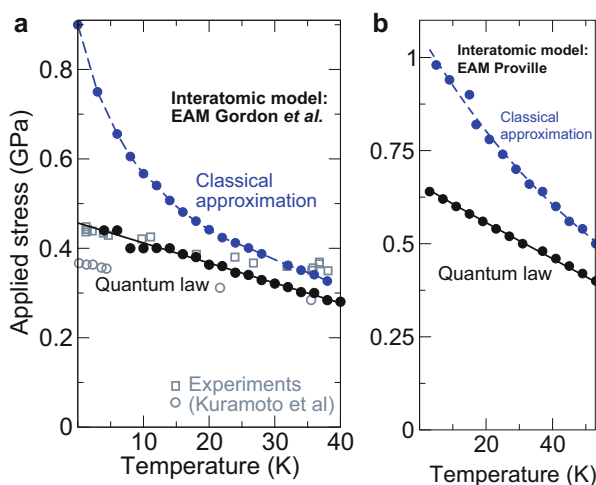

**Fig. 5** (**a**) Comparison of the temperature dependence of the flow stress predicted through the quantum Orowan law (solid curve), its classical approximation (dashed curve) and experimental data obtained in iron (the open circles and squares refer to two different orientations of the traction axis) (Kuramoto et al. 1979). The calculations were performed with the EAM potential for $\alpha$-iron developed by Gordon et al. (2011). (**b**) The same computations as in (**a**) with a different energetic model for iron (Proville et al. 2012)

data because of a rapid increase of the flow stress at low temperatures, while the quantum law does not show this rapid increase and is much closer to the experimental data, particularly in the case of the EAM potential developed by Gordon et al. (2011).

To evaluate the importance of the quantum correction, the zero-point energy of the crystal can be computed along the MEP from the Hessian diagonalization of each NEB image. If the $3N$ eigenvalues of $\mathscr{H}$ are denoted by $\lambda_u$, the zero-point energy of the system is evaluated through the harmonic approximation as

$$U_{ZP} = \frac{\hbar}{2} \sum_{u=1}^{3N} \sqrt{\lambda_u}, \tag{13}$$

where the unstable mode for which $\lambda_u < 0$ is excluded from the summation. The amplitude of the associated imaginary frequencies remains negligible in comparison to the variations of the zero-point energy along the MEP. The latter is reported in Fig. 6a for a straight screw dislocation as a function of its position in the crystal.

According to the quantum harmonic theory employed here, one can expect that the crystal quantum fluctuations are large enough to reduce the effect of the Peierls barriers the dislocations have to overcome. Figure 6a shows the case of a screw dislocation in $\alpha$-Fe. We see that the variation of the zero-point energy is opposite to that of the Peierls barrier and is approximately half its amplitude with the present interatomic potential (Proville et al. 2012). In absence of thermal

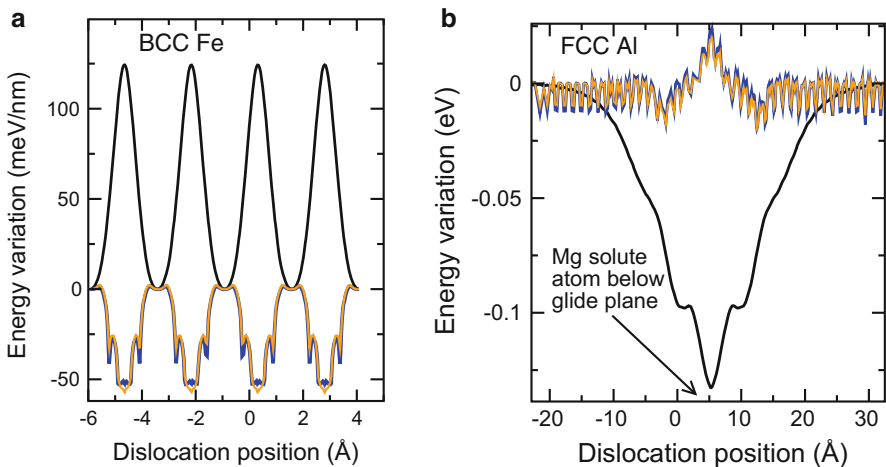

**Fig. 6** Comparison between the potential and zero-point energy variations during the glide of a straight screw dislocation in BCC $\alpha$-Fe (**a**) and of an edge dislocation in FCC Al in presence of a Mg solute atom in the plane just below the glide plane (**b**). The energies were computed along the minimum potential energy path obtained with the NEB method. The potential energy is shown in black, and the zero-point energy is computed from the exact diagonalization of the Hessian matrix (blue) and from an Einstein approximation (orange)

effects, the decrease of the Peierls stress by quantum fluctuations can therefore be understood from the consideration that the total energy of the system is composed of the sum of (i) the potential energy which is computed from the EAM interaction potential and (ii) the zero-point energy, which is itself the result of a combination between kinetic and vibrational energies. The zero-point energy variation has been computed in various FCC crystals following the same method (Landeiro Dos Reis et al. 2017). Figure 6b shows the example of an edge dislocation crossing an Mg solute in a FCC crystal of Al (see Fig. 3a–e). The impurity is located below the glide plane in a region of attraction and therefore induces a negative variation of the potential energy. We see in this example that the variation of the zero-point energy is again opposite to the potential energy and therefore decreases the attraction between the dislocation and the Mg solute, although the effect is not as marked as for the BCC screw dislocation. In all cases considered so far, the variation of the zero-point energy was opposite to the potential energy and therefore systematically decreases the energy barrier.

To gain some insight into the zero-point energy variation along the MEP of dislocations, we tested the approximation, which consists in computing the eigenfrequencies from the on-site frequencies of each atom with the other atoms frozen, that is, from the diagonal elements of the Hessian matrix only. The solid is then modeled as an assembly of independent oscillators, which corresponds to an Einstein approximation. The corresponding zero-point energy variation is shown in orange in Fig. 6 and closely follows the full calculation in both BCC and FCC crystals (Landeiro Dos Reis et al. 2017). This very good agreement between the Einstein approximation and the exact zero-point energy calculation shows that the main quantum contribution comes from vibrational modes with short wavelengths, since the acoustic modes are not included in the Einstein approximation.

## 6    Conclusion

The thermally activated mobility of dislocations can be studied at the atomic scale in model crystals with the help of the transition state theory to predict the dislocation jump rate. All the parameters of the model can be derived from the atomic scale, demonstrating the feasibility of a multi-scale modeling with no adjustable parameter. Comparison with experimental deformation tests in BCC Fe shows that the predictions established from the present method are satisfactory, provided that the quantum effect due to zero-point energy fluctuations is taken into account at low temperatures. To that purpose, we have employed a harmonic approximation. Both the TST and the harmonic approximation are the purpose of constant improvements (Mills et al. 1995), but these developments imply in general a much heavier computational load, which is difficult to apply to systems including thousands of atoms as is typical in simulation cells with dislocations. In pure BCC crystals where the Peierls landscape is the main barrier impeding screw dislocation glide, we have found that the zero-point energy variation is negative and therefore eases the motion of the dislocation. In FCC solid solutions, the interaction between

dislocations and solute atoms is the main barrier and can be either attractive or repulsive. However, the zero-point energy variation is systematically opposite to that of the potential energy and therefore always eases dislocation glide. The magnitude of the effect however depends on the case considered. Such a systematic observation through atomic simulations allows us to expect that the softening effect due to zero-point energy fluctuations is ubiquitous, although such a conclusion should require more theoretical investigations.

Based on the developments presented here, we believe that the present atomic-scale solid-state theory is getting close to establish predictions conforming to the experimental deformation tests performed in model materials as pure BCC crystals. However many challenges still remain to be faced, and questions remain to be addressed, as, for instance:

(i) We have used the simplest approximation (harmonic TST) but more accurate rate theories, which in particular include anharmonicity, should be tested (Saroukhani and Warner 2017).

(ii) Can we obtain more quantitative estimates of the zero-point energy using ab initio calculations? The accuracy of Einstein approximation allows to significantly reduce the computational cost, but computing force derivatives requires a precision higher than usual.

(iii) Ab initio calculations are still too computationally demanding to model kinked dislocations, but we should popularize the use of higher-scale models, like the line tension model (Dezerald et al. 2015), to predict dislocation mobility based on quantitative ab initio data.

(iv) In the particular case of BCC crystals, non-Schmid effects are known to significantly affect dislocation mobility (Dezerald et al. 2016), and we should in particular include the effect of non-glide components of the stress tensor (Barvinschi et al. 2014; Cereceda et al. 2016), which are unavoidable in experimental conditions of uniaxial tensile tests.

(v) The case of high-secondary Peierls valleys as in semiconductors or ceramics should also be investigated.

## Contents

**Abstract**

Precise analysis and meaningful visualization of dislocation structures in molecular dynamics simulations are important steps toward physical insights. This chapter provides an introduction to the dislocation extraction algorithm (DXA), which is a computational method for identifying and quantifying dislocations in atomistic crystal models. It builds a bridge between the atomistic world of crystal defects and the discrete line picture of classical dislocation theory.

## 1    Introduction

Dislocations have two sides: On one hand, they are commonly viewed in dislocation theory as discrete line objects, which possess a characteristic topological charge – the *Burgers vector* – and which can glide through a crystal to produce plasticity or participate in various kinds of reactions. On the other hand, they constitute a partic-

**Fig. 1** In this section a computer algorithm is introduced that can convert an atomistic crystal model (left) to a discrete line representation of the contained dislocation defects (right)

ular kind of irregularity in the otherwise regular arrangement of atoms in the crystal lattice. Boundaries of extra planes of atoms are what we call edge dislocations, and screw dislocations denote helical distortions of atomic planes. Thus, to fully grasp the phenomenon of crystal dislocations, we must consider – and somehow unify – two complementary pictures: the *explicit* one (discrete line objects) and the *implicit* one (glitches in the lattice arrangement). Both pictures are extensively used by different modeling strategies, with discrete dislocation dynamics (DDD) and molecular dynamics (MD) being the most prominent ones to represent the two dislocation descriptions. This section will introduce ways to unify these seemingly disparate pictures of the same physical phenomenon and to accomplish a conversion between them (Fig. 1). Given the atomic positions in a crystal containing dislocation defects, we want to reconstruct the geometry of the one-dimensional lines these dislocations can be described as mathematically. The computational method introduced here to solve this problem has practical relevance for the modelling of dislocations at multiple length scales as it builds a bridge between the atomistic world and the mesoscale and, at the same time, provides a powerful analysis tool for MD simulations that greatly helps to understand dislocation processes.

## 2 Burgers Circuit Method

As an introductory example for the connection between dislocation line theory and atomistic crystal defects, we take a look at the classical Burgers circuit construction (Frank 1951), which is the canonical method (Bulatov and Cai 2006) already proposed in the 1950s to discriminate dislocations from other crystal defects and to determine their Burgers vectors. In the formulation employed here, a Burgers circuit $C$ is a path in the dislocated crystal consisting of a sequence of atom-to-atom steps (line elements $\Delta\mathbf{x}$), as shown in Fig. 2a. The circuit is closed, thus $\sum_C \Delta\mathbf{x} = \mathbf{0}$.

We assume that there exists a mapping $\Delta\mathbf{x} \rightarrow \Delta\mathbf{x}'$ that translates each line element of the path to a corresponding image, $\Delta\mathbf{x}'$, in a perfect crystal
**Fig. 2** Burgers circuit method to identify a dislocation. A closed circuit around the dislocation is translated from (**a**) the dislocated crystal to (**b**) the perfect reference crystal. The closure failure **b** is called the Burgers vector of the dislocation

lattice (Fig. 2b). Summing these transformed line elements algebraically along the associated path, $C'$, gives the true Burgers vector of the dislocation enclosed by $C$:

$$\mathbf{b} = -\sum_{C'} \Delta\mathbf{x}'. \tag{1}$$

The Burgers vector **b** is the closure failure of the path after transferring it to the perfect reference crystal.

   Note that the Burgers circuit procedure is typically performed by hand to analyze two-dimensional crystal images obtained from high-resolution microscopy or atomistic computer simulations. Human intuition and cognitive capabilities are required to spot irregularities in the crystal lattice that are potential dislocation defects and to apply the Burgers circuit test to them. Automating these steps poses a challenge when developing a computational dislocation identification method for three-dimensional atomistic crystal models.

   The Burgers circuit procedure represented by Eq. 1 above is the discrete analogue of an equation used in continuum mechanics to define the Burgers vector of a Volterra dislocation:

$$\mathbf{b} = -\int_C (\mathbf{F}^{\mathbf{e}})^{-1}\mathrm{d}\mathbf{x}. \tag{2}$$

Here, $C$ denotes any contour enclosing the mathematical dislocation line, and $(\mathbf{F}^{\mathbf{e}})^{-1}$ denotes the inverse of the elastic deformation gradient. This second-rank tensor acts on the infinitesimal line element $\mathrm{d}\mathbf{x}$ and transforms it from the dislocated crystal configuration to an ideal, elastically unstrained reference configuration. This mapping is analogous to the explicit translation of atomic steps we did in the discrete formulation of the Burgers circuit procedure.

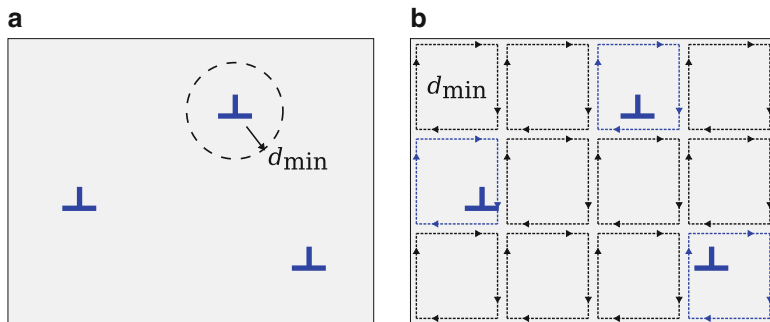
   Notably, the resulting vector **b** stays the same if we change the original circuit $C$, as long as it still encloses the same dislocation. On the other hand, if $\mathbf{b} = \mathbf{0}$, we


**Fig. 3** Schematic depiction of the dislocation finding approach described in the text. (**a**) The given domain contains a set of dislocations with unknown positions. The parameter $d_{\min}$ denotes the lower bound for the separation distance between dislocations, which is on the order of one atomic lattice spacing and corresponds to the dislocation core diameter. (**b**) The domain is tessellated by a grid of Burgers circuits of diameter $d_{\min}$. Circuits highlighted in blue exhibit a closure failure and are marked as containing a dislocation

know that the Burgers circuit did not enclose any defect with dislocation character. Here, however, we are deliberately ignoring the possibility that the circuit encloses multiple dislocations whose Burgers vectors cancel. One may thus ask, in the absence of a priori knowledge of the spatial distribution of dislocations in a given crystal, how can we – or rather a computer algorithm – construct the circuit $C$ such that it encloses exactly one of the dislocations?

This general situation is depicted schematically in Fig. 3a: A set of dislocations with unknown positions which we would like to determine is distributed across a given continuum domain. It is safe to assume that any distribution of dislocations is such that one can specify a lower-bound $d_{\min}$ for the separation distance between any two distinct dislocations. In reality, this lower bound is given by the interatomic spacing in the crystal lattice, because that is also the minimum distance when the cores of two nearby dislocations necessarily start to overlap; hence they can no longer be treated as distinct defects. As shown in Fig. 3b, it is possible to construct a large number of non-overlapping circuits, each having size $d_{\min}$, to completely cover the entire domain. By virtue of our construction, each circuit can contain at most one dislocation, and we effectively excluded the possibility of "missing" dislocations. The Burgers circuit test tells us which of the circuits contain a dislocation, and since their diameters are small, we can pinpoint the dislocations' positions with great precision (on the order of $d_{\min}$) using this method.

## 3 Simple Algorithm for Finding Dislocations in Atomistic Crystals

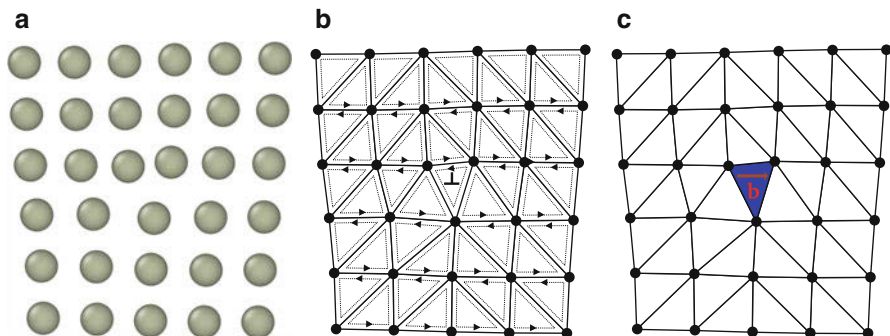
The approach outlined above can be translated into a simple computer algorithm to detect and find all dislocations in an atomistic crystal (Stukowski 2014). We


**Fig. 4** (**a**) Input atomic positions. (**b**) Tessellation of the input domain into triangular circuits using the Delaunay construction. (**c**) Burgers circuit test, performed on each Delaunay triangle, reveals exactly one cell that contains the dislocation

assume that the crystal to be analyzed is specified as a set of atomic coordinates $\{\mathbf{x}_i\}$ as depicted in Fig. 4a. The Delaunay construction is used to tessellate the crystal domain into a set of triangles (Fig. 4b). The elements of the triangulation are space-filling and non-overlapping, and we can regard them as small, elementary Burgers circuits, which will allow us to find and locate all dislocations contained in the atomistic crystal.

Since every edge of a triangle *abc* of the Delaunay tessellation represents an atom-to-atom step, we can apply the discrete version of the Burgers circuit method to calculate the per-triangle closure failure $\mathbf{b}_{abc} = \Delta\mathbf{x}'_{ab} + \Delta\mathbf{x}'_{bc} + \Delta\mathbf{x}'_{ca}$ after mapping each edge vector $\Delta\mathbf{x}_{ij} = \mathbf{x}_j - \mathbf{x}_i$ connecting two successive atoms $i$ and $j$ to its corresponding ideal vector $\Delta\mathbf{x}'_{ij}$ in a perfect reference crystal lattice. Triangle circuits with closure failure $\mathbf{b}_{abc} \neq 0$ are marked as containing a dislocation, as shown in Fig. 4c.

There are different ways to accomplish the mapping of interatomic vectors from the dislocated crystal to the virtual reference lattice, $\Delta\mathbf{x}_{ij} \rightarrow \Delta\mathbf{x}'_{ij}$. In cases where the orientation of the dislocated crystal in the simulation coordinate system is known a priori, we can simply pick the vector $\Delta\mathbf{x}'_{ij}$ from a prescribed set of ideal lattice vectors taking the one that is closest to the elastically distorted vector $\Delta\mathbf{x}_{ij}$ (Stukowski 2014). In more general situations, a structure identification method such as common neighbor analysis (CNA) (Honeycutt and Andersen 1987; Faken and Jonsson 1994) or polyhedral template matching (PTM) (Larsen et al. 2016) must be used to first determine the local lattice orientation and then map atomic neighbor vectors to corresponding ideal lattice directions.

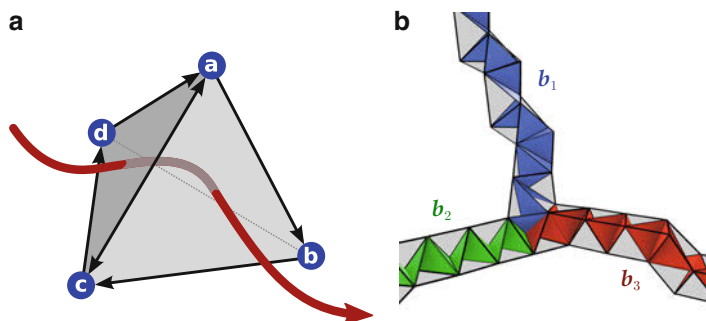
So far, we have considered only two-dimensional crystals where dislocations are point-like object in the plane. How does this approach extend to three-dimensional crystals containing linear dislocations? Here, the Delaunay tessellation of the atomistic model consists of tetrahedral cells, each being bordered by four triangular facets (Fig. 5). In the three-dimensional version of the algorithm, the closure failure $\mathbf{b}_{abc}$ must be computed for every triangular facet of the tetrahedral Delaunay cells.


**Fig. 5** (**a**) A tetrahedral cell of the three-dimensional Delaunay tessellation, which is spanned by four vertex atoms. A dislocation line enters and exits through the triangular facets of the cell. The algorithm described in the text identifies such facets using the Burgers circuit test. (**b**) Linear defects with dislocation character lead to "chains" of dislocated Delaunay cells, which may form junctions in three-dimensions as exemplarily shown here

If $\mathbf{b}_{abc} \neq 0$, a facet is marked as being intersected by a dislocation line. Since dislocations cannot end within an otherwise perfect crystal, because of the Burgers vector conservation law, a line entering a Delaunay cell through one of its triangular facets must exit the cell again through one of its other three facets. Accordingly, the dislocation can be viewed as a line piercing through a sequence of triangular facets and tetrahedral cells as illustrated by Fig. 5b.

## 4    Dislocation Extraction Algorithm (DXA)

So far we have deliberately ignored several important aspects that can play a role in more general situations. First and foremost, crystal dislocations have a finite core size (Fig. 6a). That means they are not mathematically thin, one-dimensional objects but rather tubelike objects spread over a certain space region. The core region typically extends over more than one interatomic spacing and is thus covering more than one Delaunay triangle element. In order to capture such dislocations, larger Burgers circuits are necessary to fully enclose the core (which is represented by a connected set of Delaunay elements that have been marked as "bad"; see Fig. 6b).

Secondly, dislocations may dissociate into partial dislocations. If we want to identify partial dislocations individually, e.g., Shockley partials in fcc crystals, using the Burgers circuit procedure, we have to take special provisions, as the circuit enclosing the dislocation necessarily passes through the adjacent stacking fault defect (Fig. 6c). Only if we map the atomic step leading through that stacking fault plane to the correct fractional lattice vector, we will obtain the right (fractional) Burgers vector of the partial dislocation.

Finally, crystals often contain other defects in addition to dislocations. A general dislocation identification algorithm must therefore be able to deal with non-dislocation irregularities such as free surfaces, point defects, grain boundaries, other
**Fig. 6** (**a**) Dislocation with an extended core. Atoms that are part of the core (darker color) can be identified using a structural characterization technique such as common neighbor analysis. (**b**) Bad tessellation elements, for which no unambiguous mapping to the perfect reference lattice is possible, have been marked with a gray color. (**c**) Schematic depiction of a dissociated dislocation. Identification of the two partial dislocations requires Burgers circuits passing through the stacking fault

types of interfaces, and even disclinations in a robust way. And, as mentioned before, the crystal orientation and crystal structure may not be known in advance and can vary across space and time. The algorithm needs to adapt to these situations appropriately.

In order to address these challenges, a computer algorithm named the *dislocation extraction algorithm (DXA)* (Stukowski et al. 2012; Stukowski and Albe 2010) has been devised on the basis of the fundamental ideas described in the preceding sections. The DXA is capable of building a discretized line representation of all dislocations contained in a given atomistic crystal model (Fig. 1). The generated representation of dislocation lines found in the crystal is very similar to those employed by dislocation dynamics simulation models. The DXA is available as part of the OVITO (Stukowski 2010) data analysis and visualization software for atomistic simulations.

The DXA proceeds in several steps, starting with the atomic input coordinates, to arrive at the final line representation of the dislocations. Here is a synopsis of these processing steps, which are described in more detail in Stukowski et al. (2012):

1. The three-dimensional Delaunay tessellation is computed.
2. Atoms in the input crystal are identified that form a perfect crystal lattice. For this, the common neighbor analysis (CNA) method is used, which allows to identify common lattice types such as fcc, bcc, hcp, and diamond. The information is also used to determine local lattice orientations and map atom-to-atom vectors in the Delaunay tessellation to the ad hoc reference lattice.
3. Elements in the Delaunay tessellation are flagged as "bad" crystal regions if they contain disordered atomic arrangements. This includes the dislocation cores, where the atomic structure deviates considerably from one of the perfect crystals, but also other types of defects (Fig. 6b).
4. The separating surface between the "good" and the "bad" crystal regions in the Delaunay tessellation, the so-called interface mesh, is generated (see Fig. 7).
**Fig. 7** Illustration of the interface mesh constructed by the DXA to enclose all defect atoms of a dislocation core. The algorithm uses an "elastic" Burgers circuit (red) that is moving on the interface mesh to sweep the dislocation line. While this circuit is being advanced in a stepwise fashion, triangle by triangle, a continuous line representation of the dislocation defect is produced (green)

5. The algorithm then generates a large number of trial circuits on the interface mesh until it encounters a first circuit that fully encloses a dislocation. This is detected by computing the Burgers sum (Eq. 1). The maximum size of the trial circuits is bounded by a user parameter controlling how wide dislocation cores may be for the algorithm to detect them.
6. The first circuit is subsequently used to discover the rest of the current dislocation line. This happens by advancing the circuit on the interface mesh and sweeping along the dislocation line as depicted in Fig. 7.
7. During this sweeping phase, a one-dimensional line representation of the dislocation is generated by computing the new center of mass of the circuit every time it is advanced along the boundary of the dislocation core. Here, a circuit can be pictured as a rubber band tightly wrapped around the dislocation's core. As the circuit moves along the dislocation segment, it may need to locally expand to sweep over wider sections of the core, e.g., kinks or jogs. To prevent the circuit from sweeping past dislocation junctions or interfaces, again a limit is imposed on the circuit length.
8. As a last step, a post-processing of the discretized dislocation lines is performed to reduce the number of sampling points.

The sweeping of dislocation lines, performed in steps 6 and 7 of the algorithm, in fact happens simultaneously on all segments of a dislocation network as depicted in Fig. 8. The initial seed circuits, constructed at the slimmest spots of the dislocation segments, split into pairs of circuits, each sweeping along the cores' surfaces in opposite directions. During this sweeping process, the upper limit for each circuit's maximum length is continuously raised, letting the circuits approach closer and closer to the dislocation junctions, which typically exhibit a wider cross section than
**Fig. 8** Schematic depiction of the DXA line tracing process for a network of dislocations. All dislocation arms are simultaneously swept by pairs of Burgers circuits advancing on the core's surface in opposite directions (cf. Fig. 7). At junctions, the inbound circuits from different arms meet, and the algorithm outputs a nodal point to connect all lines traced by these circuits

**Fig. 9** Left: Molecular dynamics simulation of dislocation-based single crystal plasticity (Zepeda-Ruiz et al. 2017). The piece of tantalum crystal (33 million atoms) is being deformed under uniaxial compression. Common neighbor analysis filtering (Stukowski 2012) of the atomic coordinates reveals a high density of defects in the bcc lattice (inset). Right: After processing with the DXA, non-dislocation defects such as vacancies have been filtered out. The resulting line representation allows measuring dislocation densities and studying dislocation processes in great detail. Green and magenta lines represent $\frac{1}{2} \langle 111 \rangle$ and $\langle 100 \rangle$ dislocations, respectively

the dislocation arms. At some point, the converging circuits all meet in a junction, and the algorithm links up their corresponding line ends at a nodal point.

## 5    Use Cases of the DXA

The DXA can serve as a measurement tool to quantify the density of dislocations in molecular dynamics simulations, thanks to the conversion of the identified defects to a mathematical line representation (Fig. 9). The average dislocation density in a
**Fig. 10** Analysis of a complex dislocation junction in fcc Al that has formed through a reaction of two $\frac{1}{2}\langle 110\rangle$ dislocation loops on intersecting glide planes. Left: Atomic input configuration with applied CNA filtering to highlight stacking fault atoms (red) and defect core atoms (gray). Center: Visualization of the *interface mesh*, the intermediate structure constructed by the DXA to enclose the defect cores. Right: Output dislocation lines and Burgers vector labeling generated by the DXA

crystal, $\rho$, is simply computed from the integral line length divided by the simulation box volume (see, e.g., Zepeda-Ruiz et al. 2017). The generated description of the dislocation geometry may also be used, for instance, to measure the size of the plastic zone in nanoindentation simulations (Gao et al. 2015; Voyiadjis and Yaghoobi 2015; Remington et al. 2014; Yaghoobi and Voyiadjis 2016; Alhafez et al. 2016; Alabd Alhafez et al. 2017) or to obtain local dislocation densities. Since the DXA does not only yield the shape but also the Burgers vector of each dislocation segment, the total (or statistical) density as well as the geometrically necessary density of dislocations (GND) are accessible via the DXA.

Another typical use case of the DXA is detailed analyses of dislocation reactions in molecular dynamics and statics simulations (e.g., Zhang et al. 2017). These reactions include the formation and nucleation of new dislocations at other defects, e.g., free surfaces (Trushin et al. 2016), grain boundaries (Stukowski et al. 2010), crack tips (Vatne et al. 2013), or pores (Ruestes et al. 2014) in a material. Here, the DXA can generate a precise labeling of dislocations forming complex network configurations as demonstrated in Fig. 10.

## 6    Current Limitations of the DXA

While the DXA represents a great improvement over conventional, atom-based analysis techniques such as the CNA, it still has certain limitations that one should be aware of when using this analysis tool. This section provides a roundup of key issues that need to be taken into account while working with the DXA and its output. Note, however, that the DXA is the subject of ongoing research seeking to improve the algorithm and overcome some of the issues mentioned here.

**Accuracy and ambiguity of dislocation representations** In general, given an atomistic crystal configuration, the representation of the contained defects in terms of a set of discrete dislocation lines is not uniquely defined. For instance,

dislocations in fcc crystals typically dissociate into pairs of partial dislocations (see upper left corner in Fig. 10). If the separation distance between such two partials becomes very small (on the order of 1–2 interatomic spacings), it is up to the algorithm to decide whether this particular atomistic configuration is better represented by a single dislocation line or two partials. The algorithm's choice is based on its particular notion of the dislocation core (in DXA terminology termed the "bad" crystal region, following Frank 1951). If the two dislocation core regions overlap, the algorithm is only able to construct a single Burgers circuit enclosing both defects. As a result, the two dislocations are fused into a single discrete dislocation line in the DXA's output representation. On the other hand, if the two cores are separated by just some "good" crystal region in between, then the DXA generates Burgers circuits around each of the individual partials, and two separate lines will be generated in the output. Thus, some "good" crystal atoms are required in between the two dislocations to separate them, cf. Figs. 6c and 10. A second type of ambiguity arises for very short dislocation segments and at dislocation junctions. Figure 11 depicts a detail of a dislocation network where four arms merge into a junction (a "4-junction"). However, they do not meet exactly in one point, and due to this slight dissociation of the junction, there is freedom of whether to describe this configuration as two separate 3-junctions instead, which are connected by an additional short dislocation segment. Which topology the DXA prefers depends on minutiae of the core morphology at this junction. As the four inbound Burgers circuits approach the junction, the upper limit on the circuits' lengths is continuously raised, letting the circuits stretch and advance further into the junction step by step. Simultaneously, the algorithm tries to generate an additional seed circuit around the core of the dissociated junction, i.e., in the inner area that has not been swept by the existing circuits yet. If the algorithm succeeds in spawning another Burgers circuit for the connecting segment before the existing circuits have met in the junction, then a topology with two 3-junctions results. Otherwise, the algorithm yields a single 4-junction. Effectively, the outcome is determined by the ratio of the core diameter of the dissociation segment and its length.

**Supported crystal structures** The DXA relies on an ad hoc mapping being established between the dislocated crystal and a corresponding ideal reference crystal lattice. This mapping is accomplished by means of an atomic structure identification method (Stukowski 2012), which maps the nearest neighbor vectors of each identified input atom to corresponding ideal lattice directions. The current implementation of the DXA uses the common neighbor analysis (CNA) method (Honeycutt and Andersen 1987) as a subroutine for this step, and it is thus currently limited to bcc, fcc, and hcp crystals and, thanks to a recent extension of the CNA method (Maras et al. 2016), also cubic and hexagonal diamond structures. Since the chemical types of atoms are not relevant to the DXA itself, crystalline compounds with a sub-lattice matching one of these supported structure types can also be processed by feeding only atoms from a sub-lattice to the algorithm. It is expected that future implementations of the DXA will employ new structure identification techniques other than the CNA in order to support a wider range of crystal structures.
**Fig. 11** At slightly dissociated dislocation junctions like the one shown here, an ambiguity arises of whether to connect all arms at a single node or instead create two nodes that are connected by a short extra segment

In principle, any computational method that establishes a local mapping between atomic neighbor vectors and the ideal reference lattice can serve as foundation for the dislocation detection part of the DXA.

**Glide plane identification** The DXA yields the geometric shape of a dislocation as well as its Burgers vector. This information alone, however, is not sufficient to identify the glide plane the dislocation is moving on. Thus, the DXA falls short of answering the question of active slip systems in a deforming crystal. In certain cases, however, one can use heuristic criteria to guess the glide planes of dislocations. For Shockley partials in fcc crystals, a dislocation's Burgers vector uniquely determines its glide plane, and no other information is needed. In other cases, if a dislocation has an edge component (is not pure screw), its glide plane can be determined from the Burgers vector and the line direction. In general, however, it is important to recognize that the glide plane of a dislocation is a dynamic property and requires the analysis of the dislocation's path it takes through the crystal, which is beyond the DXA's capabilities (see next item).

**Tracking dislocations through time and space** It is important to note that the DXA operates on instantaneous snapshots of an atomistic crystal and builds a line model of the dislocations at certain simulation times. In other words, it is a static analysis method, not a kinematic one. Since dislocations are not physical objects (see our introductory discussion), they do not possess unique identities that would allow to track them over time. This makes it difficult to automatically correlate successive snapshots of the evolving dislocation configuration as dislocations can move arbitrary distances between MD simulation snapshots, undergo reactions, and appear newly via nucleation and disappear via absorption or annihilation processes. In particular, the DXA cannot directly deliver dislocation velocity

information, because tracking of dislocations would require additional heuristics to link dislocations in successive DXA snapshots.

## Contents

## Abstract

Discrete dislocation dynamics (DDD) simulations provide a technique for examining the effects of fundamental dislocation physics on the plastic response of crystalline solids. Many DDD simulations focus on relatively "simple" materials and loading conditions, such as glide-motion-dominated plasticity of pure cubic crystals. The goal of this chapter is to provide an overview of the more "complex" physical aspects of dislocation-mediated plasticity in the context of DDD. We

consider both physics that are intrinsic to the crystal lattice (elastic anisotropy, nonlinear drag, and low crystallographic symmetry) and extrinsic physics that are due to defects other than dislocations (solutes, vacancies, precipitates, and grain boundaries). For each of these classes of physics, we first discuss the conditions under which they are relevant, followed by an examination of the fundamental ways in which the behaviors of dislocations are affected by the physics, and finally a presentation of the methods that have been developed for incorporating the physics in DDD. We end the chapter by discussing three example simulations where complex physics are consequential.

# 1    Introduction

Plastic, or permanent, deformation in crystalline materials is often due to the motion of defects called dislocations. Dislocations are line defects – taking the shape of lines as they weave their way through a crystal – and their motion causes the two halves of a crystal on either side of the dislocation to shift relative to each other, thereby permanently changing the crystal's shape. Dislocations are characterized by the direction and magnitude of the shift they induce, known as the Burgers vector, $b$. They have long-range stress fields that cause two dislocations to interact with each other at a distance. Dislocations can also interact over very short distances and combine together to form new dislocation lines. Depending on the material, load state, and environmental conditions, dislocation motion is usually anisotropic, with a few preferred crystallographic directions of motion. In order to understand dislocation-mediated plasticity, we need an approach that can combine all of these aspects of dislocation physics into a versatile computational framework; this is precisely what is accomplished with discrete dislocation dynamics (DDD).

Using DDD, we study plasticity in crystalline materials by simulating the motion of individual dislocation lines in space and time. Usually the length scale of these simulations is on the order of several microns at the so-called mesoscale. At this length scale, we treat crystalline defects such as dislocations, precipitates, or grain boundaries as specialized objects embedded in an elastic medium. Treating the defects explicitly in this manner allows for their connection to mechanical properties to be accurately captured. However, unlike with atomic-scale simulations where the properties of defects are inherited from the governing interatomic interactions, the properties of defects at the mesoscale must be directly incorporated into the model framework. For example, the types of interactions between dislocations and precipitates must be defined and explicitly incorporated into the code. The benefit of the mesoscale approach is efficiency; while mesoscale simulations are lower fidelity than atomic-scale simulations, they can access length and time scales more relevant to experiments and applications. Most atomistic simulations examine the behavior of just one or a few dislocations, whereas DDD simulations may consider many thousands of dislocation lines.

For pure face-centered cubic (FCC) and body-centered cubic (BCC) metals, the physical models and algorithms used in DDD simulations are fairly well

established. This includes computation of dislocation-dislocation interaction forces using isotropic linear elasticity (Sect. 2.1), linear mobility laws for determining dislocation velocities (Sect. 2.2), and rules for junction formation (Sect. 2.3). These methods are well developed and thoroughly documented in a number of review papers, chapters, and textbooks (Tang 2005; Van der Giessen and Needleman 2005; Zbib and Khraishi 2005; Bulatov and Cai 2006; Arsenlis et al. 2007; Sills et al. 2016). However, most engineering materials are not pure FCC and BCC metals; most have comparatively complex physics governing their plastic response, and it is the study of these materials that is the focus of this chapter.

The goal of this chapter is to summarize and present methods for incorporating complex physics into a three-dimensional DDD simulation. This will necessarily involve some discussion of dislocation physics and strengthening mechanisms; however for more thorough treatments, readers are encouraged to study the works of Hirth and Lothe (1992), Hull and Bacon (2011), Argon (2008), and Kubin (2013). Our primary aim is threefold: (1) inform the reader of physics relevant to a broad range of materials and applications, (2) discuss methods and algorithms for incorporating these physics into a DDD simulation, and (3) provide several examples where complex physics are important. A key point emphasized throughout is that the material system and application of interest will motivate the relevant physics. Since DDD is a mesoscopic method, the physics of interest must be explicitly added into a simulation, and this usually requires significant time and effort; it is important to scope out the problem appropriately from the get-go to avoid wasted time.

The balance of the chapter is organized as follows. We will first concisely summarize basic DDD methods – those applied to "simple" materials. We will then discuss the ways in which additional physics may be incorporated into a DDD simulation. The bulk of the chapter focuses on discussing the different types of "complex" physics, divided into two categories: intrinsic physics, meaning physics intrinsic to the underlying crystal lattice, and extrinsic physics or physics that are due to crystal defects other than dislocations. Finally, we provide a few examples before concluding the chapter.

## 2 Basic Physics

### 2.1 Driving Forces

In discrete dislocation dynamics, the dislocation structure can be discretized and represented by a network of dislocation segments connected at nodes. The dislocation line network evolves under the influence of driving forces acting on each segment. In an infinite medium, the origin of these driving forces is threefold:

1. The force due to the external applied stress $\sigma_{\text{ext}}$. This is given by the Peach-Koehler formula for the force per unit length on a dislocation with Burgers vector $\boldsymbol{b}$ and line direction $\boldsymbol{\xi}$:

$$F = (\sigma_{\text{ext}} \cdot b) \times \xi. \tag{1}$$

2. The elastic force due to the stress fields of the rest of the dislocation network. Computation of this force is the most expensive aspect of the DDD method. Arsenlis et al. (2007) showed that in isotropic elasticity the elastic force can be computed analytically.
3. The dislocation self-force acting on a segment. This is caused by the Peach-Koehler force from the segment's own stress field. This self-force is perpendicular to the segment and tends to rotate the segment away from high-energy orientations. When an orientation-independent core energy is added, the self-force acquires a longitudinal component, which tends to shorten the segment.

The expressions used for elastic force computation apply strictly to an infinite, homogeneous medium. When determining the interaction forces in heterogeneous materials, such as multi-materials, multiphase metals, or materials containing precipitates or solutes (see Sects. 3.2.1 and 3.2.3), additional driving forces are needed to account for the presence of interfaces or boundaries between the different material domains. These forces are known as *image forces* and are necessary to ensure that the boundary conditions between the different regions of the domain are properly enforced. Similarly, in domains containing free surfaces (e.g., half-spaces, thin films (Weinberger et al. 2009b), and cylinders (Weinberger and Cai 2007; Weinberger et al. 2009a), or for arbitrary geometries (Van der Giessen and Needleman 1995; Lubarda et al. 1993; Crone et al. 2014)), image forces are necessary to ensure that free surfaces are traction-free. Lastly, in anisotropic, polycrystalline materials (as most are, see Sects. 3.1.1 and 3.2.4), image forces arise to enforce compatibility between the grains. In all of these cases, a boundary value problem can be defined to determine the image forces and can be solved using a numerical technique (such as the finite element method).

## 2.2 Mobility Laws

In DDD, we typically assume overdamped dynamics such that the inertia of the dislocation lines can be neglected. This leads to equations of motion of the form

$$F_i^{\text{drive}} + F_i^{\text{drag}}(v_i) = 0, \tag{2}$$

where $F_i^{\text{drive}}$ is the total driving force acting on dislocation node/segment $i$, $F_i^{\text{drag}}$ is the total drag force resisting its motion, and $v_i$ is the velocity of the node/segment. Since the drag force depends on the velocity, Eq. (2) relates the driving force to the dislocation velocity. Many sources of drag may exist in a crystalline solid arising from the intrinsic properties of the crystal lattice (e.g., phonon dispersion) or from extrinsic features of the solid, such as solute atoms (see Sect. 3.2.1).

The response of dislocation lines to the driving force $\boldsymbol{F}_i^{\text{drive}}$ is defined by the dislocation mobility function that may depend on crystal type, local stress state, and temperature, as well as on the dislocation's geometry (e.g., Burgers vector, glide plane, segment orientation). Although in general dislocation mobility laws are nonlinear, simpler linear mobility laws have been proposed for BCC (Arsenlis et al. 2007) and FCC (Cai and Bulatov 2004) crystals.

Assuming that Eq. (2) can be solved explicitly for the velocity, we typically express the mobility law as

$$\boldsymbol{v}_i = \mathscr{M}_i(\boldsymbol{F}_i^{\text{drive}}), \tag{3}$$

where $\mathscr{M}_i$ is a generally nonlinear vector function. When the mobility function is linear, Eq. (3) simplifies to

$$\boldsymbol{v}_i = \boldsymbol{M}_i \cdot \boldsymbol{F}_i^{\text{drive}} \tag{4}$$

where $\boldsymbol{M}$ is a $3 \times 3$ matrix (its dependence on external conditions and the geometry of the system is omitted in Eq. (4)).

In principle, molecular dynamics (MD) simulations can supply mobility $\mathscr{M}$ functions for any point $\boldsymbol{x}$ on a dislocation line taking into account the glide and climb (refer to Sect. 3.2.2) of dislocations of arbitrary orientation (character). However, in practice, MD dislocation mobility data is available only for a limited set of dislocation characters and straining conditions. Commonly, mobility simulations are conducted only for pure edge and pure screw dislocations in a few specific slip planes (see, e.g., Groh et al. 2009 and Gilbert et al. 2011). Given mobility data obtained from either MD simulations or experiments, interpolation and extrapolation must be used to complete a dislocation mobility function for DDD simulations over the rest of orientation and velocity space.

Two families of drag functions – planar and pencil-glide mobility laws – are often used in DDD simulations depending on the crystal structure of the material, with the difference between them being how screw dislocations are treated. In planar mobility laws, the velocity of a screw dislocation is constrained to remain in its glide plane until a cross-slip operation occurs. This approach is suitable when cross-slip is a thermally activated, rare event, typically handled in DDD using a Monte Carlo implementation (Kubin et al. 1992). In pencil-glide mobility laws, screw dislocations are able to move freely in any plane that contains their dislocation line, and the notion of a glide plane becomes ambiguous. Two orthogonal glide directions (both orthogonal to the dislocation line) need to be defined to compute the screw mobility. For instance, in BCC crystals at elevated temperatures, dislocations are observed to follow a pencil-glide-type behavior, and the two glide directions are usually a nonlinear function of projection of the velocity along the {110} and the {112} family planes. In both the planar and pencil-glide approach, an edge mobility is defined for motion in the plane containing the Burgers vector and the dislocation line (the glide plane) and for motion out of this plane (climb).

## 2.3 Junctions

When two dislocation lines come into contact with each other, they are able to combine together and react to form a new dislocation called a junction dislocation. Not all dislocation intersections result in junction formation; the junction reaction only proceeds if the formation of the junction results in a reduction of the system's energy. In DDD, a number of algorithms have been developed to test for this condition (i.e., a junction formation operator) (Weygand et al. 2002; Schwarz 2003; Bulatov and Cai 2006). One example is the principle of maximum dissipation (Bulatov and Cai 2006; Arsenlis et al. 2007), which says that a junction should only be formed if doing so maximizes the dissipation rate, given by the sum of the dot products between the force and velocity vectors of each the dislocation segments. And finally, in materials with low crystallographic symmetry (e.g., hexagonal close-packed materials), junctions may form with "large" Burgers vectors, and these junctions may then subsequently "splinter" apart into a new pair of dislocation lines. We will discuss this mechanism in Sect. 3.1.3 and provide an example of junction splintering in Sect. 4.2.

## 3 Complex Physics

The incorporation of complex physics into DDD simulations typically manifests itself in two ways: (1) a change in the driving forces on the dislocation lines and/or (2) a change in the rules governing how dislocation lines can move through the simulation cell. Some physics require changes to both.

In the following we will go through examples of complex physics associated with dislocation-mediated plasticity. Our primary focus is on examples that have already been the subject of DDD studies. Each example begins with a *Background* section where the physics of interest are discussed in the greater context of crystal plasticity, followed by a *Nature of the Physics* section where the basic physics relevant to dislocation dynamics are presented, and an *Incorporation in DDD* section where specific algorithms and formulations are discussed.

### 3.1 Intrinsic Physics

#### 3.1.1 Anisotropic Elastic Media

**Background**
DDD simulations often assume isotropic elasticity to compute stresses at points in the simulation volume and forces between dislocations. Strictly speaking, however, essentially all crystalline materials exhibit some degree of elastic anisotropy. The strength of the deviation from isotropy – typically expressed in terms of the anisotropy ratio, with a value of 1 indicating perfect isotropy – is dictated by the

crystal structure and the nature of the interactions between the atoms. Under the normal range of temperature and pressure, many materials have an anisotropy ratio that is not too far from 1. In cubic crystals, the anisotropy ratio is often defined as $A = \frac{2C_{44}}{C_{11}-C_{12}}$ where $C_{11}$, $C_{12}$, and $C_{44}$ are the cubic elastic constants. For some materials, using isotropic theory might be appropriate (Rhee et al. 2001); however this assumption is not always valid. For example, aluminum is very nearly isotropic with $A = 1.21$ at room temperature (Hirth and Lothe 1992), whereas at elevated temperatures around 1200 K, $\alpha$-Fe is highly anisotropic with $A = 7.4$ (Fitzgerald et al. 2012).

### Nature of the Physics

Two features of dislocation physics can be strongly impacted by elastic anisotropy: dislocation line tension and elastic interactions between dislocations. A dislocation's line tension controls how it bows out in response to an applied stress and is dictated by the orientation dependence of the elastic energy (screw vs. edge). Strong anisotropy can cause large elastic energy differences between edge and screw dislocations, causing the line tension to vary dramatically with character angle. For example, dislocation loops in $\alpha$-Fe exhibit sharp corners, a feature that cannot be captured using isotropic elasticity theory (Aubry et al. 2011). The elastic interactions between two dislocations, which dictate the strength of attraction or repulsion between them, are also affected by elastic anisotropy. One example is junction formation; dislocation junctions only form if the two lines are attracted to each other (see Sect. 2.3).

### Incorporation in DDD

In dislocation dynamics simulations, the stress at a point due to a dislocation segment and the interaction force between a pair of segments can be defined using linear elasticity. Its definition is based on the derivatives of the Green's function. While the Green's function is known analytically for isotropic media, no closed-form expression exists for anisotropic media. Hence, analytical stress and force expressions cannot be derived for anisotropic media, and instead they must be evaluated numerically for a given dislocation configuration.

In Rhee et al. (2001) and Yin et al. (2010), several approaches were explored for simulating anisotropic elastic media. In Yin et al. (2010), the authors show that the Willis-Steeds-Lothe expression (Hirth and Lothe 1992) is more computationally efficient than Brown's formula (Hirth and Lothe 1992) and that the matrix formalism is only slightly faster than the integral formalism. However, they also found that computing interaction forces in anisotropic elasticity was 220 times more computationally expensive than in isotropic elasticity. This fact motivated the development of a different approach by Aubry and Arsenlis (2013), where the spherical harmonics expansion of the derivative of the Green's function is derived. The advantage of writing the stress and the force expressions in terms of an expansion in spherical harmonics is that some integration can be carried out analytically, leading to improved efficiency. Within this approach, the accuracy and the computational cost of the calculations can be controlled by selecting the order of the expansion.

The cost of this method depends on the anisotropy ratio. For a small anisotropy ratio (less than 2, as with aluminum), the computational cost only increases by about 50% relative to isotropic elasticity. The higher the anisotropy ratio, the more expensive the method becomes. For instance, for $\alpha$-Fe at high temperature with an anisotropy ratio of 7.4, anisotropic simulations are about 60 times more expensive.

### 3.1.2 Nonlinear Lattice Drag

**Background**

Most of the time in DDD simulations, the velocity of a dislocation segment is assumed to be linearly related to the total driving force, i.e., the mobility law is linear as in Eq. (4). For many materials and many states of stress, this is a good approximation. However, under some conditions, nonlinear drag effects may become important. For example, it has been shown using MD simulations that in pure FCC (Olmsted et al. 2005; Marian and Caro 2006) and BCC (Barton et al. 2011) metals the force-velocity relation can be highly nonlinear at elevated stresses ($\gtrsim 100$ MPa). The physics governing these nonlinearities is complex and not entirely understood. Nonlinear drag effects can also be relevant when accounting for extrinsic sources of drag (like solute drag, see Sect. 3.2.1).

**Nature of the Physics**

A schematic showing different types of nonlinear mobility laws is presented in Fig. 1. In pure crystals, nonlinear drag is often due to non-phononic dissipative effects, such as radiative dissipation (Marian and Caro 2006). Oftentimes these non-phononic effects result in plateaus in the force-velocity relation, i.e., regions where the velocity becomes nearly independent of the force (Olmsted et al. 2005;

**Fig. 1** Schematic showing nonlinear mobility laws representing different drag mechanisms including linear drag, nonlinear lattice drag with velocity plateaus, solute friction (see Sect. 3.2.1), and kink-pair nucleation-limited motion
Marian and Caro 2006). Also, when the primary mechanism of dislocation motion is kink-pair nucleation and migration, as with BCC metals at low temperatures, a nonlinear mobility can result (Gilbert et al. 2011).

### Incorporation in DDD

Some closed-form nonlinear mobility laws have been implemented in DDD simulations (Po et al. 2016). However, because of the fact that we often determine nonlinear dislocation mobility laws using numerical data from MD, we rarely have a closed-form mobility law which can be explicitly solved for the velocity. This means that there are (at least) two issues that make usage of nonlinear mobility laws difficult: (1) interpolation of numerical MD data and (2) solution of an implicit, nonlinear system of equations. For example, cubic splines may be used to provide a continuous mobility function and Newton's method applied to iteratively solve the resulting nonlinear system. While neither of these issues is insurmountable, together they can make large-scale DDD simulations difficult. We recommend that nonlinear mobility laws are employed only if absolutely necessary.

### 3.1.3 Low-Symmetry Materials

### Background

The DDD method has predominantly been developed to evaluate the plastic behavior of cubic metals (e.g., FCC and BCC). These materials exhibit a high degree of crystalline symmetry, so that only a single class of Burgers vector is active ($\frac{1}{2}\langle 1\,1\,0 \rangle$ for FCC and $\frac{1}{2}\langle 1\,1\,1 \rangle$ for BCC). In order to consider crystals with relatively lower symmetry, such as the hexagonal close-packed (HCP), rhombohedral, or tetragonal crystal structures, additional physics are necessary to address the fact that more than one class of Burgers vector may be active.

### Nature of the Physics

In low-symmetry materials, some energetically favorable dislocation reactions lead to the formation of "composite" dislocations with Burgers vectors larger than the unit vectors of the crystal's lattice. In HCP crystals, such as magnesium or titanium, these large Burgers vectors have been associated with low ductility (Agnew et al. 2002; Wu and Curtin 2015). Formation of these composite Burgers vectors may not result in the greatest energy reduction for the system, however. It may be possible for the composite Burgers vectors to decompose into a new pair of dislocation lines that lead to a further energy reduction. This feature of low-symmetry materials motivates the need for new topological processes not necessary for cubic crystals.

### Incorporation in DDD

When the interaction force between the component dislocations that make up the composite dislocation is repulsive, the DDD algorithm should allow the splitting of the composite dislocation into its components. An additional topological operator, called "splintering," is needed to allow for the dissociation of composite dislocations

into two component dislocations when appropriate (Aubry et al. 2016). This operator behaves very similarly to the junction operator discussed in Sect. 2.3; an energy-based criterion is used to decide when and how it is appropriate to "splinter" a composite dislocation. An application of the splintering topological operation is shown in Sect. 4.2.

## 3.2 Extrinsic Physics

### 3.2.1 Solute Interactions

**Background**

We denote as "solutes" in a crystal the atoms that are different from those of the base lattice. They can exist as substitutional solutes occupying lattice sites of the base crystal or as interstitial solutes residing in lattice interstitial sites. The combined lattice-solute system is called a solid solution. Solid solutions arise in many settings. One example is alloying, the process of mixing multiple chemical species together in a crystalline solid. Most alloys are comprised of a base crystal with a few weight percent of an additional element mixed in, often in the form of a substitutional solid solution (Reed-Hill and Abbaschian 1992).

Forming a solid solution alters the behavior of the material in many ways. Our main focus here is on how solute atoms interact with dislocations to change their behavior, thereby altering the plastic response of a material – this phenomenon is often referred to as solid solution strengthening. Our key objective in studying solid solutions with DDD is to understand the major effects solute atoms have on the response of dislocation ensembles and the resulting impact on mechanical properties.

**Nature of the Physics**

Because solute atoms have a misfit in the parent lattice, they are commonly treated as misfitting Eshelby inclusions (Cai et al. 2014). As such, they have stress fields – both as a result of their misfit and the fact that they locally modify the modulus of the material – and can interact with dislocations through Peach-Koehler forces. Solutes are also able to interact with dislocations through interactions with the dislocation core (Medvedeva et al. 2005; Ventelon et al. 2015). Typically, the misfit effect is considered to be the dominant interaction mechanism (Argon 2008). As a consequence of this misfit, solutes tend to segregate around (predominantly edge) dislocations and form so-called Cottrell atmospheres.

The behavior of solid solution systems can be split into two categories based on the relative mobilities of the dislocations and solutes, as shown in Fig. 2. In the immobile solute case shown in Fig. 2a, the dislocations in a material are much more mobile than the solutes. In this case the solute population can often be treated as randomly distributed, and dislocation lines encounter each solute one by one as they move through the solid. Dislocation interactions with stationary solute atoms are usually considered to be thermally activated (Argon 2008). In contrast, in the
**Fig. 2** Schematics showing dislocation-solute interactions when (**a**) solutes are immobile and (**b**, **c**) solutes are mobile. (**a**) A dislocation line gliding through a field of stationary solutes. (**b**) A Cottrell atmosphere exerting a drag force on an edge dislocation gliding with velocity $v$. (**c**) A shear dislocation loop expanding under an applied stress with Cottrell atmospheres dragging the edge components

mobile solute case, the mobility of the solutes is greater than or comparable to that of the dislocations; Cottrell atmospheres are able to move with and exert drag forces on their dislocations. Figure 2 shows a schematic of a dragging Cottrell atmosphere with (b) a straight edge dislocation and (c) an expanding shear loop. The mobile solute regime is commonly referred to as the dynamic strain aging regime and is most relevant at elevated temperatures and with interstitial solutes, since solute diffusivities are largest under these conditions.

A number of solute effects on the properties of dislocations have been identified, including reduction in dislocation mobility (solute drag) (Cottrell and Jaswon 1949; Sills and Cai 2016; Varvenne et al. 2017), alteration of dislocation stress fields (Sofronis and Birnbaum 1994; Chateau et al. 2002; Cai et al. 2014), modification of the cross-slip rate (Wen et al. 2007; Nöhring and Curtin 2017), and reduction of line tension (Kirchheim 2007; Delafosse 2012; Sills and Cai 2018). Of these effects, the most significant is solute drag, which is our major focus here.

### Incorporation in DDD

One approach for incorporating solutes in a DDD simulation is to treat them as discrete solute objects. These solute objects can occupy predefined lattice positions set by the type of solid solution, with each having its own misfit-dependent stress field. They interact with dislocation segments through their stress fields, leading to solute drag forces. Mobile solutes can be accounted for using kinetic Monte Carlo methods, according to which solutes move by hopping between lattice sites with a rate set by the activation energy for diffusion of the solutes. This approach has been used to study solute impacts on junction formation and dissolution (Chen et al. 2008). The discrete solute approach is limited, however, by the large number of solutes contained within even a relatively small volume of material; the computational cost of the solutes can very quickly supersede that of the dislocations.

A less accurate but much more efficient approach is to incorporate solute drag into the mobility law. With immobile solutes, this is often accomplished by imposing a so-called friction stress, $\tau_f$, on the dislocations. In this model, a dislocation

segment is pinned by solutes and rendered immobile until the net driving force per unit length exceeds $\tau_f b$ (see Fig. 1). The magnitude of the friction stress is dependent upon the materials composing the solid solution, the solute concentration, the temperature, and the character of the dislocation line and can be determined with atomistic simulations (Olmsted et al. 2005). Friction stress models have been utilized by a number of researchers to incorporate solute drag effects (e.g., Monnet and Devincre 2006).

When the solutes are mobile, a friction stress model is inadequate. In this case, the effect of the dislocation velocity on the concentration field of solutes (Cottrell atmosphere) around the dislocation must be considered and the resulting drag forces computed. A nonlinear mobility law that incorporates these effects has been proposed on the basis of continuum theory calculations (Sills and Cai 2016); further research is necessary to better understand solute drag by mobile solutes.

### 3.2.2    Vacancy Interactions

**Background**
Vacancies are main crystal lattice sites where an atom is missing. Vacancies are always present in crystalline solids because they increase the entropy of the solid, with the vacancy concentration typically increasing with temperature. In fact, for a given material at a given temperature, there is a well-defined *equilibrium concentration* of vacancies. Many settings exist, however, where the vacancy concentration exceeds this equilibrium value. In these cases, the solid is said to be *supersaturated* with vacancies. Common examples include quenching from an elevated temperature and irradiation-damaged materials.

Although solute atoms and vacancies are both point defects, they interact with dislocations in very different ways. Vacancies primarily interact with dislocations by promoting *climb* motion, or motion out of the glide plane. In contrast to solutes, vacancies actually enhance dislocation mobility. In order for dislocation climb to have a significant impact on plasticity, the time scale of climb motion must be of the same order of magnitude as the time scale of interest. Hence, climb is typically a concern at elevated temperatures where vacancy diffusivities are large (and concentrations are higher) and/or when a material is under sustained load for an extended period of time (e.g., creep loading).

**Nature of the Physics**
As shown in Fig. 3a, in order for a non-screw dislocation line to move out of its glide plane (climb), vacancies or self-interstitials need to diffuse into or out of the dislocation core (depending on the climb direction). Mathematically, we define the *climb velocity* as the velocity component orthogonal to the glide plane, i.e., $v_{cl} = \mathbf{v} \cdot (\boldsymbol{\xi} \times \mathbf{b}/b_e)$, where $b_e$ is the magnitude of the edge component of the Burgers vector $\mathbf{b}$ and $\boldsymbol{\xi}$ is the dislocation line direction. The fundamental problem at hand is to determine the climb velocity for a given climb force, $f_{cl} = \mathbf{f} \cdot (\boldsymbol{\xi} \times \mathbf{b}/b_e)$, and vacancy concentration; this is akin to determining the "climb mobility law."

Vacancies can induce climb motion at a given point on a dislocation line by diffusing toward or away from the dislocation either through the bulk of the crystal *or* through the core of the climbing dislocation line. The latter is commonly referred to as *pipe diffusion* and is typically considered to be much more rapid than bulk diffusion (Hirth and Lothe 1992). In general, the climb velocity is related to the total vacancy flux into or away from the dislocation line per unit length, $I$, according to the relation (Hirth and Lothe 1992)

$$v_{cl} = \frac{I\Omega}{b_e},\qquad(5)$$

where $\Omega$ is the volume per atom. Determining this vacancy flux requires solving a coupled pipe-bulk diffusion problem. The problem is further complicated by the fact that dislocations act as sources and/or sinks for vacancies; one climbing dislocation line may act as a vacancy source for another climbing (sink) dislocation line as shown in Fig. 3b.

In order to determine the climb velocity, the climb force acting on the dislocation line must interact in some way with the vacancy concentration field, $c(\boldsymbol{x})$. This is usually accomplished by assuming that the vacancies and the dislocation line are in chemical equilibrium, leading to the relation $c_d = c_0 \exp\left[-f_{cl}\Omega/(b_e k_\mathrm{B} T)\right]$ (Hirth and Lothe 1992) where $c_0$ is the equilibrium vacancy concentration, $c_d$ is the concentration at the dislocation (on the surface of a tube of radius $r_d$ centered on the dislocation line), $T$ is the absolute temperature, and $k_\mathrm{B}$ is Boltzmann's constant. This relation represents the coupling between the dislocation microstructure and the vacancy concentration field. Finally, we note that a dislocation may have a nonzero climb velocity even when the stress state is zero if the vacancy concentration in the solid is not at equilibrium, as shown in Fig. 3c. In this case, we call the effective

**Fig. 3** Schematics showing dislocation-vacancy interactions resulting in dislocations climbing with velocity $v_{cl}$. (**a**) Edge dislocations climbing with velocity "upward" by consuming vacancies and "downward" by emitting vacancies. (**b**) A pair of collapsing prismatic dislocation loops, with one loop emitting and the other absorbing vacancies. (**c**) A shear dislocation loop climbing out of its glide plane in the presence of a supersaturation of vacancies that produces osmotic forces

(thermodynamic) force exerted by the super- or subsaturated solid on the climbing dislocation line an *osmotic force*.

### Incorporation in DDD

While the physics governing vacancy-dislocation interactions are fairly complex, the overall process of computing the climb velocity is fairly straightforward: determine the vacancy flux $I$ at each point on the dislocation lines while enforcing the local equilibrium condition for $c_d$, and then compute the climb velocity with Eq. (5). All of the below approaches compute $I$ while assuming that the vacancy concentration field rapidly goes to steady state as the dislocation microstructure evolves.

The simplest approach is to neglect pipe diffusion and determine the vacancy flux by solving the steady-state bulk diffusion equation: $\nabla^2 c(\boldsymbol{x}) = 0$. In the earliest DDD implementations, the analytical solution for a straight, infinitely long edge dislocation in a cylinder of radius $r_\infty$ was employed (Mordehai et al. 2008). This solution is readily linearized, giving an expression of the form $v_{cl} = M_{cl}(f_{cl} + f_{os})$, where $M_{cl}(\theta)$ and $f_{os}(\theta)$ are the character-angle-dependent climb mobility and osmotic force, respectively (Bakó et al. 2011). In this approach, the dislocation lines are uncoupled from each other. In order to properly solve the diffusion equation, however, all of the sources and sinks (climbing dislocation lines) in the domain need to be coupled together. Obtaining such a solution is complex but can be accomplished readily using the Green's-function-based approach recently developed by Gu et al. (2015). In their method, the climb velocity for each dislocation segment can be determined by solving a coupled linear system.

Finally, none of these approaches account for pipe diffusion. Gao et al. (2011) implemented a pipe-diffusion-only climb model, finding that the climb velocity is proportional to the concentration gradient along the dislocation line. Recently, Niu et al. (2017) have derived a coupled pipe-bulk diffusion model by considering the micromechanics of vacancy diffusion, finding that the pipe contribution to the climb velocity is proportional to the second derivative of the core concentration field.

### 3.2.3    Precipitate Interactions

### Background

Precipitates are particles of a secondary phase embedded in a crystalline matrix. They come in many shapes and sizes, depending on how they are formed, the crystal structures involved, and the thermal and deformation history of the material. In many instances, they are intentionally introduced into a material in order to strengthen it, an approach that is called *precipitation strengthening*. Usually these precipitates are formed by first "solutionizing" an alloy by holding it at an elevated temperature and then subsequently "aging" it at a reduced temperature. During the aging process, solute atoms diffuse together and nucleate precipitates, which then continue to grow. Often, the properties and spatial distribution of the precipitates

change as they are aged. In other instances, precipitate formation is undesirable and can result in degraded mechanical properties. Finally, we can also think of voids, which can form during solidification, or gas-filled bubbles, which arise in radiation environments, as precipitates with a modulus of zero. Typically, voids and bubbles adversely affect mechanical properties. Whether favorable or not, the predominant way that precipitates alter a material's mechanical properties is through their interactions with dislocations. This makes DDD a valuable tool for studying precipitation-driven phenomena.

## Nature of the Physics

The mechanical properties of a precipitate-containing material are controlled by two things: the properties of the individual precipitates and their spatial distribution in the material. While individual precipitates are relatively well-understood, their distributions in space are difficult to characterize. Most often it is assumed that precipitates are randomly distributed; however some researchers have developed more sophisticated techniques for constructing realistic precipitate distributions (Mohles and Fruhstorfer 2002). It is also important to note that precipitates usually have a distribution of sizes as well. Some analytical models exist for incorporating a size distribution (Mohles 2004), or experimentally measured size distributions can be used (e.g., Boyd and Nicholson 1971).

Precipitates can interact with dislocations via both long-range and short-range mechanisms. We denote long-range interactions as those that do not require contact with a precipitate to act on the dislocation. Two types of long-range interactions exist. The first is due to the lattice mismatch of coherent precipitates, which gives rise to a lattice-mismatch stress field in both the precipitate and the matrix. The second type of long-range interaction exists if the elastic constants of the precipitate are different from those of the matrix; the resulting modulus mismatch gives rise to an additional stress field. Eshelby developed a mathematical procedure for computing the stress field of a precipitate with a lattice and/or modulus mismatch using elasticity theory (Eshelby 1961). Note that the stress field of a precipitate typically scales as $1/r^3$, in comparison to the (longer range) $1/r$ fields of the dislocation lines themselves.

Short-range interactions are present while a dislocation is in contact with and/or penetrating a precipitate. These interactions result from the resistance of a precipitate as a dislocation transmits into it. This transmission can only occur if the precipitate is coherent or semi-coherent. If a dislocation transmits all the way through a precipitate, we say that the precipitate was "cut" by the dislocation. We note that if a dislocation is unable to penetrate and cut a precipitate, it can still bypass the precipitate by bowing out and forming a dislocation (Orowan) loop around it. A number of mechanisms can give rise to contact interactions including stacking fault, modulus, or core energy differences between the precipitate and matrix, the formation of a step at the precipitate's surface, the disruption of superlattice ordering, and reactions with misfit dislocations (Argon 2008). Since these interactions occur over a very short length scale, they are dictated by nonlinear

interatomic interactions, making them difficult to characterize with continuum models. Atomistic simulations are currently the most accurate way to characterize the dislocation-precipitate cutting process (e.g., Singh and Warner 2013 or Monnet 2015).

### Incorporation in DDD

Precipitates are usually introduced into DDD as special objects that affect both the driving forces and mobility laws of the dislocation lines, with the specific details being dependent upon the properties of each precipitate. Typically the long-range interactions affect the driving forces, and the short-range interactions modify the mobility law.

In terms of long-range force calculation, the lattice-mismatch stress field is significantly easier to compute than the modulus-mismatch stress field. To compute the lattice-mismatch field of a single precipitate, all we need to know is the magnitude and character of the mismatch (expressed in terms of an eigenstrain tensor (Mura 1987)) and the size and shape of the precipitate. For many lattice mismatches and precipitate geometries, analytical solutions exist for the lattice-mismatch field. The total lattice-mismatch field is simply the superposition of the field from each precipitate in the problem domain. The resulting driving force can be computed using the Peach-Koehler formula.

When a modulus mismatch is present, the story is quite different. The modulus-mismatch field of a precipitate is dependent upon the type and magnitude of the modulus mismatch, the precipitate shape, *and* the stress field exerted on the precipitate by the applied stress and every other object in the domain, including all dislocation lines and all other precipitates. Calculating the modulus-mismatch field usually requires a numerical approach. Researchers have developed finite element (Shin et al. 2003; Munday et al. 2015) and boundary element (Takahashi and Ghoniem 2008) methods for computing the modulus-mismatch field (which is often referred to as the "image" field). Computation of this field is often expensive and time-consuming. For this reason, many researchers simply neglect the influence of a modulus mismatch in DDD simulations.

Short-range interactions are usually incorporated into the mobility law. Three different approaches have been used. For impenetrable precipitates, dislocation segments are simply pinned with their velocity set to zero at the surface of the precipitates (Mohles 2003; Queyreau et al. 2010). Given the complex nature of precipitate cutting discussed above, penetrable precipitates are more difficult to model. A commonly used approach is to impose a "friction stress," similar to the solute drag-induced friction stress discussed in Sect. 3.2.1, on any dislocation segments that penetrate precipitates (Mohles 2001; Rao et al. 2004; Monnet 2006). The magnitude of the friction stress should depend on the physical processes associated with precipitate cutting and could be selected on the basis of atomic simulations. And finally, Monnet (2015) has recently developed a more rigorous method for incorporating atomistic results into DDD while accounting for thermally activated cutting processes.

### 3.2.4  Grain Boundaries

**Background**

Nearly all DDD studies focus on single crystalline materials, despite the fact that most engineering materials are polycrystalline and grain boundaries are known to influence plastic behavior. The primary reason that grain boundaries are neglected is their complexity; many different types of grain boundaries exist, and they can interact with dislocations in numerous ways. Given that so few researchers have focused their studies on grain boundaries, we will only present a brief sketch of their consideration in the context of DDD.

**Nature of the Physics**

Grain boundaries are usually characterized by the amount and type of misorientation between the two grains forming them; the grains can be twisted with respect to each other, tilted with respect to each other, or a combination of both. Furthermore, depending on the misorientation, there may be a set of *coincidence sites* where the two crystals share a lattice site, or there may be no shared sites at all. In the former case, the grain boundaries are referred to as *singular boundaries* because they have lower energies than more general boundaries without coincidence sites. Singular boundaries are interesting because they can be described in terms of a set of grain boundary dislocations whose Burgers vectors are dictated by the so-called *displacement shift complete* (DSC) lattice of the boundary. Some of these grain boundary dislocations may be mobile within the boundary. When a bulk lattice dislocation encounters a singular grain boundary, it may absorb into the boundary and disassociate into grain boundary dislocations (such that the Burgers vector is conserved). Or the inverse can happen, with grain boundary dislocations transferring into the bulk. In general, it is difficult to quantify the probability for dislocation absorption/emission into/out of a grain boundary, and typically atomistic simulations are necessary to analyze a particular grain boundary of interest (de Koning et al. 2003; Sangid et al. 2011; Spearot and Sangid 2014). In the simplest case, transmission into/across a grain boundary is impossible, which leads to dislocation pileups forming on either side of the boundary. See Cai and Nix (2016) for a more detailed discussion on grain boundaries.

**Incorporation in DDD**

The key rules governing dislocation-grain boundary interactions that must be considered for DDD simulations are as follows: (1) criteria for transmission of a bulk dislocation into a grain boundary, (2) criteria for emission of a grain boundary dislocation into the bulk, and (3) selection of the particular bulk/grain boundary dislocation topology (Burgers vectors, glide planes, etc.) associated with a transmission/emission event. Also, if grain boundary dislocations are glissile, mobility laws must be defined for their motion within the boundary. Strength criteria have been employed by a number of authors to model transmission/emission (Fan et al. 2012; Zhou and LeSar 2012), such that a dislocation may only transmit/emit if

the local shear stress exceeds some minimum. Typically this strength is dictated by the amount of misorientation, and an infinite strength corresponds to an impenetrable grain boundary. Selection of the associated topology is trickier, because the DSC lattice typically has smaller Burgers vectors than the bulk lattice (Cai and Nix 2016), meaning a bulk dislocation has many possible disassociated forms. Criteria have been developed based on energy/dissipation rate considerations similar to those used for junction formation and splintering (see Sects. 2.3 and 3.1.3) (Fan et al. 2012, 2015).

## 4    Examples

### 4.1    Orowan Looping Around Misfitting Platelet Precipitates

Depending upon the heat treatment and alloy composition, aluminum-copper alloys form four different platelet-shaped precipitates. $\theta'$ precipitates are arguably the most important. These precipitates are $Al_2O$ compounds, reside in {001} planes, and are coherent with the FCC Al matrix. However, the lattice mismatch on the faces of the precipitate is different from the mismatch around the rim, leading to a non-dilatational eigenstrain (Biswas et al. 2011). This mismatch makes it difficult for dislocations to transmit into and cut the precipitates. To study Orowan looping around these precipitates, we treat them as impenetrable ellipsoids with two major axes, setting a node's velocity to zero upon contact with the precipitate surface. The lattice-mismatch stress field is pre-computed numerically on a nonuniform grid and then interpolated for Peach-Koehler force calculation (Sills 2016). For simplicity, we neglect the modulus-mismatch field. We compute the shear stress necessary for Orowan looping by starting with a straight edge dislocation and incrementing the applied stress until Orowan looping occurs. An infinite array of parallel, ellipsoidal precipitates with major diameters of 4000 Å and aspect ratios of 30 is considered.

Figure 4a shows the critical dislocation configuration just below the looping stress. The misfit shear stress field is shown as well. Figure 4b shows how the looping stress varies with the spacing between the precipitates. We also show results without a lattice-mismatch field. The lattice-mismatch field is shown not to significantly influence the results, when the dislocation approaches the precipitate array both from the right and from the left.

### 4.2    Junction Splintering in HCP Metals

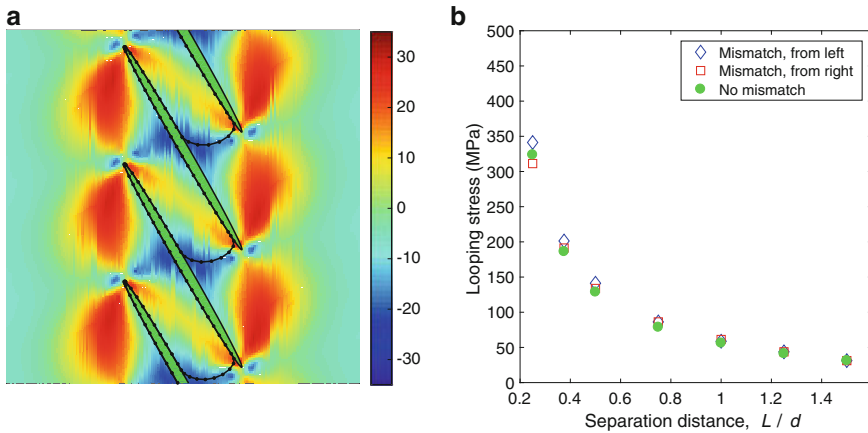
Discrete dislocation dynamics simulations can add some insights into mechanisms of formation and dissociation of <c + a> dislocations in HCP metals. We consider here the behavior of two reacting <c + a> dislocations. Taking into account the symmetry of the HCP lattice, there are eight distinct types of binary reactions between two <c + a> dislocations (Aubry et al. 2016). Out of those, only four are elastically attractive, and of those four, two reactions lead to the formation of composite dislocations.


**Fig. 4** Orowan looping results for $\theta'$ precipitates in aluminum-copper. (**a**) Cross section of a precipitate array at the midplane showing the dislocation configuration just below the Orowan looping stress. The color map shows the lattice-mismatch shear stress field in MPa. (**b**) The shear stress necessary for an edge dislocation to Orowan loop as a function of separation distance. $L$ is the separation distance between precipitates and $d$ is their major diameter. The results with and without a lattice-mismatch field are shown. With a mismatch field, we show results when the dislocation approaches from the right and from the left. (Figure adapted from Sills 2016 with permission)

Initial configuration          No dissociation          Dissociation allowed
**Fig. 5** DDD simulation of junction formation and splintering between two <c+a>-type dislocations. (**a**) Initial configuration, (**b**) resultant configuration when no composite dislocation dissociation (splintering) occurs, and (**c**) resultant configuration when dissociation of composite dislocations is allowed. Colors denote Burgers vector types: orange = <c+a>, blue = <a>, green = <c>, red = <2a>. (Figure adapted from Aubry et al. 2016 with permission)

Let us analyze a specific example. Consider two parent dislocations with Burgers vectors $\boldsymbol{b}_1 = 1/3[\bar{1}\bar{1}23]$ and $\boldsymbol{b}_2 = 1/3[\bar{1}\bar{1}2\bar{3}]$. The Burgers vector of the intermediate product dislocation formed after their reaction is $\boldsymbol{b}_{ip} = \frac{2}{3}[\bar{1}\bar{1}20]$. Since $\boldsymbol{b}_{ip}$ is twice the Burgers vector of a primary <a> dislocation $\boldsymbol{b}$, the junction should further dissociate into two <a> dislocations. The expected total dislocation reaction can be written as

$$\boldsymbol{b}_1 + \boldsymbol{b}_2 \rightarrow \boldsymbol{b}_{ip} \rightarrow \boldsymbol{b} + \boldsymbol{b}.$$

In Fig. 5a, we consider the collision of two <c+a> dislocations with Burgers vectors $\boldsymbol{b}_1$ set on the pyramidal plane $(01\bar{1}1)$ and $\boldsymbol{b}_2$ set on the prismatic plane $(1\bar{1}00)$. Both parent dislocations form a 40° angle with respect to the junction axis in

their initial orientations. The incidence angle between the intersecting dislocations is such that the dislocation lines are attracted to each other, causing them to react and form a <2a> junction product in the manner shown in Fig. 5b. The resulting <2a> junction dislocation is contained in the same prismatic plane as one of the parents. We then allow the junction to disassociate (splinter) into two <a> primary dislocations. Note that the nodes bounding the junction are then able to split further, leading to a pair of <c> dislocation segments as shown in Fig. 5c. A large-scale study on the effects of junction dissociation on the stress-strain curve was conducted by Aubry et al. (2016).

# 5    Conclusions

In this chapter, we have shown that discrete dislocation dynamics is a diverse, powerful tool for studying dislocation microstructure evolution and the plastic response of materials. However, it is clear that engineering materials are complex and that the inclusion of all relevant physics can be a daunting task. Indeed, many of the DDD algorithms that have been developed are simple and approximate, if only to render them tractable. A DDD formulation with "all of the physics" is simply not practical. As materials modeling continues to mature as a field and our understanding of these physics grows, DDD codes will be expected to incorporate more and more complexity. This will make it even more important that researchers "keep their eyes on the prize" and remember what it is that they are trying to achieve through DDD in the first place.

## Contents

### Abstract

The continuum theory of dislocation fields is discussed in this chapter with an emphasis on the formulations relevant to infinitesimal deformation of single crystals. Both the classical and contemporary developments are concisely outlined. The classical theory of dislocation fields is introduced first for static and dynamic dislocation configurations, followed by a brief discussion of the shortcomings of

the classical theory in predicting plasticity of crystals. In this regard, the lack of connection between the evolution of the dislocation field and internal stress state of the crystal is particularly highlighted. The more recent phenomenological and statistically-based formalisms of continuum dislocation dynamics are then introduced. As discussed in the pertinent sections, these formalisms properly connect the evolution of the dislocation fields with the internal stress state in and thus offer frameworks for predicting the plastic behavior of crystals.

# 1    Introduction

The interpretation of plastic deformation of metals in terms of dislocation motion (Orowan 1934; Polanyi 1934; Taylor 1934), together with the subsequent imaging of crystal dislocations by electron microscopy, marked the beginning of the dislocation-based theory of plasticity (Hirth 1985; Hirsch et al. 2006). Since then, the theory has been instrumental in rationalizing many aspects of metal plasticity in terms of the elementary properties of dislocations (Hirth and Lothe 1982; Argon 2008; Kubin 2013). Such a fundamental understanding has permeated through the field of continuum plasticity up to phenomenological theories developed and used at the scale of engineering components (McDowell 2010; Roters et al. 2010).

Despite the fact that most mechanisms of plasticity are known at the single-dislocation level, several features of plastic deformation related to the collective behavior of dislocations have remained hard to understand and predict, such as the phenomena of strain localization, hardening, self-organization, and patterning. Such phenomena were first investigated by simple models such as those developed by Walgraef and Aifantis (1988), before the method of discrete dislocation dynamics simulation was introduced (Lepinoux and Kubin 1987; Ghoniem and Amodeo 1988), eventually leading to elaborate density-based continuum dislocation dynamics approaches; see Sect. 3. The latter theories build upon early attempts to model plasticity through a density-type representation of dislocations, based on the dislocation density tensor introduced by Nye (1953) and Kröner (1981).

The method of discrete dislocation dynamics simulation tracks the trajectory of an ensemble of dislocations evolving under the influence of external stress and their mutual interactions (Kubin 2013; Bulatov and Cai 2006). A typical strain-controlled simulation provides the average dislocation density and stress evolution as a function of imposed strain. The dislocation density corresponding to a given Burgers vector or a slip system can also be determined from the simulation. The method thus provides full diagnostics of dislocation processes during evolution, including cross slip and dislocation annihilation and junction formation. Density-based models of dislocation dynamics, which are termed continuum dislocation dynamics (CDD) in the sequel, have the same goal of tracking the dislocation density evolution and all internal fields. Early relevant formulations used a density tensor to represent dislocations (Mura 1987). However, because this tensor represents a coarse-grained geometric representation of dislocations of all Burgers vectors, it was not possible to close the evolution problem properly and solve it to find the elastic and plastic fields

as a function of the imposed load boundary conditions. More recent theories provide closure approximations which allow the numerical implementation of continuum dislocation-based plasticity (Groma 1997; El-Azab 2000; Acharya 2001; Acharya and Roy 2006; Hochrainer et al. 2009; Xia and El-Azab 2015a). The progress made in the field prospects the possibility that continuum dislocation dynamics can be a viable approach to tackling the problem of self-organization of dislocations and crystal plasticity at the mesoscale (Xia and El-Azab 2015a, b).

This chapter provides a review of CDD approaches to plastic deformation of crystals. Both classical and contemporary models and theories are briefly discussed with a special focus on those falling within the realm of infinitesimal deformation kinematics of crystals. Following this introduction, the classical continuum theory of dislocations is introduced in Sect. 2, and its limitations are discussed. Section 3 introduces the recent attempts at overcoming these limitations.

## 2 Classical Theory of Dislocation Fields

The equations describing crystal deformation, continuum representation of dislocations, and stress fields, along with relevant constitutive relationships, are summarized in this section. In presenting these equations, we adopt the algebra and calculus of Cartesian tensors and denote by boldface symbols that tensors of all orders and adopt the index notation convention for their components (Lubarda 2002). Unless stated otherwise, all field variables are considered to be dependent on the spatial position vector $\mathbf{x} = x_i \mathbf{e}_i$ and time $t$.

In this chapter we use the following notation. The gradient operator $\nabla \equiv \mathbf{e}_i \partial_i(\cdot) \equiv \mathbf{e}_i \partial(\cdot)/\partial x_i$ applied to a scalar function, $f(\mathbf{x})$, a vector field $\mathbf{w}(\mathbf{x})$, and a second-order tensor field $\mathbf{T}(\mathbf{x})$ yields a vector, a second-order tensor, and a third-order tensor, respectively. In this notation $\mathbf{e}_i$, $i = 1, 2, 3$, refer to the base vectors of the Cartesian coordinate system. Throughout this chapter, a left convention is adopted for the gradient operator. We thus have $\nabla f = \partial_i f \mathbf{e}_i = f_{,i} \mathbf{e}_i$, $\nabla \mathbf{w} = \mathbf{e}_i \partial_i(w_j \mathbf{e}_j) = \partial_i w_j \mathbf{e}_i \mathbf{e}_j = w_{j,i} \mathbf{e}_i \mathbf{e}_j$, and $\nabla \mathbf{T} = \mathbf{e}_i \partial_i(T_{jk} \mathbf{e}_j \mathbf{e}_k) = \partial_i T_{jk} \mathbf{e}_i \mathbf{e}_j \mathbf{e}_k = T_{jk,i} \mathbf{e}_i \mathbf{e}_j \mathbf{e}_k$. This notation also defines the comma convention for partial differentiation with respect to spatial coordinates. Finally, the summation over a repeated index is implied. The left convention for the gradient operator implies that the differential change of the function $f$, vector $\mathbf{w}$, and tensor $\mathbf{T}$ over a spatial distance $d\mathbf{x}$ is given by $df = d\mathbf{x} \cdot \nabla f$, $d\mathbf{w} = d\mathbf{x} \cdot \nabla \mathbf{w}$, and $d\mathbf{T} = d\mathbf{x} \cdot \nabla \mathbf{T}$, respectively. Component-wise, these differential quantities are expressed in the forms $df = f_{,i} dx_i$, $dw_j = w_{j,i} dx_i$, and $dT_{jk} = T_{jk,i} dx_i$. Moreover, the curls of a vector field $\mathbf{w}$ and a second-order tensor field $\mathbf{T}$ are defined by $\nabla \times \mathbf{w} = e_{ijk} \partial_j w_k \mathbf{e}_i = e_{ijk} w_{k,j} \mathbf{e}_i$ and $\nabla \times \mathbf{T} = e_{ijk} \partial_j T_{kl} \mathbf{e}_i \mathbf{e}_l = e_{ijk} T_{kl,j} \mathbf{e}_i \mathbf{e}_l$, where $e_{ikl}$ are the components of the antisymmetric permutation tensor. As with the gradient and curl operators, we adopt a left convention of the divergence operator. The divergence of a vector field $\mathbf{w}$ is given by $\nabla \cdot \mathbf{w} = \partial_i w_i = w_{i,i}$ and that of a second-order tensor $\mathbf{T}$ by $\nabla \cdot \mathbf{T} = \partial_i T_{ik} \mathbf{e}_k = T_{ik,i} \mathbf{e}_k$.

## 2.1    Distortion of Dislocated Crystals

As developed in its time-independent form by Kröner (1981) and in its dynamic version by Mura (1963, 1987), Kosevich (1979), and Kossecka and de Wit (1977a, b), the classical theory of dislocation fields aims to determine the elastic state of a crystal containing a prescribed defect distribution. At infinitesimal deformation, the kinematic basis of the theory consists in the additive split of the gradient of the total displacement field $\mathbf{u}^{\mathrm{t}}$ within the crystal, also known as total *distortion* $\boldsymbol{\beta}^{\mathrm{t}}$, which includes the following contributions:

$$\boldsymbol{\beta}^{\mathrm{t}} = \nabla \mathbf{u}^{\mathrm{t}} = \boldsymbol{\beta}^{\circ} + \boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}}. \tag{1}$$

Here $\boldsymbol{\beta}^{\mathrm{p}}$ is the plastic distortion introduced into a crystal by the creation and motion of dislocations, while $\boldsymbol{\beta}^{\mathrm{e}}$ is the elastic distortion generated by them, which is associated with the incompatibility of the plastic distortion, as we shall see in this section (Kröner 1981, 1995, 1996; Kosevich 1962, 1965, 1979; Mura 1963, 1968, 1969; Kossecka 1974, 1975; Kossecka and de Wit 1977a, b). In Eq. (1), we have included the distortion $\boldsymbol{\beta}^{\circ}$ induced by the loading system through mechanical boundary conditions. In component form, Eq. (1) reads $\beta_{ij}^{\mathrm{t}} = \beta_{ij}^{\circ} + \beta_{ij}^{\mathrm{e}} + \beta_{ij}^{\mathrm{p}}$. Both $\boldsymbol{\beta}^{\circ}$ and $\boldsymbol{\beta}^{\mathrm{e}}$ result in dragging the lattice along into an atomically distorted configuration fixed by the plastic distortion, $\boldsymbol{\beta}^{\mathrm{p}}$, and the applied boundary traction (Kröner 1981). Being elastic in nature, they are associated with internal stresses $\boldsymbol{\sigma}^{\circ} = \mathbf{c} : \boldsymbol{\beta}^{\circ}$ and $\boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\beta}^{\mathrm{e}}$, respectively, so that the total stress within the crystal is

$$\boldsymbol{\sigma}^{\mathrm{t}} = \boldsymbol{\sigma}^{\circ} + \boldsymbol{\sigma} . \tag{2}$$

The distortion $\boldsymbol{\beta}^{\circ}$ is compatible, i.e., it can be expressed as the gradient of a displacement vector $\mathbf{u}^{\circ}$. That is

$$\boldsymbol{\beta}^{\circ} = \nabla \mathbf{u}^{\circ} , \tag{3}$$

which in component form reads $\beta_{ij}^{\circ} = \partial_i u_j^{\circ}$. Equations (1) and (3) imply that the sum $\boldsymbol{\beta} = \boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}}$ is a compatible distortion field derivable from a displacement field, which is denoted by $\mathbf{u}$. The differential form of the compatibility conditions for the distortion fields $\boldsymbol{\beta}^{\circ}$ and $\boldsymbol{\beta}$ can be stated as follows:

$$\nabla \times \boldsymbol{\beta}^{\circ} = \nabla \times \nabla \mathbf{u}^{\circ} = \mathbf{0} \quad \text{and} \quad \nabla \times \boldsymbol{\beta} = \nabla \times \nabla \mathbf{u} = \mathbf{0}, \tag{4}$$

or alternatively

$$\oint_{\mathscr{C}} \mathrm{d}\mathbf{u}^{\circ} = \mathbf{0} \quad \text{and} \quad \oint_{\mathscr{C}} \mathrm{d}\mathbf{u} = \mathbf{0}, \tag{5}$$

where $\nabla \times (\cdot) = \mathbf{e}_i \times \partial_i (\cdot)$ is the curl operator and $\mathscr{C}$ is any closed curve within the (continuum) crystal. The compatibility conditions (4) follow from the orthogonality of the curl and gradient operators, while the form (5) can be reached from (4) by exploiting Stokes theorem. Introduction of this theorem is left for later after the dislocation density tensor and its areal integral are introduced. Selecting the applied traction to be zero implies that the corresponding stress, $\boldsymbol{\sigma}^\circ$, and elastic distortion $\boldsymbol{\beta}^\circ$ are also zero. In such case, the total stress $\boldsymbol{\sigma}^{\mathrm{t}}$ reduces to $\boldsymbol{\sigma}$, the total distortion $\boldsymbol{\beta}^{\mathrm{t}}$ reduces to $\boldsymbol{\beta} = \boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}}$, and the displacement $\mathbf{u}^{\mathrm{t}}$ reduces to $\mathbf{u}$. The condition (4) may then be rewritten in the form

$$\nabla \times \nabla \mathbf{u} = \nabla \times \boldsymbol{\beta} = \nabla \times (\boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}}) = \mathbf{0}. \tag{6}$$

For dynamical problems, the crystal velocity field $\dot{\mathbf{u}}$ is the time derivative of the displacement:

$$\dot{\mathbf{u}} = \partial_t \mathbf{u}, \tag{7}$$

where $\partial_t (\cdot) = \partial (\cdot)/\partial t$. In this case, it can be easily verified that

$$\nabla \dot{\mathbf{u}} = \dot{\boldsymbol{\beta}}, \tag{8}$$

meaning that the rate of the total distortion is given by the gradient of the crystal velocity field.

## 2.2    Tensor Fields of Dislocations

A number of tensor fields connected with dislocations and their motion are now introduced. These include the dislocation density tensor field, the dislocation flux tensor field, and the dislocation velocity and movement tensor fields.

### 2.2.1    The Dislocation Density Tensor Field

Equation (6) can be rearranged in the form

$$\nabla \times \boldsymbol{\beta}^{\mathrm{e}} = -\nabla \times \boldsymbol{\beta}^{\mathrm{p}}. \tag{9}$$

The curl of a distortion field measures its incompatibility. Equation (9) implies that the distortions $\boldsymbol{\beta}^{\mathrm{e}}$ and $\boldsymbol{\beta}^{\mathrm{p}}$ either are simultaneously compatible or have nontrivial curl and are thus simultaneously incompatible. The same equation also implies that the measures of incompatibility of the elastic and plastic distortion are equal and opposite. The dislocation density tensor $\boldsymbol{\alpha}$ is introduced here as that measure. According to Mura (1963, 1968, 1969) and Kossecka and de Wit (1977a, b), $\boldsymbol{\alpha}$ is given by

$$\boldsymbol{\alpha} = \nabla \times \boldsymbol{\beta}^{\mathrm{e}} = -\nabla \times \boldsymbol{\beta}^{\mathrm{p}}. \tag{10}$$

In component form, this reads $\boldsymbol{\alpha}_{ij} = e_{ikl}\partial_k\beta_{lj}^e = e_{ikl}\beta_{lj,k}^e$ or $\boldsymbol{\alpha}_{ij} = -e_{ikl}\partial_k\beta_{lj}^p = -e_{ikl}\beta_{lj,k}^p$. The dislocation density tensor is a field that depends on position $\mathbf{x}$, and its component $\alpha_{ij}$ is defined as the $x_j$ component of the sum of the Burgers vector of all dislocation lines that intersect a unit area normal to the $x_i$ direction, or, alternatively, it is the sum of $x_j$ components of the Burgers vectors times the projected line length in the $x_i$ direction of all dislocations per unit volume. Since the curl of a field is divergence-free, then

$$\nabla \cdot \boldsymbol{\alpha} = \mathbf{0}, \tag{11}$$

where $\nabla\cdot(\cdot) = \mathbf{e}_i\cdot\partial_i(\cdot)$ denotes the divergence operator. In component form, Eq. (11) reads $\partial_i\alpha_{ij} = \alpha_{ij,i} = 0$. This equation is known as the condition of the conservation of the Burgers vector. When this condition is applied to a dislocation line, it simply means that the line cannot end within the crystal.

The interpretation of the dislocation density tensor in terms of crystal dislocations is important in connecting the continuum theory of dislocation fields and the theory for line dislocations. For a family of dislocations of number $\rho^s$ crossing unit area perpendicular to their common line vector $\boldsymbol{\xi}^s$ and having Burgers vector $\mathbf{b}^s$ at a point in the crystal, the dislocation density tensor is given by

$$\boldsymbol{\alpha}^s = \rho^s\boldsymbol{\xi}^s \otimes \mathbf{b}^s, \tag{12}$$

where for two vectors $\mathbf{a}$ and $\mathbf{b}$, $\mathbf{a} \otimes \mathbf{b} = a_ib_j\mathbf{e}_i\mathbf{e}_j$ denotes their tensor product. In component form, the last equation reads $\alpha_{ij}^s = \rho^s\xi_i^s b_j^s$. When multiple families of dislocations are present, the overall dislocation density tensor is the sum of contributions of such families. That is, $\boldsymbol{\alpha} = \sum_s\boldsymbol{\alpha}^s$.

By taking the dot product of equation (10) with an oriented area element $d\mathbf{S} = \mathbf{n}dS = n_idSe_i$, with $\mathbf{n}$ being the unit normal, and integrating that product over an open surface $\mathscr{S}$ bounded by a contour $\mathscr{C}$, it can be shown that

$$\int_{\mathscr{S}} \mathbf{n} \cdot \boldsymbol{\alpha}dS = -\int_{\mathscr{S}} \mathbf{n} \cdot \nabla \times \boldsymbol{\beta}^p dS = -\oint_{\mathscr{C}} d\boldsymbol{\ell} \cdot \boldsymbol{\beta}^p = \mathbf{b}^{\mathscr{C}}. \tag{13}$$

In the above, Stokes theorem has been used to convert the areal integral over $\mathscr{S}$ to a line integral over the bounding contour $\mathscr{C}$. In the above, $\mathbf{n}$, the normal to $\mathscr{S}$, and the directed length element $\boldsymbol{\ell}$ along $\mathscr{C}$ are defined such that if $\mathscr{S}$ shrinks to a small flat element, $\boldsymbol{\ell}$ circles $\mathscr{C}$ around its normal in a right-hand screw sense. In component form, Eq. (13) reads

$$\int_{\mathscr{S}} n_i\alpha_{ij}dS = -\int_{\mathscr{S}} n_ie_{ikl}\beta_{lj,k}^p dS = -\oint_{\mathscr{C}} \beta_{ij}^p d\ell_i = b_j^{\mathscr{C}}. \tag{14}$$

The vector $\mathbf{b}^{\mathscr{C}} = b_j^{\mathscr{C}} \mathbf{e}_j$ is the resultant Burgers vector of all dislocations piercing $\mathscr{S}$ in all directions and contained within $\mathscr{C}$. This vector can be expressed in terms of the elastic distortion by replacing $\nabla \times \boldsymbol{\beta}^{\mathrm{p}}$ with $-\nabla \times \boldsymbol{\beta}^{\mathrm{e}}$ in Eq. (13).

$$\int_{\mathscr{S}} \mathbf{n} \cdot \boldsymbol{\alpha} \mathrm{d}S = \int_{\mathscr{S}} \mathbf{n} \cdot \nabla \times \boldsymbol{\beta}^{\mathrm{e}} \mathrm{d}S = \oint_{\mathscr{C}} \mathrm{d}\boldsymbol{\ell} \cdot \boldsymbol{\beta}^{\mathrm{e}} = \mathbf{b}^{\mathscr{C}}. \qquad (15)$$

It can be shown that the second integral in Eq. (5) is satisfied by subtracting Eq. (13) from Eq. (15) and substituting $\boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}} = \nabla \mathbf{u}$. Equations (10) and (13) are, respectively, known as the differential and integral forms of the incompatibility law. It is obvious that, for a given state of deformation, $\mathbf{b}^{\mathscr{C}}$ vanishes for an arbitrary contour $\mathscr{C}$ if the plastic distortion is curl-free everywhere in the crystal. A uniform plastic distortion satisfies that criterion, in which case it is called a compatible plastic distortion. Such a distortion can be associated with a displacement field satisfying Eq. (5).

### 2.2.2 The Dislocation Velocity Tensor Field

Per Eq. (12), the dislocation density tensor $\boldsymbol{\alpha}$ represents the dislocation state corresponding to the prescribed plastic distortion in the crystal. According to the latter equation, it is possible for the dislocation density tensor to vanish at a point if equal numbers of dislocations of opposite line direction and same Burgers vector pass through that point. From the point of view of plastic deformation, however, all mobile dislocations contribute to the deformation of the crystal regardless of their line direction. As such, to completely characterize moving dislocations and hence the deformation process, different tensors must be introduced that account for the direction of motion of dislocations. One such tensor is the dislocation velocity tensor $\mathbf{V}$, which accounts for the velocity $\mathbf{v}$ of dislocation lines, in addition to their line direction and Burgers vector. Generally, the velocity of a moving dislocation varies from one point to another along its line $\mathscr{L}$. For a family of dislocations of number $\rho^{\mathrm{s}}$ crossing a unit area perpendicular to their common line vector $\boldsymbol{\xi}^{\mathrm{s}}$ and having Burgers vector $\mathbf{b}^{\mathrm{s}}$ at a point in the crystal, Mura (1968, 1969) introduced the dislocation velocity tensor of third rank in the form

$$\mathbf{V}^{\mathrm{s}} = \rho^{\mathrm{s}} \mathbf{v}^{\mathrm{s}} \otimes \boldsymbol{\xi}^{\mathrm{s}} \otimes \mathbf{b}^{\mathrm{s}}. \qquad (16)$$

In component form, the last equation reads $V_{ijk} = \rho^{\mathrm{s}} v_i^{\mathrm{s}} \xi_j^{\mathrm{s}} b_k^{\mathrm{s}}$. When multiple families of dislocations are present, the total dislocation velocity tensor $\mathbf{V}$ is given by the sum of the partial tensors, $\mathbf{V} = \sum_{\mathrm{s}} \mathbf{V}^{\mathrm{s}}$. It is obvious that, when two dislocation families of opposite direction pass at a point, their velocity tensors add together and not cancel each other as do their dislocation density tensors, since the velocities of dislocations of opposite line directions at a point are also opposite. It should be noticed that $V_{mmk} = 0$ since the motion of a dislocation along its line direction is physically insignificant.

### 2.2.3 The Dislocation Movement Tensor Field

The definition of the dislocation movement tensor was given by Eisenberg (1990). Here, this tensor is defined in a slightly different way taking into consideration that it is path dependent and as such can be defined in an incremental sense. The incremental change of the dislocation movement tensor is denoted by d$\mathbf{X}$. For a family of dislocations $\rho^s$ with line tangent $\boldsymbol{\xi}^s$ and Burgers vector $\mathbf{b}^s$, this differential tensor is given by

$$\mathrm{d}\mathbf{X}^s = \mathrm{d}\mathbf{A}^s \otimes \mathbf{b}^s, \tag{17}$$

where d$\mathbf{A}$ is an incremental second-order tensor defined by the outer product of the differential vector distance traversed by dislocations in their glide planes with the oriented dislocation density, $\rho^s \boldsymbol{\xi}^s$. In component form, Eq. (17) reads $\mathrm{d}X^s_{ijk} = \mathrm{d}A^s_{ij} b^s_k$. When multiple families of dislocations are present, $\mathrm{d}\mathbf{X} = \sum_s \mathrm{d}\mathbf{X}^s$. It is clear that

$$\mathbf{V} = \dot{\mathbf{X}} = \partial_t \mathbf{X}, \tag{18}$$

or $\dot{X}_{ijk} = V_{ijk}$. The dislocation movement tensor can thus be obtained from the velocity tensor by a path-dependent integration.

The dislocation velocity and movement tensors carry the overall character of dislocations in terms of their density, line direction, Burgers vector, and velocity vector. Therefore, the velocity tensor can be used to determine the rate of plastic distortion in the crystal containing moving dislocations. Similarly, the incremental change in the dislocation movement tensor can be used to determine the incremental change in the plastic distortion tensor.

### 2.2.4 The Dislocation Flux Tensor Field

A definition of the dislocation flux tensor is given by Kosevich (1979) who wrote Eq. (8) in the form

$$\dot{\boldsymbol{\beta}} = \partial_t \nabla \mathbf{u} = \dot{\boldsymbol{\beta}}^e + \dot{\boldsymbol{\beta}}^p . \tag{19}$$

He then defined the difference $\dot{\boldsymbol{\beta}}^e - \partial_t \nabla \mathbf{u}$ to be the second-order tensor $\mathbf{J}$ and called it the dislocation flux or current tensor. From the last equations, $\mathbf{J} = -\dot{\boldsymbol{\beta}}^p$. In the current presentation, the dislocation flux tensor is defined by

$$\mathbf{J} = \dot{\boldsymbol{\beta}}^p, \tag{20}$$

so that (19) is written as

$$\dot{\boldsymbol{\beta}} = \dot{\boldsymbol{\beta}}^e + \mathbf{J}. \tag{21}$$

By taking the curl of the last equation and using the definition of the dislocation density tensor in (9), one reaches

$$\dot{\boldsymbol{\alpha}} + \nabla \times \mathbf{J} = \mathbf{0}. \tag{22}$$

In component form, Eq. (22) read: $\alpha_{ij} + e_{ikl}\partial_k J_{lj} = 0$. It represents the continuity equation for the dislocation density tensor in a medium undergoing time-dependent plastic distortion. It will be shown later that it can be recast in the form of a transport equation for dislocations. From the definition of the dislocation velocity tensor, it can be verified that the rate of plastic distortion tensor is given by

$$\dot{\beta}_{ij}^{\mathrm{p}} = -e_{imn}V_{mnj}. \tag{23}$$

## 2.3   Dynamics of Dislocated Crystals

The classical development presented so far assumes that the plastic distortion $\boldsymbol{\beta}^{\mathrm{p}}$ and its time rate of change can be introduced arbitrarily, and it is required to determine the displacement, elastic distortion, and internal stress fields. This problem is known as the internal stress or *incompatibility* problem. We continue to present this theory with no regard to the externally imposed stresses as their effect can be simply added to the solution of the incompatibility problem itself.

The elastic distortion $\boldsymbol{\beta}^{\mathrm{e}}$ is related to the internal stress field by Hooke's law for linearly elastic crystals, which is written in the form

$$\boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\beta}^{\mathrm{e}}, \tag{24}$$

which, in component form, reads $\sigma_{ij} = c_{ijkl}\beta_{kl}^{\mathrm{e}}$, with $\mathbf{c}$ being the fourth-rank elasticity tensor of the crystal. The stress field must satisfy Cauchy's equation of motion which is written as

$$\nabla \cdot \boldsymbol{\sigma} = \rho\ddot{\mathbf{u}}, \tag{25}$$

or $\sigma_{ij,j} = \rho\ddot{u}_i$, where $\rho$ is the mass density of the crystal. For simplicity, we consider the medium to be infinitely extended so that no boundary conditions are included at this stage. Upon using $\boldsymbol{\beta}^{\mathrm{e}} = \boldsymbol{\beta} - \boldsymbol{\beta}^{\mathrm{p}}$ and $\boldsymbol{\beta} = \nabla\mathbf{u}$ into the equation of motion above, the latter can be rearranged in the form

$$\nabla \cdot (\mathbf{c} : \nabla\mathbf{u}) - \rho\ddot{\mathbf{u}} = \nabla \cdot \left(\mathbf{c} : \boldsymbol{\beta}^{\mathrm{p}}\right). \tag{26}$$

or in component form ($c_{ijkl}u_{l,ki} - \rho\ddot{u}_j = c_{ijkl}\beta_{kl,i}^{\mathrm{p}}$). Solution of the equation of motion can be obtained using the Green function technique. Omitting details, the solution for the displacement field is given by Mura (1987),

by

$$u_n(\mathbf{x}, t) = -\int c_{ijkl} G_{jn,i}(\mathbf{R}, T)\beta_{kl}^{\mathrm{p}}(\mathbf{x}', t')\mathrm{d}\mathbf{x}'^3 \mathrm{d}t', \tag{27}$$

and the total distortion tensor by

$$\beta_{mn}(\mathbf{x}, t) = \int c_{ijkl} G_{jn,i}(\mathbf{R}, T)e_{pmk}\alpha_{pl}(\mathbf{x}', t')\mathrm{d}\mathbf{x}'^3 \mathrm{d}t'$$
$$- \int \rho \dot{G}_{ln}(\mathbf{R}, T)J_{ml}(\mathbf{x}', t')\mathrm{d}\mathbf{x}'^3 \mathrm{d}t' + \beta_{mn}^{\mathrm{p}}(\mathbf{x}, t), \tag{28}$$

where $\mathbf{G}(\mathbf{R}, T)$ is the Green function (tensor), $\mathbf{R} = \mathbf{x} - \mathbf{x}'$, $T = t - t'$, and the integrals are carried out over the entire space and time from $-\infty$ to $t$. The elastic distortion tensor is given by $\boldsymbol{\beta}^{\mathrm{e}} = \boldsymbol{\beta} - \boldsymbol{\beta}^{\mathrm{p}}$, and it yields the internal stress via Hooke's law $\sigma_{ij}(\mathbf{x}, t) = c_{ijkl}\beta_{kl}^{\mathrm{e}}(\mathbf{x}, t)$. This completes the solution for the internal stress problem once the dislocation density and flux tensors are prescribed. It can be easily shown that the above results can be specialized to the case of stationary dislocation system.

## 2.4     Summary of the Continuum Dislocation Dynamics Problem

Based on the theory developed in the previous sections, the fields and field equations of continuum dislocation dynamics are summarized as follows:

- *The dislocation field*. The dynamic dislocation field is described by the density tensor $\boldsymbol{\alpha}$ and flux tensor $\mathbf{J}$ or $\boldsymbol{\alpha}$ and the velocity tensor $\mathbf{V}$. The density tensor $\boldsymbol{\alpha}$ and the flux tensor $\mathbf{J}$ are given in terms of the plastic distortion and its time rate of change:

$$\begin{cases} \boldsymbol{\alpha} = -\nabla \times \boldsymbol{\beta}^{\mathrm{p}}, \\ \mathbf{J} = \dot{\boldsymbol{\beta}}^{\mathrm{p}}. \end{cases} \tag{29}$$

These two fields, respectively, satisfy the gauge and continuity conditions

$$\begin{cases} \nabla \cdot \boldsymbol{\alpha} = \mathbf{0}, \\ \dot{\boldsymbol{\alpha}} + \nabla \times \mathbf{J} = \mathbf{0}. \end{cases} \tag{30}$$

- *The distortion fields*. The total distortion $\boldsymbol{\beta}$ is given by the gradient of the displacement field

$$\boldsymbol{\beta} = \nabla \mathbf{u} = \boldsymbol{\beta}^{\mathrm{e}} + \boldsymbol{\beta}^{\mathrm{p}}. \tag{31}$$

The total distortion satisfies the compatibility condition

$$\nabla \times \boldsymbol{\beta} = \mathbf{0}, \tag{32}$$

and the continuity condition

$$\dot{\boldsymbol{\beta}} = \nabla \partial_t \mathbf{u} = \nabla \dot{\mathbf{u}}. \tag{33}$$

• *The displacement and stress fields*. The internal stress field is related to the elastic distortion $\beta$ by Hooke's law

$$\boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\beta}^{\mathrm{e}}. \tag{34}$$

Therefore the displacement field satisfies Cauchy's equation of motion:

$$\rho \ddot{\mathbf{u}} = \nabla \cdot \boldsymbol{\sigma} = \nabla \cdot \left[ \mathbf{c} : \left( \nabla \mathbf{u} - \boldsymbol{\beta}^{\mathrm{p}} \right) \right] \tag{35}$$

The system of Eqs. (29) through (35) is valid for dynamic problems involving continuously distributed dislocations, and it can be solved provided that the plastic distortion $\boldsymbol{\beta}^{\mathrm{p}}$ and its rate $\dot{\boldsymbol{\beta}}^{\mathrm{p}}$ are prescribed. For a given system of dislocations, the evolution of the dislocation configuration and the plastic distortion can be computed once the dislocation motion is connected with the internal stress field. This closure is missing in the classical theory of dislocation fields. The stumbling block here is the fact that the dislocation density tensor $\boldsymbol{\alpha}$ does not provide sufficient information to determine the rate $\dot{\boldsymbol{\beta}}^{\mathrm{p}}$, which is necessary to evolve the dislocation configuration in time. In fact, the tensor $\boldsymbol{\alpha}$ measures only the so-called *geometrically necessary* dislocations, while $\dot{\boldsymbol{\beta}}^{\mathrm{p}}$ depends in general also on the *statistically stored* dislocation density within a certain material volume. By contrast, in the discrete dislocation dynamics method, all dislocations are fully resolved (in other words they are all geometrically necessary at the length scale of observation), and therefore the evolution of plastic distortion can be determined without complications. The recent continuum dislocation dynamics theories discussed in Sect. 3 achieve this closure of the governing equations and thus qualify as crystal plasticity theories as well.

## 2.5   The Discrete Dislocation Line

The theory presented above can be specialized to discrete dislocation lines. The results can be found in the works by Kosevich (1979), Mura (1987), and Kossecka and de Wit (1977a, b) for the dynamic case and by Kröner (1981) for the static case. Here we summarize the final results for the dynamic case. The term *discrete*

*dislocation line* is used here to represent a single curved dislocation with both ends at infinity, a dislocation line closed on itself, a dislocation network with no free ends in the bulk of the crystal, or a combination of such configurations. The collection of all points on the discrete line will be denoted by $\mathscr{L}(t)$, implying that the dislocation line changes its position and length as a function of time. The first quantity of interest for the discrete dislocation line is the dislocation density tensor field, which is given by

$$\alpha_{pl}(\mathbf{x}, t) = \int_{\mathscr{S}(t)} e_{pmk}\delta_{,m}(\mathbf{R})b_l dS'_k = \oint_{\mathscr{L}(t)} \delta(\mathbf{R})b_l d\ell'_p = \delta_p(\mathscr{L})b_l. \tag{36}$$

where, as previously defined, $\mathbf{R} = \mathbf{x} - \mathbf{x}'$, $\mathscr{S}(t)$ is the defect surface which is bounded by the dislocation line $\mathscr{L}(t)$ and $d\boldsymbol{\ell}'$ is a vector line element at $\mathbf{x}'$. The defect surface $\mathscr{S}(t)$ is the surface of discontinuity of the displacement field. For a glide dislocation loop on a specific crystallographic plane, this surface is enclosed by the loop itself. The function $\delta_p(\mathscr{L}) = \oint_{\mathscr{L}(t)} \delta(\mathbf{R})d\ell'_p$ is a vector Dirac delta function on the line $\mathscr{L}(t)$. Next, the dislocation flux tensor is defined by

$$J_{kl}(\mathbf{x}, t) = \oint_{\mathscr{L}(t)} e_{pmk}\delta(\mathbf{R})b_l v'_m(\mathbf{x}', t)d\ell'_p, \tag{37}$$

where $v_m$ is the $m$th component of the dislocation velocity at $\mathbf{x}'$. The plastic distortion in the case of a discrete dislocation is not a continuous function of space as it was assumed in the case of continuously distributed dislocations. It is the singular part of the total distortion, and it represents a deformation field that is localized on the defect surface $\mathscr{S}(t)$. It is identically zero everywhere else. Its increment or time rate of change, however, is localized on the dislocation line itself as in (37). This plastic distortion field is given by

$$\beta_{kl}^P(\mathbf{x}, t) = -\int_{\mathscr{S}(t)} \delta(\mathbf{R})b_l dS'_k = -\delta_k(\mathscr{S})b_l, \tag{38}$$

where $\delta_k(\mathscr{S})$ is a vector Dirac delta function of the surface $\mathscr{S}$. The elastic distortion for the discrete dislocation line is given by

$$\beta_{mn}(\mathbf{x}, t) = \int dt' \oint_{\mathscr{L}(t')} \left[ e_{pmk}c_{ijkl}G_{jn,i}(\mathbf{R}, T) + \rho\dot{G}_{ln}(\mathbf{R}, T)v'_k(\mathbf{x}') \right] b_l d\ell'_p, \tag{39}$$

and the stress field is given via Hooke's law. The static solution for the incompatibility problem can be obtained by dropping the inertia term in Cauchy's equation of motion and continuing the development in essentially the same way. Such solutions are available in the work of de Wit (1970, 1973).

## 3 Recent Continuum Dislocation Theories

### 3.1 2D Statistical Theory of Dislocations

Groma ([1997]) and Groma et al. ([2003]) pioneered the adoption of the concepts of statistical mechanics to modeling simple, many-dislocation systems, thus developing a first density-based model of dislocation transport in single slip. The dislocation-dislocation correlation was used to account for the impact of dislocation density fluctuations on the internal driving force of dislocations (Zaiser et al. [2001]). Further elaboration of the theory and generalization to multislip case was done by Yefimov et al. ([2004a], [b]) and Yefimov and van der Giessen ([2004], [2005]). Assuming $N$ infinitely long edge dislocations with Burgers vector $b$ distributed in a plane normal to their line direction, the fundamental evolution equation of discrete dislocation dynamics is

$$\mathbf{v}^i = M\mathbf{F}^i_{\mathrm{PK}} = Mb\tau^i_{\mathrm{eff}}\hat{\mathbf{v}}^i\,, \quad \tau^i_{\mathrm{eff}} = \tau^i_{\mathrm{ext}} + \sum_{j\neq i}^N \tau^{ij}(\mathbf{r}^i - \mathbf{r}^j)\,, \quad i, j = 1, \dots, N.$$
(40)

In the above, $\mathbf{v}$ is the dislocation velocity with unit direction $\hat{\mathbf{v}}$, $M$ is the dislocation mobility, $\mathbf{F}_{\mathrm{PK}}$ is the Peach-Koehler force, and $\tau_{\mathrm{eff}}$ is the effective resolved shear stress on the glide plane. The latter stress is split into two parts, the external stress, $\tau_{\mathrm{ext}}$, and the collective stress resulting from interaction with all other dislocations, $\tau^{ij}(\mathbf{r}^i - \mathbf{r}^j)$. A density-based form of the evolution Eq. (40) comes in the form of a pair of transport equations for the density of positively and negatively oriented dislocations, $\rho_+$ and $\rho_-$; see Groma ([1997]) for details. These transport equations have the form

$$\begin{cases} \frac{\partial\rho_+(\mathbf{r},t)}{\partial t} + Mb\frac{\partial}{\partial\mathbf{r}}\int\{\rho_{++}(\mathbf{r},\mathbf{r}',t) - \rho_{+-}(\mathbf{r},\mathbf{r}',t)\}\tau(\mathbf{r} - \mathbf{r}')\mathrm{d}^2\mathbf{r}' \\ \qquad + Mb\frac{\partial}{\partial\mathbf{r}}\rho_+(\mathbf{r},t)\tau_{\mathrm{ext}}(\mathbf{r},t) = 0, \\ \frac{\partial\rho_-(\mathbf{r},t)}{\partial t} + Mb\frac{\partial}{\partial\mathbf{r}}\int\{\rho_{--}(\mathbf{r},\mathbf{r}',t) - \rho_{-+}(\mathbf{r},\mathbf{r}',t)\}\tau(\mathbf{r} - \mathbf{r}')\mathrm{d}^2\mathbf{r}' \\ \qquad + Mb\frac{\partial}{\partial\mathbf{r}}\rho_-(\mathbf{r},t)\tau_{\mathrm{ext}}(\mathbf{r},t) = 0. \end{cases}$$
(41)

In the above, $\rho_{++}(\mathbf{r},\mathbf{r})$, $\rho_{+-}(\mathbf{r},\mathbf{r}')$, $\rho_{--}(\mathbf{r},\mathbf{r}')$, and $\rho_{-+}(\mathbf{r},\mathbf{r}')$ are pair densities, which are cast in terms of the dislocation correlations, $d_{ss'}(\mathbf{r},\mathbf{r}')$, as follows:

$$\rho_{ss'}(\mathbf{r},\mathbf{r}') = \rho_s(\mathbf{r})\rho_{s'}(\mathbf{r}')\left(1 + d_{ss'}(\mathbf{r},\mathbf{r}')\right).$$
(42)

Using these correlations and skipping details, the transport equations can be conveniently rewritten in the form

$$\begin{cases} \frac{\partial\rho(\mathbf{r},t)}{\partial t} + Mb\frac{\partial}{\partial\mathbf{r}}\kappa\{\tau_{\mathrm{int}} + \tau_{\mathrm{ext}} - \tau_{\mathrm{s}}\} = f(\rho, \kappa, \cdots), \\ \frac{\partial\kappa(\mathbf{r},t)}{\partial t} + Mb\frac{\partial}{\partial\mathbf{r}}\rho\{\tau_{\mathrm{int}} + \tau_{\mathrm{ext}} - \tau_{\mathrm{s}}\} = 0, \end{cases}$$
(43)

where $\rho = \rho_+ + \rho_-$ and $\kappa = \rho_+ - \rho_-$ and

$$\tau_{\text{int}}(\mathbf{r}) = \int \kappa(\mathbf{r}')\tau(\mathbf{r}-\mathbf{r}')\text{d}^2\mathbf{r}', \quad \tau_{\text{s}}(\mathbf{r}) = -\int \kappa(\mathbf{r}')d^{\text{t}}(\mathbf{r}-\mathbf{r}')\tau(\mathbf{r}-\mathbf{r}')\text{d}^2\mathbf{r}', \quad (44)$$

with the total correlation, $d^{\text{t}}(\mathbf{r} - \mathbf{r}')$, expressed in the form

$$d^{\text{t}}(\mathbf{r} - \mathbf{r}') = [2d_{++}(\mathbf{r} - \mathbf{r}) + d_{+-}(\mathbf{r} - \mathbf{r}) + d_{+-}(\mathbf{r}' - \mathbf{r})]/4. \quad (45)$$

In the above, $\tau_{\text{int}}$ is the long-range stress, and $\tau_{\text{s}}$ is called the back stress. It is due to the dislocation correlation. Finally, the function $f(\rho, \kappa, \cdots)$ accounts for the nucleation and annihilation of dislocations. Assuming that the correlation is short-ranged and considering an isotropic elastic medium, the back stress can be written as

$$\tau_{\text{s}}(\mathbf{r}) = \frac{\mu b}{2\pi(1 - \nu)\rho(\mathbf{r})} D \frac{\partial \kappa}{\partial \mathbf{r}}, \quad (46)$$

where $\mu$ is the shear modulus, $\nu$ is Poisson's ratio, and $D$ is a dimensionless constant.

The transport equations are solved in conjunction with crystal mechanics equations as shown by Yefimov et al. (2004a, b) and Yefimov and van der Giessen (2004, 2005). In order to do so, the long-range and external stresses are lumped together as the internal stress, which is found by solving the stress boundary value problem:

$$\begin{cases} \nabla \cdot \boldsymbol{\sigma} = \mathbf{0}, & \text{stress equilibrium,} \\ \boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\varepsilon}^{\text{e}} = \mathbf{c} : (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}^{\text{p}}), & \text{Hooke's law,} \end{cases} \quad (47)$$

subject to the appropriate traction and/or displacement boundary conditions. In the above, $\boldsymbol{\varepsilon}$, $\boldsymbol{\varepsilon}^{\text{e}}$, and $\boldsymbol{\varepsilon}^{\text{p}}$ are the total, elastic, and plastic strain tensors, respectively. The plastic strain itself is given by

$$\boldsymbol{\varepsilon}^{\text{p}} = \int \dot{\boldsymbol{\varepsilon}}^{\text{p}}(t')dt', \quad \dot{\boldsymbol{\varepsilon}}^{\text{p}} = \dot{\gamma}(\mathbf{S} + \tilde{\mathbf{S}}). \quad (48)$$

where $\mathbf{S} = \mathbf{s} \otimes \mathbf{m}$ is the Schmidt tensor and $\tilde{\mathbf{S}}$ is its transpose, with $\mathbf{s}$ and $\mathbf{m}$ being the unit slip and unit normal vectors, respectively. The plastic shear rate is given in terms of the dislocation transport rate by

$$\dot{\gamma} = \rho b v = \rho b M b(\tau_{\text{RSS}} - \tau_{\text{s}}), \quad \tau_{\text{RSS}} = \boldsymbol{\sigma} : \mathbf{S}. \quad (49)$$

Initial conditions for the dislocation field and the plastic strain are required. The transport equations depend on time explicitly. The mechanics equations depend on time implicitly via $\boldsymbol{\varepsilon}^{\text{p}}(t)$.

Various aspects of this theory have been recently revisited by Valdenaire et al. (2016). Kooiman (2015) on the other hand has developed a more formal coarse-graining procedure of dislocation dynamics of simple, edge-on configurations like the ones treated by Groma (1997) using the General Equation for Non-equilibrium Reversible-Irreversible Coupling (GENERIC) framework (Öttinger 2005).

## 3.2 Field Dislocation Mechanics Theory

Field dislocation mechanics (FDM) is the continuum theory of dislocations developed by Acharya and coworkers (Acharya 2001, 2003, 2004; Roy and Acharya 2005). FDM was formulated with the objective of reconciling conventional plasticity and the elastic theory of continuously distributed dislocations (ECDD) of Willis (1967) and Mura (1987). FDM allows to solve dislocation evolution problems in the fully nonlinear elastoplastic settings. In its early formulation, FDM was intended as a microscopic theory within the finite-deformation kinematics framework, with dislocation density tensors of individual slip systems as primary state variables of the theory. Similar to conventional continuum plasticity, in FDM, the free energy depends only on elastic strains, with no explicit dependence on the dislocation density. Therefore, the theory entails neither higher-order stresses nor a back stress in the expression for average dislocation velocity/plastic strain rate. Subsequent development introduced a new framework named phenomenological mesoscopic field dislocation mechanics (PMFDM) (Acharya and Roy 2006; Roy and Acharya 2006; Acharya 2011), which results from a space-time averaging of the equations of FDM, together with additional phenomenological closure equations. In contrast to FDM, PMFDM is a mesoscale theory, and as such the only microstructural state variable is the average dislocation density tensor field $\boldsymbol{\alpha}$. We shall sketch here a compact summary of PMFDM, limiting our attention to the small deformation case for simplicity.

In broad strokes, the objective of PMFDM simulations is to determine the displacement field $\boldsymbol{u}$ in a certain domain $\Omega$ subject to standard displacement/traction boundary conditions while concurrently evolving the average dislocation density field $\boldsymbol{\alpha}$ subject to dislocation flux boundary conditions. Clearly, the internal stress state is controlled by both the boundary loads and the dislocation density field, and the internal flux of dislocations is driven by the local stress and determines the plastic strain rate.

In PMFDM, a single time step comprises the following three phases:

1. The dislocation density tensor is evolved in time by solving the following IBVP:

$$\begin{cases} \dot{\boldsymbol{\alpha}} = -\text{curl}(\boldsymbol{\alpha} \times \mathbf{v} + \mathbf{L}^{\text{p}}) + \mathbf{s} & \text{in } \Omega \\ \boldsymbol{\alpha}(\mathbf{v} \cdot \mathbf{n}) = \boldsymbol{\phi} & \text{on } \partial_{\text{in}}\Omega \\ \boldsymbol{\alpha}(\mathbf{x}, 0) = \boldsymbol{\alpha}_{\circ}(\mathbf{x}) & \text{in } \Omega, \text{ at } t = 0 \end{cases} \tag{50}$$

Here **v** is the average dislocation velocity, $\mathbf{L}^{\mathrm{p}}$ is the rate of plastic flow carried by the statistically stored dislocations, and **s** is the dislocation nucleation rate. These three quantities are prescribed phenomenologically to provide closure equations to PMFDM. The quantity $\boldsymbol{\phi}$ represents a prescribed flux on the inflow boundary $\partial_{\mathrm{in}}\Omega$, while $\boldsymbol{\alpha}_{\circ}(\boldsymbol{x})$ is the initial condition for the dislocation density. The IBVP (50) is implemented numerically using the so-called Galerkin least-squares (GLS) method. More details on boundary conditions are discussed in Acharya and Roy (2006).

2. Next, two auxiliary fields are determined, namely, the tensor field $\chi$ and the vector field $z$. These two fields are introduced by the *orthogonal decomposition* of the elastic distortion into a compatible part $\nabla(\mathbf{u} - z)$ and an incompatible part $\chi$:

$$\boldsymbol{\beta}^{\mathrm{e}} = \nabla(\mathbf{u} - z) + \chi . \tag{51}$$

The field $\chi$ is determined directly from the dislocation density tensor $\boldsymbol{\alpha}$ by solving the following BVP, say, using least-squares finite element method (LSFEM):

$$\begin{cases} \nabla \times \chi = \boldsymbol{\alpha} & \text{in } \Omega , \\ \nabla \cdot \chi = \mathbf{0} & \text{in } \Omega , \\ \mathbf{n} \cdot \chi = \mathbf{0} & \text{on } \partial\Omega . \end{cases} \tag{52}$$

The vector field $z$ is updated in time using its rate $\dot{z}$, which in turn is found from the solution of the following elliptic BVP:

$$\begin{cases} \nabla \cdot \nabla\dot{z} = \nabla \cdot (\boldsymbol{\alpha} \times \mathbf{v} + \mathbf{L}^{\mathrm{p}}) & \text{in } \Omega \\ \mathbf{n} \cdot \nabla\dot{z} = \mathbf{n} \cdot (\boldsymbol{\alpha} \times \mathbf{v} + \mathbf{L}^{\mathrm{p}}) & \text{on } \partial\Omega \\ \dot{z} = \dot{z}_{\circ} \text{ (arbitrary value)} & \text{at one point in } \Omega. \end{cases} \tag{53}$$

3. Finally, the displacement field is found by a Galerkin FEM implementation of the following BVP:

$$\begin{cases} \nabla \cdot \{ \boldsymbol{C} : [\nabla(\mathbf{u} - z) + \chi] \} = \mathbf{0} & \text{in } \Omega \\ \boldsymbol{\sigma}\mathbf{n} = \mathbf{t} & \text{on } \partial_{\mathbf{t}}\Omega \\ \mathbf{u} = \bar{\mathbf{u}} & \text{on } \partial_{\mathbf{u}}\Omega \end{cases} \tag{54}$$

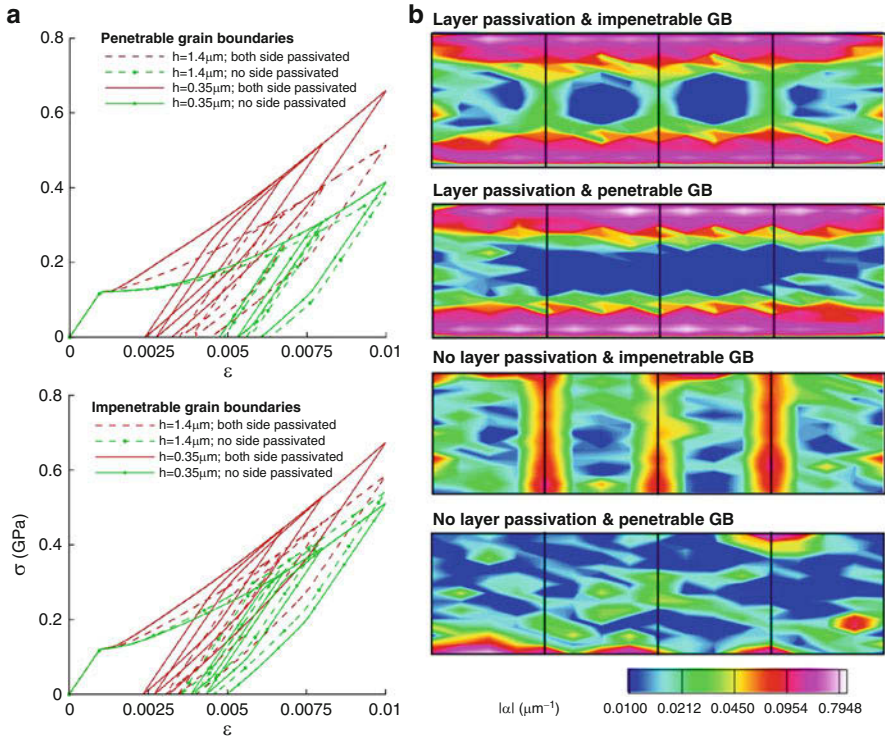
Recent applications of PMFDM include a study of multicrystalline thin films carried out by Puri et al. (2011). In this study, the mechanical response was


**Fig. 1** Thin film with four grains used in the PMFDM simulations of Puri et al. (2011). (**a**) Stress-strain curves for penetrable and impenetrable grain boundaries. (**b**) Norm of $\boldsymbol{\alpha}$ for different combinations of layer passivation and grain boundary penetrability

analyzed as a function of several parameters including the film thickness, presence of a surface passivation layer, and use of different types of dislocation flux jump conditions to mimic penetrable and impenetrable boundaries. The model predicts that the accumulation of polar dislocations along passivated layers results in a relatively (a) stiffer mechanical response, (b) thickness dependence of stress-strain response, and (c) significant Bauschinger effect in passivated films as compared to unpassivated films, as shown in Fig. 1.

Note that in FDM the dislocation density tensor $\boldsymbol{\alpha}$ ultimately controls its own evolution through the phenomenological closure equation (50). Phenomenological closure equations were also adopted by Sethna and coworkers (Limkumnerd and Sethna 2006; Chen et al. 2010), who introduced a minimal continuum dislocation theory where the evolution of plastic distortion is determined by the traceless portion of the dislocation density as $\dot{\beta}_{ij}^{\mathrm{p}} = v_a \rho_{aij} - 1/3 \delta_{ij} v_a \rho_{akk}$, where $\rho_{ijk} = \beta_{ik,j}^{\mathrm{p}} - \beta_{jk,i}^{\mathrm{p}}$ is simply the Nye tensor expressed as a skew-symmetric tensor of rank three and $v_a$ is a phenomenological dislocation velocity depending on $\rho_{aij}$ itself.

## 3.3 3D Higher-Dimensional Theory

Hochrainer and coworkers (Hochrainer et al. 2007; Sandfeld et al. 2010) developed a continuum theory of dislocations designed specifically to overcome the so-called problem of *kinematic closure*, that is, the problem of defining a set of kinematic variables possessing a sufficient amount of information to determine plastic strain rate and their own kinematic evolution. The theory enjoys kinematic closure in a higher-dimensional configuration space defined by both position and orientation coordinates, hence the name higher-dimensional continuum dislocation dynamics (hdCDD). To illustrate the main ideas, let us consider the two-dimensional case of dislocations with the same Burgers vector $\boldsymbol{b}$ moving on a specific glide plane. Let $\rho^{II}(\boldsymbol{x}, \varphi)$ be the density of dislocations which at the point $\boldsymbol{x} = (x_1, x_2)$ on the plane has a line direction forming an angle $\varphi$ with the Burgers vector. hdCDD defines the generalized line direction as the vector field $\boldsymbol{L}(\boldsymbol{x}, \varphi) = [\cos\varphi, \sin\varphi, k(\boldsymbol{x}, \varphi)]^T$ whose last component is the local line curvature $k(\boldsymbol{x}, \varphi)$. The density $\rho^{II}(\boldsymbol{x}, \varphi)$ and the curvature $k(\boldsymbol{x}, \varphi)$ are the two fundamental fields of hdCDD. Based on these two fields, the dislocation density tensor of second-order $\boldsymbol{\alpha}^{II}$ is defined as

$$\boldsymbol{\alpha}^{II}(\boldsymbol{x}, \varphi) = \rho^{II}(\boldsymbol{x}, \varphi)\boldsymbol{L}(\boldsymbol{x}, \varphi) \otimes \boldsymbol{b}. \tag{55}$$

Because dislocations cannot end within the crystal, this quantity must be divergence-free in the configuration space, which implies the condition

$$\cos\varphi\,\partial_{x_1}\rho^{II} + \sin\varphi\,\partial_{x_2}\rho^{II} + \partial_\varphi(\rho^{II}k) = 0. \tag{56}$$

Next, consider the generalized velocity vector

$$\boldsymbol{V}^{II}(\boldsymbol{x}, \varphi) = [v(\boldsymbol{x}, \varphi)\sin\varphi, -v(\boldsymbol{x}, \varphi)\cos\varphi, \vartheta(\boldsymbol{x}, \varphi)]^T. \tag{57}$$

The first two components of $\boldsymbol{V}^{II}$ represent a velocity field $\boldsymbol{v}(\boldsymbol{x}, \varphi) = v(\boldsymbol{x}, \varphi)[\sin\varphi, -\cos\varphi]$ which is orthogonal to the line direction $[\cos\varphi, \sin\varphi]$ in the glide plane, while the last component is the rotational velocity of the dislocation line. With the understanding that the velocity fields $v(\boldsymbol{x}, \varphi)$ and $\vartheta(\boldsymbol{x}, \varphi)$ are assigned by constitutive laws, it can be shown that the exact time evolution law for $\boldsymbol{\alpha}^{II}$ is

$$\dot{\boldsymbol{\alpha}}^{II}(\boldsymbol{x}, \varphi) = -\nabla \times \left[\boldsymbol{V}^{II}(\boldsymbol{x}, \varphi) \times \boldsymbol{\alpha}^{II}(\boldsymbol{x}, \varphi)\right] \tag{58}$$

Translated in terms of evolution equations for the scalar fields $\rho$ and $k$, Eq. (58) reads:

$$\begin{cases} \dot{\rho}^{II} = -\nabla \cdot (\rho^{II}\boldsymbol{v}) + \partial_\varphi\,(\nabla_{\boldsymbol{L}}v) + \rho^{II}vk \\ \dot{k} = -vk^2 - \nabla_{\boldsymbol{L}}\nabla_{\boldsymbol{L}}v + \nabla_V k \end{cases} \tag{59}$$

In Eq. (59) $\nabla\cdot$ indicates the standard spatial divergence, while $\nabla_X$ indicates the projection of the generalized gradient along direction $X$. Note that the coupling between $\rho$ and $k$ implies the necessity to have curvature as an independent field.

Because all its field equations are defined in the higher-dimensional space $(x, \varphi)$, the numerical implementation of hdCDD has proved to be rather prohibitive. For this reason, subsequent development was aimed at deriving simplified theories based on purely spatial field variables (Hochrainer et al. 2009, 2014; Sandfeld et al. 2011; Hochrainer 2015). The field variables of the simplified theories are the coefficients of the Fourier expansion of the dislocation density and curvature density fields of hdCDD. For example, the zeroth- and first-order coefficients in the expansion of $\rho(x, \varphi)$ are the total scalar dislocation density $\rho_t$ and the geometrically necessary dislocation density vector $\kappa(x)$, respectively:

$$\rho_t(x) = \int_0^{2\pi} \rho(x, \varphi)\,\mathrm{d}\varphi \qquad \kappa(x) = \int_0^{2\pi} \rho(x, \varphi) \begin{bmatrix} \cos\varphi \\ \sin\varphi \end{bmatrix} \mathrm{d}\varphi. \qquad (60)$$

From $\kappa(x)$, the classical Nye tensor is simply recovered as $\alpha = \kappa(x) \otimes b$. Moreover, under the assumption that scalar dislocation velocity and curvature fields are independent of orientation, averaging of the hdCDD evolution Eq. (59) over $\varphi$ yields the following evolution laws for $\rho_t$ and $\kappa$:

$$\begin{cases} \dot{\rho}_t = -\nabla \cdot (v\kappa^{\perp}) + v\rho_t \overline{k} \\ \dot{\kappa} = -\nabla \times (\rho_t v n) \end{cases} \qquad (61)$$

Here $n$ is the glide plane normal, $\kappa^{\perp} = \kappa \times n$, and $\overline{k}$ is the average curvature. Unfortunately, an evolution law for $\overline{k}$ cannot be expressed in terms of the fields $\rho_t$ and $\kappa$ alone. In fact, the order of truncation of the Fourier expansion defines a hierarchy of theories where the evolution of lower-order Fourier coefficients depends on the values of higher-order ones. Therefore, in contrast to hdCDD, simplified theories lack intrinsic kinematic closure, and phenomenological closure approximations must be introduced at each order. The simplest theory, called $CDD^{(1)}$, is obtained when a phenomenological evolution equation for the average curvature $\overline{k}$ is used together with Eq. (61). A detailed comparison of possible closure equations is discussed by Monavari et al. (2014). This theory was recently applied to study the formation of dislocation patterns by Sandfeld and Zaiser (2015), who found a relationship between the applied stress and the pattern wavelength which is consistent with the principle of similitude, as shown in Fig. 2. Interestingly, in this two-dimensional model, patterns emerge without the cross-slip mechanism.

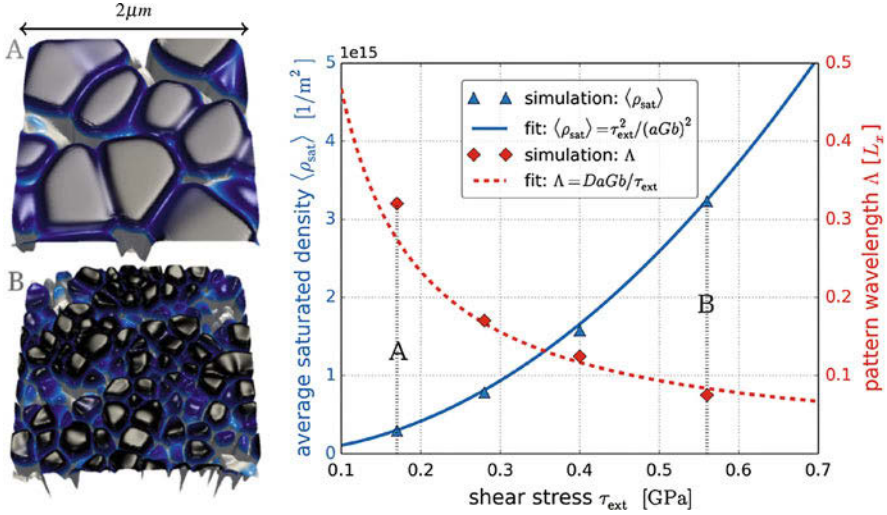
Despite its importance, it should be remarked that kinematics is only one aspect of the closure problem of CDD discussed in Sect. 2.4. Arguably, the most critical aspect of the closure problem concerns the derivation of the velocity fields in terms of the state variables. Although this process can be cast in a thermodynamically consistent formalism (Acharya 2004; Hochrainer 2016), currently the choice of the thermodynamic potentials remains largely phenomenological.


**Fig. 2** Relations between the applied stress $\tau_{ext}$, the patterning length $\Lambda$, and saturated dislocation density $\rho_t$. The evolution of dislocation density patterns in A and B shows a map of the density $\rho_t$ at different levels of $\tau_{ext}$. Plot (**A**) corresponds to a shear stress $\tau_{ext} = 170$ MPa; the plot (**B**) is at $\tau_{ext} = 560$ MPa. (From Sandfeld and Zaiser 2015)

## 3.4    3D Model with a Vector Density Representation

A 3D model of continuum dislocation dynamics was developed by Xia and El-Azab (2015a, b) and Xia et al. (2016). Based on small deformation kinematics, the model considers a vector representation of the dislocation density for the individual slip systems, which are governed by transport-reaction equations derived from the second of Eq. (30) in a few steps: first, that equation is specialized for individual slip systems by adding reaction terms at the level of slip system that cancel one another upon addition and, second, dropping the Burgers vectors from the result. Considering only cross slip as a source terms at slip system level and omitting details, the dislocation transport-reaction equations has the form

$$\dot{\boldsymbol{\rho}}_l = \nabla \times (\mathbf{v}_l \times \boldsymbol{\rho}_l) + \dot{\boldsymbol{\rho}}_{l*\to l}^{cs} - \dot{\boldsymbol{\rho}}_{l\to l*}^{cs} \tag{62}$$

where $\boldsymbol{\rho}_l$ and $\mathbf{v}_l$ are the dislocation density velocity vectors on slip system $l$, respectively, and $\dot{\boldsymbol{\rho}}_{l*\to l}^{cs}$ and $\dot{\boldsymbol{\rho}}_{l\to l*}^{cs}$ are the cross-slip rates from $l*$ to $l$ and from $l$ to $l*$. In the above, $l = 1, \ldots, N$ where $N$ is the total number of slip systems and $l*$ is the cross slip system for system $l$. The above system of equations requires the velocity fields $\mathbf{v}_l$ for all $l$ and the cross-slip rates to be solved. The velocity fields are found in terms of the local Peach-Koehler, $\mathbf{F}_{l,PK}$, via a mobility law

$$\mathbf{v}_l = M\mathbf{F}_{l,PK} = Mb\tau_l\hat{\mathbf{v}}_l \tag{63}$$
**Fig. 3** (**a**) The 5 μm cube used for the simulation at 0.5% strain, with active cross slip. Colors represent the dislocation density and highlight the 3D cell structure. (**b**) Dislocation structure on a (001) slice. (From Xia et al. 2016)

in which $M$ is the dislocation mobility, $\tau_l$ is the resolved shear stress on slip systems $l$, and $\hat{\mathbf{v}}_l = \mathbf{F}_{l,PK}/|\mathbf{F}_{l,PK}|$ is the unit direction of the velocity. The mobility equation is coupled to the crystal mechanics equations via an eigenstrain problem similar to that summarized in Eq. (47) through (49). Namely, the velocity is found from the stress solution, while the stress boundary value problem is solved by updating the eigenstrain from the dislocation motion via Orowan's law. The cross-slip rate is assumed to have the form

$$\dot{\boldsymbol{\rho}}_{l \to l*}^{cs} = \dot{p}_{l \to l*}^{cs} \boldsymbol{\rho}_{l \| \mathbf{b}}, \tag{64}$$

where $\dot{p}_{l \to l*}^{cs}$ is the cross-slip probability rate and $\boldsymbol{\rho}_{l \| \mathbf{b}}$ is the screw dislocation density. It is important to mention here that the cross-slip rate term is localized in the screw direction only. Xia et al. (2016) has obtained cross-slip rates for an fcc crystal from dislocation dynamics simulations and implemented this rate into the coupled dislocation transport/stress solution outlined above. Figure 3 shows the results of a uniaxial tension simulation in a Cu single crystal. It was found that three-dimensional cell patterns the qualitatively resemble those observed by transmission electron microscopy were obtained when cross slip is activated.

## 4   Summary

The basic concepts of the classical theory of dislocation fields were summarized in this chapter. Of particular interest here is the linking of the dislocation content with the incompatibility of the elastic and plastic distortion fields, which is accomplished by the definition of the dislocation density tensor. Such a tensor was defined on a

purely kinematical basis in the work of Kröner (1981) and de Wit (1970, 1973). Mura (1987) and Kosevich (1979) on the other hand tried to link that tensor to actual crystal dislocations by defining the plastic stain rates in terms of dislocation motion. However, that connection was left incomplete in the classical theory, and as such the theory did not materialize into a framework for predicting plasticity of crystals. Realizing the lack of ability to predict plasticity, and motivated by the method of dislocation dynamics simulation (Kubin 2013; Bulatov and Cai 2006), where the dislocation motion is connected with the internal stress, several authors started to develop predictive continuum dislocation approaches that overcome this shortcoming. The field dislocation mechanics (Acharya 2001, 2003, 2004) is one such approach in which the definition of the dislocation density is linked to the incompatibility equation much as in the classical theory. For other models the need was realized to separate dislocations based on their slip systems and a more detailed description of the transport of dislocations has been used accordingly as in the 2D statistical theory, 3D higher-dimensional theory, and the 3D model with vector representation of the dislocation density. All such approaches are under active development at present time. This development is focused upon three aspects: improving the representation of dislocation mechanisms such as cross slip, junction formation, and annihilation reactions into the transport equations, accounting for long-range stress fluctuations and dislocation-dislocation correlations, and improving the numerical coupling of the transport description of dislocations with crystal mechanics.

### Abstract

Metallic materials have a hierarchy of structures ranging in scale from nm to mm. We generalize the notion of crystalline plasticity models to include a range of model constructs that address phenomena associated with evolution of dislocations in crystals across a range of length and timescales. These model constructs range from coarse-grained atomistics, microscopic phase field models, and dislocation field models, to discrete dislocation dynamics, statistical continuum dislocation models, and on up to mesoscale generalized continuum models of gradient, micropolar, or micromorphic type, as well as local continuum crystal plasticity that can be applied over many grains. Key phenomena are introduced and mapped onto the capabilities of various scale-specific model

constructs for dislocation plasticity. We discuss concurrent and hierarchical multiscale model transitions in space and time and summarize key challenges in closing.

# 1 Introduction: Material Structure Hierarchy and Associated Models

Metal plasticity is fundamentally associated with processes of nucleation, generation, migration, interaction, trapping, and annihilation of dislocations in crystals and polycrystals (McDowell 2008, 2010). Hierarchy of material structure is prevalent in engineering alloys. Figure 1 depicts five levels of structure hierarchy, ranging from the discrete atomic structure of lattices and interfaces (atomistics), to migration and interaction of dislocation line segments (discrete dislocations), to collective pattern formation of dislocations (substructure), to heterogeneous plastic flow within sets of grains/phases (polycrystal plasticity), and finally up to the scale of engineering applications where underlying structure is "smeared" by considering a macroscopic set of properties or responses. The minimum length scale typical of each of these levels is also shown in Fig. 1 and ranges from interatomic spacing to mean free path

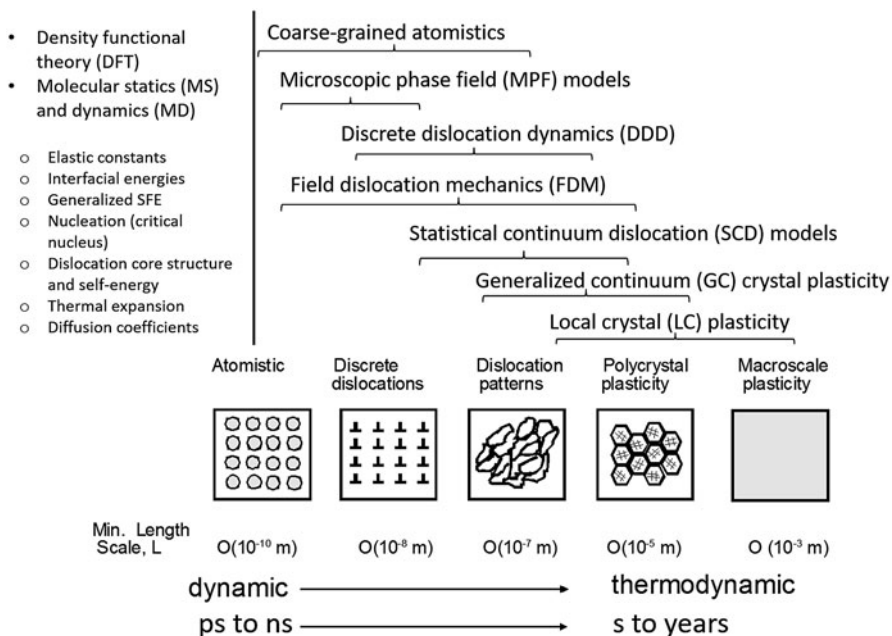

**Fig. 1** Hierarchy of length scales in metal plasticity ranging from atomic (resolution of dislocation cores), to configurations of dislocations, patterning at the mesoscale, and up to multiple grains/phases at the scale of structural applications. Various classes of crystalline plasticity model constructs appear along the top, superimposed on range of associated material structure hierarchy. Certain properties/responses computed using DFT or atomistics shown at far upper left can upscale directly to inform higher length scale models at right

for dislocations, to grain size, and on up to characteristic dimensions of components or structures. Of course, the associated issue of relative timescales of interest for processes at each level of structure hierarchy is implicit in the dynamic to thermodynamic transition indicated from left to right in Fig. 1, ranging from fs to years.

Models of dislocation plasticity are necessary to characterize properties/responses of interest over a wide range of length scales. Goals of this range of model constructs may differ according to the scales addressed. Model constructs addressing phenomena corresponding to scales to the right in Fig. 1 are typically of substantially reduced order and reflect cooperative thermodynamics and kinetics of dislocated crystals. On the other hand, discrete models that apply to scales at the left in Fig. 1 are either fully dynamical or employ some kind of overdamped dynamical scheme, tracking locations of individual defects. Degrees-of-freedom (DOF) necessary to characterize the structure of a fixed volume of material decrease from left to right in Fig. 1. Certain continuum theories are exceptions that bridge to small length scales but potentially retain access to longer timescales relevant to thermally activated dislocation interactions and migration. Examples include microscopic phase field (MPF) models and field dislocation mechanics (FDM) descriptions. FDM descriptions often share common elements with statistical continuum dislocation (SCD) models, namely, incompatibility mechanics based on the net dislocation density tensor, differing mainly in the manner in which distributions of dislocations are tracked. Only atomistic and coarse-grained atomistic approaches commonly address dislocations as naturally emergent line defects in the lattice. With the exception of atomistics (MS or MD), coarse-grained atomistics, or the application of MPF or FDM models with near atomic resolution, all other models introduce primitive representations of dislocations.

## 2 Hierarchical and Concurrent Multiscale Modeling of Dislocations

*For the present purposes, we define multiscale modeling as the practice of building and exercising models for a set of physical processes that operate over a range of length and/or time scales, regardless of the form of linkage between models expressed at various levels of fidelity or resolution.* We may distinguish between coarse-graining and model reduction approaches to multiscale/multiresolution modeling. Here we adopt the most common definition in the discrete particle/molecular modeling communities: coarse-graining reduces the number of model degrees of freedom via simplifications that retain the underlying nature of the original description but average over space and/or time. For example, a model might replace a large number of atoms in a molecular system using a simplified representation while retaining information related to bonding. On the other hand, model reduction (sometimes referred to as model order reduction) seeks to reduce model complexity/fidelity by reducing the model's associated state space dimension or degrees of freedom, offering an approximation to the original model. The key difference is that model form often changes in model reduction, whereas model

form is essentially invariant in coarse-graining. Suffice it to say that most models presented in Fig. 1 involve model reduction rather than coarse-graining; this greatly complicates pursuit of concurrent multiscale modeling approaches, discussed later in this section.

Fully concurrent models seek to simultaneously pursue solutions of models framed at different spatial resolution and corresponding model fidelity (Ghosh et al. 2001, 2007; Kouznetsova et al. 2004). The simulations carried out at different scales are coupled and interact in two-way fashion. They are by nature temporally synchronized, in that the time/strain step is limited by the most demanding resolution of any domain, typically that of highest fidelity and/or resolution. Concurrent models have at least two further classifications: (i) domain decomposition and (ii) multiresolution and/or multifidelity models exercised within or over the same spatial domain. In domain decomposition, a coarse-grained or reduced order model representation is employed over part of a spatial domain, with an abutting high fidelity representation over the remainder. For example, we may require high resolution and fidelity near an interface or a crack tip, with low fidelity and/or resolution elsewhere. For purposes of modeling dislocations, we will consider that fully concurrent models require exchange/transport of dislocations between the two domains; weaker forms of concurrency might consider dislocation migration in only one domain.

Hierarchical multiscale models are of one-way character, typically informing parameters of models at the next successive length scale of modeling within the hierarchy shown in Fig. 1. As shown to far left in Fig. 1, there are some exceptions. Certain properties computed using DFT or atomistics can upscale hierarchically to inform models at various length scales, even up the to the grain scale. Examples include elastic lattice constants, interface energy, generalized stacking fault energy (SFE), and effects of the dislocation core structure and constriction on stress-state dependent yielding.

## 3    Challenges of Dislocation Field Problems: Length and Timescale Transitions

Dislocation field problems in mechanics are particularly demanding for multiscale models, owing to the complexity of the physics (e.g., dislocation core effects, long range dislocation interactions, and short range shielding interactions). Progress has been slow and elusive on concurrent models in this regard, and no satisfactory concurrent multiscale models exist that bridge length scales from dislocation cores (order of nm) to dislocation substructures (hundreds of nm) to typical laboratory specimens ($\mu$m to mm).

There are also substantial challenges in timescaling. Short range lattice relaxation occurs on the order of tens of ps in a MD simulation. Approaches have been introduced to improve time scaling of both direct type (Kim et al. 2014; Binder et al. 2015) or statistical coarse-graining of short range interactions in cross slip of dislocations (cf. Deng and El-Azab 2010). At low applied stress levels, thermally activated bypass of larger obstacles or a field of obstacles with high

activation volume (much larger than scales of atomistic unit processes) requires coordinated thermal fluctuations having low probability of successful attempts. Activation entropy associated with dislocation nucleation and bypass phenomena has been largely neglected. Some works (Nguyen et al. 2011; Ryu et al. 2011; Saroukhani et al. 2016) have considered the limitations of harmonic transition state theory (HTST), since it does not represent anharmonic entropic effects at finite temperature, including temperature-dependence of the elastic shear modulus (thermal softening), thermal expansion, and other surface energies (e.g., stacking fault energy) that relate to dislocation nucleation and bypass.

## 4   Status of Models at Various Levels of Hierarchy

### 4.1   Concurrent Multiscale Modeling Methods from Atomistic to Continuum (QC, CADD, and CAC)

Large scale direct MD simulations of dislocations are highly intensive (e.g., 500 million atom simulations of a slab of Cu by Buehler et al. 2005) and are limited to short times and high strain rates. Historically, concurrent schemes for bridging atomistic and continuum methods in problems involving dislocation activity have employed spatial domain decomposition; fully resolved atomistic models (far left in Fig. 1) are desired in a subdomain near a crack tip or a grain boundary interface, for example, and coarse-grained or reduced order descriptions are used elsewhere. A number of these methods have been compared by Tadmor and Miller (2011).

We focus here on methods that admit moving dislocations in both fully resolved and coarse-grained or continuum regions, as well as two-way exchange of dislocations between the two regions. Clearly, the value of methods that bridge from atomistic to continuum descriptions is their strong predictive character (limited by the uncertainty in the interatomic potential and scale linking algorithms) compared to mesoscale strategies. One of the most widely cited atomistic-continuum multiscaling approaches is the Quasicontinuum (QC) method (Tadmor et al. 1996a, b; Shenoy et al. 1998, 1999; Miller et al. 1998a, b; Knap and Ortiz 2001; Tadmor and Miller 2011). QC accomplishes atomistic coarse-graining by linking lattice site positions to a reduced set of representative atoms, introducing summation rules that allow reduction of cost of ensemble sampling for force or energy, and schemes for adaptation that facilitate fully resolved atomistic simulation in regions of high local deformation (e.g., interfaces, crack tips, dislocations) but coarse-grain away from these evolving regions to minimize the degrees of freedom. In its earliest and perhaps most commonly used form, termed "local" QC, the coarse-grained continuum region makes use of a Cauchy-Born assumption of an affine deformation within each region of interpolation between representative atoms that define elements. Accordingly, it offers a precise description of the underlying interatomic hyperelastic potential even in continuum regions, subject to coarse-graining error for inhomogeneous deformation. QC requires either a priori assignment of fully atomistic and coarse-grained regions for dislocation migration

or adaptation/reassignment of associated atoms and nodes to reach a fully atomistic description near dislocations (Shenoy et al. 1999) or interfaces.

Most applications in modeling dislocations have employed quasi-static QC methods based on energy minimization. A fully nonlocal or cluster QC version was developed (Knap and Ortiz 2001) to minimize ghost forces in coarse-graining, with extensions to energy-based rather than force-based cluster sampling schemes (Eidel and Stukowski 2009. Kwon et al. (2009) have introduced higher order adaptive QC schemes to improve description of large scale inhomogeneous deformation as might occur in coarse-grained regions away from dislocations. QC has been applied to quantify lattice dislocation interactions with grain boundaries (Shimokawa et al. 2007; Yu and Wang 2012, 2014). Recent advances have sought to increase efficiency while handling arbitrary fields of dislocations (Amelang et al. 2013, 2015), as well as development of a fully nonlocal, energy-based QC method by Amelang et al. (2015). This approach has been extended recently to consider automatically adaptive modeling of fully nonlocal QC to model dislocations moving through a lattice (Tembhekar et al. 2017). A meshless QC method based on local maximum-entropy interpolation has been developed (Kochmann and Venturini 2014) that improves efficiency of model adaptation near regions of fully atomistic resolution to capture dislocations.

The Coupled Atomistic Discrete Dislocation (CADD) method introduced originally by Shilkrot et al. (2002a, b, 2004) with subsequent advances and applications (Shiari et al. 2005; Dewald and Curtin 2007a, b, 2011) employs domain decomposition with a continuum discrete dislocation representation away from the grain boundary, admitting two-way exchange of dislocations between this remote region and a fully atomistically resolved domain near the grain boundary. This kind of formulation is quite useful in studies of crack tip and interface plasticity that extends the fields to long range. It is considered fully concurrent in that dislocations can move from the atomistic to continuum regions and vice versa. With a focus on capturing the interaction stress fields of dislocations at long range, Dewald and Curtin (2007a, b) employed CADD to analyze dislocation pile-up interactions with grain boundaries.

Unlike QC, CADD uses a different elastic energy function in the remote regions – these regions are subjected to reduced order continuum models rather than atomistic coarse-graining. Accordingly, in addition to model reduction error, interpretation of temperature differs in the two regions and there is impedance to wave propagation at the atomistic-continuum interface. Impedance effects can be minimized by employing damping heuristics (Qu et al. 2005) but are inevitable in the absence of statistical coarse-graining. Initial implementations of CADD have focused on 2D problems by virtue of complexities in addressing dislocation transfer across interfaces. Progress has been achieved on passing general 3D mixed character dislocations between atomistic and continuum regions (Cho et al. 2015); Pavia and Curtin (2015) have advanced parallel algorithms for 3D CADD that enhance scalability at high accuracy for appropriate problems with long range fields, including Langevin graded stadium damping to eliminate spurious wave reflections and interface forces.

The concurrent atomistic-continuum (CAC) method was developed as an outgrowth of atomistic field theory (Chen 2009), with a local density function used to connect this continuum theory to atomistics via multiscale balance equations. The CAC method is a 3D integral finite element approach to solve the governing field equations for coarse-grained atomistics that admits description of dislocation nucleation and migration with or without adaptive coarse-graining (Xiong et al. 2011, 2012a, b, 2015). Dislocations can be modeled throughout the entire domain, whether at full atomistic resolution or coarse-grained. This sets it apart from methods that require full atomistic resolution at the dislocation core. While QC typically seeks the most accurate and efficient solution to dislocation plasticity via adaptive remeshing of the domain near dislocations to full atomistic resolution, CAC can resolve full atomistics if necessary near interfaces or crack tips, but allows dislocations to nucleate, multiply, migrate, and interact even in the coarse-grained regions along interfaces between elements, introducing the option to coarse-grain dislocation fields over larger scales. Like QC, CAC employs the same interatomic potential even in coarse-grained regions where dislocations evolve and interact. Such coarse-graining in CAC introduces systematic error, for example, in representation of dislocation core structures and short range interactions, which can be quantified and balanced with the high computational demands of remeshing, according to the purposes of the mesoscale modeling.

CAC employs either a quasi-static implementation enforcing quenched dynamics at each time step with periodic energy minimization applied every 50–100 time steps (Xu et al. 2015, 2016), or a true dynamic (full inertial effects that can address phonon interactions with wavelengths above the element size, cf. Xiong et al. 2014a, b, 2015, Pluchino et al. 2016) implementation, based on an extension of the lattice statistical mechanics approaches of Irving and Kirkwood (Kirkwood 1946; Irving and Kirkwood 1950). The quasi-static implementation is considered useful for modeling reaction pathways for thermally activated dislocation processes in a manner that is not overdriven, as typical of MD simulations. Finite temperature applications to date have assumed isothermal conditions or dynamic behavior without a thermostat. Finite temperature formulations for quasi-static (near equilibrium) and nonequilibrium dynamic conditions or heat transport via modes other than phonons remain to be fully developed (cf. QC advances by Marian et al. 2010).

Similar to CADD and static QC, the quasi-static version of CAC is useful for modeling phenomena such as detailed reactions of successive pile-up dislocations with interfaces, with the additional advantage of accessing large volumes that approach scales of TEM thin foils and nonperiodic boundary conditions (e.g., traction free surfaces), cf. Xu et al. 2017.

## 4.2  Microscopic Phase Field (MPF) Models

Continuum microscopic phase field (MPF) models (Wang et al. 2001; Shen and Wang 2003; Wang and Li 2010; Shen et al. 2014) hold significant promise to bridge from first principles and atomistic modeling to describe partial dislocations and deal

with time dependent deformation phenomena in continuum theory in a way that is not limited to the time step size of atomistic simulations. MPF models can be regarded as an application of phase field theory at or near atomic scale of refinement, including diffuse interface theory and gradient terms specific to that scale. MPF has spatial resolution at the core scale, similar to the Peierls model (Peierls 1940), and admits conveyance of information regarding core size, energy and interactions (Chen et al. 2014). Therefore, MPF is framed at a length scale that can resolve individual dislocation cores (i.e., dissociated partial dislocations) via the generalized stacking fault energy function, representing dislocations using eigenstrain methods. It can address limited numbers of dislocations with near atomic scale fidelity. It can directly employ inputs from ab initio and atomistic modeling regarding physical properties, surface energies, and elastic constants, and has the ability to predict fundamental properties of individual defects or small sets of defects, including formation energy, size, structure, saddle point configuration of the reaction pathway, and activation energy of defect nuclei, and the micromechanisms involved (Wang and Li 2010).

When used in conjunction with transition state theory or other appropriate long time kinetics, including diffusive phenomena, continuum phase field theory offers the potential to bridge to long time scales. This is quite useful in predictive computational materials science to support design of interfaces, microstructures, etc. MPF serves to bridge from atomistic modeling of generalized stacking fault energy to describe partial dislocations in a higher scale continuum theory (Wang and Li 2010).

## 4.3 Field Dislocation Mechanics (FDM)

Field dislocation mechanics applies to a theoretical continuum framework that incorporates incompatibility of elastic and plastic deformation as an explicit part of the field equations. Focus is placed on the incompatible part of the plastic distortion that establishes the excess dislocation density tensors. Accordingly, it offers a continuum coarse-graining methodology for incompatibility mechanics by changing the characteristic size of the Burgers circuit (e.g., integration point area through which dislocations cut). The theoretical construct of FDM was formalized by Acharya and co-workers over a decade ago (Acharya 2001, 2003; Acharya et al. 2006, 2008; Roy and Acharya 2006; Roy et al. 2007), providing common ground for treating incompatibilities with higher scale theories such as SCD and GC. Hence, FDM serves as a theoretical construct to consider the effect of size of Burgers circuit on response. Typically based on small strain/distortion assumptions to facilitate solution strategies, this class of theory explicitly incorporates lattice closure relations on incompatibility expressed either in terms of a single dislocation (e.g., approaching atomic scale, cf. Zhang 2015; Hartley and Mishin 2005; Mendis et al. 2006), or in terms of the Nye tensor (Nye 1953) evaluated over a finite Burgers circuit for a large number of dislocations (analogous to second gradient plasticity).

## 4.4    Discrete Dislocation Dynamics (DDD) Models

Discrete dislocation dynamics (DDD) implementations employ continuum linear elasticity solutions for dislocations to compute long range, nonlocal elastic interactions, representing the positions and velocities of all dislocations by discretizing the dislocation lines into a piecewise series of curves or segments (Lepinoux and Kubin 1987; Gulluoglu et al. 1989; Amodeo and Ghoniem 1988, 1990; Ghoniem 2005). DDD methods typically assume a simple form of dislocation force-velocity relationship (mobility) for screw and edge components of dislocations and do not explicitly distinguish partial dislocations. The influence of nonlinear dislocation core effects (which are outside the singular theory of linear elasticity) on short range dislocation interactions has been effectively addressed by non-singular formulations of DDD (Cai et al. 2006) that can replicate the influence of core spreading and attenuation of interaction energies. These approaches can be hierarchically informed using atomistic simulations (Martınez et al. 2008; Groh et al. 2009; Rudd et al. 2014).

The DDD method has received significant investment and is maturing as a tool for discrete dislocation simulations (e.g., ParaDiS code, Arsenlis et al. 2007, Tang et al. 2011; and the microMegas code, Devincre et al. 2011), including massive parallelization (Wang et al. 2006), fast multipole methods to address long range stress field interactions of segments, along with mesh adaptivity to segment the evolving dislocation lines, and employment of maximum power dissipation to assess dislocation junction node dissociation. Sills et al. (2016) have introduced advanced time integration algorithms for DDD simulations. More efficient FFT formulations of DDD have recently been advanced that offer improved efficiency and scalabilty (cf. Bertin et al. 2015). While DDD has been extensively applied to the problem of dislocation pattern formation and workhardening in single crystals under periodic boundary conditions, recent applications have considered the complexity of cyclic loading (Hussein and El-Awady 2016) for up to 80 cycles, including the role of dislocation cell walls.

DDD modeling approaches for finite size specimens have been advanced to consider size effects, influence of free surfaces and image forces, intermittent/jerky flow behavior, and source limitation/starvation phenomena at submicron to micron scale specimens (Van der Giessen and Needleman 1995; Guruprasad and Benzerga 2008; Akarapu et al. 2010). Recent advances have considered highly parallel finite element or boundary element method implementations for arbitrary finite geometries (Crone et al. 2014) and for considering elastically anisotropic crystals (Liu et al. 2016), including associated fast multipole expansions for long range interactions (Yin et al. 2012). DDD has proven extremely useful as a means to model dislocation plasticity in confined geometries such as constrained thin films, multilayers, micropillars, and nanoindentation to provide key physical insights into scale dependent dislocation phenomena and interactions with surfaces and interfaces (cf. Zbib et al. 2011) including cases where kinetics dominates elastic interactions (Ryu et al. 2013).

As a reduced order model, DDD shares certain challenges with other continuum formulations, including construction of high angle grain boundaries and treatment of dislocation slip transfer reactions with interfaces. Representation of solute distribution, associated dislocation core interactions, and drag effects, as in dynamic strain aging, is challenging with DDD and may require two-way multiscale concurrency in cases where timescales of atomic level processes cannot be separated from scales of dislocation migration. Dislocation interactions with point defects (Cai et al. 2014) or interactions with diffusive vacancies at large strain or under cyclic loading at finite temperature require extension of the framework that may vary according to modeler preference and are in early stages of development, whether involving DDD or atomistic methods that separate timescales to inform DDD (e.g., Keralavarma and Benzerga 2015; Baker and Curtin 2016; Matveev et al. 2016).

Certain thermally activated unit processes such as dislocation cross slip have been incorporated heuristically in DDD (cf. Groh and Zbib 2009; Groh et al. 2009; Deng and El-Azab 2010; Kang et al. 2014; Xia and El-Azab 2015; Xia et al. 2016; Hussein and El-Awady 2016). However, just as in coarse-grained atomistics, the ability to model coordinated thermally activated processes involving substantial activation volume (e.g., >1000 b$^3$) is limited.

In terms of two-scale transitions to the continuum crystal plasticity level, the kinematics of DDD are logically addressed by concurrent schemes advanced by Zbib and coworkers (Zbib and Diaz de la Rubia 2002; Zbib et al. 2002; 2011), including coupling with FE methods for addressing finite geometries and consideration of free surfaces (Khraishi and Zbib 2002). DDD has been used to hierarchically inform GC or LC crystal plasticity formulations (cf. Zbib et al. 1998, 2002; Zbib and Diaz de la Rubia 2002; Wallin et al. 2008, Groh et al. 2009). Accounting for continuum lattice rotation in DDD is nontrivial and of multiscale character, requiring an assignment of a volume element for this purpose in multiscale strategies (Zbib and Diaz de la Rubia 2002; Zbib et al. 2002. DDD has also been applied to initial-boundary value problems on finite domains using implementations that couple with the finite element method to model responses of structures and devices (Yasin et al. 2001; Zbib et al. 2011). Groh and Zbib (2009) provide an overview of hierarchical versus concurrent coupling methods between DDD and continuum crystal plasticity.

## 4.5    Statistical Continuum Dislocation (SCD) Models

Statistical continuum dislocation models are a class of reduced order continuum descriptions in the spirit of DDD that formulate the governing equations in a manner that pertains to a statistical population/distribution of dislocations (cf. Groma 1997, 2010; Groma et al. 2003; Arsenlis and Parks 1999, 2002; El-Azab 2000, 2006; Zaiser 2001; LeSar and Rickman 2004; El-Azab et al. 2007; Hochrainer et al. 2007, 2014; Hochrainer 2015; Deng and El-Azab 2010; Ispanovity et al. 2010; Sandfeld et al. 2011; Xia and El-Azab 2015; Kapetanou et al. 2015; Groma et al. 2015, 2016; Xia et al. 2016; Monavari et al. 2016). These models employ averaging

procedures based on the statistical mechanics of interacting many-body systems, recognizing that the Nye tensor employed in FDM and numerous GC theories typically offer a description of only geometrically necessary dislocation (GND) density in an averaged sense over all the line directions in a volume element (or Burgers circuit) and not the overall dislocation population and are therefore limited in nature. Statistical descriptions of dislocation densities and fluxes are nontrivial, as pointed out by Sandfeld et al. (2011). Limitations naturally arise associated with averaging assumptions that are made. The description of dislocations goes beyond that of the classical dislocation density tensor (e.g., El-Azab 2000; Hochrainer et al. 2007) to provide more statistical information. In some cases, the total dislocation density is also tracked (i.e., statistically stored content as well as GND density) to convey more information. In its 3D implementation (cf. Xia and El-Azab 2015), distributions of the dislocation segments of edge and screw character are each tracked at each integration point, along with mobility-dependent migration with wait times at barriers. Appropriate boundary conditions are necessary as in DDD for finite domains and free surfaces.

SCD models ostensibly bridge between DDD and GC models in appearance but have strong connectivity to the governing equations of FDM, also considering statistical moments of dislocation ensembles and their interactions. Like FDM, SCD can resolve to the nanoscale, and like GC it can bridge upward to express incompatibility mechanics at scales of hundreds of nm. A principal advantage of SCD is its potential to shed light on scaling relations for dislocation substructure formation and to explore sensitivity of these relations to various physical parameters and mechanisms. Xia and El-Azab (2015) predicted arrangements of dislocations into cell structures by treating plastic deformation as an eigenstrain field, solving an incremental elastic boundary value problem for slip system driving forces and transport of dislocation densities, similar in nature to FDM models. Cross slip has been admitted at the unit process level of junction bypass (Xia and El-Azab 2015; Xia et al. 2016) and was found to play a key role in describing formation of dislocation cell structures, as was also found using DDD by Hussein and El-Awady (2016).

## 4.6    Generalized Continua (GC) Crystal Plasticity Models

Generalized continua (GC) crystal plasticity models introduce dependence on specific dislocation configurations necessary to accommodate compatible imposed strain, as reflected through scale-dependent incompatibility of the elastic and plastic deformation gradients. GC models for dislocation plasticity are necessarily of reduced order compared to the preceding frameworks. They augment strengthening due to overall dislocation density with dislocation configuration dependent strengthening expressed by dependence on the GND density, invoking a range of model assumptions in this regard. Advanced GC theories for dislocations in a lattice typically associate higher order stress quantities that conjugate with evolution of generalized kinematical variables to contribute to dissipation. They are intended to

apply to length scales well above the average spacing of dislocations and to initial-boundary value problems with scales that are typically on the order of 500 nm and above. Because they are reduced order continuum formulations and typically require introduction of normalizing characteristic length scale(s), most GC models do not offer predictive character in the same sense as DDD, FDM, and SCD models, requiring more model assumptions, phenomenology, increased number of parameters, and influence of associated calibration schemes. Still, they have value since they are highly amenable to efficient finite element implementation and can span upwards through modeling at the length scale of polycrystals. GC models are extensions of classical local crystal (LC) plasticity models that include various nonlocal approximations to incorporate effects of size and dislocation configuration. Due to space limitations and extensive coverage elsewhere, LC models (cf. Asaro 1983) are not discussed here.

GC crystal plasticity models of strain or slip gradient (Busso et al. 2000; Gurtin 2002; Evers et al. 2004; Cheong et al. 2005; Bayley et al. 2006; Gurtin and Anand 2007; Abu Al-Rub et al. 2007; Viatkina et al. 2007; Gerken and Dawson 2008; Dunne et al. 2012), micropolar (Forest et al. 2000; Forest and Sievert 2003; Mayeur and McDowell 2011, 2013, 2014, 2015) and micromorphic (Aslan et al. 2011; Cordero et al. 2010, 2013) types have advanced substantially over the past 15 years, to the point where they are viable and efficient reduced order alternatives to DDD or SCD for modeling mechanical response of domains with scales on the order of $\mu$m to tens or hundreds of $\mu$m, including polycrystals. These models employ the phenomenological notion of so-called "characteristic length scale" parameters that normalize gradient or nonlocal terms to capture size effects. These length scale parameters do not represent physical characteristic lengths but depend to varying degree on the initial conditions, boundary conditions, and level of inelastic deformation (Voyiadjis and Abu Al-Rub 2005).

Second gradient (plastic strain gradient or slip gradient) crystal plasticity models regularize the influence of strain gradients on the material workhardening behavior (Busso et al. 2000; Gurtin 2002; Evers et al. 2004; Cheong et al. 2005; Bayley et al. 2006; Gurtin and Anand 2007; Abu Al-Rub et al. 2007; Viatkina et al. 2007; Gerken and Dawson 2008; Dunne et al. 2012). Back stress arises naturally in such models as a manifestation of GND gradients and manifest specimen size and boundary effects. As a further extension, Hurtado and Ortiz (2013) have offered a novel GC crystal plasticity framework that includes both energy created by surface steps and self-energy of dislocations based on slip gradients (GNDs) that is able to capture the significant influence of free surfaces on the stress-strain behavior of micropillars in compression.

Recent developments have cast GC crystal plasticity models into forms that express sensitivity to multiphase microstructures and complex dislocation mechanisms (cf. Keshavarz and Ghosh 2013; Ghosh et al. 2016a, b; Shahba and Ghosh 2016), along with sophisticated mechanistic evolution equations at the slip system level and associated calibration schemes. It is very difficult to incorporate comparable levels of key dislocation mechanisms and material structure hierarchy in the other model constructs shown in Fig. 1 for complex alloy systems. For example,

Keshavarz and Ghosh (2015) proposed a hierarchical GC crystal plasticity for Ni-base superalloys. Ghosh et al. (2016b) introduced a parametrically homogenized GC crystal plasticity model for γ-γ′ Ni-base superalloys that addresses transitions across three scales: subgrain precipitates and dislocation-precipitate interactions, grain level response, and collective polycrystal behavior with realistic 3D microstructures.

The extension of GC crystal plasticity to model submicron scale processes involving dislocation substructure and slip transfer at grain boundaries is still in early stages (Bieler et al. 2009). Microstructure-sensitive GC models that incorporate evolving dislocation density at the slip system level as internal variables (cf. Raabe et al. 2001; Ma et al. 2006; Roters et al. 2010; Dunne et al. 2012; Keshavarz and Ghosh 2013; Mayeur and McDowell 2013, 2014, 2015; Shahba and Ghosh 2016) offer enhanced correlative capabilities for complex loading conditions in many cases at the scale of individual grains. Still, the experimentally observed number of activated slip systems at the subgrain scale is typically limited compared to simulations using most mesoscopic crystal plasticity models of GC and LC type (Lloyd 2010; Buchheit et al. 2005); this is an issue that requires increased focus on slip system hardening relations and more intimate connection to in situ experimental data such as EBSD and digital image correlation measurements of surface deformation.

## 5   Summary and Challenges

Some of the more challenging and longstanding mesoscale gaps for the hierarchy of crystalline plasticity models listed in Fig. 1 include:

- Distinguishing dislocation nucleation and growth processes.
- Initial conditions and evolving structure of interfaces.
- Slip transfer at interfaces, including interface evolution and damage.
- Quantifying coarse-graining and model reduction errors.
- Uncertainty quantification of individual models, domain decomposition, and various two-scale transitions.
- Modeling dislocations in multicomponent material systems (cf. Rao et al. 2017), including appropriate interatomic potentials for atomistic methods that include uncertainty quantification.
- Improving fidelity and accuracy of simulation of local states of slip system activation and degree of slip within individual grains to support material fatigue, fracture, and ductility assessments.
- Coupling dislocation structure and behavior with point defect interactions, including climb, strain aging, and hydrogen, interstitial, and vacancy interactions.
- Timescaling across a spectrum of thermally activated processes involving a range of activation volumes.

    In spite of significant limitations in timescaling and incorporation of finite temperature effects, atomistic coarse-graining methods have more predictive

character than other scale transition schemes to support understanding and design of new material systems and microstructures affected by dislocation phenomena. DDD and SCD models hold great promise to predict scale-dependent dislocation strengthening, but at present are subject to greater uncertainty in addressing realistic dislocation microstructure effects such as grain or phase boundaries, crystal anisotropy, etc. at substantial strain levels. Higher length scale models (e.g., GC or LC) and associated scale transition schemes are appropriate more for systems having rather well-established understanding of dislocation mechanisms. The concern for GC and LC crystal plasticity models is their lack of predictive support for discovery and design of new alloy systems that do not have an established knowledge base. To some extent, DDD also relies on the prior knowledge base for materials (witness the large number of applications to pure metals in the literature), as well as uncertain information from atomistic models to inform parameters and algorithmic choices.

# Developing Virtual Microstructures and Statistically Equivalent Representative Volume Elements for Polycrystalline Materials

**76**

Somnath Ghosh and Michael A. Groeber

## Contents

**Abstract**

This chapter introduces computational methods for generating virtual material microstructures of engineering materials with heterogeneities. Microstructures of polycrystalline materials containing localized features such as annealing

twins, particulates or precipitates, and subgrain phases are the focus of this discussion. The methods use data from characterization methods to provide 3D statistical distribution and correlation functions that serve as inputs to the virtual microstructure generation process. Computational methods infer 3D statistical descriptors from 2D surface data and use stereology or other optimization-based projection techniques for 2D to 3D development. The chapter reviews the DREAM.3D software package and discusses newly developed methods to incorporate twins, particles, and subgrain-scale phases. Finally, the microstructure-based SERVE is introduced in the realm of establishing microstructure-property relations.

# 1    Introduction

The recent years have seen an increasing trend in the use of microstructure-based mechanistic models for predicting material deformation and extreme behavior like fracture and fatigue response. A primal need in the development of image-based micromechanical models is the creation of representative 3D virtual models of the microstructures. An obvious path is by direct image reconstruction from 3D experimental data on sample volumes of the microstructure. Such experimental data may be extracted from electron backscatter diffraction (EBSD) or scanning electron microscopy (SEM) images of serial-sectioning samples (Groeber et al. 2006) or from various computed tomography techniques (Turner et al. 2017). Deterministic models of the microstructure, representing the exact data from experiments (Bhandari et al. 2007), however, are not necessarily best suited for micromechanical simulations, since the microstructure itself may have significant spatial variations.

A less direct but effective approach is to represent structure through the use of tools that generate statistical distribution functions equivalent to desired sets obtained from experimental observations. These "statistically equivalent" virtual microstructures must capture the statistics of characteristic variables, such as grain shape and size, crystallographic orientations, and misorientations and their correlations (Groeber et al. 2008a, b). The approach generally entails quantification of experimental data followed by microstructure generation that statistically match material measurements to a predetermined degree of accuracy. It is capable of limiting the need for abundant data collection, as well as supplementing information when direct 3D data is unavailable. Furthermore it enables the incorporation of microstructural statistics in higher length-scale constitutive relations for microstructure-property relations. Finally, the ability to generate virtual microstructural instantiations allows for virtual design or sampling of the potential microstructural space, driving toward tailoring materials structure.

Creating statistically "accurate" material instantiations for many engineering materials is still in its infancy with many gaps and opportunities. Recent efforts, centered around integrated computational materials engineering (ICME) and the materials genome initiative (MGI), assume at their core that both the material

structure and functionality of materials can be captured in a digital environment. It is imperative to the success of these initiatives that the materials community develop methodologies for creating digital analogues to real materials. In practice, it is common to generate performance models with limited amount of microstructural information. Typically, simple geometric shapes or tessellations are used to represent microstructures with consideration of lower moments such as average values. The use of such lower moments is often inadequate for accurate prediction of many properties of interest, such as fatigue, fracture, creep, etc. Higher statistical moments of the microstructural distributions, depicting extreme values, are needed for these predictions. While 3D data collection plays a critical role, especially when extreme properties are of interest, 3D experimental methods alone are often not adequate for this framework. Many microstructural arrangements must be interrogated for probabilistic understanding of the relation between microstructure and these properties. To facilitate this, experimental data should be coupled with characterization methods to provide 3D statistical distribution and correlation functions that serve as the inputs to the synthetic microstructure generation process. An additional incentive in this development is to infer 3D statistical descriptors from 2D observations and surface data through the use of stereology or other projection techniques. This is particularly relevant due to the fact that 3D experimental techniques remain unavailable or prohibitively expensive to a large portion of the materials community.

Various methods have been proposed in the literature for generating polycrystalline or polyphase microstructures, e.g., in Sundararaghavan and Zabaras (2005), Kumar et al. (2016), Rollett et al. (2007), Saylor et al. (2004), Guo et al. (2014), Jiao et al. (2007, 2013) and Hasanabadi et al. (2016). In Sundararaghavan and Zabaras (2005), reconstruction of 3D microstructures is solved as a pattern recognition problem, where a microstructure database is used with limited statistical information available from planar images. Microstructures are represented in the form of undirected probabilistic graphs or Markov random fields for computing probability distribution of statistically similar microstructures in Kumar et al. (2016). In Rollett et al. (2007), a 3D grain-structure generation method is based on statistical data gathered from sections on different planes with assigned orientations. Statistically representative polycrystalline microstructures are computationally simulated in Saylor et al. (2004) from geometric and crystallographic observations from orthogonal sections. Maps on the orthogonal planes characterize the sizes, shapes, and orientations of grains, and a voxel-based tessellation technique is subsequently used to generate the microstructure. A dilation-erosion method is developed in Guo et al. (2014) for stochastic reconstruction of 3D duplex stainless steel microstructure containing percolating filamentary ferrite phase from 2D optical micrographs. In Jiao et al. (2007), the authors have concluded that the two-point correlation function space of a statistically homogeneous material can be expressed through a map, constructed on a selected set of bases of the function space. A procedure to model and predict microstructure evolution of lead-tin alloys has been developed using the two-point correlation function associated with different phases in Jiao et al. (2013). A method for 3D microstructure reconstruction from two-point correlation

functions of 2D cross sections using conditional probability theorems and a phase-recovery algorithm is developed in Hasanabadi et al. (2016). The *n*-point correlation functions have been further used in Tewari et al. (2004) and Niezgoda et al. (2010) to reconstruct the microstructure and obtain homogenized properties. Recent work by the author's group combines optimization tools like Genetic Algorithms (Goldberg 1989) with stereology-based projection techniques to develop 3D microstructures from 2D data (Pinz et al. 2018; Tu et al. 2019).

Direct numerical simulations (DNS) of large microstructural regions can be computationally prohibitive. To negotiate this, representative computational domains must be optimally defined for evaluating effective properties without having to solve large microstructural regions. This has led to the concept of a representative volume element (RVE), which is foundational to computational estimates of structure-property relations. Originally introduced in Hill (1963) as a microstructural sub-domain that is representative of the entire microstructure in an average sense, the RVE definition has undergone variations (Ostoja-Starzewski 2006; Torquato 2002; Pyrz 2006). For microstructures with nonuniformly dispersed heterogeneities, the statistically equivalent RVE or SERVE has been defined in Swaminathan et al. (2006), Swaminathan and Ghosh (2006) and McDowell et al. (2011) as the smallest microstructural domain, for which statistical distribution functions of morphological parameters, as well as material properties, converge to those for the entire microstructure. Based on the convergence property in focus, the SERVE can be classified into two categories, viz., (i) the microstructure-based SERVE or *M-SERVE*, in which morphological and crystallographic characteristics of the microstructure are the sole determinants of the representative volume, and (ii) the property-based SERVE or *P-SERVE* that are determined from convergence of selected material properties.

This chapter is aimed at discussing methods of generating 3D statistically equivalent virtual microstructures and M-SERVEs of structural materials that are characterized by polycrystalline and/or polyphase microstructures. It begins with a description of the open-source software package DREAM.3D, which is a popular, user-friendly standardized code for generating synthetic material instantiations. Subsequently some recent developments in modeling polyphase materials and polycrystalline materials, containing heterogeneities such as micro-twins and particulates, are discussed.

## 2 Creating Statistically Equivalent Virtual Polycrystalline Microstructures Using DREAM.3D

DREAM.3D is an open-source software package focused on creating a high-level programming environment to process, segment, quantify, represent, and manipulate digital microstructure data. A central goal of DREAM.3D is to enable the translation of microstructure quantification to a digital basis with easy-to-use software tools. The DREAM.3D environment is constructed to allow independently developed filters and plug-ins to interface with one another, enabling small research groups, government laboratories, start-up companies, and major industrial corporations to

collaborate and leverage each other's work. While DREAM.3D is a general suite of microstructure processing tools, one of the most common uses of the software is generating virtual material volumes for input into simulations of various types. This can readily be seen by viewing the references to the original publication introducing DREAM.3D (Groeber and Jackson 2014). The latest release of DREAM.3D can be downloaded from the website given in Jackson (2018).

Synthetic builders generally consist of two major processes, viz., generating features and spatial arrangements within a computational volume. Features may be generated by sampling the size, shape, and morphological and crystallographic orientation distributions observed by some experimental technique. Next, the features are placed in the volume with specific focus on the local neighborhoods of features. The sampling procedure, as well as the constraints used to place the features in the volume, is briefly described here. More detailed descriptions of the synthetic generation procedure can be found in Groeber et al. (2008a, b).

## 2.1 Representative Feature Generation

Idealized geometric objects have distributions of size, shape, and morphological orientation equivalent to those observed in the experimental volume, representing grains. In this representation, each feature is modeled as a geometric object (i.e., ellipsoid, super-ellipsoid, cube-octahedron, etc.) with a volume (V), a set of aspect ratios (b/a, c/a), and a morphological orientation ($\phi_1$, $\Phi$, $\phi_2$) corresponding to the orientation of the major principal axes (a,b,c) relative to the global axes. First the experimental feature volume distribution is sampled, which is represented by the cumulative distribution function (CDF) fit to the experimental data. Many investigations have shown the feature volume distribution to be well represented within $1 \to 2$ standard deviations of the mean, by a log-normal distribution (Zhang et al. 2004; Groeber et al. 2008b). It has been shown in Donegan et al. (2013) that grain size distributions tend to deviate from log-normal near the tails of the distribution. This can be accounted for by sampling from a piecewise distribution using a different form near the tails. Features are sampled until the total volume of all features generated is slightly larger than the volume of the synthetic microstructural model (typically around 10% larger). Additional volume is needed because some features may lie partially outside the domain or overlap other features. If the volume being generated is to have periodic boundaries, then additional volume is not needed because the portion of the features that fall outside of the domain will be placed on the opposite side. Subsequent to the volume assignment, feature shapes are assigned in conformity with CDFs of the aspect ratios (b/a, c/a). The corresponding CDFs are represented in terms of a beta distribution, due to its bounds of [0,1]. Additionally, the shape distributions are treated as a function of grain size by assigning unique shape distribution functions to discretely binned volume ranges of grain size. The morphological orientation of each feature is defined by a set of rotations ($\phi_1$, $\Phi$, $\phi_2$) needed to transform the global coordinates (X,Y,Z) onto the principal axes of the feature (X', Y', Z'). The orientation space is discretized into cubic bins, and the density in each bin represents the fraction of grains with that morphological

orientation. Ellipsoidal orientations are created and assigned based on sampling this probability density function (PDF), similar to the size and shape distributions. The output of this process is a set of geometric objects, representative of the features having statistically equivalent volume, aspect ratio, and morphological orientations as the experimental reference data.

## 2.2    Feature Placement

Spatial arrangement of features in a microstructure and their subsequent interactions drive local material response that can manifest in macroscopic heterogeneity. After generating a set of geometric objects, it is important that the placement of the features captures the local microstructural discontinuities. There are multiple issues to consider when packing the features. The density of the objects, represented by the features, is one of the largest factors in developing the packing algorithm. For example, features representing particles of a low volume fraction phase will certainly be placed differently than features representing grains in a fully dense polycrystalline material. In the fully dense grain, for example, care must be taken to pack the volume as densely as possible, but minimize overlap between features in order to retain each feature's prescribed shape. In both cases, the local neighborhood of the feature (i.e., neighboring features) must also be addressed during placement. The low volume fraction particles should be spaced equivalently to the experimental/reference data, and the densely packed grains should neighbor grains of sizes, shapes, and orientations similar to those seen in the experimental/reference data.

Alternative viable options for feature packing have been discussed in Groeber et al. (2008a) and Saylor et al. (2004). The approach used in DREAM.3D is a hybrid of methods in these references. The set of voxelized features are initially randomly placed in the volume. The features are then moved and swapped while enforcing constraints such as overlap or gap limits, number of neighboring features, size distributions of neighboring features etc. This approach generally yields near-optimal space filling through the overlap/gap limits and produces realistic neighborhoods by requiring local grain arrangements to match experimentally obtained metrics. The number of constraints affects the feasibility of finding a globally optimum arrangement. All clusters of unassigned voxels, corresponding to morphological incompatibility of features, are filled by a pseudo-grain coarsening process. A constrained Voronoi tessellation method discussed in Groeber et al. (2008b) is implemented to replace the voxelized representation of the grain aggregates by a solid-body surface representation of the grain boundaries.

A final step in the generation procedure is the assignment of crystallographic orientations to the placed features. The process of assigning crystallographic orientations is similar to the morphological orientation assignment process previously described, though they do not affect the grain morphology. Rotations transform the global coordinate axes to the crystal coordinate system, rather than the principal axes of the grain. Orientations are swapped and replaced while optimizing comparison to the experimental orientation and misorientation distributions.

## 2.3 Generating Statistically Equivalent 3D Virtual Microstructures

An example, demonstrating the use of the DREAM.3D software for microstructural characterization and 3D virtual microstructure reconstruction of a titanium alloy Ti-7Al, is shown in Fig. 1. This material has a predominantly *hcp* crystallographic structure (Pilchak 2013). A surface scan of the electron backscattered diffraction (EBSD) maps of the Ti-7Al alloy is shown in Fig. 1a. The morphological and crystallographic orientation, misorientation, and micro-texture distribution data from EBSD scans are input into the DREAM.3D software. The simulated statistically equivalent microstructure of dimensions $300 \times 300 \times 300\,\mu m$ containing 515 grains is shown in Fig. 1b with colors representing the $< c >$-axis misorientation with neighboring grains. The simulated pole figures are compared with those from EBSD data in Fig. 1c. Furthermore the probability density functions of misorientation and grain size are compared with those from EBSD maps in Fig. 1d, e respectively. Good agreement is generally seen between the simulated and experimental probability density functions.

## 3 Beyond DREAM.3D: Creating Statistically Equivalent RVEs of Polycrystalline and Polyphase Microstructures

While the DREAM.3D software is capable of generating virtual polycrystalline microstructures and SERVEs for various metals and alloys, incorporation of more complex microstructural features is still in nascent stages. Such features include those contained in polyphase and polycrystalline microstructures, e.g., annealing twins or particles and precipitates inside grains. This section will summarize a suite of algorithms that have been developed for creating M-SERVEs of complex polycrystalline and polyphase microstructures belonging to three distinct categories. These are:

1. Polycrystalline microstructures with localized features like annealing $\Sigma 3$ twin boundaries, shown in Fig. 2a;
2. Multiphase microstructures like subgrain $\gamma - \gamma'$ microstructure of Ni-based superalloys, shown in Fig. 7a;
3. Polycrystalline microstructures with dispersed precipitates and particles, e.g., for Al 7075-T6, shown in Fig. 10a.

## 3.1 Polycrystalline Microstructures with Annealing Twin Boundaries

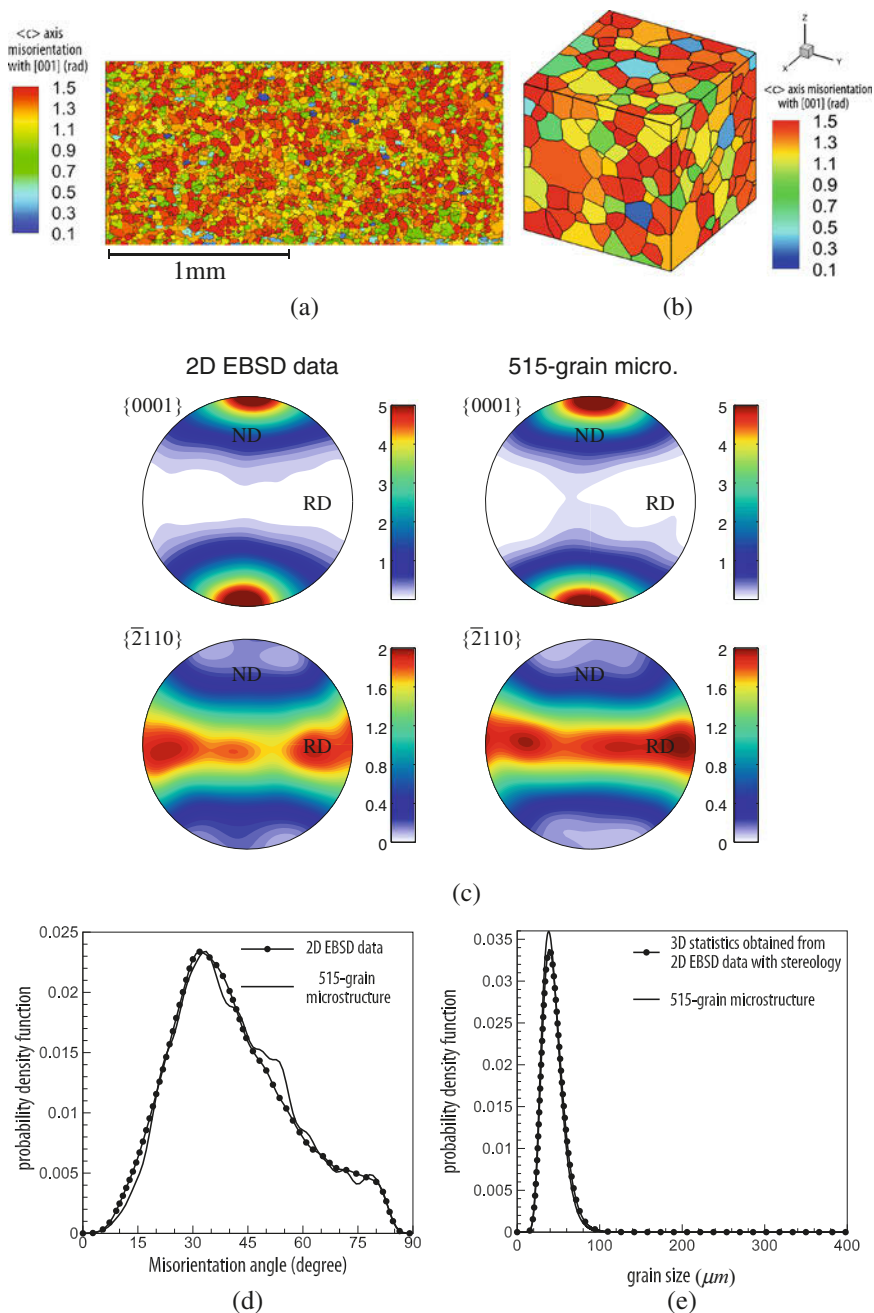
Figure 2a shows EBSD images of a set of parallel sections of the superalloy René-88 DT microstructure, obtained by wire electrical discharge machining (EDM) of


**Fig. 1** (**a**) EBSD scan of Ti-7AL; (**b**) statistically equivalent $300 \times 300 \times 300\,\mu m$ virtual microstructure containing 515 grains and showing the color plot of $< c >$-axis misorientation; comparison of (**c**) orientation distribution, (**d**) misorientation distribution, and (e) grain size distribution of the simulated microstructure with those from the EBSD data
**Fig. 2** (**a**) Serial sectioned EBSD images, (**b**) computer-assembled sections of EBSD images manifesting polycrystalline microstructure including twins, and (**c**) polycrystalline microstructure of parent grains only after removing twins, for the Ni-based superalloy René88-DT

a $10 \times 5 \times 1$ mm sample (Lenthe 2017). The 3D assembly and microstructure reconstruction are performed in the DREAM.3D software using (i) slice registration and alignment, (ii) voxel level cleanup, (iii) feature segmentation, and (iv) artifact removal as detailed in Bagri et al. (2018). Twin-related domains are grouped with a $5°$ tolerance on both the disorientation axis and the disorientation angle. The resulting stacked and assembled 3D polycrystalline microstructure containing annealing twins is shown in Fig. 2b, where the grains are segmented with a $2°$ tolerance. The ensemble contains 440 twins in 300 parent grains for a total of 740 twins and grains. The polycrystalline microstructure is dominated by large aspect ratio, annealing $\Sigma 3$ twins that have a $60°$ misorientation angle about the $< 111 >$ crystal lattice axis. Details on the reconstruction of M-SERVEs are given in Bagri et al. (2018).

The following steps are executed in sequence to generate statistically equivalent volumes of twinned polycrystalline microstructures from scanned EBSD images.

1. Process the EBSD section data and construct the digitally assembled polycrystalline ensemble including twins;
2. Identify and remove twins from the digitally assembled microstructure to manifest the parent grains shown in Fig. 2c;
3. Extract the statistics of parent grains from the EBSD data;
4. Create statistically equivalent virtual parent grain microstructures from the 3D EBSD data;
5. Extract correlation statistics of twins with respect to parent grains from the EBSD data in the digitally assembled microstructure;
6. Insert twins in the parent microstructure to match statistical correlations.

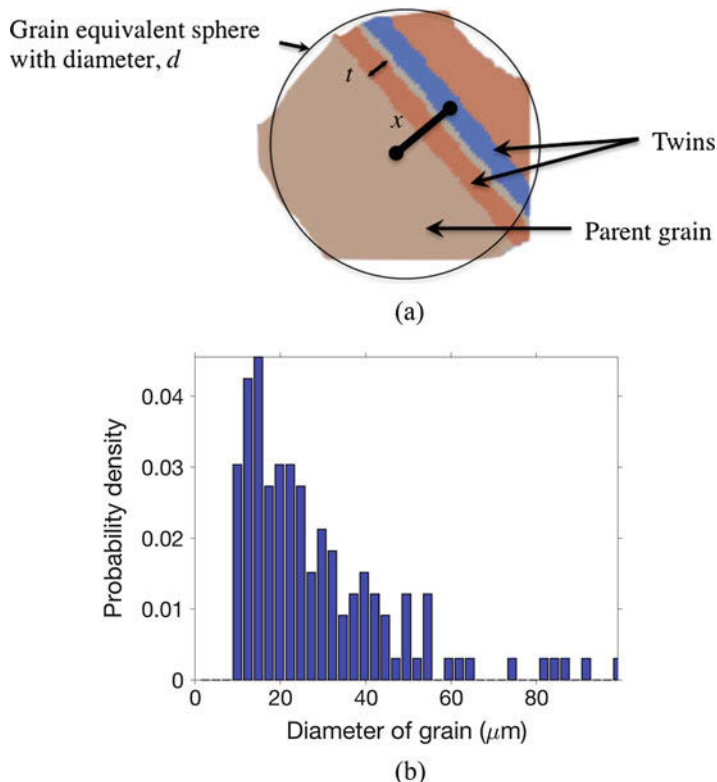
The DREAM.3D software (Groeber and Jackson 2014) is employed in steps 1–4 to create the digital polycrystalline ensembles from EBSD data in Fig. 2d: remove twins in Fig. 2c and subsequently extract statistics of the parent grains. The statistics of characteristic features in the twin-free parent grains in Fig. 2c, including probability distributions of grain size, orientation, and misorientation


**Fig. 3** (**a**) Schematic of twins and parent grain and (**b**) statistics of grain size distribution after removing twins

angle, are acquired following (Groeber et al. 2008a, b). The probability density distribution of grain size is shown in Fig. 3b. For instances where only 2D EBSD are available, methods of estimating 3D grain sizes from 2D surface data, e.g., through the stereology relation $d_{3D} \sim 4/\pi d_{2D}$ (Groeber et al. 2008a), may be used.

In step 5, sample statistics are extracted from the EBSD data to generate probability distribution and correlation functions of twins with respect to parent grains. These are subsequently used to insert twins in the parent microstructure. A schematic representing the relation of a twin with the parent grain is shown in Fig. 3a. Statistical analysis shows the parent grain size $d$, number of twins in parent grain $n$, minimum distance $x$ of the twin from the parent grain centroid, and the twin thickness $t$ are strongly correlated. The joint probability distribution of the correlation between twins and parent grains is expressed through a function $P_0(d, n, t, x)$. The correlation statistics and joint probability distributions are shown in Fig. 4.

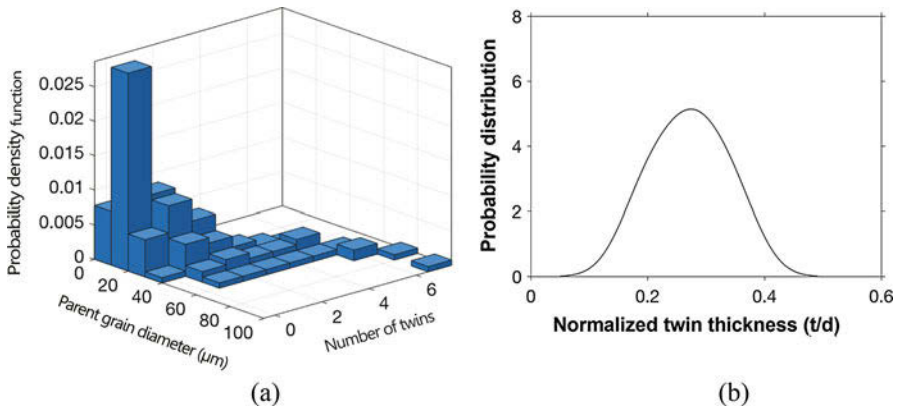
The algorithm to insert twins in the parent grain microstructure consists of the following steps.


**Fig. 4** Correlation statistics from the EBSD data: (**a**) joint probability density distribution of the parent grain size and number of twins and (**b**) conditional probability density distribution of twin thickness

1. Use the joint probability distribution of parent grain size and number of twins $P_1(d, n) = \iint P_0(d, n, t, x) \, dt \, dx$ and the conditional probability distributions of both twin distance from parent centroid $P_2(x | d = D, n = N)$ and twin thickness $P_3(t | d = D, n = N)$ for twin insertion.
2. Determine the number of twins, twin thickness, and the twin distance from parent centroid using a Monte Carlo-based acceptance-rejection scheme.
3. Locate the (111) plane at a distance $x$ from the parent centroid.
4. Identify voxels that are at a distance $\frac{t}{2}$ from the mid-thickness (111) plane.
5. Calculate the rotation matrix from the rotation matrices of the parent grain and the twin with respect to parent, i.e., $\mathbf{R} = \mathbf{R}_{\text{parent}} \mathbf{R}_{\text{twin}}$
6. Determine Euler angles of the twin, and reassign them to voxels of the twin.

The four-dimensional probability distribution $P_0(d, n, t, x)$ requires a very large number of grains. Hence, a marginal probability function is used, when a smaller set of statistical information is available. In step 1, the joint probability density distribution, e.g., in Fig. 4a, is used for parent grain and number of twins per parent, while the conditional probability distributions are used for the twin thickness (Fig. 4b) and twin distance from the parent centroid. With this assumption, the four-dimensional distribution space is approximated as:

$$P_0(d, n, t, x) \approx P_1(d, n) P_2(x | d = D, n = N) P_3(t | d = D, n = N) \qquad (1)$$

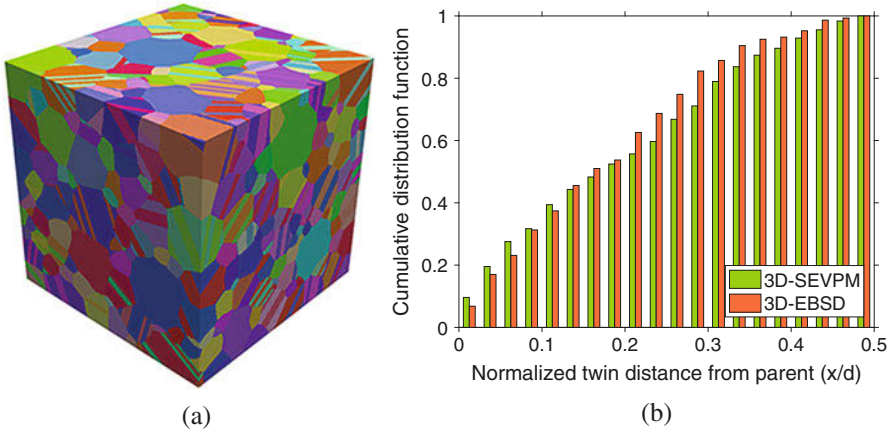
This approximation is valid for any parent grain size and associated twins, where the twin size and distance from the parent centroid are uncorrelated. When inserting the coherent twins, they must be placed with the proper orientation relationship to the parent. The twin boundary plane orientation in the specimen frame $\mathbf{m}_s$ is first determined using the crystallographic orientation vector of the parent grain as


**Fig. 5** (**a**) Simulated 3D statistically equivalent polycrystalline microstructure (3D-SEVPM) with twins inserted in the parent grains and (**b**) comparison of the cumulative distribution function of twin distance $d$ from parent centroid in the EBSD scan and 3D-SEVPM of size $250\,\mu$m

$\mathbf{m}_s = \mathbf{R}_{\text{parent}}\mathbf{m}_p$, where $\mathbf{R}_{\text{parent}}$ and $\mathbf{m}_p = (111)$ are the parent grain rotation matrix and grain boundary plane orientation vector in the crystal coordinates, respectively. Subsequently, the plane is located at a previously selected distance $x$ from the parent centroid. The grain boundary plane will pass through the point $\mathbf{x}_p = \mathbf{x}_c + x\frac{\mathbf{m}_s}{\|\mathbf{m}_s\|}$. Here, $\mathbf{x}_p$ is the position vector of a point in the grain boundary, $\mathbf{x}_c$ is the position vector of the parent grain centroid, and $\|\mathbf{m}_s\|$ is the norm of the grain boundary normal. The rotation matrix of the twin in the specimen frame $\mathbf{R}$ is obtained from the rotation matrix of parent grain $\mathbf{R}_{\text{parent}}$ and the rotation matrix of the twin with respect to parent grain $\mathbf{R}_{\text{twin}}$ as $\mathbf{R} = \mathbf{R}_{\text{Parent}}\mathbf{R}_{\text{twin}}$. Using the components of $\mathbf{R}$, the Euler angles of twins are expressed as:

$$\phi_1 = tan^{-1}(-\frac{R_{13}}{R_{23}}), \quad \Phi = cos^{-1}(R_{33}), \quad \phi_2 = tan^{-1}(\frac{R_{31}}{R_{32}}) \tag{2}$$

Repeating steps 1–6, the set of twins are inserted into the parent grain microstructure.

### 3.1.1 An Example of Validated M-SERVE Generation

The algorithm is used with EBSD data in Alam et al. (2016) for validating the virtual microstructure generation process. The statistics shown, e.g., in Fig. 4 are used to insert twins in the parent grain microstructure. A $250 \times 250 \times 250\,\mu$m 3D-SEVPM consisting a total of 1700 parent and twins is shown in Fig. 5a. The cumulative distribution function of the twin distance $d$ from parent centroid for this 3D-SEVPM is compared with that from the EBSD scan in Fig. 5b.

Studies in Bagri et al. (2018) have shown that the 3D-SEVPM converges to the M-SERVE at $150\,\mu$m, which corresponds to approximately 400 grains and
**Fig. 6** Probability distribution of (**a**, **b**) misorientation angle and (**c**, **d**) twin thickness from the EBSD data and the M-SERVE, respectively

twins. Comparison of the M-SERVE statistics with the EBSD data is made through a few probability distributions. The distribution of the global misorientation and twin thickness is compared in Fig. 6. The prominent peak in misorientation angle distribution at 60° indicates the presence of twins in the microstructure. A good agreement is obtained for all the distribution plots. This is a step in validating the virtual microstructure generation method. In both the EBSD data and M-SERVE, about 40% of the parent grains are seen to remain untwinned.

## 3.2    Two-Phase Microstructures Underlying Polycrystalline Grains

Polycrystalline nickel-based superalloys like René-88 DT have an underlying subgrain-scale two-phase microstructure consisting of a dispersion of $\gamma$ and $\gamma'$ precipitates, as shown in Fig. 7a. Subgrain-scale morphological characteristics like volume fraction, mean size, and channel-width or spacing of $\gamma'$ precipitates have a major effect on their mechanical properties (Unocic et al. 2011). Modeling
**Fig. 7** (**a**) Scanning electron microscope image of a microstructural section of Ren*é*-88 DT acquired by FIB serial sectioning, (**b**) segmented SEM image after thresholding and despeckling, and (**c**) spurious connectivity from serial sectioning after segmentation

their mechanical and physical behavior requires robust representation of these morphological features in the M-SERVE. Many approaches have been employed to include precipitate structure in performance simulations, e.g., Pollock and Argon (1992), Nouailhas and Cailletaud (1996), Busso et al. (2000), Fromm et al. (2012), Parthasarathy et al. (2004) and Keshavarz and Ghosh (2015).

This section discusses a methodology developed in Pinz et al. (2018) for generating M-SERVEs of two-phase $\gamma-\gamma'$ microstructures from 2D microstructural scans of 3D data, using the following steps.

1. *FIB-SEM serial sectioning*: Acquisition of high-fidelity 3D $\gamma-\gamma'$ microstructural data necessitates a high-throughput automated serial-sectioning process coupled with high-resolution SEM data extraction.
2. *Image processing and data cleanup*: Cleanup and subsequent segmentation of $\gamma$ and $\gamma'$ phases generate a reference 3D voxelization of the microstructure.
3. *Feature extraction and statistical characterization*: Parametrization and statistical characterization of the $\gamma'$ precipitate morphology and designation of the relative precipitate positions are needed for establishing spatial distributions.
4. *Statistically equivalent microstructural reconstruction*: Optimally minimum microstructures are generated with morphological and spatial statistics equivalent to those of the large-imaged microstructures.

### 3.2.1 Data Extraction with 3D FIB Serial Sectioning and SEM-Based Imaging

Recent advances in tomographic methods, e.g., in Uchic et al. (2006), and Echlin et al. (2014) and image processing tools have greatly increased the accessibility of 3D data sets for a variety of materials. Microstructural data used for the generation of the polyphase M-SERVE is obtained from Lenthe (2017), where a FIB is used to expose parallel layers of the material that are imaged with a SEM. A sample section is shown in Fig. 7a. The in-plane resolution is 2.5 nm per pixel with 20 nm between

the slices. The sections are aligned via a convolution method to reduce the effects of instrumental drift. The contrast difference between the $\gamma$ and $\gamma'$ phases is not large enough to allow for robust automatic segmentation of the SEM images (Pollock and Tin 2006) and can require extensive cleanup.

### 3.2.2   Image Segmentation

The FIB-SEM technique in Lenthe (2017) is used to collect 180 gray-scale images, each with a size of 1996 × 1596 pixels. The resultant image stack yields a 3 × 4 × 5 µm volume. An automated image segmentation process begins with local noise reduction followed by image sharpening to enhance the contrast between the phases. The sharpened image stack is segmented with a minimum entropy threshold (Li and Lee 1993) as shown in Fig. 7b. Sections are interpolated between extracted images in all three directions. The interaction volume of the SEM causes spurious connectivity between the precipitates as shown in Fig. 7c. A watershed segmentation procedure (Meyer 1994) is used to separate the conjoined precipitates using a gradient field given as:

$$
\mathcal{G}(i, j, k) = \mathcal{B}_{\text{int}}(i, j, k) \frac{\sum_{\bar{i}=0}^{N_x} \sum_{\bar{j}=0}^{N_y} \sum_{\bar{k}=0}^{N_z} \mathcal{D}_{\text{int}}(\bar{i}, \bar{j}, \bar{k}) e^{-\left[\left(\frac{(\bar{i}-i)^2}{2\sigma^2}\right)+\left(\frac{(\bar{j}-j)^2}{2\sigma^2}\right)+\left(\frac{(\bar{k}-k)^2}{2\sigma^2}\right)\right]}}{\sum_{\bar{i}=0}^{N_x} \sum_{\bar{j}=0}^{N_y} \sum_{\bar{k}=0}^{N_z} e^{-\left[\left(\frac{(\bar{i}-i)^2}{2\sigma^2}\right)+\left(\frac{(\bar{j}-j)^2}{2\sigma^2}\right)+\left(\frac{(\bar{k}-k)^2}{2\sigma^2}\right)\right]}}
$$

$$(3)$$

where $\bar{i}, \bar{j}, \bar{k}$ are dummy indices, $N_x$, $N_y$, and $N_z$ are the number of voxels in the $x, y, z$ directions, respectively, and $N_{\text{slice}}$ is the total number of slices after interpolation. $\mathcal{D}_{\text{int}}$ is a map from each voxel to the value of its distance to the nearest boundary in the plane, and $\mathcal{B}_{\text{int}}$ is a binarized map relative to $\mathcal{D}_{\text{int}}$. The latter is an indicator function of whether a voxel $(i, j, k)$ is in a precipitate or not. The standard deviation $\sigma$ of the Gaussian blur is set to $\frac{1}{10}$th of the mean particle radius. This gradient field is chosen to reduce disconnected over-segmentation by the watershed algorithm. The purpose of the 3D Gaussian blur is to mitigate effects from the voxelization of the precipitate edges. After application to the initially connected inclusions, the watershed segmentation algorithm produces a final binary voxelized map $\mathcal{B}_{\text{final}}$ that contains approximately 6000 contiguous precipitates.

### 3.2.3   Mapping Precipitate Domain to a 3D Parametric Function Model

Homogenized constitutive models require the precipitate morphology to be described by a parametrized function with a finite number of parameters and coefficients. These parameters may be calibrated from the actual surface profiles by optimization. The chosen parametric function for surface representation represents a generalized super-ellipsoid (GSE), delineated as:

$$
\left(\frac{\bar{x}}{a}\right)^{N1} + \left(\frac{\bar{y}}{b}\right)^{N2} + \left(\frac{\bar{z}}{c}\right)^{N3} = 1
$$

$$(4)$$

The position vector $\bar{\mathbf{x}}(= \bar{x}, \bar{y}, \bar{z})$ corresponds to the location of a GSE surface point $\mathbf{x}_p(= x_p, y_p, z_p)$ relative to its centroid $\mathbf{x}_0(= x_0, y_0, z_0)$ in its principal coordinate system represented by the Euler angles $(\phi_1, \Phi, \phi_2)$. The relative coordinates are expressed as $\{\bar{\mathbf{x}}\} = [\mathbf{R}]\{\mathbf{x}_p - \mathbf{x}_0\}$, where $[\mathbf{R}]$ is the rotation matrix for the precipitate coordinate system. In Eq. (4) $a, b, c$ correspond to the principal axis lengths of the super-ellipsoid, and $N1, N2, N3$ are exponents representing the shape. The parametrized function in Eq. (4) entails evaluation of the parameter set $Y_{\text{par}} \in \{x_0, y_0, z_0, N1, N2, N3, a, b, c, \phi_1, \Phi, \phi_2\}$. The parameters are calibrated by solving an optimization problem that minimizes the orthogonal distance between $m$ surface points of a precipitate and the parametrized surface as:

$$\underset{Y_{\text{par}}}{\text{Minimize}} \sum_{i=1}^{m} D_i^2 = \sum_{i=1}^{m} \|\mathbf{x}_i - (\mathbf{x}_p)_i\|^2 = \sum_{i=1}^{m} \left\{ x_i - (x_p)_i \right\}^2$$

$$+ \left\{ y_i - (y_p)_i \right\}^2 + \left\{ z_i - (z_p)_i \right\}^2 \tag{5a}$$

subject to the constraint that each point $i$ belongs to the GSE surface

$$\left( \frac{\bar{x}_i}{a} \right)^{N1} + \left( \frac{\bar{y}_i}{b} \right)^{N2} + \left( \frac{\bar{z}_i}{c} \right)^{N3} = 1 \ \ \forall \ i \in [1, m] \tag{5b}$$

The variable $D_i$ corresponds to the absolute Euclidean distance between a surface point on the precipitate at coordinates $(\mathbf{x}_i = (x_i, y_i, z_i))$ for a point $i$ and its conjugate surface point $(\mathbf{x}_p)_i = (x_p)_i, (y_p)_i, (z_p)_i$ on the parametrized GSE in the current iterate.

### 3.2.4 Validation of Precipitate Mapping and Reconstruction

Distributions of morphological parameters of the precipitates generated are used to validate the effectiveness of the parametrization.

*I. Dice Index:* The Dice index (DI) is used as a goodness-of-fit metric to compare the orthogonal distance minimization (ODM) algorithm with an alternate moment-based algorithm proposed in MacSleyne et al. (2009). DI is defined as the volume of overlap between two objects (the actual precipitate and the GSE) divided by the composite volume of the union of the two objects as: $DI = \frac{V_{FIB} \cap V_{GSE}}{V_{FIB} \cup V_{GSE}}$. It ranges from 0 corresponding to no overlap to 1 for perfect intersection. In Fig. 8a, the distribution of DI is compared for GSE's generated by alternate methods. "FULL" corresponds to $N1 \neq N2 \neq N3$, while "REDUCED" has $N = N1 = N2 = N3$.

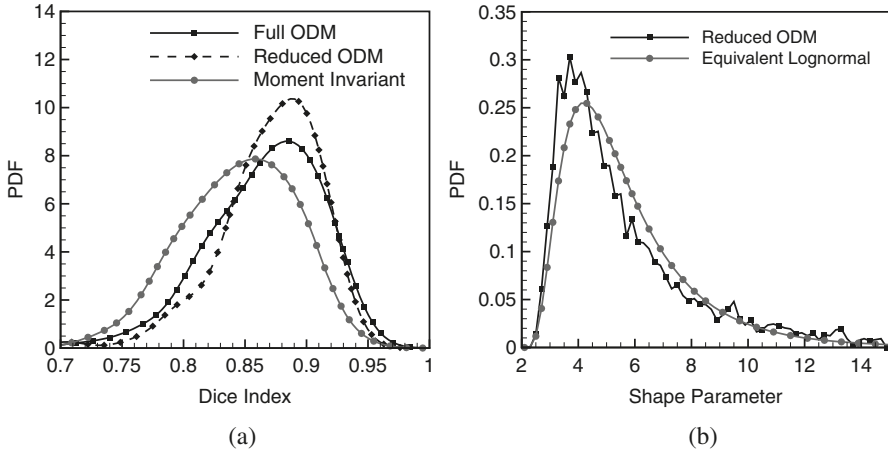
*II. Size, Shape, and Orientation Distributions:* The distributions of the major, minor, and intermediate axes $a$, $c$, and $b$, respectively, represent the size and aspect ratio of the precipitate. Figure 8b compares the distribution of the shape parameter $N$ obtained in the ODM algorithm to a log-normal distribution representation of the same by the maximum likelihood estimation (MLE). Orientations of the GSEs by the ODM algorithm with reduced shape parameters are used to generate equivalent orientation distribution functions using spherical harmonics for crystallographic texture.


**Fig. 8** Probability distribution of (**a**) the DI for equivalent ellipsoids generated by alternative methods and (**b**) shape parameters in the ODM algorithm and MLE shifted log-normal distribution

### 3.2.5   Statistically Equivalent Microstructure by Dispersing Precipitates

A set of precipitates with representative morphological parameters are generated to yield a desired volume fraction. A placement algorithm that involves random allocation with local perturbation to avoid precipitate overlap, as well as microstructural shuffling through an energy minimization scheme for positional stability, is implemented. This method is iteratively continued with precipitate size scaling until the experimental volume fraction is attained.

An optimization schedule is executed to minimize the difference in the two-point correlation function $S_2$ for the experimental microstructure and the 3D statistically equivalent virtual microstructures (3D-SEVMs). The two-point correlation function $S_2$ is a statistically convergent measure of the microstructural heterogeneity in Tewari et al. (2004) and Jiao et al. (2007). For isotropic distributions, it can be approximated by a closed-form solution as:

$$S_2(r) = V_f{}^2 + V_f(1 - V_f)e^{\frac{-r}{r_0}} \frac{\sin\left(\frac{2\pi r}{a_0}\right)}{\frac{2\pi r}{a_0}} \tag{6}$$

where $V_f$ represents the volume fraction of precipitates and $a_0$ and $r_0$ are calibrated parameters. A genetic algorithms (GA)-based optimization (Goldberg 1989) is used to minimize the difference in the $S_2$ function. The fitness function is expressed as:

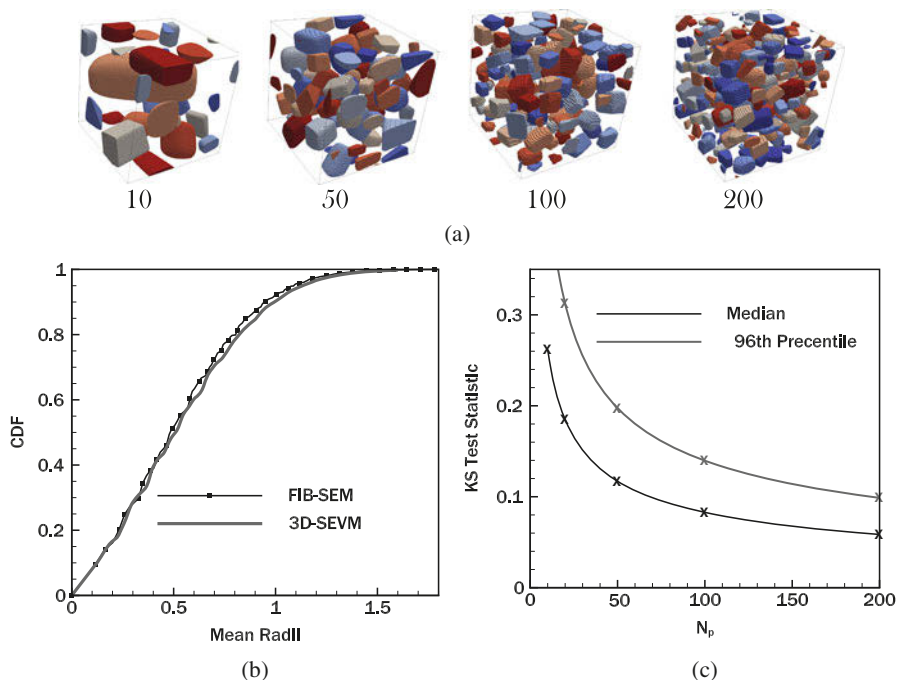
$$FF_{S_2} = \left(\frac{a_o - a_o^{\text{target}}}{a_o^{\text{target}}}\right)^2 + \left(\frac{r_o - r_o^{\text{target}}}{r_o^{\text{target}}}\right)^2 \tag{7}$$


**Fig. 9** (**a**) Reconstructed 3D-SEVMs with 10, 50, 100, and 200 precipitates; (**b**) cumulative distribution function of distance to precipitate surface, generated from experimental data and 3D-SEVM; and (**c**) median and 96th percentile expected KS test statistic with 10, 50, 100, and 200 precipitates

Figure 9a shows examples of the reconstructed 3D-SEVMs for $N_p = 10, 50, 100,$ and 200 precipitates. Validation tests of 3D-SEVMs are conducted by comparing morphological metrics that are not optimized during the reconstruction process. One relevant metric for plastic deformation is the *distance to precipitate surface* (DPS) distribution. Figure 9b shows a cumulative distribution function of DPS for experimental and 3D-SEVM volumes, exhibiting good agreement. Figure 9c plots the Kolmogorov-Smirnov (KS) test (Massey 1951) statistic between the 3D-SEVM with $N_p = 10, 50, 100,$ and 200 precipitates and the FIB-SEM microstructural data. Both the median and an upper bound of the sampling error with frequency of 0.96 are plotted in this figure. The 3D-SEVM with 200 precipitates is sufficient for convergence, and hence this is the designated M-SERVE as detailed in Pinz et al. (2018).

## 3.3   Polycrystalline Microstructures with Dispersed Precipitates

Many engineering alloys have precipitates or particles dispersed in their polycrystalline microstructure. For example, the 7000-series aluminum alloys,
**Fig. 10** Inverse pole figure maps of EBSD data and SEM images of TD/ND plane of the Al7075-T651 sample containing particles in polycrystalline microstructure; (**b**) DREAM.3D reconstructed 392-grain virtual microstructure; comparing statistical distributions of the virtual grain morphology with EBSD data for (**c**) grain size, (**d**) aspect ratio c/b

e.g., Al 7075-T6, contain iron-rich or magnesium-rich precipitates in the aluminum matrix, as shown in Fig. 10a. Various models have been proposed for microstructure generation of porous materials and particle-reinforced metals, e.g., in Baniassadi et al. (2011), Rollett et al. (2006) and Guo et al. (2014). Following developments in the previous sections, this section discusses a method for constructing 3D virtual microstructures from 2D micrographs, accounting for grain and particle shape distributions, spatial arrangements of precipitates, as well as precipitate-grain spatial correlations. Stereological concepts are numerically implemented into a genetic algorithm (GA)-based optimization framework as detailed in Tu et al. (2019).

### 3.3.1   Stereological Reconstruction of the Grain Microstructure

Figure 10a shows a representative EBSD scan of a cross section from an aluminum alloy (7075-T6). Crystallographic orientation and misorientation distributions, as
**Fig. 11** Comparing crystallographic distributions of the virtual grain with EBSD data for (**a**) orientation distribution (pole figures) and (**b**) misorientation distribution

well as morphological distributions, e.g., grain size, aspect ratio distributions, are extracted from these scans. Stereological estimations of 3D size and aspect ratio distributions are made from 2D surface data following (Underwood 1972), and the 3D microstructure is constructed by DREAM.3D using these distributions. Figures 10 and 11 compare the morphological and crystallographic statistics of a 392-grain virtual microstructure with those from EBSD data.

### 3.3.2    Mapping Distributions of Precipitates to Parametrized GSEs

SEM images of precipitates are mapped to distributions of 3D generalized super-ellipsoids (GSEs), similar to Sect. 3.3. Image processing of the SEM images includes contrast enhancement (adaptive histogram equalization), binarization (gray level thresholding), and noise removal (Wiener filtering). The SEM particle contours on the 2D surface are fitted to generalized super-ellipse using the 2D version of Eq. (5). The microstructures show precipitate clustering along the rolling direction (RD) (Rollett et al. 2007). The isotropic two-point correlation function or radial distribution function in Jiao et al. (2007) and Wang et al. (2016) is unable to characterize this directional clustering. The two-point correlation analysis of precipitates in the RD/ND plane in Fig. 12a shows a clear trend of directional clustering along the RD direction. Furthermore, the precipitate-grain spatial correlation is represented by the conditional probability distribution of the minimum distance to grain boundaries for a given precipitate size. Fracture toughness of aluminum alloys is sensitive to the closeness of precipitates to grain boundaries (Cai et al. 2007), which is obtained by overlaying the EBSD and SEM 2D data sets. Figure 12b manifests the clustering of precipitates of various sizes near grain boundaries.

### 3.3.3    GA-Based Stereological Mapping from 2D to 3D Microstructures

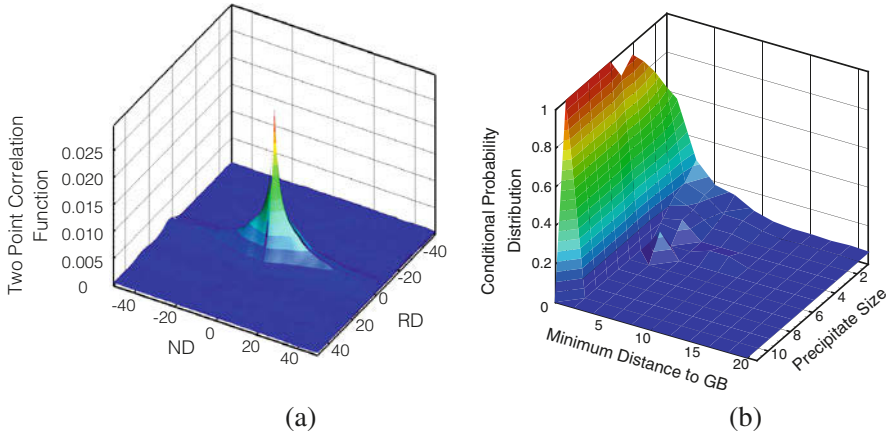
A genetic algorithm (GA)-based optimization method (Goldberg 1989) is used to search for parameters of the 3D precipitate distributions, by minimizing the


**Fig. 12** (**a**) Anisotropic two-point correlation function for precipitates and (**b**) conditional probability distribution of the distance to grain boundaries and precipitate size in the RD/ND plane

difference in cumulative distribution functions (CDFs) of 2D statistics of the virtual and experimental microstructures, using the equation:

$$\underset{X_k}{\text{Minimize}} \frac{1}{N_{\text{descriptor}}} \sum_{k=1}^{N_{\text{descriptor}}} \frac{1}{N_{\text{bin}}^{(k)}} \sum_{i=1}^{N_{\text{bin}}^{(k)}} \left| CDF_i^{\text{experimental}} - CDF_i^{\text{virtual}} \right| \tag{8}$$

where $N_{\text{descriptor}}$ corresponds to the number of descriptors, e.g., precipitate size, aspect ratio, shape parameter, and principal axes orientation. $X_k$ stores the 3D shape distribution parameters for the $k$-th descriptor, and $N_{\text{bin}}^{(k)}$ is the number of bins allocated to represent the cumulative distribution of descriptor $k$. Candidate sets of 3D super-ellipsoid semiaxis length $(a, b, c)$, shape parameter $(n)$, and principal axes orientation $(\alpha, \beta, \gamma)$ distribution parameters are stored in the array **X**. For every candidate set, representative 2D orthogonal sections are derived statistically from 3D virtual microstructures and compared with the EBSD surface image data. Subsequently, the parameters of the sectioned super-ellipses are solved with the method of undetermined coefficients. With known statistics of the virtually sectioned super-ellipses and experimental surface data, individual fitnesses are calculated from the minimization problem involving crossover and mutation operations.

### 3.3.4   Planting Precipitates in the DREAM.3D-Generated Grain Microstructure

The 3D super-ellipsoidal precipitates are now spatially dispersed in the 3D parent polycrystalline matrix. The dispersion of precipitate centroids is optimized by the GA methodology such that the anisotropic $S_2$ function and precipitate-grain spatial correlations of the sections match the experimental distributions. The fitness function of the optimization process is written as:

$$\text{Minimize} \atop \mathbf{C} \quad \frac{1}{N_{\text{descriptor}}} \sum_{k=1}^{N_{\text{descriptor}}}$$

$$\left\{ \frac{1}{N_{\text{section}}} \sum_{m=1}^{N_{\text{section}}} \frac{1}{N_{\text{bin}}^{(k)} * M_{\text{bin}}^{(k)}} \sum_{j}^{N_{\text{bin}}^{(k)}} \sum_{i}^{M_{\text{bin}}^{(k)}} \left| CDF_{ij}^{\text{virtual}} - CDF_{ij}^{\text{experimental}} \right| \right\}$$

$$(9)$$

where $\mathbf{C}$ is the centroidal coordinates of precipitates, $N_{\text{descriptor}}$ is the number of descriptors, $N_{\text{section}}$ is the number of sections, and $N_{\text{bin}}^{(k)}$ and $M_{\text{bin}}^{(k)}$ are the number of bins used for the cumulative distribution function of a descriptor $k$.

The resulting two-phase reconstructed microstructure is shown in Fig. 13b. Figure 13b shows that the precipitates cluster along the RD (x-axis) in good agreement with the experimentally obtained microstructural distribution. Quantitative comparison of virtual and experimental microstructures in Fig. 14 shows good match of the 2D precipitate-precipitate and precipitate-grain boundary correlations.

### 3.3.5 Convergence of the M-SERVE

The convergence of various microstructural descriptors is studied for assessing the M-SERVE size. The descriptors include grain morphology, grain crystallography, particle morphology, and particle-grain spatial correlation. The errors in these distributions are estimated by the Kolmogorov-Smirnov test. From the M-SERVE convergence characteristics in Fig. 15 for two-point and precipitate-grain correlations, it is found that the M-SERVE size is controlled by precipitate-grain correlations. It converges for approximately 450 grains with 4500 precipitates.

## 4 Conclusions

This chapter discusses the development of computational methods for simulating statistically equivalent virtual microstructures of materials with complex hetero-geneities. The methods consider polycrystalline materials containing localized features such as annealing twins, particulates or precipitates, and subgrain-scale precipitates in their polycrystalline structure. Data from image analysis and charac-terization are used to construct 3D statistical distribution and correlation functions. This serves as input to the virtual microstructure generation process. 3D experimen-tal data extraction techniques are sometimes unavailable or prohibitively expensive to generate. Consequently, the methods accommodate computational approaches that infer 3D statistical descriptors and functions from 2D observations and surface

data, from stereology and other optimization-based projection techniques. The chapter introduces the open-source software package DREAM.3D that is now widely used for generating virtual microstructures of polycrystalline materials. It then goes beyond DREAM.3D into more newly developed methods for incorporating twins, particles, and subgrain-scale phases in polycrystalline microstructures. Finally the concept of the microstructure-based SERVE or *M-SERVE*, in which morphological and crystallographic characteristics of the microstructure are determinants of the statistically equivalent representative volume element, is introduced.

# Polycrystal Plasticity Models Based on Green's Functions: Mean-Field Self-Consistent and Full-Field Fast Fourier Transform Formulations

**77**

Ricardo A. Lebensohn

## Contents

### Abstract

In this chapter, we review two crystal plasticity methodologies based on Green's functions for the prediction of microstructure-property relations in polycrystalline aggregates. The first, known as the viscoplastic self-consistent (VPSC) formulation, is a mean-field theory. The second, known as the viscoplastic fast Fourier transform-based (VPFFT) formulation, is a full-field method. The assumptions and main equations of these Green's function-based crystal plasticity formulations are presented using a unified notation, pointing out their similarities and differences and cross-validating their predictions.

# 1    Introduction

An accurate prediction of the mechanical behavior of polycrystalline aggregates undergoing plastic deformation based on their evolving microstructure and the directional properties and substructure of their constituent single crystal grains is indispensable to establish physically based relationships between microstructure and properties of this ubiquitous class of materials.

On the one hand, advances in the theories linking microstructures and properties of heterogeneous materials, in particular approaches based on Green's functions, have enabled the development of very accurate mean-field models for the prediction of the effective plastic response of statistically defined classes of polycrystalline aggregates. On the other hand, novel and very efficient full-field approaches also based on Green's function formalism have been proposed and applied to the prediction of the actual micromechanical fields developing inside the grains of polycrystalline unit cells with specific microstructures. In this chapter, the assumptions and main equations of these Green's function-based crystal plasticity formulations are presented using a unified notation, pointing out their similarities and differences and cross-validating their predictions.

Concerning mean-field approximations, the computation of effective mechanical response and texture evolution of polycrystalline materials using homogenization approaches has a long tradition (e.g., Sachs 1928; Taylor 1938). Presently, self-consistent approximations are extensively used to deal with this problem. The one-site viscoplastic (VP) self-consistent (SC) theory of polycrystal deformation can be traced back to the works of Molinari et al. (1987), who established an homogenization procedure based on an iterative method involving the computation of integrals in ellipsoidal domains of the *infinite medium* Green's function, customarily used in the solution of the partial derivative equations (PDEs) governing the micromechanical response of heterogeneous materials, and Lebensohn and Tomé (1993), who implemented numerically this formulation to fully account for polycrystal anisotropy, developing the first version of the VPSC code. Since its inception, the VPSC code has experienced several improvements and extensions, e.g., Wenk et al. 1997 (recrystallization), Lebensohn and Canova 1997 (two-site VPSC approximation for two-phase polycrystals), Lebensohn et al. 1998 (VPSC modeling of lamellar structures), Lebensohn et al. 2007 (second-order linearization), Proust et al. 2007 (improved VPSC modeling of twinning), Beyerlein and Tomé 2008 (dislocation density-based hardening models), Lebensohn et al. 2011 (*dilatational* VPSC for porous polycrystals), Lebensohn et al. 2016 (lattice rotation rate fluctuation calculation), Wen et al. 2016 (improved hardening laws for strain path changes), Zecevic et al. 2017 (VPSC prediction of intragranular misorientation evolution), etc., and it is nowadays extensively used to simulate plastic deformation of polycrystalline aggregates and for interpretation of experimental evidence on metals, minerals, and polymers. (Access to the VPSC code can be obtained from the author by email request.) Moreover, beyond applications involving single material point calculations, VPSC has been adapted to account for microstructural effects in multiscale calculations by either coupling it directly with finite elements (FE)

(e.g., Tomé et al. 2001; Segurado et al. 2012; Knezevic et al. 2013; Barton et al. 2015) or using VPSC in combination with uniaxial experiments to fit anisotropic yield functions for subsequent use in the FE analysis (e.g., Plunkett et al. 2006; Nixon et al. 2010; Knezevic et al. 2013). These new multiscale developments greatly expanded the scope of applications of the model.

The self-consistent theory is one of the most commonly used homogenization methods to estimate the mechanical response behavior of polycrystals and was originally proposed by Hershey (1954) for linear elastic materials. For nonlinear aggregates (as those formed by grains deforming in the VP regime), several SC approximations that were subsequently proposed differ in the procedure used to linearize the nonlinear mechanical behavior at grain level, but eventually all of them end up making use of the original linear SC theory. Among the nonlinear SC formulations, we can mention the secant (Hill 1965; Hutchinson 1976), the tangent (Molinari et al. 1987; Lebensohn and Tomé 1993), and the affine (Masson et al. 2000) approximations. All these are first-order SC approximations, since they are based on linearization schemes that, at grain level, make use of information on field averages only, disregarding higher-order statistical information inside the grains. However, the above assumption may be questionable, especially for materials having strong directionality and/or large variations in local properties, as in the case of low rate-sensitivity materials, aggregates made of highly anisotropic grains, voided and/or multiphase polycrystals. In all those cases, strong deformation gradients are likely to develop inside grains because of differences in properties with neighboring crystals.

To overcome the above limitations, more accurate nonlinear homogenization methods were developed by Ponte Castañeda and collaborators, using linearization schemes at grain level that also incorporate accessible information on the second moments of the stress field distributions in the grains. These more elaborate SC formulations are based on the concept of linear comparison material, which express the effective potential of the nonlinear VP polycrystal in terms of that of a linearly viscous aggregate with properties that are determined from suitably designed variational principles. Among these improved linearization schemes, the second-order method, proposed for nonlinear composites (Ponte Castañeda 2002), later extended to VP polycrystals (Liu and Ponte Castañeda 2004) and implemented in the VPSC code (Lebensohn et al. 2007), uses the SC approximation for a general class of linearly viscous polycrystals, having a nonvanishing strain rate at zero stress, to generate the most accurate SC estimates for VP polycrystals.

Until recently, another limitation of the VPSC formulation was that only the average values of the micromechanical fields inside the single crystal grains were used to update the microstructure as deformation proceeded. In particular, the average lattice rotation calculated for each grain was applied to update its average orientation after each deformation increment, and therefore the evolution of deformation texture was based on these average orientation updates. This approximation, which neglects the progressive buildup of intragranular misorientation, has two deleterious effects on the quality of the predicted texture and microstructure evolution. First, the predicted deformation textures are systematically sharper than the experimental

textures. Second, since intragranular misorientation is not accounted for, phenomena like grain size reduction by grain fragmentation and other important mechanisms affecting microstructure evolution that are driven in part by local lattice misorientation, like recovery and recrystallization, cannot be predicted based on strictly micromechanical considerations. Below it is reported how the numerically tractable problem of estimating average fluctuations of the stress field distribution inside each grain – already implemented in the VPSC code as part of the second-order linearization procedure – can also be used to calculate the corresponding second moments of the lattice rotation rate field in each grain.

In what concerns full-field approaches, crystal plasticity finite element (CPFE) implementations have been extensively applied to obtain solutions for the plastic deformation of polycrystalline materials with intracrystalline resolution (e.g., Becker 1991; Mika and Dawson 1998; Delaire et al. 2001; Barbe et al. 2001; Raabe et al. 2001; Delannay et al. 2006; Musienko et al. 2007; Roters et al. 2010; Cruzado et al. 2015; Cheng and Ghosh 2015; Quey et al. 2015, etc.). However, the large number of degrees of freedom required by such FE calculations limits the size of the microstructures that can be simulated by these methods. Conceived as a very efficient alternative to FE methods, a numerical formulation based on the use of the efficient fast Fourier transform (FFT) algorithm to compute convolution integrals over the entire periodic unit cell involving the *periodic* Green's function was originally proposed by Moulinec and Suquet (1994) for the prediction of the micromechanical behavior of heterogeneous materials. The latter includes both composites (e.g., Moulinec and Suquet 1998; Eyre and Milton 1999; Michel et al. 2000; Idiart et al. 2006; Brisard and Dormieux 2010; Willot 2015, etc.), in which the source of heterogeneity is related to the spatial distribution of phases with different mechanical properties, and polycrystals (e.g., Lebensohn 2001; Lebensohn et al. 2005, 2008, 2012, 2013; Brenner et al. 2009; Grennerat et al. 2012; Eisenlohr et al. 2013; Lebensohn and Needleman 2016, etc.), in which the heterogeneity is related to the spatial distribution of crystals with directional mechanical properties.

## 2    Models

### 2.1    VPSC Model

The self-consistent formulation consists in representing a polycrystal by means of weighted, ellipsoidal, statistically representative (SR) grains. Each of these SR grains represents the average behavior of all the grains with a particular crystallographic orientation and morphology but different environments. These SR grains should be regarded as representing the behavior of mechanical phases, i.e., all the single crystals with a given orientation (r) belong to mechanical phase (r) and are represented by SR grain (r). Note the difference between *mechanical phases*, which differ from each other only in terms of crystallographic orientation and/or morphology, and actual *phases* differing from each other in crystallographic structure and/or composition. In what follows, *SR grain (r)* and *mechanical phase*

*(r)* will be used interchangeably. Each representative grain will be treated as an ellipsoidal viscoplastic inclusion embedded in an effective viscoplastic medium. Plastic deformation in the inclusion is accommodated by dislocation slip activated by a resolved shear stress.

### 2.1.1 Local Constitutive Behavior and Homogenization

Let us consider a macroscopic velocity gradient $V_{i,j}$ applied to a polycrystalline aggregate, which can be decomposed into an average symmetric strain rate $\dot{E}_{ij} = \frac{1}{2}\left(V_{i,j} + V_{j,i}\right)$ and an average antisymmetric rotation rate $\dot{\Omega}_{ij} = \frac{1}{2}\left(V_{i,j} - V_{j,i}\right)$ and that the plastic component of the deformation is much larger than the elastic part such that the latter can be neglected and the flow is incompressible. Under these assumptions, we can use small-strain kinematics to express the constitutive behavior as a relation between Cauchy stress and velocity gradient in the current configuration. Once the local velocity gradient field is obtained, the evolution of microstructure and micromechanical variables can be calculated by integrating the velocity gradient field in small time increments to explicitly update the current configuration of the material. Under this kinematic framework, the viscoplastic constitutive behavior at each material point $\mathbf{x}$ can be phenomenologically described by means of the following nonlinear, *rate-sensitive equation*:

$$
\begin{aligned}
\dot{\boldsymbol{\varepsilon}}(\mathbf{x}) = \sum_k \mathbf{m}^k(\mathbf{x}) \;\; \dot{\gamma}^k(\mathbf{x}) &= \dot{\gamma}_o \sum_k \mathbf{m}^k(\mathbf{x}) \left( \frac{\left| \mathbf{m}^k(\mathbf{x}) : \boldsymbol{\sigma}'(\mathbf{x}) \right|}{\tau_o^k(\mathbf{x})} \right)^n \\
&\times \operatorname{sgn}\left( \mathbf{m}^k(\mathbf{x}) : \boldsymbol{\sigma}'(\mathbf{x}) \right)
\end{aligned}
\tag{1}
$$

where $\tau_o^k$ is the threshold resolved shear stress of slip system (k); $m_{ij}^k = \frac{1}{2}\left(n_i^k b_j^k + n_j^k b_i^k\right)$ is the symmetric Schmid tensor associated with slip system (k), where $\mathbf{n}^k$ and $\mathbf{b}^k$ are the normal and Burgers vector direction of such slip system; and $\dot{\boldsymbol{\varepsilon}}$ and $\boldsymbol{\sigma}'$ are the deviatoric strain rate and stress. The local shear rate on slip system (k), $\dot{\gamma}^k$, is given by:

$$
\begin{aligned}
\dot{\gamma}^k(\mathbf{x}) = \dot{\gamma}_o \left( \frac{\left| \tau^k(\mathbf{x}) \right|}{\tau_o^k(\mathbf{x})} \right)^n \times \operatorname{sgn}\left( \tau^k(\mathbf{x}) \right) &= \dot{\gamma}_o \left( \frac{\left| \mathbf{m}^k(\mathbf{x}) : \boldsymbol{\sigma}'(\mathbf{x}) \right|}{\tau_o^k(\mathbf{x})} \right)^n \\
&\times \operatorname{sgn}\left( \mathbf{m}^k(\mathbf{x}) : \boldsymbol{\sigma}'(\mathbf{x}) \right)
\end{aligned}
\tag{2}
$$

where $\tau^k$ is the resolved shear stress on slip system (k), $\dot{\gamma}_o$ is a normalization factor, and the stress exponent $n$ is the inverse of the rate-sensitivity. If the shear rates are known, the lattice rotation rate or plastic spin associated with slip activity at single crystal material point $\mathbf{x}$ is given by:

$$-\dot{\boldsymbol{\omega}}^p(\mathbf{x}) = -\sum_k \boldsymbol{\alpha}^k(\mathbf{x}) \ \dot{\gamma}^k(\mathbf{x}) \tag{3}$$

where $\alpha_{ij}^k = \frac{1}{2}\left(n_i^k b_j^k - n_j^k b_i^k\right)$ is the antisymmetric Schmid tensor. Note that although Eqs. (1), (2), and (3) can be used to deal with crystal deforming by slip and twinning, in the examples that follows (in the context of both homogenization and full-field approaches), we will only consider crystal deformation by slip. In this way we avoid the additional complication of having to deal with twinning reorientation.

Let us assume that the following linear relations, which are approximations of the actual nonlinear relations, Eqs. (1) and (2), hold for the SR grain (r), i.e., for $\mathbf{x} \in \Omega^{(r)}$:

$$\dot{\boldsymbol{\varepsilon}}(\mathbf{x}) = \mathbf{M}^{(r)} : \boldsymbol{\sigma}'(\mathbf{x}) + \dot{\boldsymbol{\varepsilon}}^{o\,(r)} \tag{4}$$

$$\dot{\gamma}^k(\mathbf{x}) = \eta^{k(r)} \ \tau^k(\mathbf{x}) + \dot{g}^{ok(r)} \tag{5}$$

where the moduli $\mathbf{M}^{(r)}$ and $\dot{\boldsymbol{\varepsilon}}^{o\,(r)}$ are the compliance and back-extrapolated strain rate (strain rate under zero stress) of grain (r), respectively, and $\eta^{k(r)}$ and $\dot{g}^{ok(r)}$ are the slip-level compliance and back-extrapolated shear rate, respectively. Depending on the linearization assumption, the above moduli can be chosen differently. For example, under the first-order affine linearization, the moduli are given by:

$$\mathbf{M}^{(r)} = n\dot{\gamma}_o \sum_k \frac{\mathbf{m}^{k(r)} \otimes \ \mathbf{m}^{k(r)}}{\tau_o^{k(r)}} \left(\frac{\mathbf{m}^{k(r)} : \ \boldsymbol{\sigma}'^{(r)}}{\tau_o^{k(r)}}\right)^{n-1} \text{and} \quad \dot{\boldsymbol{\varepsilon}}^{o(r)} = (1-n) \ \dot{\boldsymbol{\varepsilon}}^{(r)} \tag{6}$$

$$\eta^{k(r)} = n\frac{\dot{\gamma}_o}{\tau_o^{k(r)}} \left(\frac{\tau^{k(r)}}{\tau_o^{k(r)}}\right)^{n-1} \text{and} \quad \dot{g}^{ok(r)} = (1-n) \ \dot{\gamma}^{k(r)} \tag{7}$$

where index (r) indicates average (first moment) of the field over SR grain (r). Following Hill (1965) and Hutchinson (1976), let us express the homogenized behavior of a linear heterogeneous medium whose local behavior is described by Eq. (4) assuming an analogous linear relation at the effective medium (macroscopic) level:

$$\dot{\mathbf{E}} = \overline{\mathbf{M}} : \boldsymbol{\Sigma}' + \dot{\mathbf{E}}^o \tag{8}$$

where $\dot{\mathbf{E}}$ and $\boldsymbol{\Sigma}'$ are the overall (macroscopic) deviatoric strain rate and stress tensors and $\overline{\mathbf{M}}$ and $\dot{\mathbf{E}}^o$ are, respectively, the viscoplastic compliance and back-extrapolated term of an a priori unknown homogeneous equivalent medium (HEM). The procedure followed to obtain this homogenized response is the linear self-consistent method. The problem underlying the self-consistent method is that of an

inhomogeneous domain (r) of moduli $\mathbf{M}^{(r)}$ and $\dot{\boldsymbol{\varepsilon}}^{o(r)}$, embedded in an infinite medium of moduli $\overline{\mathbf{M}}$ and $\dot{\mathbf{E}}^o$. Invoking the concept of the equivalent inclusion (Mura 1987), the local constitutive behavior in domain (r) can be rewritten as:

$$\dot{\boldsymbol{\varepsilon}}(\mathbf{x}) = \overline{\mathbf{M}} : \boldsymbol{\sigma}'(\mathbf{x}) + \dot{\mathbf{E}}^o + \dot{\boldsymbol{\varepsilon}}^*(\mathbf{x}) \tag{9}$$

where $\dot{\boldsymbol{\varepsilon}}^*(\mathbf{x})$ is an eigen-strain-rate field, which follows from replacing the inhomogeneity by an equivalent inclusion. Rearranging and subtracting Eq. (8) from Eq. (9) gives:

$$\tilde{\boldsymbol{\sigma}}'(\mathbf{x}) = \overline{\mathbf{L}} : \left( \dot{\tilde{\boldsymbol{\varepsilon}}}(\mathbf{x}) - \dot{\boldsymbol{\varepsilon}}^*(\mathbf{x}) \right) \tag{10}$$

The symbol "$\sim$" denotes local deviations from macroscopic values of the corresponding magnitudes, and $\overline{\mathbf{L}} = \overline{\mathbf{M}}^{-1}$. Combining Eq. (10) with the equilibrium condition gives:

$$\sigma_{ij,j}(\mathbf{x}) = \tilde{\sigma}_{ij,j}(\mathbf{x}) = \tilde{\sigma}'_{ij,j}(\mathbf{x}) + \tilde{\sigma}^m_{,i}(\mathbf{x}) \tag{11}$$

where $\sigma_{ij}$ and $\sigma^m$ are the Cauchy stress tensor and the mean stress, respectively. Using the relation $\dot{\tilde{\varepsilon}}_{ij}(\mathbf{x}) = \frac{1}{2}\left(\tilde{v}_{i,j}(\mathbf{x}) + \tilde{v}_{j,i}(\mathbf{x})\right)$ between the strain-rate and velocity gradient deviations, and adding the incompressibility condition associated with plastic deformation, we obtain:

$$\left| \begin{array}{l} \overline{L}_{ijkl} \ \tilde{v}_{k,lj}(\mathbf{x}) + \tilde{\sigma}^m_{,i}(\mathbf{x}) + \phi_{ij,j}(\mathbf{x}) = 0 \\ \tilde{v}_{k,k}(\mathbf{x}) = 0 \end{array} \right. \tag{12}$$

where:

$$\varphi_{ij}(\mathbf{x}) = -\overline{L}_{ijkl}\dot{\varepsilon}^*_{kl}(\mathbf{x}) \tag{13}$$

is a heterogeneity or *polarization field*, and its divergence $f_i(\mathbf{x}) = \varphi_{ij,j}(\mathbf{x})$ is an (artificial) external volumetric force field applied to the material. System (12) consists of four differential equations with four unknowns: three are the components of velocity deviation vector $\tilde{v}_i(\mathbf{x})$, and one is the mean stress deviation $\tilde{\sigma}^m(\mathbf{x})$. A system of N linear differential equations with N unknown functions and a polarization term can be solved using Green's function method. Let us call $G_{km}(\mathbf{x})$ and $H_m(\mathbf{x})$ Green's functions associated with $\tilde{v}_i(\mathbf{x})$ and $\tilde{\sigma}^m(\mathbf{x})$, respectively, which solve the auxiliary problem of a unitary volumetric force, with a single nonvanishing m-component:

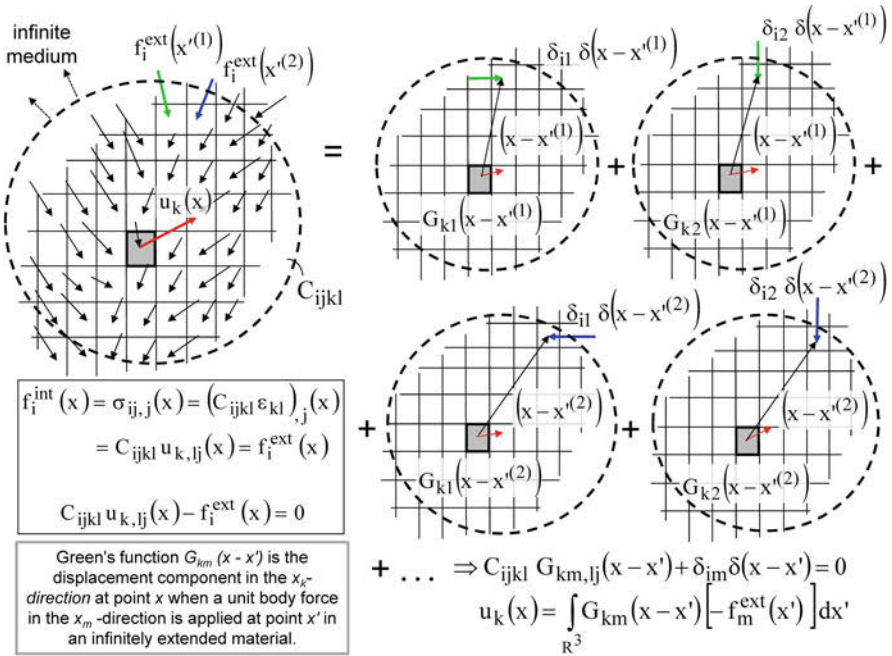
$$\left| \begin{array}{l} \overline{L}_{ijkl} \ G_{km,lj}\left(\mathbf{x} - \mathbf{x}'\right) + H_{m,i}\left(\mathbf{x} - \mathbf{x}'\right) + \delta_{im}\,\delta\left(\mathbf{x} - \mathbf{x}'\right) = 0 \\ G_{km,k}\left(\mathbf{x} - \mathbf{x}'\right) = 0 \end{array} \right. \tag{14}$$


**Fig. 1** Schematic illustration of Green's function associated with the displacement field of an elastic infinite medium. $G_{km}(\mathbf{x} - \mathbf{x}')$ is the component of the displacement in the $x_k$-direction at point $\mathbf{x}$ when a unit external force in the $x_m$-direction is applied at point $\mathbf{x}'$. Red arrows indicate displacement vectors at point $\mathbf{x}$ in reaction to external forces applied at different points $\mathbf{x}'$ indicated by black, green, and blue arrows

Green's function $G_{km}(\mathbf{x} - \mathbf{x}')$ is the local deviation in displacement (or velocity) component in the $x_k$-direction at point $\mathbf{x}$ when a unit body force in the $x_m$-direction is applied at point $\mathbf{x}'$ in an infinitely extended material. In the incompressible case of Eq. (14), $H_m(\mathbf{x} - \mathbf{x}')$ is the corresponding response in mean stress. For illustration, Fig. 1 shows a schematic explanation of Green's function of the displacement field $G_{km}(\mathbf{x} - \mathbf{x}')$ for an infinite (compressible) elastic medium.

Once the solution of Eq. (14) is obtained, the solution for the velocity field is given by the convolution integral:

$$\tilde{v}_k(\mathbf{x}) = \int_{R^3} G_{ki}(\mathbf{x} - \mathbf{x}') \; f_i(\mathbf{x}') \; d\mathbf{x}' = \int_{R^3} G_{ki}(\mathbf{x} - \mathbf{x}') \; \varphi_{ij,j}(\mathbf{x}') \; d\mathbf{x}' \qquad (15)$$

System (14) can be solved using Fourier transforms. Expressing Green's functions in terms of their inverse Fourier transforms, the differential system (14) can be transformed into an algebraic system:

$$\left|\begin{matrix} \alpha_j \ \alpha_l \ \overline{L}_{ijkl} \ k^2 \hat{G}_{km}(\boldsymbol{\xi}) + \alpha_i \ ik\hat{H}_m(\boldsymbol{\xi}) = \delta_{im} \\ \alpha_k \ k^2 \hat{G}_{km}(\boldsymbol{\xi}) = 0 \end{matrix}\right. \tag{16}$$

where k and $\boldsymbol{\alpha}$ are the modulus and the unit vector associated with a point of Fourier space $\boldsymbol{\xi} = k\boldsymbol{\alpha}$, respectively. Solving system (16) (see Lebensohn et al. 2007) one obtains:

$$k^2 \hat{G}_{ij}(\boldsymbol{\xi}) = A_{ij}^{-1}(\boldsymbol{\alpha}) \tag{17}$$

where $A_{ik}'(\boldsymbol{\alpha}) = \alpha_j \ \alpha_l \ \overline{L}_{ijkl}$ and

$$A(\boldsymbol{\alpha}) \quad = \quad \begin{vmatrix} A_{11}' & A_{12}' & A_{13}' & \alpha_1 \\ A_{21}' & A_{22}' & A_{23}' & \alpha_2 \\ A_{31}' & A_{32}' & A_{33}' & \alpha_3 \\ \alpha_1 & \alpha_2 & \alpha_3 & 0 \end{vmatrix} \tag{18}$$

Knowing Green's function expression in Fourier space, we can write the solution of the eigen-strain-rate problem using convolution integrals. Taking partial derivatives to Eq. (15) and after some manipulation (see Lebensohn et al. 2007; Mura 1987), we obtain:

$$\tilde{v}_{k,l}(\mathbf{x}) = \int_{R^3} G_{ki,jl}(\mathbf{x} - \mathbf{x}') \ \varphi_{ij}(\mathbf{x}') \ d\mathbf{x}' \tag{19}$$

The integral Eq. (19) provides an exact implicit solution to the problem. Furthermore, it is known from Eshelby's elastic inclusion formalism that if the eigen-strain is uniform over an ellipsoidal domain where the stiffness tensor is uniform, then the stress and strain are constant over the domain of the inclusion (r). The latter suggests the use of an a priori unknown constant polarization within the volume $\Omega$ of the ellipsoidal inclusion. This allows us to average the local field (19) over the domain $\Omega$ and obtain an average strain rate inside the inclusion of the form:

$$\tilde{v}_{k,l}^{(r)} = T_{klij} \ \overline{L}_{ijmn} \ \dot{\varepsilon}_{mn}^{*(r)} \tag{20}$$

where $T_{klij}$ is an integral of Green's function over domain $\Omega$. For an ellipsoidal inclusion of radii (a,b,c) (see Berveiller et al. 1987; Lebensohn et al. 2007 for details), $T_{klij}$ can be reduced to:

$$T_{klij} = \frac{abc}{4\pi} \int_0^{2\pi} \int_0^{\pi} \frac{\alpha_j \ \alpha_l \ A_{ki}^{-1}(\boldsymbol{\alpha})}{[\rho(\boldsymbol{\alpha})]^3} \sin\theta \ d\theta \ d\varphi \tag{21}$$

where $\rho(\boldsymbol{\alpha}) = [\ (a\alpha_1)^2 + (b\alpha_2)^2 + (c\alpha_3)^2]^{1/2}$. The symmetric and antisymmetric Eshelby tensors (functions of $\overline{L}$ and the shape of the ellipsoidal inclusion, representing the morphology of the SR grains) are defined as:

$$S_{ijkl} = \frac{1}{4}\left(T_{ijmn} + T_{jimn} + T_{ijnm} + T_{jinm}\right)\ \overline{L}_{mnkl} \tag{22a}$$

$$\Pi_{ijkl} = \frac{1}{4}\left(T_{ijmn} - T_{jimn} + T_{ijnm} - T_{jinm}\right)\ \overline{L}_{mnkl} \tag{22b}$$

Taking symmetric and antisymmetric components to Eq. (19) and using Eqs. (22), we obtain the average strain-rate and rotation rate deviations in the ellipsoidal domain:

$$\tilde{\dot{\boldsymbol{\varepsilon}}}^{(r)} = \mathbf{S} : \dot{\boldsymbol{\varepsilon}}^{*(r)} \tag{23}$$

$$\tilde{\dot{\boldsymbol{\omega}}}^{(r)} = \boldsymbol{\Pi} : \dot{\boldsymbol{\varepsilon}}^{*(r)} = \boldsymbol{\Pi} : \mathbf{S}^{-1} : \tilde{\dot{\boldsymbol{\varepsilon}}}^{(r)} \tag{24}$$

where $\tilde{\dot{\boldsymbol{\varepsilon}}}^{(r)} = \dot{\mathbf{E}} - \dot{\boldsymbol{\varepsilon}}^{(r)}$ and $\tilde{\dot{\boldsymbol{\omega}}}^{(r)} = \dot{\boldsymbol{\Omega}} - \dot{\boldsymbol{\omega}}^{(r)}$ are deviations of the average strain rate and rotation rate inside the inclusion, with respect to the corresponding overall magnitudes, and $\dot{\boldsymbol{\varepsilon}}^{*(r)}$ is the average eigen-strain rate in the inclusion. Therefore, the lattice rotation rate field is given by:

$$\dot{\boldsymbol{\omega}}\ (\mathbf{x}) = \dot{\boldsymbol{\Omega}} + \tilde{\dot{\boldsymbol{\omega}}}^{(r)} - \dot{\boldsymbol{\omega}}^p\ (\mathbf{x}) \tag{25}$$

### 2.1.2   Interaction and Localization Equations

Taking volume averages over the domain of the inclusion on both sides of Eq. (10) gives:

$$\tilde{\boldsymbol{\sigma}}'^{(r)} = \overline{\mathbf{L}} : \left(\tilde{\dot{\boldsymbol{\varepsilon}}}^{(r)} - \dot{\boldsymbol{\varepsilon}}^{*(r)}\right) \tag{26}$$

Replacing the eigen-strain rate given by Eq. (23) into Eq. (26), we obtain the *interaction equation*:

$$\tilde{\dot{\boldsymbol{\varepsilon}}}^{(r)} = -\tilde{\mathbf{M}} : \tilde{\boldsymbol{\sigma}}'^{(r)} \tag{27}$$

where the interaction tensor is given by:

$$\tilde{\mathbf{M}} = (\mathbf{I} - \mathbf{S})^{-1} : \mathbf{S} : \overline{\mathbf{M}} \tag{28}$$

Replacing the constitutive relations of the inclusion and the effective medium in the interaction equation and after some manipulation, one can write the following *localization equation*:

$$\boldsymbol{\sigma}'^{(r)} = \mathbf{B}^{(r)} : \boldsymbol{\Sigma}' + \mathbf{b}^{(r)} \tag{29}$$

where the localization tensors are defined as:

$$\mathbf{B}^{(r)} = \left(\mathbf{M}^{(r)} + \tilde{\mathbf{M}}\right)^{-1} : \left(\overline{\mathbf{M}} + \tilde{\mathbf{M}}\right) \quad \text{and} \quad \mathbf{b}^{(r)} = \left(\mathbf{M}^{(r)} + \tilde{\mathbf{M}}\right)^{-1} : \left(\dot{\mathbf{E}}^{o} - \dot{\boldsymbol{\varepsilon}}^{o(r)}\right) \tag{30}$$

### 2.1.3   Self-Consistent Equations

The derivation presented in the previous sections solves the problem of an equivalent inclusion embedded in an effective medium. In this section, we use the previous result to construct a polycrystal model, consisting in regarding each SR grain (r) as an inclusion embedded in an effective medium that represents the polycrystal. The properties of such medium are not known a priori but have to be found through an iterative procedure. Replacing the stress localization equation (Eq. 29) in the local constitutive equation (Eq. 4) averaged over the SR grain (r), we obtain:

$$\dot{\boldsymbol{\varepsilon}}^{(r)} = \mathbf{M}^{(r)} : \mathbf{B}^{(r)} : \boldsymbol{\Sigma} + \mathbf{M}^{(r)} : \mathbf{b}^{(r)} + \dot{\boldsymbol{\varepsilon}}^{o(r)} \tag{31}$$

Taking volumetric average to Eq. (31), enforcing the condition that the average of the strain rates over the aggregate has to coincide with the macroscopic quantities, i.e.:

$$\dot{\mathbf{E}} = \left\langle \dot{\boldsymbol{\varepsilon}}^{(r)} \right\rangle \tag{32}$$

(where the brackets "$\langle\rangle$" denote average over the SR grains, weighted by the associated volume fraction), and using the macroscopic constitutive relation (Eq. 8), we obtain the following *self-consistent equations* for the HEM's compliance and back-extrapolated term:

$$\overline{\mathbf{M}} = \left\langle \mathbf{M}^{(r)} : \mathbf{B}^{(r)} \right\rangle \tag{33}$$

$$\dot{\mathbf{E}}^{o} = \left\langle \mathbf{M}^{(r)} : \mathbf{b}^{(r)} + \dot{\boldsymbol{\varepsilon}}^{o(r)} \right\rangle \tag{34}$$

### 2.1.4   Fluctuations Calculation

The methodology to obtain average fluctuations of the stress distributions in homogeneous domains of heterogeneous media was originally derived by Bobeth and

Diener ([1987](#)), Kreher ([1990](#)), and Parton and Buryachenko ([1990](#)) for composites and extended by Lebensohn et al. ([2007](#)) for polycrystals. The effective stress potential $\overline{U}_T$ of a linearly viscous polycrystal described by Eq. ([8](#)) may be written in the form (Laws [1973](#)):

$$\overline{U}_T = \frac{1}{2}\overline{\mathbf{M}} :: \left(\mathbf{\Sigma}' \otimes \mathbf{\Sigma}'\right) + \dot{\mathbf{E}}^o : \mathbf{\Sigma}' + \frac{1}{2}\overline{G} \tag{35}$$

where $\overline{G}$ is the power under zero applied stress. Let us rewrite the self-consistent expression for $\overline{\mathbf{M}}$ and $\dot{\mathbf{E}}^o$ (Eqs. [33](#) and [34](#)) as:

$$\overline{\mathbf{M}} = \left\langle \mathbf{M}^{(r)} : \mathbf{B}^{(r)} \right\rangle = \sum_r c^{(r)} \ \mathbf{M}^{(r)} : \mathbf{B}^{(r)} \tag{36}$$

$$\dot{\mathbf{E}}^o = \left\langle \mathbf{M}^{(r)} : \mathbf{b}^{(r)} + \dot{\mathbf{\varepsilon}}^{o\ (r)} \right\rangle = \sum_r c^{(r)} \ \left( \mathbf{M}^{(r)} : \mathbf{b}^{(r)} + \dot{\mathbf{\varepsilon}}^{o\ (r)} \right) \tag{37}$$

where $c^{(r)}$ is the volume fraction associated with SR grain (r). The corresponding expression for $\overline{G}$ is:

$$\overline{G} = \sum_r c^{(r)} \ \dot{\mathbf{\varepsilon}}^{o\ (r)} : \mathbf{b}^{(r)} \tag{38}$$

The second moment of the stress field over a SR grain (r) of this polycrystal is a fourth-rank tensor given by:

$$\left\langle \mathbf{\sigma}' \otimes \mathbf{\sigma}' \right\rangle^{(r)} = \frac{2}{c^{(r)}} \frac{\partial \overline{U}_T}{\partial \mathbf{M}^{(r)}} \tag{39}$$

Replacing Eqs. ([35](#)), ([36](#)), ([37](#)), and ([38](#)) in ([39](#)), we obtain:

$$\left\langle \mathbf{\sigma}' \otimes \mathbf{\sigma}' \right\rangle^{(r)} = \frac{1}{c^{(r)}} \frac{\partial \overline{\mathbf{M}}}{\partial \mathbf{M}^{(r)}} :: \left(\mathbf{\Sigma}' \otimes \mathbf{\Sigma}'\right) + \frac{1}{c^{(r)}} \frac{\partial \dot{\mathbf{E}}^o}{\partial \mathbf{M}^{(r)}} : \mathbf{\Sigma}' + \frac{1}{c^{(r)}} \frac{\partial \overline{G}}{\partial \mathbf{M}^{(r)}} \tag{40}$$

The algorithmic expressions to calculate the partial derivatives on the right-hand side are given in Lebensohn et al. ([2007](#)). These average stress fluctuations in the grains are necessary for (a) the formulation of the more accurate second-order approximation (Liu and Ponte Castañeda [2004](#)) to linearize the behavior of the SR grains (see Lebensohn et al. [2007](#) for details of its implementation in VPSC) and (b) the calculation based on strictly micromechanical arguments of intragranular misorientations, for further improved prediction of microstructure evolution (Lebensohn et al. [2016](#)). In connection with the latter, the second moment of the plastic spin field in SR grain (r) is given by:

$$\langle \dot{\boldsymbol{\omega}}^{\mathrm{p}} \otimes \dot{\boldsymbol{\omega}}^{\mathrm{p}} \rangle^{(\mathrm{r})} = \left\langle \left( \sum_{\mathrm{k}} \boldsymbol{\alpha}^{\mathrm{k}}(\mathbf{x}) \; \dot{\gamma}^{\mathrm{k}}(\mathbf{x}) \right) \otimes \left( \sum_{\mathrm{k}} \boldsymbol{\alpha}^{\mathrm{k}}(\mathbf{x}) \; \dot{\gamma}^{\mathrm{k}}(\mathbf{x}) \right) \right\rangle^{(\mathrm{r})} \tag{41}$$

Assuming crystal orientation is uniform inside grain (r):

$$\langle \dot{\boldsymbol{\omega}}^{\mathrm{p}} \otimes \dot{\boldsymbol{\omega}}^{\mathrm{p}} \rangle^{(\mathrm{r})} = \sum_{\mathrm{k},\mathrm{k}'} \left( \boldsymbol{\alpha}^{\mathrm{k}(\mathrm{r})} \otimes \boldsymbol{\alpha}^{\mathrm{k}'(\mathrm{r})} \right) \left\langle \dot{\gamma}^{\mathrm{k}} \; \dot{\gamma}^{\mathrm{k}'} \right\rangle^{(\mathrm{r})} \tag{42}$$

Using the linearized expression for the shear rates (Eq. 5), the above can be expressed in terms of the second moment of the stress field $\langle \boldsymbol{\sigma}' \otimes \boldsymbol{\sigma}' \rangle^{(\mathrm{r})}$ (Eq. 40) as (Lebensohn et al. 2016):

$$\begin{aligned}
\langle \dot{\boldsymbol{\omega}}^{\mathrm{p}} \otimes \dot{\boldsymbol{\omega}}^{\mathrm{p}} \rangle^{(\mathrm{r})} = & \left\{ \sum_{\mathrm{k},\mathrm{k}'} \left( \eta^{\mathrm{k}(\mathrm{r})} \eta^{\mathrm{k}'(\mathrm{r})} \right) \left( \boldsymbol{\alpha}^{\mathrm{k}(\mathrm{r})} \otimes \boldsymbol{\alpha}^{\mathrm{k}'(\mathrm{r})} \right) \otimes \left( \mathbf{m}^{k(\mathrm{r})} \otimes \mathbf{m}^{\mathrm{k}'(\mathrm{r})} \right) \right\} :: \langle \boldsymbol{\sigma}' \otimes \boldsymbol{\sigma}' \rangle^{(\mathrm{r})} \\
& + \left\{ \sum_{\mathrm{k},\mathrm{k}'} \left( \boldsymbol{\alpha}^{\mathrm{k}(\mathrm{r})} \otimes \boldsymbol{\alpha}^{\mathrm{k}'(\mathrm{r})} \right) \otimes \left[ \left( \eta^{\mathrm{k}(\mathrm{r})} \dot{\mathrm{g}}^{\mathrm{ok}'(\mathrm{r})} \right) \mathbf{m}^{\mathrm{k}(\mathrm{r})} + \left( \eta^{\mathrm{k}'(\mathrm{r})} \dot{\mathrm{g}}^{\mathrm{ok}(\mathrm{r})} \right) \mathbf{m}^{\mathrm{k}'(\mathrm{r})} \right] \right\} : \langle \boldsymbol{\sigma}' \rangle^{(\mathrm{r})} \\
& + \sum_{\mathrm{k},\mathrm{k}'} \left( \boldsymbol{\alpha}^{\mathrm{k}(\mathrm{r})} \otimes \boldsymbol{\alpha}^{\mathrm{k}'(\mathrm{r})} \right) \left( \dot{\mathrm{g}}^{\mathrm{ok}(\mathrm{r})} \dot{\mathrm{g}}^{\mathrm{ok}'(\mathrm{r})} \right)
\end{aligned} \tag{43}$$

For spherical inclusions/equiaxed SR grains, $\boldsymbol{\Pi} = \mathbf{0} \Rightarrow \tilde{\dot{\boldsymbol{\omega}}}^{(\mathrm{r})} = \mathbf{0}$ (see Eq. 24), and, therefore:

$$\langle \dot{\boldsymbol{\omega}} \otimes \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} = \langle \dot{\boldsymbol{\omega}}^{\mathrm{p}} \otimes \dot{\boldsymbol{\omega}}^{\mathrm{p}} \rangle^{(\mathrm{r})} \tag{44}$$

The covariance of the lattice rotation rate fluctuations is obtained as:

$$\left\langle \left( \dot{\boldsymbol{\omega}} - \langle \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} \right) \otimes \left( \dot{\boldsymbol{\omega}} - \langle \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} \right) \right\rangle^{(\mathrm{r})} = \langle \dot{\boldsymbol{\omega}} \otimes \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} - \langle \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} \otimes \langle \dot{\boldsymbol{\omega}} \rangle^{(\mathrm{r})} \tag{45}$$

Representing the antisymmetric rotation rate tensors as the corresponding pseudo-vectors, the above covariance can be expressed as a symmetric matrix. Diagonalization of such covariance matrix gives an orthonormal basis of eigenvectors $(\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3)$ and three associated eigenvalues: $\dot{\Omega}_1^{(\mathrm{r})} \geq \dot{\Omega}_2^{(\mathrm{r})} \geq \dot{\Omega}_3^{(\mathrm{r})}$. The square root of these eigenvalues:

$$\mathrm{SD}_{\mathrm{i}}^{(\mathrm{r})}(\dot{\boldsymbol{\omega}}) = \sqrt{\dot{\Omega}_{\mathrm{i}}^{(\mathrm{r})}} \quad (\mathrm{i} = 1, 2, 3) \tag{46}$$

are measures of the standard deviation of the rotation rate distribution along the rotation axes given by the corresponding eigenvectors. A scalar magnitude of the

rate at which intragranular orientations are spreading is given by the geometric mean of these SDs:

$$SD^{(r)}(\dot{\omega}) = \sqrt[3]{SD_1^{(r)}(\dot{\omega}) \times SD_2^{(r)}(\dot{\omega}) \times SD_3^{(r)}(\dot{\omega})} \qquad (47)$$

### 2.1.5 Numerical Implementation

To illustrate the practical use of the VPSC formulation, we describe here the steps required to predict the local and overall viscoplastic response of a polycrystal. Figure 2 shows the corresponding flow chart. Starting for convenience with an initial Taylor guess, i.e., $\dot{\varepsilon}^{(r)} = \dot{E}$, for all grains, we solve the following nonlinear equation to get $\sigma'^{(r)}$:

$$\dot{E} = \dot{\gamma}_o \sum_k \mathbf{m}^{k(r)} \left( \frac{\left| \mathbf{m}^{k(r)} : \sigma'^{(r)} \right|}{\tau_o^{k(r)}} \right)^n \times \mathrm{sgn}\left( \mathbf{m}^{k(r)} : \sigma'^{(r)} \right) \qquad (48)$$

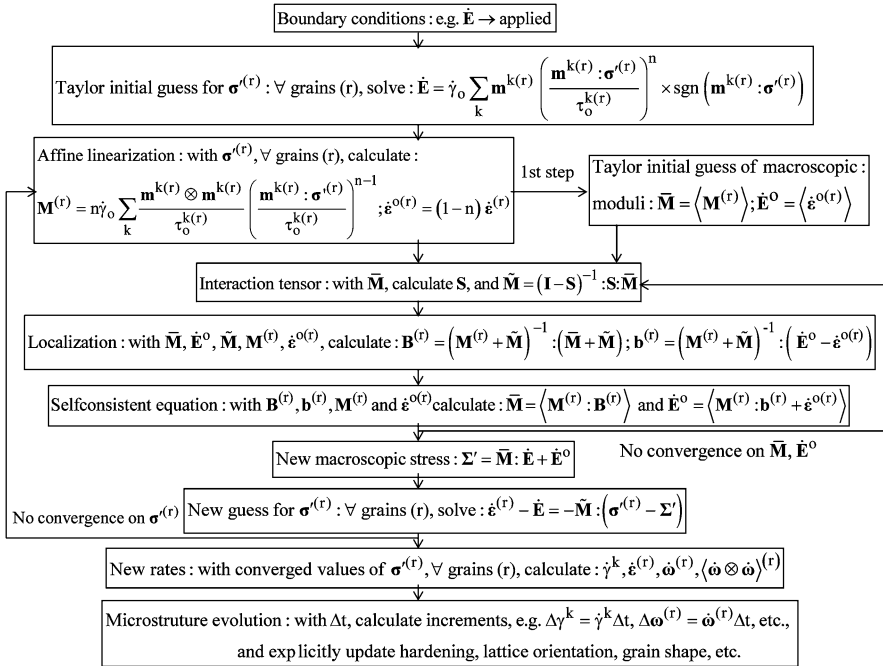

**Fig. 2** Flow chart of the numerical implementation of the VPSC formulation to predict microstructure evolution. The red arrows correspond to the two iterative loops necessary to satisfy self-consistency of the macroscopic moduli and the grain stresses

and we use an appropriate first-order linearization scheme to obtain initial values of $\mathbf{M}^{(\mathrm{r})}$ *and* $\dot{\boldsymbol{\varepsilon}}^{\mathrm{o}(\mathrm{r})}$, for each SR grain (r). Next, initial guesses for the macroscopic moduli $\overline{\mathbf{M}}$ and $\dot{\mathbf{E}}^{\mathrm{o}}$ are obtained (usually as simple averages of the local moduli). With them and the applied strain rate, the initial guess for the macroscopic stress $\boldsymbol{\Sigma}'$ can be obtained, while the Eshelby tensors $\mathbf{S}$ and $\boldsymbol{\Pi}$ can be calculated using the macroscopic moduli and the ellipsoidal shape of the SR grains, by means of the procedure described in Sect. 2.1.1. Subsequently, the interaction tensor $\tilde{\mathbf{M}}$ (Eq. 28), and the localization tensors $\mathbf{B}^{(\mathrm{r})}$ and $\mathbf{b}^{(\mathrm{r})}$ (Eq. 30), can be calculated as well. With these tensors, new estimates of $\overline{\mathbf{M}}$ and $\dot{\mathbf{E}}^{\mathrm{o}}$ are obtained, by solving iteratively the self-consistent equations (Eqs. 33 and 34). After achieving convergence on the macroscopic moduli (and, consequently, also on the macroscopic stress and the interaction and localization tensors), a new estimation of the grain stresses can be obtained, using the localization relation (Eq. 29). If the recalculated grain stresses are different (within certain tolerance) from the input values, a new iteration should be started, until convergence is reached. When the iterative procedure is completed and the grain stresses have converged, the average shear rates on each slip system are obtained using Eq. (2), and the lattice rotation rates associated with each SR grain can be calculated with the latter and Eqs. (3) and (24) and (25) averaged over the domain of each grain (r). With these rates, the above numerical scheme can be used to predict microstructure evolution, by applying viscoplastic deformation to the polycrystal in incremental steps. The latter is done explicitly, assuming constant rates during a time interval $\Delta$t (such that $\dot{\mathbf{E}}$ $\Delta t$ corresponds to a macroscopic strain increment of 1%) and using (a) lattice rotation rates (Eq. 25) (times $\Delta t$) to update crystallographic orientation of each SR grain (r) (this can be done using the average values of the latter or accounting for average rotation rate fluctuations, Zecevic et al. 2017), (b) the strain rates $\dot{\mathbf{E}} - \tilde{\dot{\boldsymbol{\varepsilon}}}^{(\mathrm{r})}$ and rigid body rotation rates $\dot{\boldsymbol{\Omega}} + \tilde{\dot{\boldsymbol{\omega}}}^{(\mathrm{r})}$ (times $\Delta t$) to update the shape and orientation of the ellipsoid representing each SR grain (r) (or, for a more efficient computation, the fluctuation terms can be neglected, keeping track of the average stretching of the grains only), and (c) the shear rates (times $\Delta t$) to update the critical stress of the deformation systems due to strain hardening, after each deformation increment.

## 2.2 VPFFT Model

The FFT-based full-field formulation for viscoplastic polycrystals is conceived for periodic unit cells, provides an "exact" solution (within the limitations imposed by the unavoidable discretization of the problem and the iterative character of the numerical algorithm, see below) of the governing equations, and has better numerical performance than a standard FE calculation for the same purpose and resolution. It was originally developed (Moulinec and Suquet 1994, 1998; Michel et al. 2000) as a fast algorithm to compute the elastic and elastoplastic effective and local response of composites and later adapted (Lebensohn 2001; Lebensohn et al. 2008) to deal with the viscoplastic deformation of polycrystals.

Briefly, the viscoplastic FFT-based formulation consists in iteratively adjusting a compatible strain-rate field, related with an equilibrated stress field through a constitutive potential, such that the average of local work-rates is minimized. The method is based on the fact that the local mechanical response of a heterogeneous medium can be calculated as a convolution integral between Green's functions associated with appropriate fields of a linear reference homogeneous medium and the actual heterogeneity field. For a periodic medium, the use can be made of the Fourier transform to reduce convolution integrals in real space to simple products in Fourier space. Thus, the FFT algorithm can be utilized to transform the heterogeneity field into Fourier space and, in turn, to get the mechanical fields by transforming that product back to real space. However, the actual heterogeneity field depends precisely on the a priori unknown mechanical fields. Therefore, an iterative scheme has to be implemented to obtain, upon convergence, a compatible strain-rate field and a stress field in equilibrium.

### 2.2.1  Periodic Unit Cell: Green Function Method

A periodic unit cell representing the polycrystal is discretized into $N_1 \times N_2 \times N_3$ Fourier points. This discretization determines a regular grid in the Cartesian space $\{\mathbf{x^d}\}$ and a corresponding grid in Fourier space $\{\boldsymbol{\xi^d}\}$. Velocities and tractions along the boundary of the unit cell are left undetermined. A velocity gradient $V_{i,j}$ (which can be decomposed into a symmetric strain rate and an antisymmetric rotation rate: $V_{i,j} = \dot{E}_{ij} + \dot{\Omega}_{ij}$) is imposed to the unit cell. The local strain-rate field is a function of the local velocity field, i.e., $\dot{\varepsilon}_{ij}(v_k(\mathbf{x}))$, and can be split into its average and a fluctuation term: $\dot{\varepsilon}_{ij}(v_k(\mathbf{x})) = \dot{E}_{ij} + \dot{\tilde{\varepsilon}}_{ij}(\tilde{v}_k(\mathbf{x}))$, where $v_i(\mathbf{x}) = \dot{E}_{ij}x_j + \tilde{v}_i(\mathbf{x})$. By imposing periodic boundary conditions, the velocity fluctuation field $\tilde{v}_k(\mathbf{x})$ is assumed to be periodic across the boundary of the unit cell, while the traction field is antiperiodic, to meet equilibrium on the boundary between contiguous unit cells.

The local constitutive relation between the strain rate $\dot{\varepsilon}_{ij}(\mathbf{x})$ and the deviatoric stress $\sigma'_{ij}(\mathbf{x})$ is given by the same rate-sensitivity relation used within the VPSC framework (Eq. 1). Let us choose a fourth-order tensor $L^o$ to be the stiffness of a linear reference medium (the choice $L^o$ of can be quite arbitrary, but the speed of convergence of the method will depend on this choice) and define the polarization field $\varphi_{ij}(\mathbf{x})$ (c.f. Eq. 13) as:

$$\varphi_{ij}(\mathbf{x}) = \tilde{\sigma}'_{ij}(\mathbf{x}) - L^o_{ijkl}\,\dot{\tilde{\varepsilon}}_{kl}(\mathbf{x}) \tag{49}$$

Then, the Cauchy stress deviation can be written as:

$$\tilde{\sigma}_{ij}(\mathbf{x}) = L^o_{ijkl}\dot{\tilde{\varepsilon}}_{kl}(\mathbf{x}) + \varphi_{ij}(\mathbf{x}) + \tilde{\sigma}^m(\mathbf{x})\,\delta_{ij} \tag{50}$$

Combining Eq. (50) with the equilibrium $\left(\sigma_{ij,j}(\mathbf{x}) = \tilde{\sigma}_{ij,j}(\mathbf{x}) = 0\right)$, the incompressibility condition, and the relation: $\dot{\tilde{\varepsilon}}_{ij}(\mathbf{x}) = \frac{1}{2}\left(\tilde{v}_{i,j}(\mathbf{x}) + \tilde{v}_{j,i}(\mathbf{x})\right)$

$$\left|\begin{array}{l} L^o_{ijkl}\tilde{v}_{k,lj}(\mathbf{x}) + \tilde{\sigma}^m_{,i}(\mathbf{x}) + \varphi_{ij,j}(\mathbf{x}) = 0 \\ \tilde{v}_{k,k}(\mathbf{x}) = 0 \end{array}\right. \tag{51}$$

This system of differential equations is formally equivalent to system (12). However, both systems actually differ in that (a) the HEM's stiffness modulus $\bar{L}$ of Eq. (12) is replaced in Eq. (51) by the stiffness of a linear reference medium $L^o$ and (b) the polarization field in Eq. (51) has in general nonvanishing values throughout the unit cell and is periodic (owing to the unit cell's periodicity), while the polarization field in Eq. (12) vanishes outside the domain of the inclusion. The auxiliary system involving periodic Green functions is then given by (c.f. Eq. 18):

$$\left|\begin{array}{l} L^o_{ijkl}\ G_{km,lj}\ (\mathbf{x} - \mathbf{x}') + H_{m,i}\ (\mathbf{x} - \mathbf{x}') + \delta_{im}\ \delta(\mathbf{x} - \mathbf{x}') = 0 \\ G_{km,k}(\mathbf{x} - \mathbf{x}') = 0 \end{array}\right. \tag{52}$$

After some manipulation, the convolution integral that gives the velocity gradient deviation field is:

$$\tilde{v}_{i,j}(\mathbf{x}) = \int_{R^3} G_{ik,jl}(\mathbf{x} - \mathbf{x}')\,\varphi_{kl}(\mathbf{x}')\,d\mathbf{x}' \tag{53}$$

Convolution integrals in direct space are simply products in Fourier space:

$$\hat{\tilde{v}}_{i,j}(\boldsymbol{\xi}) = \hat{\Gamma}_{ijkl}(\boldsymbol{\xi})\ \hat{\varphi}_{kl}(\boldsymbol{\xi}) \tag{54}$$

where the symbol "$\wedge$" indicates a Fourier transform. The Green operator in Eq. (54) is defined as $\Gamma_{ijkl} = G_{ik,jl}$. The tensors $\hat{G}_{ij}(\boldsymbol{\xi})$ and $\hat{\Gamma}_{ijkl}(\boldsymbol{\xi})$ can be calculated by taking Fourier transform to system (52):

$$\left|\begin{array}{l} \xi_l\xi_j\ L^o_{ijkl}\hat{G}_{km}(\boldsymbol{\xi}) + i\xi_i\hat{H}_m(\boldsymbol{\xi}) = \delta_{im} \\ \xi_k\hat{G}_{km}(\boldsymbol{\xi}) = 0 \end{array}\right. \tag{55}$$

Defining the $3 \times 3$ matrix $A'_{ik}(\boldsymbol{\xi}) = \xi_l\xi_j L^o_{ijkl}$, and the $4 \times 4$ matrix $A(\boldsymbol{\xi})$:

$$\mathbf{A}(\boldsymbol{\xi}) = \begin{vmatrix} A'_{11} & A'_{12} & A'_{13} & \xi_1 \\ A'_{21} & A'_{22} & A'_{23} & \xi_2 \\ A'_{31} & A'_{32} & A'_{33} & \xi_3 \\ \xi_1 & \xi_2 & \xi_3 & 0 \end{vmatrix} \tag{56}$$

we obtain from Eq. (57) (c.f. Eqs. 17–18):

$$\hat{G}_{ij}(\boldsymbol{\xi}) = A^{-1}_{ij}\ (i,j = 1,3) \quad \text{and} \quad \hat{\Gamma}_{ijkl}(\boldsymbol{\xi}) = -\xi_j\xi_l\hat{G}_{ik}(\boldsymbol{\xi}) \tag{57}$$

### 2.2.2 FFT-Based Algorithm

Assigning initial guess values to the strain-rate field in the regular grid $\{\mathbf{x^d}\}$ (e.g., $\tilde{\dot{\varepsilon}}_{ij}^{o}\left(\mathbf{x^d}\right) = 0 \Rightarrow \dot{\varepsilon}_{ij}^{o}\left(\mathbf{x^d}\right) = \dot{E}_{ij}$) and computing the corresponding stress field $\sigma_{ij}^{\prime o}\left(\mathbf{x^d}\right)$ from the local constitutive relation (Eq. 1), which requires to know the initial values of the critical stresses $\tau_{o}^{s}\left(\mathbf{x^d}\right)$ (these can be assumed, e.g., to have an uniform value $\forall\mathbf{x^d}$, adjusted to reproduce the initial macroscopic yield stress of the polycrystal) and the Schmid tensors $m_{ij}^{s}\left(\mathbf{x^d}\right)$, e.g., from an orientation image, in which the image's pixels coincide with the Fourier grid), allow us to obtain an initial guess for the polarization field in direct space $\varphi_{ij}^{o}\left(\mathbf{x^d}\right)$ (Eq. 49), which in turn can be Fourier-transformed to obtain $\hat{\varphi}_{ij}^{o}\left(\mathbf{\xi^d}\right)$. Furthermore, assuming that $\lambda_{ij}^{o}\left(\mathbf{x^d}\right) = \sigma_{ij}^{o}\left(\mathbf{x^d}\right)$ is the initial guess for a field of Lagrange multipliers associated with the compatibility constraints, the iterative procedure based on augmented Lagrangians proposed by Michel et al. (2000) reads as follows. With the polarization field after iteration $n$ being known, the $n + 1$-th iteration starts by computing the new guess for the kinematically admissible strain-rate deviation field:

$$\hat{\dot{d}}_{ij}^{n+1}\left(\mathbf{\xi^d}\right) = -\hat{\Gamma}_{ijkl}^{sym}\left(\xi^d\right) \ \hat{\phi}_{kl}^{n}\left(\xi^d\right), \quad \forall\xi^d \neq \mathbf{0}; \quad \text{and} \quad \hat{\dot{d}}_{ij}^{n+1}\left(\mathbf{0}\right) = 0 \qquad (58)$$

where $\hat{\Gamma}_{ijkl}^{sym}$ is the Green operator, appropriately symmetrized. The corresponding field in real space is thus obtained by application of the inverse FFT, i.e.:

$$\tilde{d}_{ij}^{n+1}\left(\mathbf{x^d}\right) = \text{fft}^{-1}\left\{\hat{\dot{d}}_{ij}^{n+1}\left(\mathbf{\xi^d}\right)\right\} \qquad (59)$$

and the new guess for the deviatoric stress field is calculated from (omitting subindices):

$$\sigma^{\prime n+1}\left(\mathbf{x^d}\right) + \ \mathbf{L}^{o} : \dot{\gamma}_{o}\sum_{k}\mathbf{m}^{k}\left(\mathbf{x^d}\right) \ \left(\frac{\left|\mathbf{m}^{k}(\mathbf{x^d}):\sigma^{\prime n+1}(\mathbf{x^d})\right|}{\tau^{k}(\mathbf{x^d})}\right)^{n}$$
$$\times \text{sgn}\left(\mathbf{m}^{k}\left(\mathbf{x^d}\right) : \sigma^{\prime n+1}\left(\mathbf{x^d}\right)\right) = \lambda^{n}\left(\mathbf{x^d}\right) + \mathbf{L}^{o} : \left(\dot{\mathbf{E}} + \tilde{\mathbf{d}}^{n+1}\left(\mathbf{x^d}\right)\right) \qquad (60)$$

The iteration is completed with the calculation of the new guess of the Lagrange multiplier field:

$$\lambda^{n+1}\left(\mathbf{x^d}\right) = \lambda^{n}\left(\mathbf{x^d}\right) + \mathbf{L}^{o} : \left(\tilde{\dot{\varepsilon}}^{n+1}\left(\mathbf{x^d}\right) - \tilde{\mathbf{d}}^{n+1}\left(\mathbf{x^d}\right)\right) \qquad (61)$$

Equations (61) and (62) guarantee the convergence of $\dot{\varepsilon}\left(\mathbf{x^d}\right)$ (i.e., the strain-rate field related with the stress through the constitutive equation) toward $\mathbf{d}(\mathbf{x^d})$ (i.e., the kinematically admissible strain-rate field) to fulfill compatibility and the Lagrange multiplier field $\lambda(\mathbf{x^d})$ toward the stress field $\sigma^{\prime}(\mathbf{x^d})$ to fulfill equilibrium.

Upon convergence, the microstructure can be updated using an explicit scheme (see Lebensohn et al. 2008 for details).

## 3   Results

### 3.1   Validation of the Full-Field Formulation Using an Analytical Result

Let us consider a model polycrystal consisting of columnar orthorhombic grains with symmetry axes aligned with the $x_3$ axis, such that, when loaded in antiplane mode with shearing direction along $x_3$, the only two slip systems that can be activated in the grains are those defined by the following Schmid tensors:

$$\mathbf{m}^s = \left(\mathbf{e}_1 \otimes \mathbf{e}_3 + \mathbf{e}_3 \otimes \mathbf{e}_1\right)/2 \;\; , \quad \mathbf{m}^h = \left(\mathbf{e}_2 \otimes \mathbf{e}_3 + \mathbf{e}_3 \otimes \mathbf{e}_2\right)/2 \tag{62}$$

where $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ is an orthonormal basis of crystallographic axes and "s" and "h" stand for soft and hard slip systems, respectively. If we further consider that $\mathbf{e}_3$ lies parallel to $x_3$, and the material is incompressible, the problem becomes two-dimensional (2-D). The local stress and strain rate are characterized by 2-D vectors with components $\sigma_{13}$ and $\sigma_{23}$ and $\mathbf{e}_3$ and $\dot{\varepsilon}_{23}$ (denoted hereafter $\sigma_1$ and $\sigma_2$ and $\dot{\varepsilon}_1$ and $\dot{\varepsilon}_2$, respectively) and the viscous stiffness tensor $\mathbf{L} = 2\mu$, by a 2-D symmetric second-order tensor with diagonal components $2\mu_{1313}$ and $2\mu_{2323}$ and off-diagonal components $2\mu_{1323}$ (denoted $2\mu_{11}$, $2\mu_{22}$, and $2\mu_{12}$, respectively). In addition, let us assume that the constituent grains exhibit a linear response:

$$\dot{\boldsymbol{\varepsilon}}\left(\mathbf{x}\right) = \mathbf{L}^{-1} : \boldsymbol{\sigma}\left(\mathbf{x}\right) = \left(\frac{1}{\tau_o^s}\mathbf{m}^s \otimes \mathbf{m}^s + \frac{1}{\tau_o^h}\mathbf{m}^h \otimes \mathbf{m}^h\right) : \boldsymbol{\sigma}\left(\mathbf{x}\right) \tag{63}$$

with $\tau_o^s$ and $\tau_o^h$ being the viscosities of the soft and hard slip systems $\left(\tau_o^s < \tau_o^h\right)$. It can be shown that the behavior of such polycrystal is characterized by an effective 2-D viscous stiffness tensor $\overline{\mathbf{L}} = 2\overline{\mu}$ such that $\dot{\mathbf{E}} = \overline{\mathbf{L}}^{-1} : \boldsymbol{\Sigma}$ (where $\boldsymbol{\Sigma}$ and $\dot{\mathbf{E}}$ are the 2-D effective stress and strain rate, respectively), such that (Dykhne 1970):

$$\det\left(\overline{\boldsymbol{\mu}}\right) = \overline{\mu}_{11} \times \overline{\mu}_{22} - \overline{\mu}_{12}^2 = \tau_o^s \times \tau_o^h \tag{64}$$

In the particular case of an isotropic 2-D polycrystal, $\overline{\mu}_{11} = \overline{\mu}_{22} \left(= \overline{\mu}\right)$ and $\overline{\mu}_{12} = 0$, so that the effective shear modulus becomes:

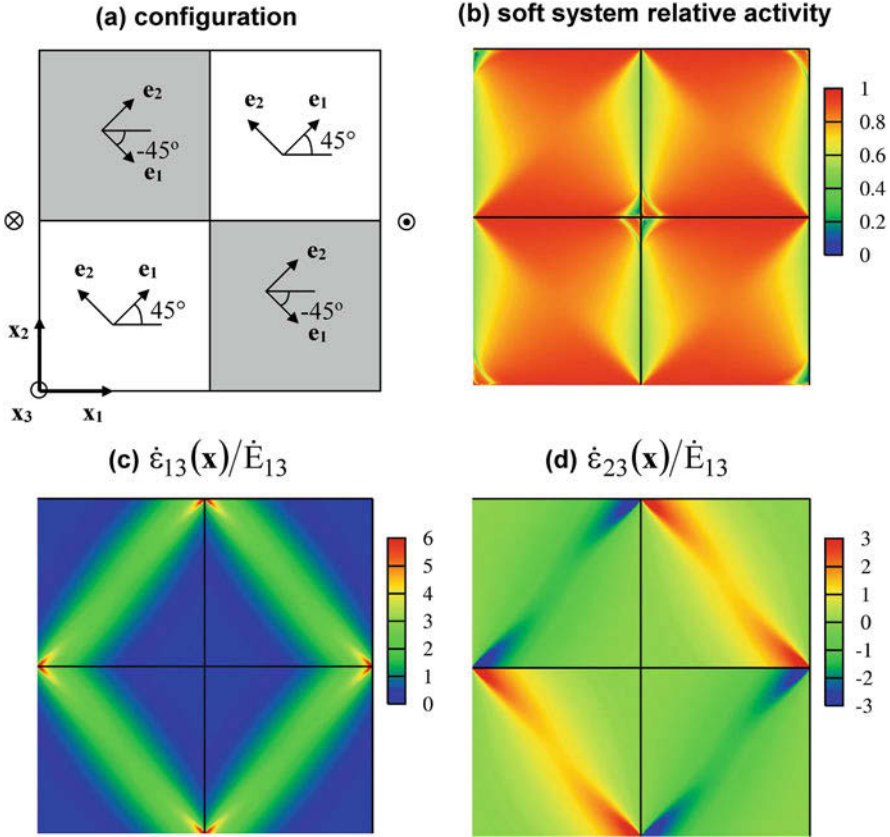
$$\overline{\mu} = \sqrt{\tau_o^s \times \tau_o^h} \tag{65}$$


**Fig. 3** (**a**) Two-dimensional two-phase isotropic unit cell undergoing antiplane deformation. VPFFT results of (**b**) relative activity field of the soft slip system. (**c, d**) Shear components 13 and 23 of the strain rate

Note that the above result is independent of the 2-D microstructure as far as it remains isotropic. This analytical result can be used for validating the VPFFT formulation. Let us consider the periodic 2-D two-phase composite shown in Fig. 3a (Lebensohn et al. 2005), whose unit cell consists of four square grains, with the crystallographic orientations of the two pairs of opposite grains (i.e., each pair shearing only the central vertex) being characterized by angles $+45$ and $-45°$, respectively (note that the orientation of each 2-D crystal is fully characterized by the angle between the crystal direction $\mathbf{e}_1$ and the sample direction $x_1$).

The antiplane deformation of this unit cell for an applied strain rate of the form $\dot{\mathbf{E}} = (\dot{E}_{13}, 0)$ was solved numerically using different discretizations: 64, 128, 256, and 512 Fourier points along each direction (i.e., 1024, 4096, 16384, 65536 Fourier points per grain), for a contrast of $\tau_o^h/\tau_o^s = 25$, which gives theoretical polycrystal viscosity of $\overline{\mu}/\tau_o^s = 5$. Figure 4 shows the relative deviations of the

**Fig. 4** Relative deviations from the theoretical (th) value $(\overline{\mu}/\tau_o^s = 5)$ of the polycrystal's viscosity predicted with the present formulation (FFT) for different grid refinements, in the case 2-D antiplane deformation of the isotropic unit cell of Fig. 3a, consisting of grains having linear behavior (Eq. 63) with $\tau_o^h/\tau_o^s = 25$

polycrystal viscosities calculated with the VPFFT model from the theoretical value, as the number of iterations of the VPFFT method increases. It is seen that (a) the convergence of $\overline{\mu}^{FFT}$ toward its theoretical value is rather good, although it saturates at different levels, depending on the number of discretization points used, and (b) the precision of the FFT solution can be increased by refining appropriately the Fourier grid. This is due to the fact that a more refined grid provides a higher spatial resolution to represent the strong gradients and jumps of the local fields, localized at grain boundaries (see Fig. 3c, d).

## 3.2    Validation of Mean-Field Formulations Using Full-Field Computations

In this section, we analyze the orientation dependence of the lattice rotation rate distributions given by Eqs. (45), (46), and (47) for the cases of axisymmetric deformation of fcc and bcc polycrystals (Lebensohn et al. 2016).

First, the statistical parameters describing the lattice rotation rate distributions predicted with VPSC are validated by comparison with corresponding full-field predictions obtained with the VPFFT model for the case of asymmetric tension of an fcc polycrystal with random texture and equiaxed grains.

Figure 5a shows VPSC predictions of the per-grain rotation rate averages and standard deviations normalized by $\overline{\dot{\omega}} = \langle \dot{\omega}^{(r)} \rangle$, corresponding to an fcc polycrystal made of 400 randomly oriented spherical grains deforming by {111}<110> slip and stress exponent $n = 10$, deformed axisymmetrically in tension at an applied strain rate of 1 s$^{-1}$. Figure 5b compares the same statistical parameters obtained
**Fig. 5** VPSC (left) and VPFFT (right) predictions of per-grain (**a**, **b**) rotation rate averages and (**c**, **d**) geometric mean standard deviations, for the case of tensile deformation of an fcc polycrystal made of 400 randomly oriented spherical/equiaxed grains deforming by {111}<110>

by sampling and ensemble averaging VPFFT predictions of the rotation rate fields, calculated for 50 different periodic Voronoi unit cell realizations, made of the same 400 orientations randomly assigned to the Voronoi grains, with identical constitutive behavior and applied boundary conditions.

The comparison between the VPSC predictions and the corresponding full-field statistics shows reasonable agreement. Both models predict very similar orientation dependence of the average rotation rates and, most importantly, of the average dispersions, with maximum near <112>, which incidentally coincides with the predominant recrystallization texture component of an fcc material after being heavily deformed in tension. The minor differences between VPSC and VPFFT

predictions can be ascribed to two reasons. (1) The unavoidable adoption of a linearization scheme in VPSC, affine in this case. As discussed above, this implies an approximation of the actual nonlinear response of the material, which the VPFFT solutions strictly account for. In the present case of relatively mild single crystal anisotropy and nonlinearity, the results of the first-order affine linearization match reasonable well the reference full-field solutions. Materials with higher local mechanical contrast would require the use of second-order linearization, for more accurate results. (2) The imperfect statistical representation of the distributions obtained by ensemble averaging of VPFFT solutions.

## 4  Summary and Further Reading

In this chapter, we have reviewed two crystal plasticity methodologies for the prediction of microstructure-property relations in polycrystalline aggregates. The mean-field VPSC and the full-field VPFFT formulations rely on Green's function-based solution of the PDEs governing the micromechanical response of polycrystals – a class of heterogeneous materials, in which the heterogeneity is related to the inherent directional properties of single crystal grains with respect to mechanical solicitation along different crystal directions and the different crystallographic orientations of each of these grains in the aggregate. The non-space-resolved VPSC formulation is based on a certain linearization assumption for the behavior of the single crystal grains, along with the integration – utilizing Fourier transforms – in an ellipsoidal domain of the Green's function for an infinite medium with homogenous properties and an iterative procedure to adjust the properties of this HEM. The space-resolved VPFFT method is based on the evaluation of convolution integrals over the entire periodic unit cell, between the Green's function for a periodic medium and a polarization term containing all the information on the heterogeneity and nonlinearity of the crystalline material's behavior. The numerical evaluation of such convolutions is performed in Fourier space and anti-transformed to Cartesian space by means of the efficient FFT algorithm. Both Green's function-based crystal plasticity formulations were presented using a unified notation, pointing out their similarities and differences and cross-validating their predictions.

The VPSC formulation has been extensively applied to predict microstructure-property relationships, including texture-induced anisotropy and microstructure evolution, both in stand-alone, single material point calculations and as part of multiscale frameworks, coupling the homogenization-based model with FE codes. Presenting these applications is beyond the scope of this chapter, but a list of stand-alone applications of VPSC to metals, minerals, and polymers can be found in Lebensohn et al. (2007), and the different multiscale strategies are discussed in, e.g., Tomé et al. (2001), Plunkett et al. (2006), Nixon et al. (2010), Segurado et al. (2012), and Barton et al. (2015).

Beyond the rigid-viscoplastic regime in which this chapter has been focused, the FFT-based formulation has been implemented for other deformation regimes, including polycrystal elasticity (Brenner et al. 2009), dilatational viscoplasticity (Lebensohn et al. 2013), and elasto-viscoplasticity (EVPFFT) (Lebensohn et al. 2012; Grennerat et al. 2012, for small strains; Eisenlohr et al. 2013, for finite strains). In particular, the standard EVPFFT formulation based on local plasticity was recently extended to consider strain-gradient and high-order plasticity theories, including field dislocation mechanics (FDM), by Berbenni et al. (2014), Brenner et al. (2014), and Lebensohn and Needleman (2016), etc.

### Abstract

Crystal plasticity models allow incorporation of physics of plastic deformation at length scales smaller than a single crystal or individual grains in a polycrystalline

sample. As such, they present an important avenue for improving the fidelity of multiscale modeling and simulation for a variety of phenomena involving plastic deformations in crystalline materials. However, crystal plasticity models are extremely computationally expensive, limiting their adoption by materials development community and manufacturing industries. In this chapter, a spectral database approach is presented to carry out the computations involved in the crystal plasticity framework in a highly efficient manner. In this approach, the important variables of interest from crystal plasticity computations can be stored in precomputed databases based on discrete Fourier transforms (DFTs). Although the database generation requires one-time high computational cost, it dramatically reduces the computational cost in all subsequent computations. Several case studies illustrating the benefits of this approach are presented in this chapter.

# 1      Introduction

Modern manufacturing industry relies heavily on metal forming processes, which form the backbone of today's manufacturing world. Globally, hundreds of million tons of metals are subjected to metal forming processes every year. In metal forming processes (examples include rolling, extrusion, forging, deep drawing, and die forming), the products are shaped and often strengthened by plastic deformation. Plasticity also influences material failure (e.g., necking and fracture, fatigue). Consequently, a deeper understanding of plastic deformation in metals and alloys is central to efforts aimed at improving the manufacturing processes for optimizing the cost and the performance of the finished product.

Plasticity describes the deformation of a (solid) material undergoing nonreversible changes of shape in response to applied forces (Lubliner 2008). Most commercially used metals and alloys exhibit polycrystalline microstructures (material structure at the mesoscale) that are composed of numerous grains (individual crystals). In such materials, plastic deformation occurs predominantly by dislocation glide on specific crystallographic planes (typically close-packed planes) in specific crystallographic directions (typically close-packed directions) (Callister 2007). Consequently, the details of the material microstructure (such as the distribution of grain orientations, also referred as the crystallographic texture) play an important role in plasticity (Barlat 2007).

Most simulations of metal forming employ phenomenological descriptions of the constitutive laws controlling the macroscale (effective) elastic-plastic response of polycrystalline materials. These models are based on discrete macroscopic experimental observations and the assumption of material homogeneity. Although such models require relatively short computation times due to which they are the preferred choice for industrial process simulations, they are often not able to capture accurately the evolving anisotropy and properties (i.e., mechanical performance) of the finished product. For example, when it comes to processes involving ultra-thin sheet metals (few grains in the thickness), phenomenological models often

fail to capture material response accurately as these sheet metals present a strong heterogeneity of deformation during processing (Adzima et al. 2017). In such situations, it is essential to employ more physics-based descriptions of the material constitutive laws. For crystalline solids, these can be expressed in the form of crystal plasticity theories (Adams et al. 2013). A salient feature of these models is that they aim to express the constitutive relations of the material starting from the description of the key physical mechanisms at the single crystal scale. These constitutive relations account for the relevant microstructural mechanisms at this scale, such as slip on specific crystallographic planes and directions, the lattice rotation, and the dislocation motion and multiplication in the description of the strain hardening. The behavior at the macroscale is then subsequently derived from that of the constituent single crystals via suitable scale-transition schemes. Such micromechanical modeling approaches have demonstrated significant improvements in the predictions of the concomitant anisotropic mechanical response in polycrystalline materials and the evolution of the underlying texture in finite plastic deformation (e.g., Asaro and Needleman 1985; Kalidindi et al. 1992).

The transition from the response of single crystals to the overall (effective) response of the polycrystalline aggregate is usually accomplished using a suitable homogenization scheme. The commonly employed homogenization schemes can be classified based on the assumptions made with regards to the local interactions between grains, such as Taylor-type (also known as full constraints) (Taylor 1938), relaxed constraints (Kocks and Mecking 2003), LAMEL (Van Houtte et al. 2005), self-consistent (Molinari et al. 1987; Lebensohn et al. 2004; Lebensohn et al. 2007), and crystal plasticity finite element (Needleman et al. 1985; Kalidindi et al. 1992; Kalidindi and Anand 1994; Bachu and Kalidindi 1998; Kalidindi and Schoenfeld 2000; Raabe et al. 2005) models. The simplest and the most widely used approach is the Taylor-type model. In this method, the applied velocity gradient tensor at the microscale is assumed to be the same as the one applied at the macroscale (on the polycrystal). The macroscopic stress is obtained as a volume average over the entire polycrystalline aggregate. The Taylor-type model usually provides good predictions of the overall anisotropic stress-strain response and the averaged texture evolution for single-phase, high stacking faulty energy, cubic metals (Bronkhorst et al. 1992). However, it usually lacks good predictions at the scale of individual crystals and it fails to capture the development of heterogeneities within the grains (Kalidindi et al. 2004; Van Houtte et al. 2005). Crystal plasticity finite element method (called CPFEM) is a powerful modeling tool for a wide range of mechanical problems that take into account the local interactions between all grains in the sample. This approach uses the finite element (FE) method to find the response of the polycrystal by placing a finite element mesh over the grains such that each element represents one grain or a part of the grain (Roters et al. 2010).

The use of crystal plasticity models is extremely computationally expensive and has not been adopted broadly by the advanced materials development community. Even when the constitutive equations are developed and implemented efficiently, the time integration of the highly nonlinear single crystal response demands high computational resources. Consequently, in recent years, much attention has been devoted

to the development of novel techniques that reduce the computational cost involved, without significant loss of accuracy. The explored strategies have included both efficient numerical schemes and high-performance computing hardware (Knezevic and Kalidindi 2017). In the field of crystal plasticity modeling, these have included the Bunge–Esling approach (Bunge and Esling 1984; Kalidindi and Duvvuru 2005), Fourier transform (FFT)-based formulations (Lebensohn 2001; Lebensohn et al. 2008), Newton–Krylov method in place of the Newton–Raphson (NR) method for solving sets of highly nonlinear crystal plasticity equations (Chockalingam et al. 2013), and the database approaches which rely primarily on databases of precomputed solutions either in the form of Fourier (spectral) coefficients of the generalized spherical harmonics (GSH) (Kalidindi et al. 2006) or discrete Fourier transforms (DFTs) (Knezevic et al. 2008a; Knezevic and Savage 2014; Alharbi and Kalidindi 2015; Zecevic et al. 2015a). Among these, the database approaches have demonstrated the most dramatic reduction in the computational cost without any significant loss of accuracy. This is mainly because the database approaches retrieve the solutions to the single crystal constitutive equations from the precomputed databases instead of computing them directly (e.g., using the iterative NR method).

In this chapter, the DFTs-based database approach to speeding up the conventional crystal plasticity computations is presented and demonstrated using several exemplar case studies. More specifically, a database is designed and utilized to efficiently reproduce the solutions for the crystal plasticity constitutive descriptions. The versatility of this approach is demonstrated through a broad range of applications.

## 2    Crystal Plasticity Framework

In this section, the main details of rigid-viscoplastic crystal plasticity framework (Asaro and Needleman 1985) used in the Chapter are presented. Plastic deformation is assumed to be only due to the slip on the crystallographic slip systems. The velocity gradient, $\mathbf{L}$, at the single crystal scale can be expressed as

$$\mathbf{L} = \mathbf{W}^* + \mathbf{L}^P, \quad \mathbf{L}^P = \sum_\alpha \dot{\gamma}^\alpha \mathbf{m}^\alpha \otimes \mathbf{n}^\alpha \tag{1}$$

where $\mathbf{W}^*$ is the lattice spin tensor, $\mathbf{L}^P$ is the plastic velocity gradient tensor, $\dot{\gamma}^\alpha$ is the shearing rate on the slip system $\alpha$, and $\mathbf{m}^\alpha$ and $\mathbf{n}^\alpha$ denote the slip direction and the slip plane normal of the slip system $\alpha$, respectively, in the current configuration. The $\mathbf{m}^\alpha$ and $\mathbf{n}^\alpha$ are related to their counterparts $\mathbf{m}_0^\alpha$ and $\mathbf{n}_0^\alpha$, expressed in the isoclinic relaxed configuration by the lattice rotation tensor $\mathbf{R}^*$ as, $\mathbf{m}^\alpha = \mathbf{R}^* \cdot \mathbf{m}_0^\alpha$ and $\mathbf{n}^\alpha = \mathbf{R}^* \cdot \mathbf{n}_0^\alpha$ (Gupta et al. 2018). In the rate dependent formulation (Pan and Rice 1983), the shearing rate on each slip system depends on the resolved shear stress, $\tau^\alpha$, and the slip resistance, $s^\alpha$, of that slip system $\alpha$. It can be expressed in a power-law relationship as (Kalidindi et al. 1992):

$$\dot{\gamma}^\alpha = \dot{\gamma}_0 \left| \frac{\tau^\alpha}{s^\alpha} \right|^{\frac{1}{m}} \text{sgn}\left(\tau^\alpha\right), \quad \tau^\alpha = \boldsymbol{\sigma}' \cdot \mathbf{P}^\alpha \tag{2}$$

where $\dot{\gamma}_0$ is the reference value of the shearing rate, $m$ is the strain rate sensitivity parameter, $\boldsymbol{\sigma}'$ is the deviatoric part of the Cauchy stress tensor, and $\mathbf{P}^\alpha$ is the symmetric part of the Schmid tensor $\mathbf{m}^\alpha \otimes \mathbf{n}^\alpha$ given by

$$\mathbf{P}^\alpha = 0.5 \left(\mathbf{m}^\alpha \otimes \mathbf{n}^\alpha + \mathbf{n}^\alpha \otimes \mathbf{m}^\alpha\right) \tag{3}$$

Using Eqs. (1) and (3) stretching tensor $\mathbf{D}$ (the symmetric part of $\mathbf{L}$) is expressed as

$$\mathbf{D} = \sum_\alpha \dot{\gamma}^\alpha \mathbf{P}^\alpha \tag{4}$$

The evolution of the slip resistance can be described by a saturation-type law as follows:

$$\dot{s}^\alpha = h_0 \left(1 - \frac{s^\alpha}{s^s}\right)^a \sum_\beta |\dot{\gamma}^\beta| \tag{5}$$

where $h_0$, $s^s$, and $a$ denote the slip hardening parameters. Finally, the lattice spin tensor $\mathbf{W}^*$ (and the related lattice rotation tensor, $\mathbf{R}^*$ ) in the crystalline region is given by:

$$\mathbf{W}^* = \dot{\mathbf{R}}^* \mathbf{R}^{*\mathrm{T}} = \mathbf{W} - \mathbf{W}^\mathrm{p}, \qquad \mathbf{W}^\mathrm{p} = \sum_\alpha 0.5\dot{\gamma}^\alpha \left(\mathbf{m}^\alpha \otimes \mathbf{n}^\alpha - \mathbf{n}^\alpha \otimes \mathbf{m}^\alpha\right) \tag{6}$$

where $\mathbf{W}$ is the applied spin tensor, and $\mathbf{W}^\mathrm{p}$ is the plastic spin tensor.

## 3      Spectral Databases for Crystal Plasticity Computations in Cubic Metals

The crystal plasticity framework described in the previous section demands significant computational resources. The numerically stiff behavior of the crystal plasticity constitutive equations is a direct consequence of the fact that most metals have a very weak dependence on strain rate at room temperature, demanding the use of a small value for the strain rate sensitivity parameter in the flow rule (see Eq. (2)). Consequently, one typically needs several iterations to arrive at an acceptable solution. Additionally, the constitutive equations need to be solved several times in most crystal plasticity simulations. For example, the implementation of the crystal plasticity equations in a finite element tool requires solving the set of stiff constitutive equations for every crystal orientation at every integration point at every trial strain increment in the simulations. Consequently, the use of crystal

plasticity models for simulating practical engineering problems requires extremely high computational effort.

A spectral database approach (Knezevic et al. 2008a; Knezevic and Savage 2014; Alharbi and Kalidindi 2015; Zecevic et al. 2015a) has been developed for speeding up the crystal plasticity constitutive calculations. The main idea of this new approach is based on building a database of Fourier coefficients (based on DFTs) that efficiently capture the main solutions of the crystal plasticity constitutive formulations. As mentioned earlier, we intend to use such a database in performing all calculations in a multiscale crystal plasticity simulation, avoiding the need to solve directly the crystal plasticity equations.

The new database approach seeks compact representations for the following three functions corresponding to the main variables in the crystal plasticity solutions: (i) the deviatoric stress tensor $\boldsymbol{\sigma}'(g, \mathbf{L})$, (ii) the plastic spin tensor $\mathbf{W}^p(g, \mathbf{L})$, and (iii) the total shear rate $\sum_\alpha |\dot{\gamma}^\alpha| (g, \mathbf{L})$, where $g$ denotes the crystal lattice orientation represented using Bunge–Euler angles, and $\mathbf{L}$ is the traceless applied velocity gradient tensor. However, the space of $\mathbf{L}$ (i.e., the set of all possible values assigned to $\mathbf{L}$) is unwieldy and needs to be suitably parametrized. We seek parametrization of the velocity gradient as (Van Houtte 1994):

$$\mathbf{L} = \mathbf{D} + \mathbf{W}, \quad \mathbf{D} = \dot{\varepsilon}\mathbf{D}_0, \mathbf{D}_0 = \sum_{j=1}^{3} D_j \boldsymbol{e}_j^p \otimes \boldsymbol{e}_j^p, \quad \dot{\varepsilon} = \|\mathbf{D}\| \tag{7}$$

$$D_1 = \sqrt{\frac{2}{3}} \cos\left(\theta - \frac{\pi}{3}\right), \quad D_2 = \sqrt{\frac{2}{3}} \cos\left(\theta + \frac{\pi}{3}\right), \quad D_3 = -\sqrt{\frac{2}{3}} \cos(\theta) \tag{8}$$

where $\left\{\boldsymbol{e}_j^p, \ j = 1, 2, 3\right\}$ denotes the principal frame of the stretching tensor $\mathbf{D}$, and $\{D_j, \ j = 1, 2, 3\}$ are the components of a diagonal and traceless $\mathbf{D}_0$. It should be noted that none of the functions of interest identified above are dependent on $\mathbf{W}$ (can be seen from the constitutive model described in Sect. 2). As a result of the above parametrization, the functions of interest can then be expressed in terms of $\left(\left\{\boldsymbol{e}_j^p\right\}, \theta, \dot{\varepsilon}\right)$ instead of $\mathbf{L}$. For example, the function of interest for the deviatoric stress tensor can be expressed as $\boldsymbol{\sigma}'\left(g, \left\{\boldsymbol{e}_j^p\right\}, \theta, \dot{\varepsilon}\right)$.

One approach to reducing the number of independent variables in the functions is to select a specific reference frame where the components of the tensors will be described. For example, we could decide that the function will be described in the principal frame of $\mathbf{D}$. Making this choice implies that we would have to use a suitable coordinate transformation law to recover the values of the function of interest in a different reference frame (such as the sample reference frame). Selecting the principal frame of $\mathbf{D}$ as the reference frame also implies that the crystal lattice orientation has to be defined with respect to this frame (note that $g$ denotes the crystal lattice orientation with respect to the sample reference frame). Let $g^p$ denote

the crystal orientation with respect to the principal frame of $\mathbf{D}$ (defined by $\left\{e_j^p\right\}$). With the choices made above, the functions of interest can now be expressed over $(g^p, \theta, \dot{\varepsilon})$. As an example, the expected functional dependence of the components of the deviatoric stress tensor in the $\left\{e_j^p\right\}$ reference frame can be expressed as $\sigma\prime_{ij}(g^p, \theta, \dot{\varepsilon})$. The central significance of the rationale described above is that the number of independent input parameters for the functions of interest has been reduced from 11 to 5. More importantly, of the five independent input parameters, four are angles (three for $g^p$ and one for $\theta$). This is very significant because the angular variables have naturally periodic domains (often expressed as $[0, 2\pi)$) and are ideally suited for DFT representations. It is also pointed that although $\dot{\varepsilon}$ is not defined on a bounded space, it will not present a hurdle for our application, as we will be able to express the dependence of the functions of interest on this variable in explicit (i.e., analytical) forms.

The orientation variable $g^p$ is most conveniently described by a set of three Bunge–Euler angles denoted as $(\varphi_1, \Phi, \varphi_2)$. Since each of this variable is an angle, the natural domain for the orientation can be expressed in the most general case as $(\varphi_1 \epsilon [0, 2\pi), \Phi \epsilon [0, 2\pi), \varphi_2 \epsilon [0, 2\pi))$. Although the crystal and sample symmetries generally identify as significantly smaller space as the fundamental zone (i.e., the set of all distinct crystal orientations), it is most convenient to stay with the full orientation space identified above to take advantage of the fact that this space is naturally periodic and therefore once again ideally suited for DFT representations. For the variable $\theta$, we can identify periodic domain as $\theta \epsilon [0, 2\pi/3)$ (see Fig.1).

The DFT representations of the functions of interest mentioned above are expressed as:

**Fig. 1** Variation of components $D_1$, $D_2$ and $D_3$ as a function of $\theta$
$$\mathbf{W}_{rutq}^p = \dot{\varepsilon}\, \frac{1}{N_{\varphi_1}\, N_\varphi N_{\varphi_2} N_\theta} \sum_{k=0}^{N_{\varphi_1}-1} \sum_{l=0}^{N_\varphi-1} \sum_{m=0}^{N_{\varphi_2}-1} \sum_{n=0}^{N_\theta-1} B_{klmn} e^{\frac{2\pi i k r}{N_{\varphi_1}}} e^{\frac{2\pi i l u}{N_\varphi}} e^{\frac{2\pi i m t}{N_{\varphi_2}}} e^{\frac{2\pi i n q}{N_\theta}}$$

(9)

$$\boldsymbol{\sigma}_{rutq}' = s\, \dot{\varepsilon}^m\, \frac{1}{N_{\varphi_1}\, N_\varphi N_{\varphi_2} N_\theta} \sum_{k=0}^{N_{\varphi_1}-1} \sum_{l=0}^{N_\varphi-1} \sum_{m=0}^{N_{\varphi_2}-1} \sum_{n=0}^{N_\theta-1}$$

$$C_{klmn} e^{\frac{2\pi i k r}{N_{\varphi_1}}} e^{\frac{2\pi i l u}{N_\varphi}} e^{\frac{2\pi i m t}{N_{\varphi_2}}} e^{\frac{2\pi i n q}{N_\theta}}$$

(10)

$$\left( \sum_\alpha |\dot{\gamma}^\alpha| \right)_{rutq} = \dot{\varepsilon}\, \frac{1}{N_{\varphi_1}\, N_\varphi N_{\varphi_2} N_\theta} \sum_{k=0}^{N_{\varphi_1}-1} \sum_{l=0}^{N_\varphi-1} \sum_{m=0}^{N_{\varphi_2}-1} \sum_{n=0}^{N_\theta-1}$$

$$G_{klmn} e^{\frac{2\pi i k r}{N_{\varphi_1}}} e^{\frac{2\pi i l u}{N_\varphi}} e^{\frac{2\pi i m t}{N_{\varphi_2}}} e^{\frac{2\pi i n q}{N_\theta}}$$

(11)

In Eqs. (9), (10), and (11), $r$, $u$, $t$, and $q$ enumerate the grid points in the orientation space (domain of $g^p$ or $(\varphi_1, \Phi, \varphi_2)$) and the $\theta$ space (describing the deformation mode), respectively, while $N_{\varphi_1}$, $N_\varphi$, $N_{\varphi_2}$, and $N_\theta$ represent the corresponding total number of grid points in the same spaces. In other words, the variables $r$, $u$, $t$, and $q$ take positive integer values. The sets of Fourier coefficients $B_{klmn}$, $C_{klmn}$, $G_{klmn}$ are generally referred to as the DFTs and constitute the spectral databases needed for facilitating the fast crystal plasticity solutions described here. Equations (9), (10), and (11) are given for three components ($W_{12}^p$, $W_{13}^p$, $W_{23}^p$) of plastic spin tensor, six components ($\sigma'_{11}$, $\sigma'_{22}$, $\sigma'_{33}$, $\sigma'_{12}$, $\sigma'_{13}$, $\sigma'_{23}$) of deviatoric stress tensor, and total shear rate, respectively. Note also that Eqs. (9), (10), and (11) have explicitly accounted for the dependence of the different functions on the variable $\dot{\varepsilon}$, which can be derived directly from the crystal plasticity theory presented earlier in Sect. 2. As a result, the DFT representations in these equations involve only a four-dimensional space. To incorporate hardening, slip resistance $s$ is included in Eq. (10) for calculation of the deviatoric stress, with the assumption $s = s^\alpha$ (i.e., the slip resistance is same for all the slip systems within a grain but varies from grain-to-grain). At the beginning of the time integration, the slip resistance is generally assigned the same initial value for all the grains. For subsequent time steps, the total shear rate calculated from Eq. (11) is used in Eq. (5) to update the slip resistance ($s^\alpha$) which determines the amount of strain hardening on slip system α for the next strain increment. An important consequence of this strategy is that the database of Fourier coefficients established in Eqs. (9), (10), and (11) is completely independent of the values of the hardening parameters. In fact, the Fourier coefficients are also independent of the exact form of the hardening equation as long as we make the assumption that all the slip systems exhibit the same slip resistance.

In order to build the spectral databases, we need to sample the functions of interest on a uniform grid in their domains. This sampling can be accomplished

by carrying out the crystal plasticity computations for the selected inputs using the model presented in Sect. 2. This does entail a significant computational cost. However, the main benefit of the approach presented here is that building the database constitutes a one-time cost, i.e., there is no need to rebuild this database because the database designed here is applicable to any fcc crystal subjected to any deformation path and exhibiting a broad range of hardening responses. In order to compute the DFTs, we need to sample the functions of interest on a uniform grid in 4-D (defined by $(\varphi_1, \Phi, \varphi_2, \theta)$). One has to decide on the resolution of the sampling grid. Obviously, finer grids will result in higher accuracy but can increase the (one-time) computational cost of generating the database. Furthermore, below a certain level of discretization, one would expect that there would be no new peaks in the frequency spectrum of the function of the interest, especially for the physics-based functions of interest identified above (i.e., these are expected to vary smoothly over their domain spaces). Multiple trials have shown that the crystal plasticity spectral databases produced with the one-degree grid discretization (Gupta et al. 2018) provide excellent results. Although there is an additional computation cost in calculating the database on the finer one-degree grid, it should be remembered that it is only a one-time expense. The periodic domain of independent variables on 4-D grid is chosen as $(\varphi_1 \epsilon [0, 2\pi), \Phi \epsilon [0, 2\pi), \varphi_2 \epsilon [0, 2\pi)), \theta \epsilon [0, 2\pi/3)$; thus, for one-degree discretization, it means that total simulations required to generate initial data for building database are 360 x 360 x 360 x 120 $\approx 6 \times 10^9$ simulations. This is a huge number of simulations, which will require significant computational resources and time even if simulations are run in parallel. We, therefore, explore ideas that can reduce the total number of required simulations.

The number of simulations required for generating DFT database can be reduced by taking advantage of the symmetry relations for cubic crystals (Adams et al. 2013) and the mirror symmetry evident within the periodic domain of $\theta$ (refer Fig.1). Simulations using Taylor-type model are done only for orientations in FZ3 (3 times fundamental zone of cubic crystals), and symmetry relations are used to fill up entire grid for generating DFTs. FZ3 is defined as (Adams et al. 2013)

$$FZ3 = \left\{ g = (\varphi_1, \Phi, \varphi_2) \left| \begin{array}{c} \left(0 \leq \varphi_1 < 2\pi, \ 0 \leq \Phi < \frac{\pi}{2}, \ 0 \leq \varphi_2 < \frac{\pi}{2}\right) \\ \left(0 \leq \varphi_1 < \pi, \ \Phi = \frac{\pi}{2}, \ 0 \leq \varphi_2 < \frac{\pi}{2}\right) \end{array} \right| \right\}$$

(12)

For the chosen one-degree grid, middle of the bin is chosen to be grid point. That is, grid points are 0.5, 1.5, 2.5, and so on; therefore, single point simulations using Taylor-type model were done to get initial data for grid points spaced in one degree increments over the space $(\varphi_1 \epsilon [0.5, 359.5], \Phi \epsilon [0.5, 89.5], \varphi_2 \epsilon [0.5, 89.5]), \theta \epsilon [0.5, 59.5]$. Therefore, total number of simulations required reduces to $360 \times 90 \times 90 \times 60 \approx 2 \times 10^8$, which is only 3% of the simulations required for the total periodic 4-D grid identified earlier.

The parameters for conventional crystal plasticity model for these simulations were chosen as: slip hardening parameter $(h_o) = 0$, initial slip resistance $(s_o) =$

100 MPa, reference value of the shearing rate $(\dot{\gamma}_o) = 0.001/s$, rate-sensitivity $(m) = 0.01$, strain rate $(\dot{\varepsilon}) = 0.001$. As noted earlier, the functions of interest were sampled for the input values selected on a uniform grid by performing these simulations. While generating the database hardening variable $s$ is kept constant and established Fourier coefficients database is independent of the values of the strain hardening parameters in Eq. (5).

Simulation results corresponding to each orientation in FZ3 will have to be assigned (copied) to fifteen other orientations which are equivalent to it before carrying out the DFTs. This is because there are sixteen equivalent orientations in the periodic grid; eight of these are obtained from crystal lattice symmetry operations and another eight directly from the definitions of the Bunge-Euler angles. The definitions of the Bunge-Euler angles require that locations $(\varphi_1, \Phi, \varphi_2)$ and $(\varphi_1 + \pi, 2\pi - \Phi, \varphi_2 + \pi)$ correspond to the exact same crystal lattice orientation for crystals of any symmetry. Furthermore, consideration of eight of the lattice symmetry operations associated with a cubic crystal lattice (e.g., face-centered cubic (fcc), body-centered cubic (bcc)) requires that locations corresponding to $(\varphi_1 + \pi, \pi - \Phi, 2\pi - \varphi_2)$, $(\varphi_1 + \pi, \pi - \Phi, \pi - \varphi_2)$, $(\varphi_1 + \pi, \pi - \Phi, \pi/2 - \varphi_2)$, $(\varphi_1 + \pi, \pi - \Phi, 3\pi/2 - \varphi_2)$, $(\varphi_1, \Phi, \varphi_2 + \pi/2)$, $(\varphi_1, \Phi, \varphi_2 + \pi)$ and $(\varphi_1, \Phi, \varphi_2 + 3\pi/2)$ also correspond to the exact same crystal lattice orientation defined by $(\varphi_1, \Phi, \varphi_2)$ (Adams et al. 2013). For deformation mode angle $\theta$, mirror symmetry of periodic domain is used to fill the remaining grid $(f(\theta) = f(120 - \theta))$. Thus, after considering above symmetry relations, we can fill up entire 4-D periodic grid of size 360 x 360 x 360 x 120 for all functions of interest. Since 4-D matrices for doing DFTs are large, it requires a large amount of computer memory (RAM) $\sim$ 128 GB to calculate DFTs and to perform further operations on them such as sorting. DFTs for each output variable (i.e., the functions of interest in crystal plasticity computations identified earlier) are converted from a 4-D matrix to a vector and stored in descending order of their magnitude with corresponding frequencies in a separate matrix. It should be noted that for each output variable, the size of the vector containing all DFTs is 5,598,720,000 $(= 360 \times 360 \times 360 \times 120)$ which requires $\sim$ 40 GB storage space. Therefore, these DFTs are sorted in descending order of magnitude, and only a reasonable number of the dominant DFTs are stored for further use. As an example, the reduced database for one output variable containing a vector of 50,000 DFTs requires $\sim$ 700 KB storage space. In producing such a compact set, we have also taken advantage of the fact that about half of the DFTs are complex conjugates of the other half for all real-valued functions. Considering the size of matrices and memory requirement, it is recommended to do all the steps together starting from populating the 4-D periodic grid from single point simulation data to storing sorted set of dominant DFTs. After obtaining the simulation data from conventional crystal plasticity model, it took a computational time of $\sim$70 h on a 2 GHz clock speed machine with a memory (RAM) of $\sim$ 128 GB to generate the complete DFT database for all output variables of interest (a total of ten). From the computed DFTs, the DFTs of interest defined in Eqs. (9), 10), and (11) are extracted.

Note that the DFTs were generated independently for all six components of the deviatoric stress, even though one of the components is redundant. For example, one of the components can be computed using the relation $\sigma'_{33} = -\left(\sigma'_{11} + \sigma'_{22}\right)$ to ensure that the trace of deviatoric stress tensor is zero. Our trials have shown that the strategy of building the database only for the five independent components and then computing the sixth component by setting the trace of the tensor to zero resulted in a larger error for $\sigma'_{33}$. This was a consequence of the addition of the truncation errors for $\sigma'_{11}$ and $\sigma'_{22}$, in computing $\sigma'_{33} = -\left(\sigma'_{11} + \sigma'_{22}\right)$. A better strategy is to establish an independent database for $\sigma'_{33}$ (Knezevic et al. 2009; Alharbi and Kalidindi 2015). For imposing the condition that the trace of the deviatoric stress tensor has to be zero, the hydrostatic part was subtracted from each of the normal stress components, after computing the full tensor using the spectral database. This approach produced much more accurate predictions of the entire deviatoric stress tensor, as will be evident from the results presented later.

For the estimation of the function values at points other than the grid points, there exist several methods that utilize the DFT representations of the function. All of these approaches implicitly assume that the original grid employed in computing the DFTs is sufficiently refined to capture all of the important frequencies embedded in the function of interest and perform some sort of an interpolation with global support. One approach is the spectral interpolation approach (Knezevic et al. 2009; Alharbi and Kalidindi 2015), where the DFTs are suitably padded to recover the function values on any finer grid on the same domain (Knezevic et al. 2008a). This methodology is known to be insensitive to the phenomenon of aliasing, which arises when trying to recover function values at locations other than those originally sampled. The DFT corresponding to the finer grid can then be used to compute efficiently an interpolated value of the function at any of the grid points on the finer grid. However, it was observed that spectral interpolation introduced certain rounding errors, which can be eliminated by the use of trigonometric interpolation, which is a continuous interpolation scheme (Zecevic et al. 2015a). Using the trigonometric interpolation scheme resulted in excellent accuracy of the crystal plasticity computations, as demonstrated in recent studies (Zecevic et al. 2015a; Gupta et al. 2018). The details of this interpolation scheme are presented next.

The main functions of crystal plasticity solutions are recovered as continuous functions of orientation and deformation mode from spectral DFT database with trigonometric interpolation using Inverse Discrete Fourier Transforms (IDFTs) equations in principal frame of $\mathbf{D}$, given by (Zecevic et al. 2015a):

$$
\mathbf{W}^p\left(g^p, \theta\right) = \dot{\varepsilon}\,\frac{1}{N_{\varphi_1} N_\varphi N_{\varphi_2} N_\theta}
$$

$$
\left[\sum_{k=-\frac{N_{\varphi_1}}{2}+1}^{\frac{N_{\varphi_1}}{2}} \sum_{l=-\frac{N_\varphi}{2}+1}^{\frac{N_\varphi}{2}} \sum_{m=-\frac{N_{\varphi_2}}{2}+1}^{\frac{N_{\varphi_2}}{2}} \sum_{n=-\frac{N_\theta}{2}+1}^{\frac{N_\theta}{2}} B_{klmn} e^{\frac{2\pi i k \varphi_1}{L_{\varphi_1}}} e^{\frac{2\pi i l \varphi}{L_\varphi}} e^{\frac{2\pi i m \varphi_2}{L_{\varphi_2}}} e^{\frac{2\pi i n \theta}{L_\theta}}\right]
$$

$$(13)$$

$$\sigma'\left(g^p, \theta\right) = s\dot{\varepsilon}^m \frac{1}{N_{\varphi_1} N_\varphi N_{\varphi_2} N_\theta}$$

$$\left[ \sum_{k=-\frac{N_{\varphi_1}}{2}+1}^{\frac{N_{\varphi_1}}{2}} \sum_{l=-\frac{N_\varphi}{2}+1}^{\frac{N_\varphi}{2}} \sum_{m=-\frac{N_{\varphi_2}}{2}+1}^{\frac{N_{\varphi_2}}{2}} \sum_{n=-\frac{N_\theta}{2}+1}^{\frac{N_\theta}{2}} C_{klmn} e^{\frac{2\pi i k \varphi_1}{L_{\varphi_1}}} e^{\frac{2\pi i l \varphi}{L_\varphi}} e^{\frac{2\pi i m \varphi_2}{L_{\varphi_2}}} e^{\frac{2\pi i n \theta}{L_\theta}} \right]$$

(14)

$$\sum_\alpha \mid \dot{\gamma}^\alpha \mid \left(g^p, \theta\right) = \dot{\varepsilon} \frac{1}{N_{\varphi_1} N_\varphi N_{\varphi_2} N_\theta}$$

$$\left[ \sum_{k=-\frac{N_{\varphi_1}}{2}+1}^{\frac{N_{\varphi_1}}{2}} \sum_{l=-\frac{N_\varphi}{2}+1}^{\frac{N_\varphi}{2}} \sum_{m=-\frac{N_{\varphi_2}}{2}+1}^{\frac{N_{\varphi_2}}{2}} \sum_{n=-\frac{N_\theta}{2}+1}^{\frac{N_\theta}{2}} G_{klmn} e^{\frac{2\pi i k \varphi_1}{L_{\varphi_1}}} e^{\frac{2\pi i l \varphi}{L_\varphi}} e^{\frac{2\pi i m \varphi_2}{L_{\varphi_2}}} e^{\frac{2\pi i n \theta}{L_\theta}} \right]$$

(15)

where $N_{\varphi_1}, N_\varphi, N_{\varphi_2}, N_\theta$ are the total number of grid points and $L_{\varphi_1}, L_\varphi, L_{\varphi_2}, L_\theta$ represent the domain of variables in the orientation space ($g^p$ or ($\varphi_1, \Phi, \varphi_2$)) and the deformation mode space ($\theta$). For one-degree grid, $N_{\varphi_1} = N_\varphi = N_{\varphi_2} = 360$, $N_\theta = 120$ and $L_{\varphi_1} = L_\varphi = L_{\varphi_2} = 360, L_\theta = 120$, since the periodic domain of variables considered are $\varphi_1 \epsilon [0, 360^o), \Phi \epsilon [0, 360^o), \varphi_2 \epsilon [0, 360^o), \theta \epsilon [0, 120^o)$. When retrieving Fourier coefficients ($B_{klmn}, C_{klmn}, G_{klmn}$) referred as DFTs for use in above equations to reconstruct values of above functions, we use only dominant DFTs and also take advantage of the fact that about half of the DFTs are complex conjugates of other half for all real valued functions. In the DFT-based spectral approach used to solve the crystal plasticity constitutive equations, only a small number of terms in the DFT (called dominant DFTs) are required to reconstruct directly the solutions for the main functions of the conventional crystal plasticity theory for any given crystal orientation and under any applied deformation mode. The use of small number of dominant DFTs speeds up crystal plasticity calculations by about two orders of magnitude without significantly compromising accuracy (Knezevic et al. 2009). Even with using one-degree grid discretization as in case study presented here (Gupta et al. 2018), the cost of recovering the solutions from database is roughly the same as the three-degree grid database (Knezevic et al. 2009), which is about two orders of magnitude faster than the conventional computations.

Once the spectral database is developed, it can be used for various applications as described in Sects. 4 and 6. Given a set of crystal orientations, an initial value of slip resistance per crystal orientation, hardening parameters, and an imposed value of the strain rate tensor, we can use Eqs. (13), (14), and (15) to compute required microscale quantities (i.e., grain scale stress, grain spin, and shearing rates on slip systems). A desired deformation process can be simulated by applying a suitable sequence of strain increment steps. The computed spin tensor for each crystal is used to update its lattice orientation. The updated set of crystal lattice orientations

are then used to define the starting conditions for the next strain increment. Total shear rate is used to update the slip resistance using Eq. (5) for the next strain increment. For the polycrystalline response (i.e., macroscale quantities such as the homogenized stress–strain response and texture), the Taylor model is used, in which the applied strain rate tensor at the grain level is assumed to be the same as the one applied at the polycrystal level. The macroscopic stress for the polycrystal is then obtained by volume averaging the stresses inside the polycrystal.

## 4   Application of Spectral Databases for Crystal Plasticity Computations of Cubic Metals

### 4.1   Taylor-Type Crystal Plasticity Simulations Using Spectral Database

In this section, case study of Taylor-type crystal plasticity simulations using spectral database built in Sect. 3 is presented. Uniaxial tension simulations were performed, and the hardening parameters were taken from Kalidindi et al. (1992) and correspond to oxygen-free high conductivity (OFHC) copper: $h_0 = 180$ MPa, $s_s = 148$ MPa, $a = 2.25$, $s_0 = 16$ MPa, and $m = 0.01$. The polycrystal was assumed to consist of 1000 FCC single crystals possessing a random initial texture. A comparative analysis of results predicted by the one-degree and three-degree grid databases is also performed.

The results of uniaxial tension simulations are presented in Fig. 2. The averaged polycrystal responses are plotted in this figure as macroscale deviatoric stress-strain curves. Deformed textures (pole figures) obtained using conventional crystal plasticity Taylor-type model (CP) and DFT database (SCP) show an excellent agreement. Comparison of deviatoric stress-strain curves of CP and SCP using one-degree grid and three-degree grid show that one-degree grid provides more accurate predictions. It should be noted that simulations are rigid-viscoplastic. For SCP model, 500 dominant DFTs were chosen for deviatoric stress components ($C_{klmn}$) and total shear rate ($G_{klmn}$) and 2000 dominant DFTs for plastic spin components ($B_{klmn}$) with a strain step of 0.06.

Computational cost of DFT database approach improved by two orders of magnitude compared to conventional crystal plasticity simulation without significantly compromising accuracy. It should be noted that we can further improve the accuracy of SCP model by using more number of dominant DFTs, but then computational cost will be higher. The number of dominant DFTs chosen here represents a compromise between computational time and accuracy.

### 4.2   Fast Computation of Yield Surfaces Using Spectral Databases

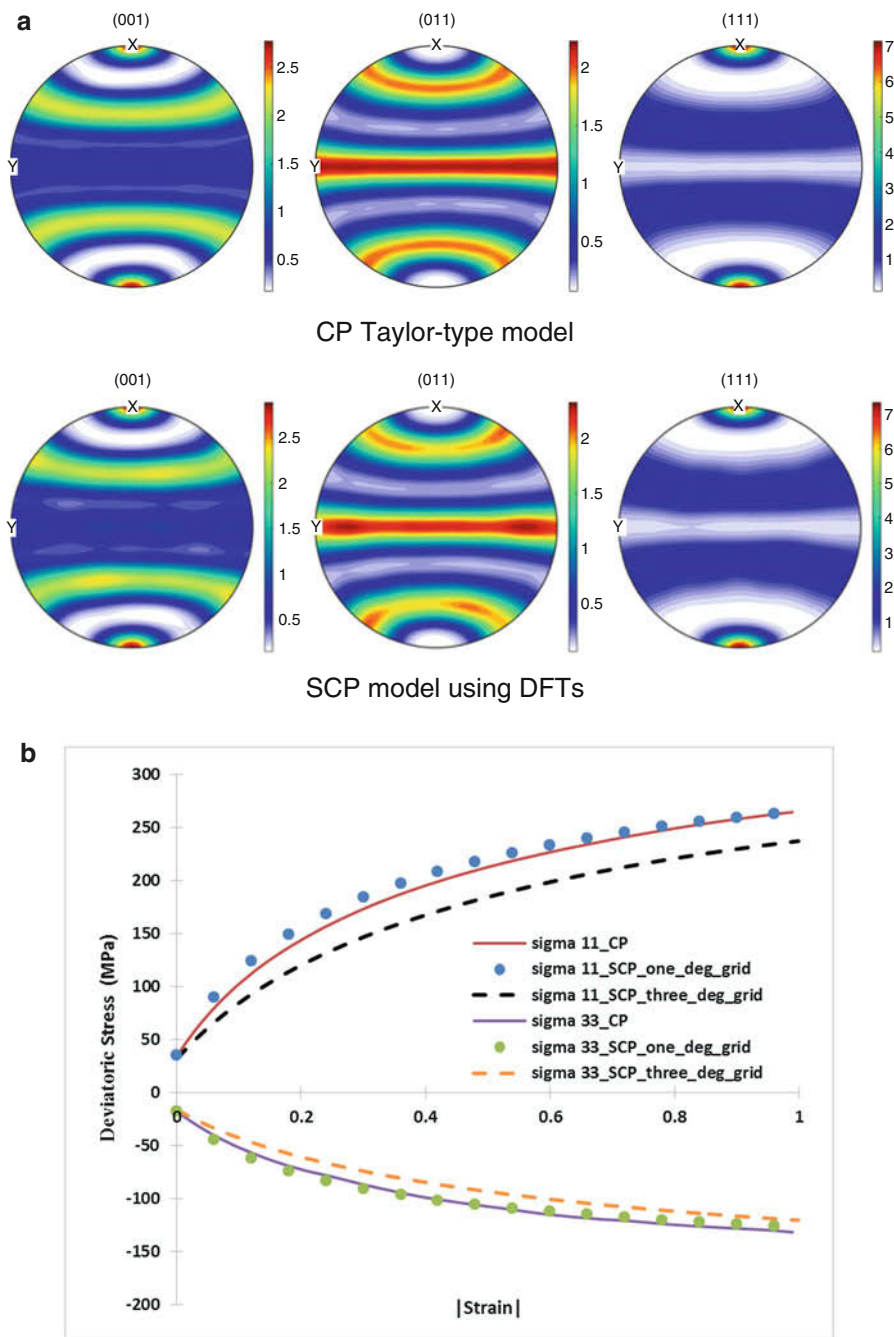
In this section, a new method for the fast computation of the yield surface in the five-dimensional deviatoric stress space is described using the DFT-based databases. Since the computational cost of delineation of the anisotropic yield surface in stress


**Fig. 2** Comparison of predictions from SCP model using one-degree grid and three-degree grid database against corresponding predictions from conventional CP Taylor-type model for uniaxial tension simulation of OFHC Copper: (**a**) pole figures of deformed texture and (**b**) different components (sigma 11 and sigma 33) of deviatoric stress vs. strain curves

space using crystal plasticity is very high, the spectral database approach can be used to tackle this problem.

The orientation distribution function (ODF), denoted as $f(g)$, reflects the normalized probability density associated with occurrence of the crystallographic orientation, $g$, in the sample. ODF is formally defined as

$$f(g)dg = \frac{N_{g \pm dg/2}}{N}, \qquad \int_{FZ} f(g)dg = 1 \tag{16}$$

where $N$ is the total number of orientations measured in the sample, $N_{g \pm dg/2}$ is the number of orientations that lie within an invariant measure, $dg$, centered about the orientation, $g$, and $FZ$ denotes the fundamental zone of distinct Bunge-Euler angles. The invariant measure is then defined as:

$$dg = \sin \varphi \, d\varphi_1 d\varphi d\varphi_2 \tag{17}$$

In this work, it is convenient to establish the DFT representation for texture as (Kalidindi et al. 2009):

$$\widetilde{F}_{klm} = \sum_{b_1=0}^{N_{\varphi_1}-1} \sum_{b_2=0}^{N_{\varphi}-1} \sum_{b_3=0}^{N_{\varphi_2}-1} f_{b_1 b_2 b_3} \sin \varphi_{b_2} e^{\frac{-2\pi i k b_1}{N_{\varphi_1}}} e^{\frac{-2\pi i l b_2}{N_{\varphi}}} e^{\frac{-2\pi i m b_3}{N_{\varphi_2}}} \tag{18}$$

where $N_{\varphi_1} \text{x } N_{\varphi} \text{x } N_{\varphi_2}$ represents a uniform discretization of three-dimensional Bunge-Euler space, $(b_1, b_2, b_3)$ enumerate the grid points, and $f_{b_1 b_2 b_3}$ denotes the value of the ODF at the grid point.

In the Taylor model (Taylor 1938), the macroscopic deviatoric stress tensor, $\overline{\sigma}'$, is given by the volume averaged value of the local stress tensors in the constituent crystals of the polycrystalline aggregate. The volume-averaged value can be efficiently evaluated using Eqs. (10) and (18) and the orthogonal properties of the spectral representations. It can be shown that

$$\overline{\sigma}'_q = s \, \dot{\varepsilon}^m \, \frac{1}{N_{\varphi_1} \, N_{\varphi} N_{\varphi_2} N_{\theta}} \sum_k \sum_l \sum_m \sum_n \widetilde{F}_{klm} C_{klmn} e^{\frac{2\pi i n q}{N_{\theta}}} \tag{19}$$

where $\overline{\sigma}'$ denotes the volume averaged deviatoric stress tensor evaluated on a uniform grid in $\theta$, with the grid points enumerated by $q$. Equation (19) is used to establish the points on the yield surface corresponding to a particular principal frame of **D**. However, to establish the complete yield surface in the sample reference frame, one needs to explore the space of all possible principal frames. Thus, the space of all possible principal frames can be identified using a set of Euler angles, analogous to the Bunge-Euler angles used in the definition of the crystal lattice orientation. The spectral representations of the ODF and the stress functions do not implicitly assume any sample symmetry, and consequently, the yield surface can be constructed for any texture in the sample, without the need to invoke any simplifying assumptions
**Fig. 3** (**a**) Three-dimensional projection of the yield surface computed using the DFT-based spectral method for IF-steel with a random texture; (**b**) plots of the predicted $(\sigma_{11}, \sigma_{22})$ -yield locus for the same material comparing the spectral approach with the conventional Taylor-type model

of sample symmetry. It should be noted that since only a limited number of the $C_{klmn}$ transforms need to be accounted in evaluating Eq. (19), this leads to very efficient computations.

The results of the successfully implemented spectral method to construct the complete five-dimensional yield surface for BCC polycrystalline material are presented in Fig. 3. A set of 1000 discrete crystal orientations with random texture is used in the simulations. The time required for computing the entire five-dimensional yield surface (involving computations of the values of 7,200,000 stress tensors) was only 170 s. Figure 3a represents a selected projection of the five-dimensional yield surface computed here for IF-steel using 500 dominant DFTs. In order to check the accuracy of the yield surface, we compare in Fig. 3b the $(\sigma_{11}, \sigma_{22})$ section of the IF-steel yield surface computed using 500 dominant DFTs against the one computed using the conventional approach. The DFT-based computations are in excellent agreement with the conventional computations (Al-Harbi et al. 2010).

## 4.3    Plastic Closures Using Spectral Databases

Property closures delineate the complete set of all theoretically achievable combinations of selected effective anisotropic properties in a given material system and for a selected homogenization theory and are of great interest in optimizing the performance of engineering components. In general, these are very difficult to compute as they aim to map the complete space of theoretically feasible microstructures in the given material system into the property space of interest. Clearly, the availability of theoretically predicted closures for elastic-plastic properties of polycrystalline materials is of tremendous value in the design and development of new materials

with enhanced properties or performance characteristics. The complete space of all theoretically feasible microstructure distribution functions is identified as a microstructure hull, which for the first-order statistics in polycrystalline microstructures essentially constitutes a texture hull that is conveniently expressed using Fourier representations. First-order property closures in polycrystalline materials are essentially obtained by mapping the texture hulls into the selected property spaces.

The typical plastic properties of interest such as the tensile yield strength are defined in the stress space. The challenge consists in identifying an imposed deformation mode (i.e., stretching tensor, $\mathbf{D}$) that corresponds to the stress state. As an example, consider the computation of the uniaxial yield strength of the polycrystal. Since most crystal plasticity models (Kalidindi et al. 1992) take the imposed deformation as the input and predict the corresponding stress states, it becomes necessary to guess the deformation mode that would result in a uniaxial stress state. Without the assumption of orthorhombic sample symmetry, this search has to take place on at least a four-dimensional surface (equivalent to establishing the yield surface in five-dimensional stress space). However, with the assumption of orthorhombic sample symmetry, the search can be restricted to a single parameter space.

This case study demonstrates how the spectral methods can be utilized for the fast computation of the yield surface to produce a class of plastic property closures that include cubic-triclinic textures (Al-Harbi et al. 2010). It should be emphasized that the highly efficient computation of the yield surface using the spectral databases described in Sect 4.2 allows us to establish these plastic property closures. The methodology used here for building the first-order plastic closures follows the genetic-like algorithms described in Ref. (Knezevic et al. 2008b). The property combinations of interest were first evaluated for a set of crystal orientations that are uniformly distributed over the entire FZ. Then, weighted combinations of crystal orientations located on the boundary were used to expand the property closure. The process was repeated until the closure did not expand any more.

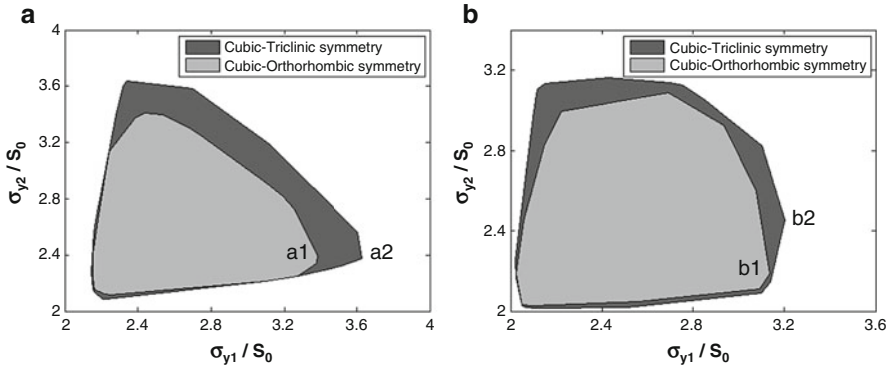
Since the property closures denote potential design spaces, it is important to ascertain how the cubic-triclinic closures expand the available design space. Therefore, in this case study, we computed the example plastic property closures based on the full-constraints Taylor model for both FCC copper and BCC IF-steel. Figure 4 shows the first-order closures delineating all of the feasible combinations of the normalized yield strengths in the sample $\mathbf{e}_1$ and $\mathbf{e}_2$ directions (i.e., $\sigma_{y1}$ and $\sigma_{y2}$) for copper and IF-steel computed assuming both orthorhombic and triclinic sample symmetries. Figure 4 clearly indicates that some combinations of $\sigma_{y1}$ and $\sigma_{y2}$ cannot be attained with the cubic-orthorhombic textures. Comparison of the closures in Fig. 4a and b reveals that the difference between the cubic-orthorhombic and the cubic-triclinic property closures is considerably larger for FCC metals compared to BCC metals. This observation is attributed to the availability of the higher number of slip systems in the BCC metals (48 slip systems in BCC compared to only 12 in the FCC crystals). The higher number of slip systems is expected to lower the degree of anisotropy in the response of the bcc metals and should therefore reduce the


**Fig. 4** First-order cubic-triclinic and cubic-orthorhombic plastic closures for ($\sigma_{y1}/s_o$, $\sigma_{y2}/s_o$) computed using the DFT-based methods developed in this work. (**a**) OFHC Copper, (**b**) IF-steel

difference between cubic-orthorhombic and cubic-triclinic closures for these metals compared to the FCC metals.

## 4.4 Crystal Plasticity Based Forming Limit Diagram Predictions Using a Spectral Database

Accurate prediction of localized necking in thin metal sheets continues to represent a major challenge in the design of sheet metal forming of structural components. The onset of localized necking represents the ultimate deformation state that a stretched metal sheet can undergo, since this phenomenon is often precursor to material failure. The most common representation of this limit of material formability, under a variety of plane stress conditions (relevant to sheet forming), is through the concept of forming limit diagram (FLD). Since the experimental determination of FLDs has proven to be both expensive and difficult, considerable effort has been expended to develop reliable theoretical and/or numerical predictions. Such approaches require the use of a suitable constitutive framework to describe the evolution of the material state, in conjunction with an instability criterion, to predict the onset of plastic flow localization. A numerical tool has been developed recently (Gupta et al. 2018) for a fast and robust prediction of the forming limit diagrams (FLDs) for thin polycrystalline metal sheets using a Taylor-type (full constraints) crystal plasticity model. The occurrence of localized necking is predicted by the initial imperfection approach, which is based on the well-known Marciniak- Kuczynski (M-K) model (Marciniak et al. 1973; Marciniak and Kuczynski 1979). Recently, several multiscale models employing crystal plasticity constitutive descriptions have been coupled with the M–K analysis in order to predict localized necking and the associated FLDs. The solutions to the highly nonlinear crystal plasticity constitutive equations involved in these computations are known to be computationally very expensive. This presents a major impediment

to the wider adoption of crystal plasticity theories in the computation of FLDs. In this work, this limitation is addressed by using spectral database approach based on DFTs.

A rigid-viscoplastic framework was employed to model the mechanical behavior at the single crystal scale. Furthermore, we have restricted our attention to FCC crystals and employed Taylor-type scale-transition scheme in order to compute the overall mechanical behavior of the polycrystalline aggregate. This case study demonstrates the application of the DFT spectral database strategy to predict localized necking and the associated FLDs of thin metal sheets, represented as spectral crystal plasticity FLD (SCP-FLD). This new tool is validated by comparing the predicted SCP-FLDs with the predictions from conventional methods, represented as CP-FLD.

The M–K analysis is based on the assumption of a preexisting initial geometric imperfection in the form of a narrow band (also known as groove) across the width of the metal sheet. During the deformation, more plastic deformation occurs in the band, eventually leading to localized thinning in the band. FLD is predicted using M-K method in conjunction with spectral crystal plasticity by applying polycrystal model to two polycrystalline aggregates, representing the band and the homogeneous zone. For details of algorithm to predict FLD and other numerical aspects involved in this study, readers should refer to Gupta et al. (2018).

The spectral DFT database of one-degree grid is used with the SCP model for the FLD predictions (SCP-FLD). These predictions are compared in Fig. 5 with the FLDs predicted using conventional crystal plasticity model (CP-FLD). For both simulations, we have fixed the initial imperfection factor to 0.99. The polycrystals used in these simulations are made of 1000 FCC single crystals possessing initial random texture for Fig. 5a and initial textured material for Fig. 5b. In general, a textured material exhibits more anisotropic behavior. The initial texture corresponding to a textured material used in Fig. 5b corresponds to the texture predicted by a Taylor-type model after a plane strain compression (PSC) to a true strain of $-0.5$. The SCP parameters used for the FLD predictions are 500 dominant DFTs for deviatoric stress components and total shear rate and 2000 dominant DFTs for plastic spin components. By analyzing Fig. 5, we can easily see that the results obtained by both models (namely the SCP-FLD and CP-FLD) match very well and are indeed independent of the initial texture. The computational time (CPU time) required for predicting FLD reduces dramatically when using SCP model, resulting in about 96% savings.

## 5    Implementation of Spectral Databases in Finite Element Models

The case studies discussed so far used Taylor-type models, where a uniform deformation gradient is assumed for all grains. Crystal plasticity finite element models (CPFEM) would highly benefit from DFT databases, since computational time presents a significant constraint for CPFEM. This section explains how the

(a)                                                (b)

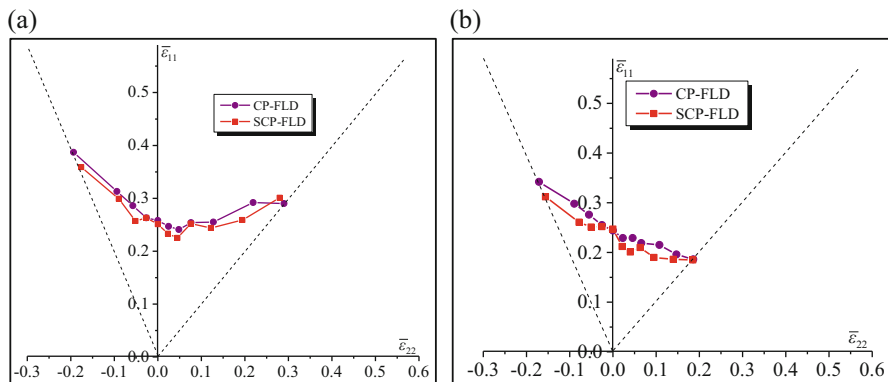

**Fig. 5** Predicted FLDs using conventional crystal plasticity model (CP-FLD) and spectral crystal plasticity model using DFT database (SCP-FLD) for the following hardening parameters: $h_0 = 500$ MPa, $s_s = 230$ MPa, $a = 2.8$, $s_0 = 50$ MPa and $m = 0.01$ and polycrystal consisting of 1000 single crystals corresponding to (**a**) random initial texture, (**b**) textured material (texture corresponding to plane strain compression to a true strain of $-0.5$ on the initially random texture using a Taylor-type model)

crystal plasticity DFT databases can be integrated with the commercial finite element package ABAQUS through a user materials subroutine (UMAT). To use the new spectral database scheme in the FE analysis, two tasks must be accomplished. Both of these developments have been discussed in Alharbi and Kalidindi (2015) and are summarized next.

## 5.1 Including Elastic Deformation in the DFT Database Approach

The crystal plasticity calculations using spectral databases need to be extended from rigid-viscoplastic behavior to elastic-viscoplastic deformation. Although the elastic deformation in most metals subjected to finite plastic deformation is indeed very small and can be neglected, it is essential to include elasticity for implementing crystal plasticity computations with most commercial FE codes. This is mainly because most FE simulation tools, such as ABAQUS, provide the total deformation gradient at each integration point as an input to the user-defined material constitutive response (through subroutines such as UMAT in ABAQUS) and expect to be returned the full stress tensor (not just the deviatoric stress tensor).

The following constitutive relations are used to include the elastic deformation with the spectral crystal plasticity approach described in the previous section:

$$\boldsymbol{\sigma}^{\nabla *} = \widetilde{\mathcal{L}} \, \mathbf{D}^* \tag{20}$$

where $\mathbf{D}^*$ is the elastic stretching tensor, $\widetilde{\mathcal{L}}$ is the fourth-rank elasticity tensor, and $\boldsymbol{\sigma}^{\nabla *}$ is the Jaumann rate of the Cauchy stress based on the axes that spin together

with the lattice and is defined as:

$$\boldsymbol{\sigma}^{\nabla *} = \dot{\boldsymbol{\sigma}} - \mathbf{W}^* \boldsymbol{\sigma} + \boldsymbol{\sigma} \mathbf{W}^* \tag{21}$$

In order to use the above relations, the total stretching tensor $\mathbf{D}$ (symmetric part of the velocity gradient tensor) needs to be decomposed into elastic and plastic parts. This decomposition must be accomplished such that the deviatoric stresses computed from both the crystal plasticity DFT databases (see Eq. (10), denoted here as $\boldsymbol{\sigma}'^{\mathrm{DFT}}(\mathbf{D}^p)$) and the above Jaumann rate relations (denoted as $\boldsymbol{\sigma}'^{\mathrm{Jmn}}(\mathbf{D}^*, \mathbf{W}^*, \Delta\mathrm{t})$) are equal to each other within an acceptable tolerance. The following modified Newton-Raphson scheme has been developed to accomplish this decomposition:

$$\left[\mathbf{D}'^*\right]_{n+1} = \left[\mathbf{D}'^*\right]_n - \lambda \ [\mathbf{J}]_n^{-1}[\mathbf{Err}]_n \tag{22}$$

$$\mathbf{Err} = \boldsymbol{\sigma}'^{\mathrm{DFT}}\left(\mathbf{D}^p\right) - \boldsymbol{\sigma}'^{\mathrm{Jmn}}\left(\mathbf{D}^*, \mathbf{W}^*, \Delta\mathrm{t}\right) \tag{23}$$

$$\mathbf{J} = \frac{\partial \mathbf{Err}}{\partial \mathbf{D}'^*} = -\frac{\partial \boldsymbol{\sigma}'^{\mathrm{DFT}}\left(\mathbf{D}^p\right)}{\partial \mathbf{D}^p} - \frac{\partial \boldsymbol{\sigma}'^{\mathrm{Jmn}}\left(\mathbf{D}^*, \mathbf{W}^*, \triangle\mathrm{t}\right)}{\partial \mathbf{D}^*} \tag{24}$$

The subscripts $n$ and $n + 1$ in Eq. (22) correspond to the estimates of $\mathbf{D}'^*$ at $n$ and $n + 1$ iterations, respectively, and the scalar parameter $\lambda$ is selected such that the magnitude of the step correction $\|\Delta\mathbf{D}'^*\| = \|[\mathbf{D}'^*]_{n+1} - [\mathbf{D}'^*]_n\| \leq \eta \, \varepsilon_{\mathrm{yield}}$, where $\varepsilon_{yield}$ denotes the magnitude of the total strain at yielding and $\eta$ is a numerical constant taken as 0.1.

## 5.2   Computation of the Jacobian

The implementation of UMAT in ABAQUS (ABAQUS 2010) requires the computation of the Jacobian defined as

$$\mathcal{J} = \frac{\partial \Delta \boldsymbol{\sigma}}{\partial \Delta \boldsymbol{\varepsilon}} \equiv \frac{\partial \boldsymbol{\sigma}}{\partial \mathbf{E}_t} \tag{25}$$

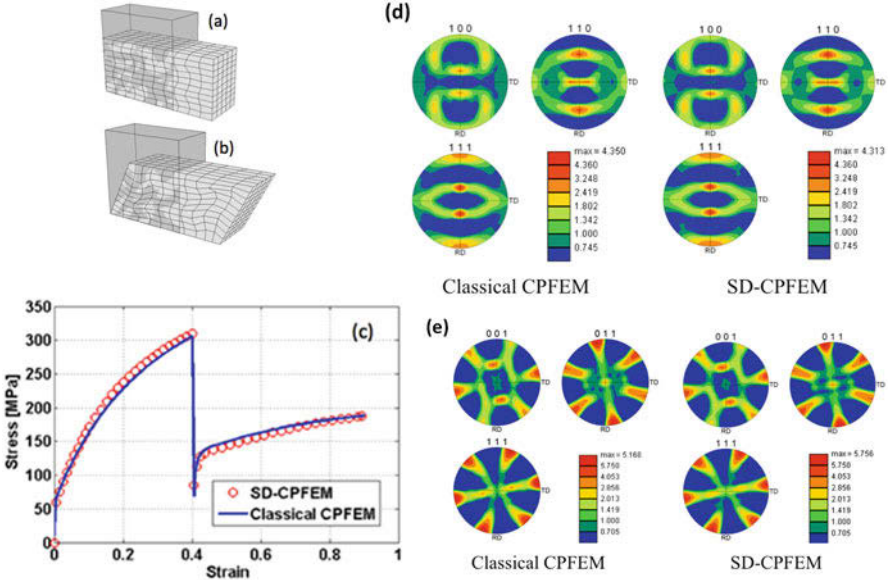
where $\Delta\boldsymbol{\sigma}$ and $\Delta\boldsymbol{\varepsilon}$ are the increments in the stress and strain tensors in a given time increment, respectively, and $\mathbf{E}_t$ is the relative strain tensor in the same time increment. The Jacobian matrix of Eq. (25) is used in the Newton-Raphson iterative method for revising the estimated displacements such that the corresponding stresses are likely to better satisfy the principle of virtual work at the end of the increment. It should be noted that the Jacobian matrix plays an important role in the rate of convergence of the solution to the global equilibrium equations but has no effect on the accuracy of the solution. The following analytical expression for the Jacobian is developed:


**Fig. 6** Comparison of the predicted stress-strain curves and texture from the SD-CPFEM against the corresponding results from the conventional CPFEM for plane strain compression followed by simple shear deformation of OFHC copper: (**a**) mesh after plane strain compression, (**b**) mesh after simple shear deformation, (**c**) stress-strain curves, (**d**) pole figures after plane strain compression, (**e**) pole figures after simple shear deformation

$$\mathcal{J} = \frac{\partial \boldsymbol{\sigma}}{\partial \mathbf{E}_t} = \frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{E}_t} + \mathbf{I} \otimes \frac{\partial p}{\partial \mathbf{E}_t} = \frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}'} \frac{\partial \mathbf{D}'}{\partial \mathbf{E}_t} + \mathbf{I} \otimes \frac{\partial p}{\partial \mathbf{E}_t} \tag{26}$$

with

$$\frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}'} = \left[ \mathbb{I} + \frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}^p} \frac{\partial \mathbf{D}'^*}{\partial \boldsymbol{\sigma}'} \right]^{-1} \frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}^p} \tag{27}$$

where $p$ denotes the pressure, and $\mathbf{I}$ and $\mathbb{I}$ are the second-rank and fourth-rank identity tensors, respectively. The term in Eq. (27) that requires long computations is $\frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}^p}$. It should be noted that, in any time step in the simulation, the term $\frac{\partial \boldsymbol{\sigma}'}{\partial \mathbf{D}^p}$ will be already calculated as a part of the iteration scheme to decompose the stretching tensor into elastic and plastic part (see Eq. (24)). Consequently, there is tremendous computational advantage in formulating the Jacobian computation as described in this section.

**Table 1** Elastic and plastic parameters of the OFHC copper used in the case study (Kalidindi et al. 1992)

| C$_{11}$ (MPa) | C$_{12}$ (MPa) | C$_{44}$ (MPa) | m | s$_o$ (MPa) | h$_o$ (MPa) | s$_s$ (MPa) | a |

# 6     Case Study of Spectral Database Application to CPFEM: Plane Strain Compression Followed by Simple Shear

In order to demonstrate the viability and computational advantages of the spectral CPFEM (SD-CPFEM), we present case study of simulations performed using spectral database and classical CPFEM models. The predictions from the two approaches are produced using the commercial FE package ABAQUS (ABAQUS 2010) and specially developed user material subroutines (described in Ref. (Alharbi and Kalidindi 2015)). To validate the SD-CPFEM for the case of nonproportional loading, we simulated a plane strain compression followed by simple shear of a FCC polycrystalline OFHC copper. The FE model consisted of 500 C3D8 elements with one crystal orientation per integration point. The initial texture is assumed to be random. Four thousand different crystal orientations with random texture were randomly assigned to each integration point inside each element. The first step in this simulation involved an imposed displacement boundary condition on the top surface of the model, which resulted in a 35% reduction in height corresponding to an axial true strain of about $-0.4$. All faces of the sample are constrained to remain planar in this step. In the second step, an imposed simple shear deformation is applied up to a shear strain of $\gamma = 0.5$ as shown in Fig. 6a and b. The elastic and plastic parameters of the OFHC copper used in this case study are shown in Table 1.

The stress-strain response from the SD-CPFEM is compared against the corresponding predictions from the classical CPFEM in Fig. 6c. The predicted textures from the two approaches after each deformation step are shown in Fig. 6 (d) and (e). It can be seen that the predictions from the spectral database approach matched very well with the corresponding predictions from the classical CPFEM at a dramatically reduced computation cost. This prediction took 6380 s for the classical CPFEM and only 527 s for the SD-CPFEM when using 500 DFTs for the stress, the shearing rate, and the lattice spin components. Examples of other case studies such as the simulation of extrusion and rolling process using the spectral database approach can be found in recent literature (Zecevic et al. 2015b).

# 7     Conclusions and Future Outlook

In this chapter, readers were introduced to recently developed spectral approach to crystal plasticity framework, where important variables of interest from crystal plasticity computations can be accessed directly from precomputed spectral database

based on discrete Fourier transform (DFT). The generation of databases requires one-time high computational cost, and once generated they can be used for wide variety of applications as demonstrated by various case studies discussed in this chapter.

The chapter provided details of DFT database generation for the deviatoric stresses, the lattice spins, and the strain hardening rates using Taylor-type crystal plasticity model. These variables depend on the crystal lattice orientations and deformation mode angle and database built for one-degree grid spacing in this 4-D grid gives very accurate results. Trigonometric interpolation can be used to obtain values for points other than grid points. The case studies using spectral database for FCC and BCC materials of Taylor-type simulations, computation of yield surface, property closures, and forming limit diagrams revealed tremendous savings in the computational time compared to conventional approaches based on crystal plasticity. The extension of the spectral database framework to do CPFEM simulations was also discussed with a case study that also shows a remarkable reduction in the computational time.

The computational benefit of spectral DFT database in speeding up crystal plasticity calculations is clearly evident from case studies discussed here. Further, it has been demonstrated in (Knezevic and Savage 2014) that there can be a further gain in the computational speed of doing crystal plasticity computations using spectral DFT database, if the computations are performed on a specialized computer hardware that utilizes graphics-processing units (GPU). Therefore, there is clear potential of further speeding up calculation using database if calculations are performed on advanced hybrid CPU–GPU computational platforms. The spectral database framework presented in this chapter will also be helpful to the manufacturing industry for performing multiscale simulations of forming operations where computational speed of crystal plasticity models is usually the bottleneck. Proper utilization of these toolsets can lead to accelerated insertion of new and improved materials into practice saving millions of dollars.

**Abstract**

Image-based computational models are essential for predicting microstructure-property relationships. Crystal plasticity finite element models, or CPFEM, constitute a major part of these computational models. These models generally adopt conventional finite element analysis tools such as available commercial codes.

S. Ghosh (✉)
JHU Center for Integrated Structure-Materials Modeling and Simulation (CISMMS), Air Force Center of Excellence on Integrated Materials Modeling (CEIMM), US Association of Computational Mechanics (USACM), Department of Civil Engineering, Departments of Mechanical Engineering and Materials Science and Engineering, Johns Hopkins University, Baltimore, MD, USA
e-mail: sghosh20@jhu.edu

However, they face severe challenges when modeling complex microstructures undergoing extreme phenomena. This chapter examines a few challenges of conventional CPFEM and proposes remedies through advanced methods of computational mechanics. The methods discussed include element stabilization, multi-time-domain subcycling, and efficiency enhancement through adaptivity. It demonstrates the need for such numerical advances and the advantages gained. It provides motivation for looking beyond the available tools and making fundamental advances in field of computational mechanics that can benefit predictive modeling.

# 1    Introduction

Structural materials, like metals and alloys, are often characterized by microstructural heterogeneities in the form of nonuniform grain distributions, multi-colony sites, or polyphase aggregates in a polycrystalline ensemble. Morphological and crystallographic characteristics of microstructures strongly govern their mechanical behavior and failure response. For example, disparities in grain size, crystallographic orientations, micro-texture, and slip system resistance cause large stress concentrations and grain boundary dislocation pileups, leading to localized plastic flow and crack nucleation in Ti alloys (Sinha et al. 2006). Robust predictive models of deformation and failure, incorporating microstructural features and physical mechanisms, are necessary for effective material simulation and design.

The recent years have seen a surge in the use of image-based computational micro-mechanics models for predicting microstructure-property relationships. For polycrystalline microstructures undergoing large plastic deformation, image-based computational modeling entails determining micromechanical solution fields in statistically equivalent representative volume elements (SERVEs) of the material microstructure by executing computational methods like the finite element method (FEM), boundary element method (BEM), or fast Fourier transform (FFT) method. A SERVE is an optimally small computational domain that is created to capture the statistics of characteristic morphological and crystallographic variables in experimentally obtained electron backscattered diffraction (EBSD) or scanning electron microscopy (SEM) images. Methods of generating SERVEs are discussed in a previous chapter (by Ghosh and Groeber) of this handbook. The SERVE creation is generally followed by conforming mesh generation through discretization of the microstructure into simple geometric elements. Figure 1 shows a 3D SERVE constructed from a 2D EBSD scan of a Ti-7Al specimen and strain evolution in the image-based crystal plasticity finite element analysis.

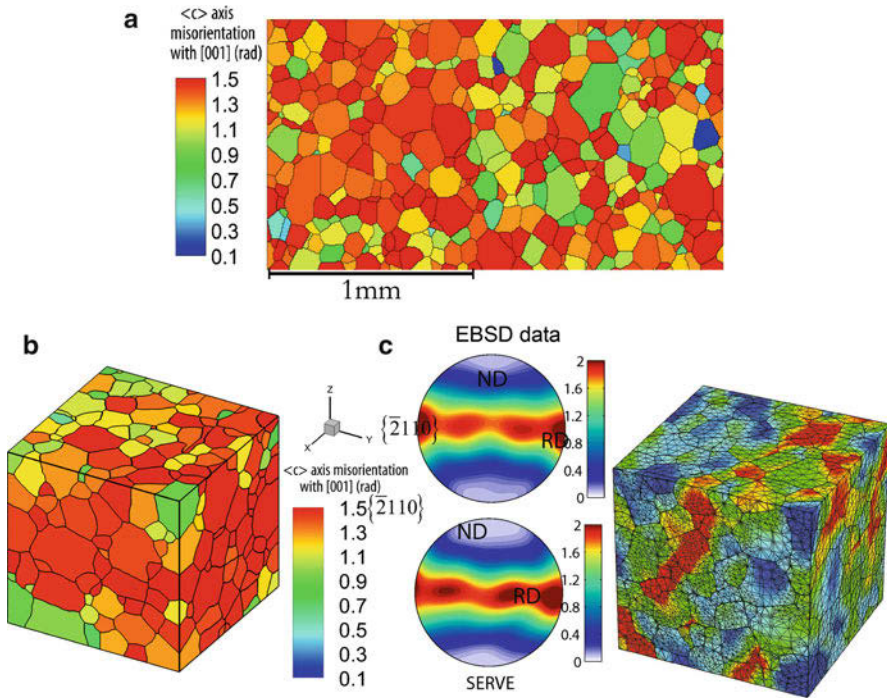
A majority of the computational models for polycrystalline microstructures undergoing large plastic deformation implement crystal plasticity constitutive models. Crystal plasticity finite element models, e.g., in Pierce et al. (1983), Busso et al. (2000), Staroselsky and Anand (2003), Matous and Maniatty (2004), Bridier et al. (2009), Roters et al. (2010a, b), Hasija et al. (2003), Deka et al. (2006), Venkataramani et al. (2007), Anahid et al. (2011), Meissonnier et al. (2001), Dunne et al. (2012), and Kalidindi and Schoenfeld (2000), generally incorporate these


**Fig. 1** (**a**) EBSD scan of the alloy Ti-7Al, (**b**) 529-grain 3D SERVE of dimension 300 μm showing $< c >$-axis misorientation and pole figures comparing SERVE data to EBSD, (**c**) contour plot of plastic strain at 20% strain with an applied compressive strain rate of $10^4 \, \text{s}^{-1}$

constitutive models in conventional finite element analysis codes like ABAQUS, LS-DYNA, etc. for full field analysis of short- and long-range evolution of state variables. Image-based CPFEM, in which microstructural SERVEs are modeled for predicting complex deformation mechanisms including crack nucleation, twin propagation, etc., are discussed in Thomas et al. (2012), Shahba and Ghosh (2016), Cheng and Ghosh (2015, 2017), and Ozturk et al. (2017).

A number of challenges arise when using CPFEM for modeling deformation mechanisms in complex microstructures, especially those involving phenomena like localization, twinning, crack propagation, fatigue, etc. Special methods in advanced computational mechanics should be developed to overcome these challenges and render robust predictive tools. This chapter begins with a brief description of CPFEM formulations, crystal plasticity constitutive relations, and their implementation. Subsequently, it examines three challenges that commonly persist with conventional CPFEM and offers remedies for overcoming them.

- *Element Stabilization*: Plastic incompressibility causes volumetric locking of commonly used tetrahedral elements in CPFE analyses. Special element technology should be developed for stabilizing spurious modes in these elements.

- *Time-Domain Subcycling for Disparate Deformation Rates*: Modeling local-ization phenomena, e.g., discrete twin evolution, in CPFEM often has low computational efficiency due to very fine simulation time steps. This is a major bottleneck in predicting rapidly evolving twin bands. A multi-time-domain subcycling algorithm can improve computational efficiency through the introduction of complementary sub-domains with selective fine and coarse time stepping.
- *Enhanced Efficiency with Adaptive CPFEM*: Conventional 3D CPFEM with high-resolution mesh can be computationally prohibitive, especially with algo-rithms for solving complex constitutive models. Increased efficiency can com-promise accuracy due to the use of coarse mesh and simplified computational domains. Hierarchical adaptive methods in CPFEM are capable of providing a solution to this shortcoming.

## 2    Crystal Plasticity FE Formulation and Solution Methods

Finite deformation, crystal plasticity finite element models typically invoke an incremental solution method, where the time (or equivalent loading) domain is discretized into finite number of steps. In an updated Lagrangian formulation (Bathe 2006) for a body under quasi-static conditions, the principle of virtual work for an increment transcending discrete temporal points $t$ and $t + \Delta t$ is written as:

$$\int_{\Omega^t} \delta \mathbf{E}_t^{t+\Delta t} : \mathbf{S}_t^{t+\Delta t} \, d\Omega = R^{\text{ext}\, t+\Delta t} \tag{1}$$

where $\Omega^t \subset \mathcal{R}^3$ is the computational domain at time $t$ and $\mathbf{E}_t^{t+\Delta t}$ and $\mathbf{S}_t^{t+\Delta t}$ correspond to the Green-Lagrange strain and the second Piola-Kirchhoff (PK) stress tensors, respectively, with respect to the reference configuration at time $t$. The weak form at time $t + \Delta t$ requires the following relations:

Incremental displacement : $\mathbf{u}^{t+\Delta t} = \mathbf{u}^t + \Delta \mathbf{u}$ \hfill (2a)

Green-Lagrange strain tensor : $\mathbf{E}_t^{t+\Delta t} = \dfrac{1}{2} \left( \dfrac{\partial \Delta \mathbf{u}}{\partial \mathbf{x}^t} + \left( \dfrac{\partial \Delta \mathbf{u}}{\partial \mathbf{x}^t} \right)^T + \left( \dfrac{\partial \Delta \mathbf{u}}{\partial \mathbf{x}^t} \right)^T \dfrac{\partial \Delta \mathbf{u}}{\partial \mathbf{x}^t} \right)$

\hfill (2b)

Second Piola-Kirchhoff stress : $\mathbf{S}_t^{t+\Delta t} = J_t^{t+\Delta t} \left( \mathbf{F}_t^{t+\Delta t} \right)^{-1} \boldsymbol{\sigma}^{t+\Delta t} \left( \mathbf{F}_t^{t+\Delta t} \right)^{-T}$

\hfill (2c)

External virtual work : $R^{\text{ext}\, t+\Delta t} = \displaystyle\int_{\Omega^{t+\Delta t}} \delta \mathbf{u}^{t+\Delta t} \mathbf{b} \, d\Omega + \int_{\Gamma_\sigma^{t+\Delta t}} \delta \mathbf{u}^{t+\Delta t} \bar{\mathbf{t}} \, d\Gamma_\sigma$

\hfill (2d)

In these relations, $\boldsymbol{\sigma}$ is the Cauchy stress, $\mathbf{u}$ is the displacement, $\mathbf{b}$ is the body force per unit volume, $\delta\mathbf{u}$ is a displacement variation, $\mathbf{F}$ is the deformation gradient, and $J$ is its determinant or Jacobian. All quantities in Eqs. (2) are at time $t + \triangle t$ and referred to the configuration at time $t$. The second Piola-Kirchhoff (PK) stress and the Green-Lagrange strain are, respectively, decomposed as:

$$\mathbf{S}_t^{t+\triangle t} = \boldsymbol{\sigma}^t + \triangle\mathbf{S}^t \quad \text{and} \quad \mathbf{E}_t^{t+\triangle t} = \triangle\mathbf{E}^t = \triangle\mathbf{e}^t(\triangle\mathbf{u}) + \triangle\boldsymbol{\eta}^t(\triangle\mathbf{u}) \tag{3}$$

where $\triangle\mathbf{S}^t$ denotes the increment of second PK stress from time $t$ to $t + \triangle t$ and the Green-Lagrange strain tensor is decomposed into a linear part $\triangle\mathbf{e}^t(\triangle\mathbf{u}) = \frac{1}{2}\left[\left(\frac{\partial\triangle\mathbf{u}}{\partial\mathbf{x}^t}\right)^T + \frac{\partial\triangle\mathbf{u}}{\partial\mathbf{x}^t}\right]$ and a nonlinear part given as $\triangle\boldsymbol{\eta}^t(\triangle\mathbf{u}) = \frac{1}{2}\left(\frac{\partial\triangle\mathbf{u}}{\partial\mathbf{x}^t}\right)^T \frac{\partial\triangle\mathbf{u}}{\partial\mathbf{x}^t}$. Substituting the strain decomposition, the incremental crystal plasticity constitutive relation $\triangle\mathbf{S}^t = \mathbb{C}^t(\mathbf{u}) : \triangle\mathbf{E}^t(\mathbf{u}) \approx \mathbb{C}^t(\mathbf{u}) : \triangle\mathbf{e}^t(\mathbf{u})$, and the relation $\delta\mathbf{E}^t \approx \delta\mathbf{e}^t$ in Eq. (1), the linearized weak form is written as:

$$\int_{\Omega^t} \delta\mathbf{e} : \mathbb{C}^t(\mathbf{u}) \cdot \triangle\mathbf{e}(\mathbf{u})d\Omega + \int_{\Omega^t} \delta\boldsymbol{\eta} : \boldsymbol{\sigma}^t d\Omega = R^{\text{ext}\,t+\triangle t} - \int_{\Omega^t} \delta\mathbf{e} : \boldsymbol{\sigma}^t \, d\Omega \tag{4}$$

where $\mathbb{C}^t$ is the local material tangent stiffness matrix. The nonlinear weak form in Eq. (4) is solved by using an iterative scheme such as the Newton-Raphson method (Bathe 2006). In the $i$-th Newton-Raphson iteration, the spatially discretized linearized Eq. (4) is written as:

$$\mathbf{K}_t^i\mathbf{u} = \boldsymbol{b}_{t+\triangle t} - \mathbf{R}_t^i \quad \text{where} \quad \triangle\mathbf{u}^{i+1} = \triangle\mathbf{u}^i + \mathbf{u} = \triangle\mathbf{u}^i + \mathbf{u} \tag{5}$$

where $\mathbf{K}_t^i$ is the global tangent stiffness matrix, $\triangle\mathbf{u}^{i+1} = \triangle\mathbf{u}^i + \mathbf{u}$ is the displacement update, and $\boldsymbol{b}_{t+\triangle t} - \mathbf{R}_t^i$ is the residual force vector for every iteration. These are, respectively, expressed as:

$$\mathbf{K}_t^i = \int_{\Omega^t} \mathbf{B}^T\mathbb{C}^{t,i}\mathbf{B}d\Omega + \int_{\Omega^t} \mathbf{B}_{NL}^T\boldsymbol{\sigma}^{t,i}\mathbf{B}_{NL}d\Omega \, , \, \mathbf{R}_t^i = \int_{\Omega^t} \mathbf{B}^T\boldsymbol{\sigma}^{t,i}d\Omega$$

$$\boldsymbol{b}_{t+\triangle t} = \int_{\Omega^t} \mathbf{N}^T\mathbf{f}^{t+\triangle t} \, d\Omega + \int_{\Gamma^t} \mathbf{N}^T\boldsymbol{t}^{t+\triangle t} \, d\Gamma$$

where $\mathbb{C}^{t,i}$ is the elastoplastic tangent stiffness matrix in the $i$-th iteration; $\mathbf{B}$ and $\mathbf{B}_{NL}$ are the linear and nonlinear strain-displacement matrices, respectively; and $\mathbf{N}$ is the matrix of shape functions. The Newton-Raphson iterations continue till the residual $\boldsymbol{b}_{t+\triangle t} - \mathbf{R}_t^i$ reaches a predetermined tolerance.

## 2.1     Crystal Plasticity Constitutive Models

Crystal plasticity constitutive models account for dislocation glide on crystallographic slip systems. A significant body of work exists on micromechanical modeling using crystal plasticity models due to glide on slip systems, using, e.g., power law description (Pierce et al. 1983; Asaro and Needleman 1985), the thermally activated theory of plastic flow (Kocks et al. 1975), or the dislocation density-based models (Roters et al. 2010a, b). While computational mechanics advances are in general independent of the constitutive relations used, a crystal plasticity constitutive model for *hcp* materials developed in Cheng and Ghosh (2015, 2017) is summarized here.

### 2.1.1     Kinematic Relations, Flow Rule, and Slip System Resistances

The deformation gradient at time $t$ admits a multiplicative decomposition into elastic and plastic components as:

$$\mathbf{F}_0^t = \mathbf{F}^e \mathbf{F}^p \quad \text{where} \quad \det \mathbf{F}^e > 0 \quad \text{and} \quad \det \mathbf{F}^p = 1 \tag{6}$$

where $\mathbf{F}^e$ accounts for elastic stretching and rigid-body rotation of the crystal lattice, while $\mathbf{F}^p$ corresponds to the incompressible plastic flow due to slip. The second Piola-Kirchoff stress is expressed in terms of the elastic Green-Lagrange strain tensor $\mathbf{E}^e \left( = \frac{1}{2} \left( \mathbf{F}^{eT} \mathbf{F}^e - \mathbf{I} \right) \right)$ as:

$$\mathbf{S} = \mathbb{C}^e : \mathbf{E}^e \tag{7}$$

where $\mathbb{C}^e$ is a fourth-order anisotropic elasticity tensor. The evolution of plastic deformation is expressed in terms of plastic velocity gradient $\mathbf{L}^p$ as:

$$\mathbf{L}^p = \dot{\mathbf{F}}^p \mathbf{F}^{p-1} = \sum_{\alpha=1}^{N_{\text{slip}}} \dot{\gamma}^\alpha \mathbf{s}_0^\alpha \quad \text{where} \quad \mathbf{s}_0^\alpha = \mathbf{m}_0^\alpha \otimes \mathbf{n}_0^\alpha \tag{8}$$

Here $\dot{\gamma}^\alpha$ is the slip rate on a slip system $\alpha$, $N_{\text{slip}}$ is the total number of slip systems, and the Schmid tensor $\mathbf{s}_0^\alpha$ associated with $\alpha$-th slip system is expressed in terms of the slip direction $\mathbf{m}_0^\alpha$ and slip plane normal $\mathbf{n}_0^\alpha$ in the reference configuration. The dislocation glide-based slip rate on the slip system $\alpha$ is described in Pierce et al. (1983) and Cheng and Ghosh (2015, 2017) using a power law as:

$$\dot{\gamma}^\alpha = \dot{\gamma}_0^\alpha \left| \frac{\tau^\alpha - s_a^\alpha}{s_*^\alpha} \right|^{\frac{1}{m}} \text{sign}(\tau^\alpha - s_a^\alpha) \tag{9}$$

where $\dot{\gamma}_0^\alpha$ is a reference slip rate for slip system $\alpha$ and $m$ is the exponent representing strain-rate sensitivity. The resolved shear stress on slip system $\alpha$ is expressed as $\tau^\alpha = \mathbf{F}^{eT} \mathbf{F}^e \mathbf{S} : \mathbf{s}_0^\alpha$. The athermal shear resistance $s_a^\alpha$ is due to the interaction of

the stress field between parallel dislocation lines and from grain boundaries, and the thermal shear resistance $s_*^\alpha$ is due to local repelling obstacles, such as forest dislocations and dislocation jogs.

Two types of dislocations are considered in the evolution of athermal $s_a^\alpha$ and thermal $s_*^\alpha$ shear resistances. These are (i) statistically stored dislocations (SSDs) associated with the homogeneous components of plastic flow characterized by vanishing net Burgers vector and (ii) geometrically necessary dislocations (GNDs) corresponding to stored polarized dislocation densities. GND accumulation is necessary for accommodating crystal lattice curvatures in single crystal bending or near-grain boundaries of polycrystalline aggregates. The athermal and thermal hardening rates due to the evolution of SSDs are given as:

$$\dot{s}_{a,\text{SSD}}^\alpha = \sum_{\beta=1}^N h_a^{\alpha\beta} \ |\dot{\gamma}^\beta \sin(\mathbf{n_0}^\alpha, \mathbf{t_0}^\beta)| \ \ \text{and} \ \ \dot{s}_{*,\text{SSD}}^\alpha = \sum_{\beta=1}^N h_*^{\alpha\beta} \ |\dot{\gamma}^\beta \cos(\mathbf{n_0}^\alpha, \mathbf{t_0}^\beta)|$$

(10)

where $\mathbf{t_0}^\beta$ is the dislocation line tangent vector for edge dislocation on the slip plane $\beta$ and the coefficient matrices $h_a^{\alpha\beta}$ and $h_*^{\alpha\beta}$ represent the hardening of athermal and thermal shear resistances on the slip system $\alpha$ due to activity on slip system $\beta$, respectively. The GND contributions to the slip system hardening are derived from two sources, viz., (i) dislocation components $\rho_{\text{GND},P}^\alpha$ parallel to the slip plane $\alpha$ that cause hardening due to the athermal shear resistance $s_a^\alpha$ and (ii) forest dislocation components $\rho_{\text{GND},F}^\alpha$, which contribute to hardening due to thermal shear resistance $s_*^\alpha$ as:

$$s_{a,\text{GND}}^\alpha = c_1 G b \sqrt{\rho_{P,\text{GND}}^\alpha} \ \ \text{and} \ \ s_{*,\text{GND}}^\alpha = \frac{Q_{\text{slip}}}{c_2 c_3 b^2} \sqrt{\rho_{F,\text{GND}}^\alpha}$$

(11)

where $G$ is the shear modulus, $Q_{\text{slip}}^\alpha$ is the effective activation energy for dislocation slip, and $c_1$, $c_2$, $c_3$ are constants representing the passing stress, jump-width, and obstacle-width, respectively. GND accumulation can be measured in terms of the curl of the plastic deformation gradient per unit area in the reference configuration, which corresponds to the Nye's dislocation density tensor $\boldsymbol{\Lambda} = -(\boldsymbol{\nabla}_X \times \mathbf{F}^{p^T})^T$ (Anahid et al. 2011). The Nye's tensor is related to the GND density components on each slip system as (Cheng and Ghosh 2017):

$$\boldsymbol{\Lambda} = \sum_{\alpha=1}^{\text{nslip}} \rho_{\text{GND},s}^\alpha \mathbf{b_0}^\alpha \otimes \mathbf{m_0}^\alpha + \rho_{\text{GND},et}^\alpha \mathbf{b_0}^\alpha \otimes \mathbf{t_0}^\alpha + \rho_{\text{GND},en}^\alpha \mathbf{b_0}^\alpha \otimes \mathbf{n_0}^\alpha$$

(12)

where $\boldsymbol{\rho}_{\text{GND},s}$, $\boldsymbol{\rho}_{\text{GND},et}$, and $\boldsymbol{\rho}_{\text{GND},en}$ are the GND density components with screw, in-slip-plane edge, and normal-to-slip-plane edge characteristics, per unit volume in the reference configuration and $\mathbf{b_0}^\alpha$ is the Burgers vector for a slip system $\alpha$. For *hcp* crystals, there are more slip systems than the number of components in $\boldsymbol{\Lambda}$, and hence $\rho_{\text{GND},s}$, $\rho_{\text{GND},et}$, and $\rho_{\text{GND},en}$ are obtained by solving a constrained

minimization problem of minimizing the $L_2$ norm of the GND densities subject to the constraint Eq. (12) (Anahid et al. 2011). Screw and edge GND components $\rho_{\text{GND},s}$, $\rho_{\text{GND},et}$, and $\rho_{\text{GND},en}$ on each slip system contribute, respectively, to the parallel ($\rho_{\text{GND},P}^{\alpha}$) and forest ($\rho_{\text{GND},F}^{\alpha}$) components of GNDs. The total athermal and thermal resistances are expressed as the sum of a part related to the evolving dislocation structure and another related to defects such as Peierls resistance, impurities, and point defects, as:

$$s_a^{\alpha} = s_{a,0}^{\alpha} + \sqrt{(s_{a,\text{SSD}}^{\alpha})^2 + (s_{a,\text{GND}}^{\alpha})^2} \;\; \text{and} \;\; s_*^{\alpha} = s_{*,0}^{\alpha} + \sqrt{(s_{*,\text{SSD}}^{\alpha})^2 + (s_{*,\text{GND}}^{\alpha})^2} \tag{13}$$

where $s_{a,0}^{\alpha}$ and $s_{*,0}^{\alpha}$ are initial resistances, independent of the dislocation structure.

### 2.1.2 Numerical Implementation of Crystal Plasticity Constitutive Model

The numerical time integration algorithm integrates the set of coupled differential equations in the nonlocal constitutive model using the following steps (details provided in Cheng and Ghosh 2015, 2017):

*Step A*:   Update stresses, plastic strains, and all state variables, keeping the nonlocal GND density and twin variables fixed, with known values of deformation variables at time $t$, as well as a given deformation gradient $\mathbf{F}(t + \triangle t)$;

*Step B*:   Update the GND densities and their rates of hardening by evaluating $\nabla_X \times \mathbf{F}^{p^T}$, using values in adjacent elements.

An implicit update algorithm is implemented in step A with update in step B (Cheng and Ghosh 2015, 2017). For step A, the algorithm assumes that the primary unknown variable is the second Piola-Kirchhoff stress $\mathbf{S}$ and seeks its solution from a set of six nonlinear equations by a Newton-Raphson iterative solver while updating other deformation and state variables.

$$\mathbf{S}(t + \triangle t) = \mathbf{S}^{tr} - \sum_{\alpha=1}^{N_{\text{tot}}} \triangle \gamma^{\alpha} \left( \mathbf{S}(t + \triangle t), s_a^{\alpha}(t + \triangle t), s_*^{\alpha}(t + \triangle t) \right) \mathbf{B}^{\alpha} \tag{14}$$

where $N_{\text{tot}}$ is the total number of slip systems and $\mathbf{B}^{\alpha}$ is defined as:

$$\mathbf{B}^{\alpha} = \mathbb{C} : \left[ \frac{1}{2} \left( \mathbf{A}(t + \triangle t)\mathbf{s}_0^{\alpha} + \mathbf{s}_0^{\alpha}\mathbf{A}(t + \triangle t) \right) \right] \tag{15}$$

with $\mathbf{A}(t + \triangle t) = \mathbf{F}^{p^{-T}}(t)\mathbf{F}^T(t + \triangle t)\mathbf{F}(t + \triangle t)\mathbf{F}^{p^{-1}}(t)$. The trial stress is expressed as $\mathbf{S}^{tr} = \mathbb{C} : \frac{1}{2} (\mathbf{A}(t + \triangle t) - \mathbf{I})$. In the iterative solution of Eq. (14), a residual is defined for $i$-th iteration the as:

$$\mathbf{G}(\mathbf{S}^i(t + \triangle t)) = \mathbf{S}^i(t + \triangle t) - \mathbf{S}^{tr} + \sum_{\alpha} \triangle \gamma^{\alpha} \mathbf{B}^{\alpha} \tag{16}$$

the $i + 1$-th iteration update to $\mathbf{S}$ is obtained as:

$$\mathbf{S}^{i+1}(t + \triangle t) = \mathbf{S}^i(t + \triangle t) - \left.\frac{\partial \mathbf{G}}{\partial \mathbf{S}}\right|_i^{-1} \mathbf{G}(\mathbf{S}^i(t + \triangle t)) \tag{17}$$

In this update procedure for $\mathbf{S}(t + \triangle t)$, the slip system resistances are held fixed. After convergence, the increment of shear resistances from SSDs are updated using Eqs. (10). The next step B computes the GND densities and associated hardening increments. A nonlocal, invoking the element gradient operator is implemented to evaluate $\boldsymbol{\Lambda}$. The gradient operator is calculated from nodal values using element shape functions. A super-convergent patch recovery (SPR) method is implemented to evaluate the nodal values of $\mathbf{F}_p$ from Gauss quadrature points to evaluate $\nabla_X \times \mathbf{F}^{pT}$ at quadrature points. Evolution of plastic strain in image-based CPFEM simulations of a SERVE is shown in Fig. 1c.

## 3      Stabilization of Four-Noded Tetrahedral Elements for CPFEM

Polycrystalline microstructures of metals and alloys often have sharp and tortuous grain boundaries and multiple grain junctions. Discretization, conforming to these domains in 3D, is conveniently accomplished using four-noded tetrahedral or TET4 elements. However, it has been observed, e.g., in Matous and Maniatty (2004), Gee et al. (2009), and de Souza Neto et al. (2005), that these elements suffer from severe volumetric locking when simulating incompressible materials. Crystal plasticity constitutive models exhibit near isochoric plastic flow (det $\mathbf{F}^p = 1$) and large volumetric strains in TET4 elements. High stresses induce high spurious dilatational energy and considerable error due to element locking. This is attributed to low *incompressibility constraint ratio*, defined as the ratio of number of degrees of freedom to the number of incompressibility constraints in the FE mesh.

A number of methods have been proposed for the stabilization of volumetric locking in TET4 elements (Gee et al. 2009; de Souza Neto et al. 2005; Dohrmann et al. 2000; Nguyen-Thoi et al. 2009). A key idea in these methods is to associate nodal points with patches corresponding to an assembly of surrounding sub-elements and subsequently to selectively integrate the dilatational and deviatoric parts of the FE weak form over these patches. This process reduces the incompressibility constraint ratio. However, these methods are not effective for anisotropic CPFE formulations for which the stress or the elastoplastic tangent stiffness tensor cannot be split into volumetric and deviatoric components. A finite deformation element formulation with a F-bar patch method has been introduced in de Souza Neto et al. (2005), while mixed elements have been proposed in Matous and Maniatty (2004) with augmentation strain fields in conjunction with a linearly interpolated pressure field.

Based on developments in Cheng et al. (2016), this section discusses three locking-free stabilized finite element formulations for CPFE analysis. They include a node-based uniform strain (NUS) element, a locally integrated B-bar (LIB)-based element, and a F-bar patch (FP)-based element.

## 3.1 Node-Based Uniform Strain and Locally Integrated B-Bar Elements

The node-based uniform strain (NUS) formulation, introduced in Dohrmann et al. (2000), assigns a patch of sub-elements $\hat{\Omega}^s = \sum_{i=1}^{N^s} \alpha_s^i \, \Omega_s^i$ to a node $s$ in the finite element mesh as shown in Fig. 2a. Here $N^s$ is the number of TET4 elements attached to a node $s$, $\Omega_s^i$ is the volume contribution of the $i$-th element to the patch $\hat{\Omega}^s$, and $\alpha_s^i$ is a scalar weighting factor. Within each patch, the strain increment $\hat{\mathbf{e}}^s$ is uniform and obtained by weighted averaging from surrounding elements as:

**Fig. 2** (**a**) 2D nodal patch in the NUS method, (**b**) nodal patch with strain distributions in the LIB method, and (**c**) patch of elements in the **F**-bar patch method

$$\hat{\mathbf{e}}^s = \sum_{i=1}^{N^s} w^i \mathbf{e}^{i,s} = \sum_{i=1}^{N^s} w^i \mathbf{B}^{i,t} \triangle \mathbf{q}^t = \hat{\mathbf{B}}^s \triangle \hat{\mathbf{q}}^s \tag{18}$$

$w^i$ is a relative volume-based weight for element $i$ and $\triangle \hat{\mathbf{q}}^s$ is the nodal displacement vector. $\hat{\mathbf{B}}^{s,t}$ is a strain-displacement matrix associated with the patch $s$, obtained by weighted assembling $\mathbf{B}^{i,t}$ from surrounding elements. The NUS formulation yields a constant tangent modulus and stress over the patch $s$, and one-point numerical integration is sufficient. However, this element can exhibit spurious zero or low-energy modes, causing large element distortion (Gee et al. 2009).

To overcome shortcomings of the NUS element for CPFE analysis with anisotropic elastoplastic stiffness matrix, a locally integrated B-bar (LIB) element is proposed in Cheng et al. (2016). This method alleviates volumetric locking without introducing spurious zero-energy modes. The strain increment is decomposed into volumetric and deviatoric parts by splitting the gradient matrix as $\mathbf{e} = \mathbf{e}^{\mathrm{vol}} + \mathbf{e}^{\mathrm{dev}} = \mathbf{B}^{\mathrm{vol}} \triangle \mathbf{q} + \mathbf{B}^{\mathrm{dev}} \triangle \mathbf{q}$. For reduced constraints, only the volumetric part of the strain increment $\mathbf{e}^{\mathrm{vol}}$ is assumed to be uniform inside the patch for each node $s$. The uniform volumetric strain increment $\hat{\mathbf{e}}^{s,\mathrm{vol}}$ is obtained as:

$$\hat{\mathbf{e}}^{s,\mathrm{vol}} = \sum_{i=1}^{N^s} w^i \mathbf{e}^{i,\mathrm{vol}} = \sum_{i=1}^{N^s} w^i \mathbf{B}^{i,\mathrm{vol}} \triangle \mathbf{q}^i = \bar{\mathbf{B}}^{s,\mathrm{vol}} \triangle \hat{\mathbf{q}}^s \tag{19}$$

$\bar{\mathbf{B}}^{s,\mathrm{vol}}$ is the volumetric part of the gradient matrix associated with a patch $s$. It is assembled from the $\mathbf{B}^{i,\mathrm{vol}}$ matrices of the surrounding elements with weights $w^i$. The deviatoric part of the strain increment $\mathbf{e}^{\mathrm{dev}}$ is constant in each of the contributing TET4 elements. This yields separate distributions of the volumetric and deviatoric strain increments over the domain, as illustrated in Fig. 2b. Each TET4 element is divided into four sub-domains of equal volume. Within each sub-domain, the volumetric and deviatoric parts of the strain increment are constant. The LIB element selectively reduces the volumetric strain components over the patch and keeps the deviatoric strain components unchanged.

## 3.2   F-Bar Patch-Based (FP) Element

The $\mathbf{F}$-bar patch (FP) formulation (de Souza Neto et al. 2005) has been shown to alleviate volumetric locking without introducing spurious zero-energy modes. The $\mathbf{F}$-bar patch method modifies the deformation gradient for weak enforcement of incompressibility in the element, rather than point-wise enforcement. The deformation gradient is decomposed into isochoric and volumetric components as:

$$\mathbf{F} = \mathbf{F}_{\mathrm{iso}} \mathbf{F}_{\mathrm{vol}} \quad \text{where} \quad \mathbf{F}_{\mathrm{iso}} = (\det \mathbf{F})^{-\frac{1}{3}} \mathbf{F} \text{ and } \mathbf{F}_{\mathrm{vol}} = (\det \mathbf{F})^{\frac{1}{3}} \mathbf{I} \tag{20}$$

Incompressibility in constitutive relations is enforced over a patch of elements, rather than in each element. This requires that elements in the mesh be assigned to non-overlapping patches as illustrated in Fig. 2c. For a patch $\mathscr{P}$ of a set of elements, with deformed and undeformed volumes $\Omega_{\text{patch}}^{t+\triangle t}$ and $\Omega_{\text{patch}}^{0}$, respectively, the deformation gradient in element $K \in \mathscr{P}$ is modified as:

$$\bar{\mathbf{F}}_K = \left[ \frac{\Omega_{\text{patch}}^{t+\triangle t}}{\Omega_{\text{patch}}^{0} \det \mathbf{F}_K} \right]^{\frac{1}{3}} \mathbf{F}_K \tag{21}$$

### 3.3    Performance of TET4 Element Stabilization in CPFEM

The performance of the locally integrated B-bar (LIB) element and the **F**-bar patch element with a patch size of 8 tetrahedrons (FP8) has been studied in Cheng et al. (2016) for CPFEM analysis of polycrystalline materials. Simulation results for a bicrystal compression test and a polycrystalline bending test of the *hcp* magnesium alloy *AZ*31 are compared with those for the standard TET4 element. The reference solution is for simulations with the B-bar stabilized eight-noded hexahedral element.

- **Bicrystal compression test**: A bicrystal of dimensions of $10 \times 10 \times 10\,\mu\text{m}$ is simulated under uniaxial compression using the standard TET4, LIB, and FP8 elements in CPFEM. Material constitutive models are given in Cheng and Ghosh (2015). The grain boundary is characterized by crystal orientations, which have Euler angles $[0°, 0°, 0°]$ and $[0°, 90°, 0°]$ in the $ZXZ$ convention for crystals 1 and 2, respectively, as shown in Fig. 3a. Displacement boundary conditions are applied on the top surface. A reference solution of the loading direction stress $\sigma_{zz}$ for CPFE analysis with hexahedral elements with **B**-bar stabilization is shown in Fig. 3b. Results using the standard, LIB and FP8 TET4 elements are shown in Fig. 3c, e, respectively. Non-smooth distribution of the local stress with high stress concentration is observed at the grain boundary using standard TET4 element, compared to other stabilized elements. The stress error is evaluated as the $L2$ norm of the difference with the reference solution as $\|e\|_{L2} = \frac{\left[ \int_{\Omega} \left( \sigma_{ij} - \sigma_{ij}^{ref} \right) \left( \sigma_{ij} - \sigma_{ij}^{ref} \right) d\Omega \right]^{\frac{1}{2}}}{\left( \int_{\Omega} \sigma_{ij} \sigma_{ij} d\Omega \right)^{\frac{1}{2}}}$. The corresponding error plots for different elements with increasing mesh densities are shown in Fig. 4a. The average convergence rate for LIB and FP8 elements is 0.75. For CPFE analysis, these elements exhibit similar results with much smaller errors compared to the standard TET4 element. The evolution of hydrostatic stress at the grain boundary with increasing strain is plotted in Fig. 4b. Unrealistically large stresses are observed with conventional TET4 elements, while the LIB and FP8 elements produce results that are consistent with the stabilized hexahedral element.
- **Micro-twin nucleation in polycrystalline magnesium alloy**: CPFE simulations are conducted for twin nucleation using a microstructural model of the
**Fig. 3** (**a**) Boundary conditions and crystallographic orientations in the bicrystal compression test; distribution of loading direction stress at 5% strain using simulation results of (**b**) eight-noded B-bar hexagonal elements with a mesh of 18,081 nodes, (**c**) standard TET4 element, (**d**) LIB element, and (**e**) FP8 element, all with a mesh of 11,862 nodes

polycrystalline Mg alloy AZ31 shown in Fig. 5a. The $40 \times 40 \times 40\,\mu$m statistically equivalent virtual microstructure with 103 grains of average size of $10\,\mu$m is developed from electron backscattered diffraction data. The microstructure is discretized into 113,425 TET4 elements. Displacement boundary conditions are applied at a rate of $0.004\,\mu$m/s on the two surfaces in Y-direction, which bend the microstructure about the X-axis on Y-Z plane. Details of the twin nucleation model are given in Sect. 4.1. The GND density contour plots in Fig. 5b, c show highest GND concentrations close to grain boundaries. The conventional TET4 element shows a much stiffer response in Fig. 6b compared to the other elements. The FP8 element shows a slightly lower level of locking than LIB elements due to a lower constraint ratio. The twin nucleation predictions in Fig. 6a show a much earlier twin nucleation time (97 s) with the TET4 elements in comparison with the LIB element (160 s) and FP8 element (180 s).

In summary, both the LIB and FP elements stabilize the local stresses and GND distributions in CPFE analyses and converge to the reference solution. The FP element is capable of providing slightly better results than the LIB element for an optimal patch size. A study on computational efficiency in Cheng et al. (2016) have shown that the FP element outperforms the LIB element with a considerably lower simulation time. From accuracy and efficiency considerations, the FP element is deemed more suitable for stabilized CPFE analysis.

# 4 Multi-Time-Domain Subcycling for Discrete Twin Evolution

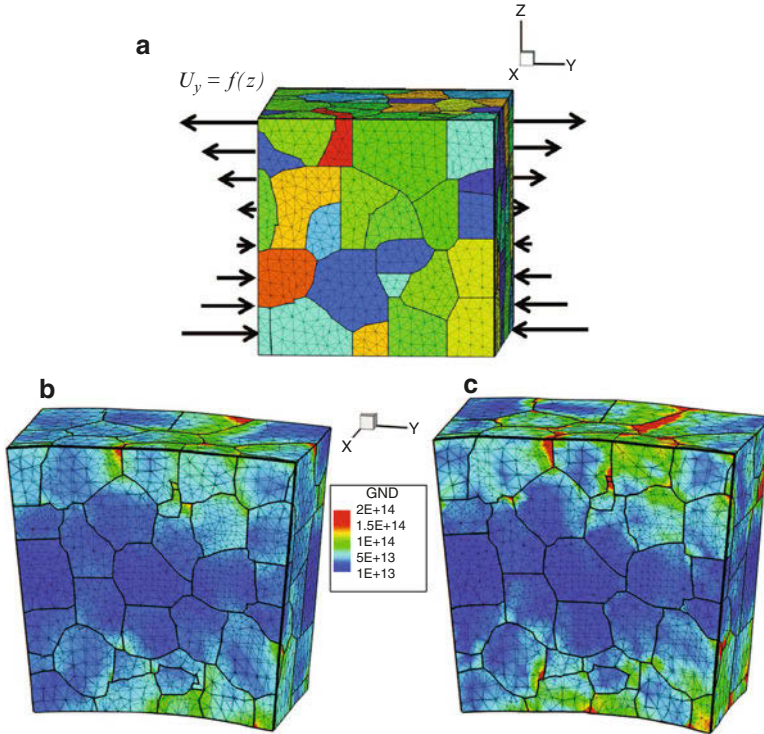
Deformation twinning is a critical deformation mechanism that causes change in lattice orientations with localized deformation inside thin twin bands. Twinning can induce characteristic features like plastic anisotropy, tension-compression asymmetry, and local softening in the material response. Many crystal plasticity-based twinning models adopt a twin volume fraction approach that treats twin


**Fig. 5** Schematic of the polycrystalline AZ31 SERVE showing the applied boundary conditions; GND densities distribution after 500s using: (**b**) TET4 and (**c**) FP8 elements

evolution in the same way as slip (Staroselsky and Anand 2003; Izadbakhsh et al. 2011; Zhang and Joshi 2012). These approaches do not account for deformation heterogeneity within discrete twins. Explicit twin formation models within the CPFE framework have been proposed based on phenomenological twin formation criteria and adaptive mesh generation methods in Abdolvand and Daymond (2013) and Knezevic et al. (2016). Explicit twinning models hold promise, provided the physics of twin nucleation, propagation, and interactions are correctly accounted for. The author has recently implemented an image-based crystal plasticity FE model with discrete twin evolution in Cheng and Ghosh (2017) and Cheng et al. (2018) to study deformation and twinning mechanisms in polycrystalline microstructures of Mg alloys.

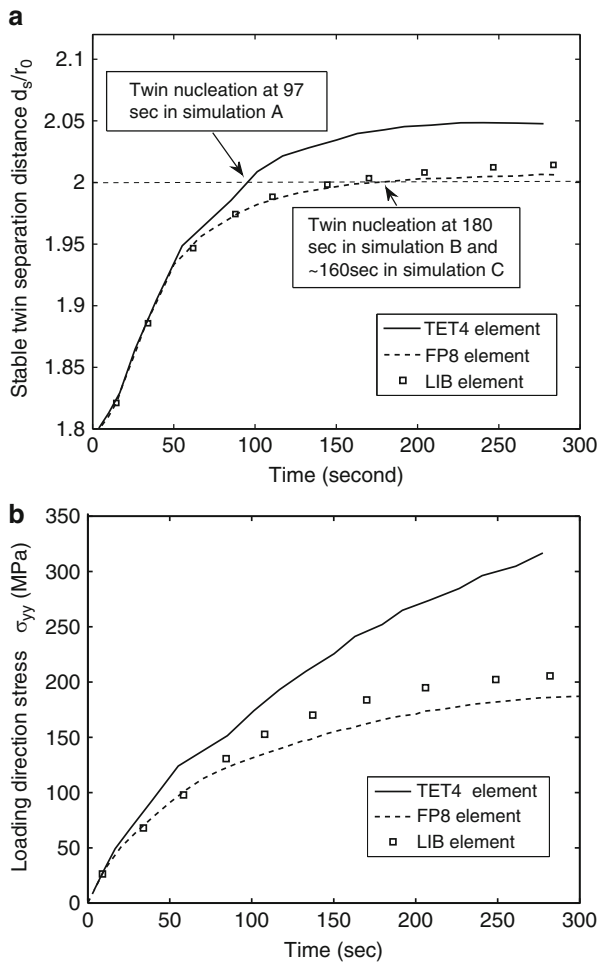
A major difficulty with image-based CPFE simulations of polycrystalline microstructures delineating explicit twin formation is the high demands on computing time. This is attributed to the discrepant deformation rates between the domains of rapidly evolving twins and the surrounding crystalline matrix. The high rates of twin evolution in localized bands lead to numerical instability with the stiff nonlinear crystal plasticity constitutive equations, requiring very fine simulation


**Fig. 6** (**a**) Micro-twin dissociation distance as a function of loading time and (**b**) loading direction stress at a material point with loading time

time steps. A quantitative study on the critical time step size required for numerical stability for a CPFE simulation of a Mg alloy with evolving explicit twins has been conducted in Ghosh and Cheng (2018). The study shows that while 97% of elements require a minimum time step size of $\Delta t = 10$ s, only 3% of the elements located in localized twin bands require a significantly smaller time step of $\Delta t = 0.0391$ s. The reduction in time step size corresponds to a factor of $\sim$255. Requiring all elements in the computational domain to be integrated with the smaller step size can cause a huge loss of efficiency and could potentially be computationally intractable. While single time step methods to accelerate slip-based crystal plasticity models have been proposed, e.g., in Roters et al. (2010a), they are insufficient for twin evolution models.

## 4.1    Crystal Plasticity Constitutive Models with Twinning

The crystal plasticity constitutive models in Sect. 2.1 are extended in this section to account for both dislocation glide and twinning on crystallographic slip and twin systems. Twinning reorients the crystallographic lattice symmetrically by reflection across a mirror or twin plane in the reference configuration. In the twinned regions, plastic flow takes place by gliding of twin partial dislocations on twin planes, as well as by dislocation glide. The plastic velocity gradient in twinned region is subsequently expressed as:

$$\mathbf{L}^p = \dot{\mathbf{F}}^p \mathbf{F}^{p-1} = \sum_{\beta=1}^{N_{\text{twin}}} \dot{\gamma}_{tw}^{\beta} \mathbf{s}_{0,tw}^{\beta} + \sum_{\alpha=1}^{N_{\text{slip}}} \dot{\tilde{\gamma}}^{\alpha} \tilde{\mathbf{s}}_{0,\text{slip}}^{\alpha} \text{ where } \mathbf{s}_{0,tw}^{\beta} = \mathbf{m}_{0,tw}^{\beta} \otimes \mathbf{n}_{0,tw}^{\beta} \quad (22)$$

$\dot{\gamma}_{tw}^{\beta}$ is the shearing rate on a twin system $\beta$, $\dot{\tilde{\gamma}}^{\alpha}$ is the slip rate in the reorientated slip system $\alpha$, $N_{\text{twin}}$ is the number of twin systems, $\mathbf{m}_{0,tw}^{\beta}$ is the twin shearing direction vector, and $\mathbf{n}_{0,tw}^{\beta}$ is the twin plane normal in the reference configuration. Dislocation slip in the twinned volume occurs on a slip plane $\tilde{\mathbf{n}}_{0,\text{slip}}^{\alpha}$ in the direction $\tilde{\mathbf{m}}_{0,\text{slip}}^{\alpha}$, with mirror symmetry to the directions $\mathbf{n}_{0,\text{slip}}^{\alpha}$ and $\mathbf{m}_{0,\text{slip}}^{\alpha}$ in the matrix region. Twin nucleation and propagation models, developed in Cheng and Ghosh (2015, 2017) for *hcp* materials, are summarized here.

- *Twin nucleation*: The twin nucleation model is based on the elastic dislocation theory of twin nucleation by non-planar dissociation of a sessile pyramidal $\langle c + a \rangle$ dislocation. Three simultaneous conditions should be satisfied for the dissociation process to spontaneously occur and form a stable twin nucleus. They are (i) dissociation condition, $E_{\text{ini}} \geq E_{tw}(d = 0) + E_r$; (ii) irreversibility condition, $E_{\text{ini}} > E_F (d = d_s, \tau_{tw})$; and (iii) reliability condition, $d_s > 2r_0$. Here $E_{\text{ini}}$ is the initial system energy prior to dissociation, corresponding to the dislocation line self-energy of sessile pyramidal $\langle c + a \rangle$ dislocations, $E_{tw}$ is the self-energy of the twinning dislocation loop, $E_r$ is the self-energy of stair-rod dislocations, and $E_F$ is the post-dissociation total system energy. The distance $d$ is the separation distance between two partial dislocations and $d_s$ is the stable separation distance. Detailed description of the various energies and other critical parameters in the twin nucleation model are provided in Cheng and Ghosh (2015, 2017).
- *Explicit twin propagation*: Twin propagation involves two motions, viz., twin elongation by rapid gliding of twin partial dislocations on twin planes and twin thickening by migrating twin boundaries from the current twin planes to every other $\{10\bar{1}2\}$ twin plane (Keshavarz and Ghosh 2013, 2015). Gliding of twin partial dislocations occurs by a mixed shear-shuffle process, for which twin propagation is deemed as thermal activation process. The velocity of twin partial dislocation on a twin plane is expressed as:

$$v_{\text{glide}} = f_{\text{shuffle}}\lambda_{\text{shear}} \left[ \exp\left( -\frac{\triangle F - \tau A_P b_{tw}}{K_B T} \right) \right] \tag{23}$$

where $f_{\text{shuffle}}$ is the shuffling frequency, $\lambda_{\text{shear}}$ is the shear distance, $b_{tw}$ represents the Burgers vector on a twin system, $\tau$ is the effective resolved shear stress on the twin plane, and $A_P$ is the shearing area. The term $\exp\left( -\frac{\triangle F - \tau A_P b_{tw}}{K_B T} \right)$ is the probability of gliding with an internal energy barrier $\triangle F$. The twin boundary migrates when the twin partial dislocation glides on the adjacent twin plane.

A stimulated slip model is used to model thickening of twins. It assumes the existence of immobile lattice dislocations, which penetrate multiple twin planes. The velocity of twin partial dislocations crossing twin planes has been derived as:

$$v_{\text{thick}} = \frac{d_{tw}}{\triangle t_{tw}} = d_{tw} P_{\text{promoter}} \rho_{\text{tot}} l_{tw} v_{\text{glide}} \tag{24}$$

where $d_{tw}$ denotes the distance between twin planes, $\triangle t_{tw}$ is the average time required to meet a promoter, $P_{\text{promoter}}$ is the fraction of dislocations that act as promoters, $\rho_{\text{tot}}$ is the total dislocation density, and $v_{\text{glide}}$ and $l_{tw}$ are, respectively, the velocity and length of moving dislocations. The time-averaged, twin system plastic shear rate in Eq. (22) due to twinning is obtained from the Orowan equation as:

$$\dot{\gamma}_{tw} = \rho_{tw} b_{tw} v_{\text{glide}} = \dot{\gamma}_{0,tw} \exp\left( -\frac{\triangle F - \tau A_P b_{tw}}{K_B T} \right) \tag{25}$$

where $\dot{\gamma}_{0,tw} = \rho_{tw} b_{tw} f_{\text{shuffle}} \lambda_{\text{shear}}$ and $\rho_{tw}$ is the density of twin partial dislocations. For $\{10\bar{1}2\}$ twin in Mg, $\gamma_{tw}^{\max} = 0.1289$. In simulations, the shear on a twin system quickly reaches this upper bound once an integration point is twinned.

The complex interaction between dislocations and twin boundaries is modeled by the evolution of a slip/twin system resistance in which Eq. (25) is reduced to a conventional shear resistance-based power law model as:

$$\dot{\gamma}_{tw} = \dot{\gamma}_{0,tw} \left| \frac{\tau}{s_{tw}} \right|^{\frac{\triangle F}{K_B T}} \text{sign}(\tau) \tag{26}$$

For a twin system $\alpha$, the rate of shear resistance is expressed as $\dot{s}_{tw}^{\alpha} = \sum_{\beta=1}^{N_{\text{slip}}} h^{\alpha\beta} |\dot{\gamma}^{\beta}|$, where the hardening matrix $h^{\alpha\beta}$ quantifies hardening due to dislocation slip in the twinned regions. Implementation of twin evolution in the CPFEM framework is discussed in Cheng and Ghosh (2017) and Cheng et al. (2018).

## 4.2    Adaptive Subcycling for Accelerated CPFEM

An adaptive multi-time-domain subcycling algorithm is developed in Cheng and Ghosh (2017) and Ghosh and Cheng (2018) to avert the low efficiency due to minimum critical time step requirements, by activating a differential temporal resolution in the computational domain. The algorithm partitions the microstructural domain into sub-domains that are classified as critical (high strain rate) and noncritical (low-strain rate). For optimal efficiency, time integration in each sub-domain is conducted with its own independent time step, as determined from stability and accuracy criteria. For a twinned microstructure, regions of twin bands are solved with fine time steps, while the remaining regions use coarse time steps. A schematic layout of the algorithm is shown in Fig. 7. With a known state at time $t$, the integration algorithm for the time increment $t$ to $t + \triangle t$ solves the noncritical sub-domain problem using the coarsest possible time increment $\triangle t$ and the critical sub-domain problem using fine time steps $\triangle \tau \ll \triangle t$. To achieve global equilibrium for the computational domain, the different sub-domains are coupled, and residuals at the interfaces of discrepant time steps in the assembled sub-domains are minimized using a predictor-corrector scheme. The subcycling algorithm evaluates displacement correctors by equilibrating nodal residual forces since displacement fields at nodal points of adjacent sub-domains will not satisfy compatibility in general. Decomposition of the computational domain necessitates the evaluation of critical time steps for each element. With known state variables at time $t$, the critical time increment in each element is estimated from convergence of time integration of the constitutive model. If the time integration fails to converge, a scaled reduction of the original time increment is made. The essential steps in a staggered algorithm for evolving twins are given next and detailed in Cheng and Ghosh (2017) and Ghosh and Cheng (2018).

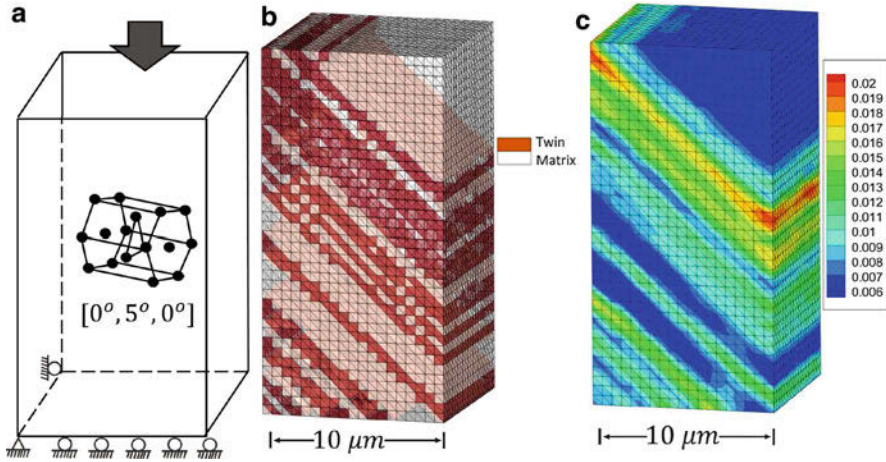
**Fig. 7** Schematic of the subcycling algorithm showing partitioning and equilibrating domains


**Fig. 8** (**a**) A pure Mg single crystal computational model subjected to constant strain rate, uniaxial loading, (**b**) simulated twins, and (**c**) Lagrangian strain $E_{yy}$ at 1% strain, using the subcycling-induced CPFE model with a time step $\triangle t = 10\,\text{s}$

1. At time $t$ compute trial displacements and partition coarse and fine sub-domains;
2. Solve the coarse sub-domains with the larger time increment $\triangle t$;
3. Solve the fine sub-domains with scaled time increments $\triangle \tau_i$;
4. From the coarse and fine sub-domain residuals, obtain displacement corrector;
5. Check for equilibrium, update twin domains, and nucleate new twins.

Two factors affect the computational speedup with the subcycling method. They are (i) the ratio of degrees of freedom (DOF) in fine timescale sub-domain to the DOF of entire domain, i.e., $\frac{N^F}{N^{\text{total}}}$, and (ii) the ratio of fine time step $\triangle \tau$ to coarse time step $\triangle t$, i.e., $\frac{\triangle \tau}{\triangle t}$. In Ghosh and Cheng (2018) it is shown that $\frac{\triangle t}{\triangle \tau}$ and $\frac{N^{\text{total}}}{N^F}$ are the key factors in reducing the number of operations. Higher acceleration rates can be achieved by the subcycling method if the deformation is localized in smaller regions and if deformation rates exhibit more heterogeneity. The effectiveness of the twin evolution algorithm with subcycling is tested for single and polycrystalline microstructures.

- **Deformation-Induced Twin Evolution in Single Crystal Mg**: A single crystal simulation of pure Mg is conducted in Cheng and Ghosh (2017) to validate the subcycling-accelerated CPFE model for discrete twin evolution. The microstructure, shown in Fig. 8a, has a dimension of $20 \times 10 \times 10\,\mu\text{m}$ with an Euler angle orientation of $[0°, 5°, 0°]$ in the ZXZ convention. It is discretized into 67,418 TET4 (FP8) elements with 13,021 nodes. The calibrated constitutive parameters for CPFE analysis are provided in Cheng and Ghosh (2017). A uniaxial, constant strain rate of $1 \times 10^{-4}$ is applied in a compressive manner

on the top surface, which causes the formation of $\{10\bar{1}2\}$ tension twins. The 5° tilt in the crystal orientation makes the Schmid factor of twin variant 1 to be highest among all 6 twin variants. Thus only twin variant 1 is formed during simulations.

The evolved discrete twins and Lagrangian strain distribution at 1% strain are shown in Fig. 8b, c, respectively. The $[0°, 5°, 0°]$ orientation causes the $(\bar{1}102)\,[1\bar{1}01]$ twin variant to have the highest Schmid factor. The only exception is that a $(10\bar{1}2)\,[\bar{1}011]$ twin variant (variant 4 of the extension twin systems) occurs at the upper left corner of the model due to the local stress state. The localized strain distribution is caused by easy gliding of twins. Approximately 3.6 times speedup is achieved with subcycling without any loss of accuracy.

- **Twin Evolution in Polycrystalline RVE**: An image-based RVE of the Mg alloy AZ31 containing 620 grains of average grain size of $32\,\mu m$ in a $300 \times 300 \times 300\,\mu m$ box is shown in Fig. 9a. A uniaxial, compressive strain rate of $1 \times 10^{-3}\,s^{-1}$ is applied normal to transverse direction (TD) surface. The figure shows texture with the propagation of twin bands, where the lattice in the twinned region is reorientated by nearly 86°. The volume-averaged stress-strain response from CPFE simulations are compared with experimental results from Beyerlein et al. (2011) in Fig. 9b. The CPFE simulation with subcycling algorithm has a speedup by a factor of 6. In summary, the multi-time-domain subcycling enhanced CPFEM is highly effective for predicting nucleation and propagation of explicit twins in single crystal and polycrystalline microstructures of metals and alloys.

## 5  Adaptive Hierarchical CPFEM with Enhanced Wavelet Basis

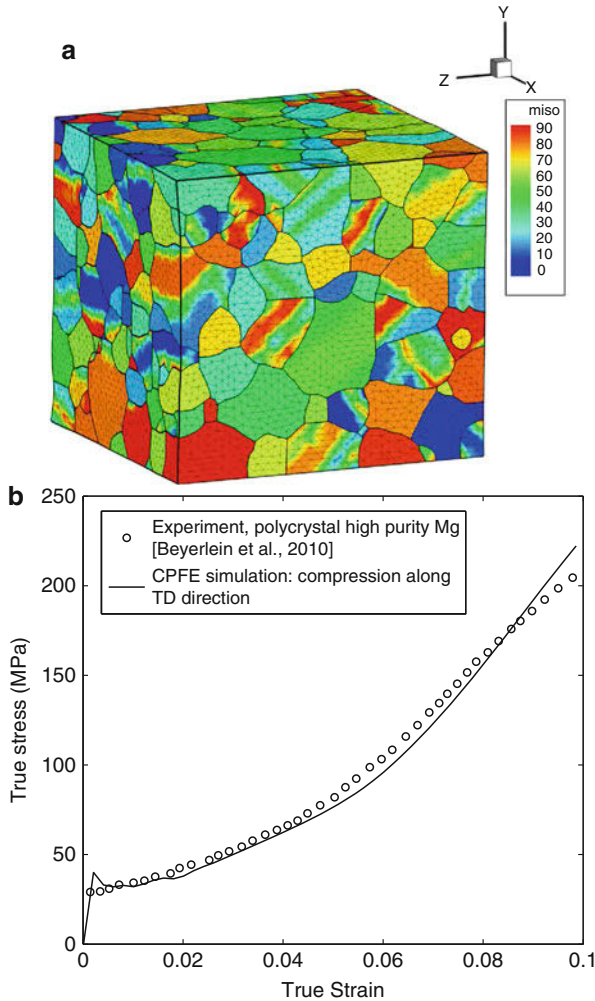
Image-based CPFE modeling of polycrystalline materials, e.g., in Roters et al. (2010b), Meissonnier et al. (2001) and Cheng and Ghosh (2017) often requires very high 3D resolution for accurate representation of realistic microstructures. This can incur prohibitively high computational costs in simulating deformation leading to localized phenomena like fatigue failure or deformation twin evolution. A few alternative computational methods have emerged to efficiency-related shortcomings of CPFEM. The elastic-viscoplastic self-consistent models in Lebensohn and Tome (1994) treat grains as embedded inclusions in a homogeneous medium and avoid the need to represent stress heterogeneity inside each grain. The fast Fourier transformation (FFT)-based methods in Moulinec and Suquet (1998) and Lebensohn et al. (2012), and discussed in another chapter of this part, are very efficient, especially for large regular sampling grid simulations with periodicity. The use of FFT methods for discontinuous or high gradient fields can however lead to truncation errors due to the Gibbs phenomenon, propagating from the discontinuity. Regularization methods are being applied to correct this effect, e.g., in Gottlieb et al. (1992). These approaches


**Fig. 9** (**a**) Texture evolution with deformation in contour plots of the angles between the [0001] lattice axis in each grain and the ND direction (Z-axis) at 2% strain and (**b**) volume-averaged stress-strain response compared with experimental results in Beyerlein et al. (2011)

can also have suboptimal convergence rates due to nonconforming sampling grids that require a large number of degrees of freedom. The present section however seeks an adaptive enrichment method for optimally augment the efficiency of CPFEM while retaining accuracy.

A wavelet-basis enhanced adaptive hierarchical CPFEM has been developed in Azdoud and Ghosh (2017) and Azdoud et al. (2017) to improve computational efficiency and accuracy of FE analyses of polycrystalline microstructures. The method adaptively creates an optimal discretization space conforming to the

solution profile by projecting the solution onto a set of scaling and multi-resolution wavelet basis functions. The multi-resolution property is particularly advantageous for approximating a field using a minimal set of wavelet basis functions. The second generation family of wavelets (Sweldens 1998) is used to generate hierarchical shape functions using the so-called *lifting scheme*. Given the scaling functions at a coarse and fine scale, the lifting scheme defines a set of wavelet functions that complement the coarser set of interpolation functions to uniquely project any function decomposed on a finer set. Complex irregular meshes are easily constructed for these wavelet bases, which make them ideal candidates for enrichment functions in the wavelet-enhanced hierarchical FEM. A summary of the methods and results from Azdoud and Ghosh (2017) and Azdoud et al. (2017) are presented here.

## 5.1 Wavelets for Optimal Enrichment Basis Functions

Wavelet basis functions span the space of square integrable functions $L^2(R)$ through translation and dilation of the scaling function $\varphi(x)$, which satisfies the refinement condition $\varphi(x) = \sum_{k=1}^{N_{\text{filt}}} h_k \varphi(x)(2x - k)$. Parameters $h_k$ and $N_{\text{filt}}$ characterize the wavelet basis and correspond to the components of a low-pass filter. These functions can be used for optimal multi-resolution hierarchical enrichment, conforming to the solution estimate $\tilde{\mathbf{u}}$ profile. Properties that render them ideal for multi-scale enrichment (Azdoud and Ghosh 2017; Azdoud et al. 2017) are:

- *Compact support*: Wavelet functions have compact support. Solutions in wavelet bases do not exhibit spurious instabilities, such as the Gibbs phenomena.
- *Multi-resolution*: Wavelet bases have multi-resolution characteristics that represent the differences between hierarchical scales. Wavelet functions with the Reisz basis property avoid aliasing by ensuring completeness of each scale.
- *Compatibility with FE discretization*: Second-generation wavelet functions (Sweldens 1998) can be constructed from any irregular hierarchical FE mesh.
- *Vanishing moments*: The integral of wavelet functions over any domain is zero. Thus a small coefficient has negligible contribution to the solution.

The lifting scheme creates wavelets for the hierarchical FE shape functions. A *lazy* wavelet $\tilde{\varphi}_\beta^{l-1}$ is first created from hierarchical shape functions, followed by transformation through the lifting scheme by adding vanishing moments to yield:

$$\varphi_\beta^{l-1}(\mathbf{x}) = \tilde{\varphi}_\beta^{l-1}(\mathbf{x}) - \sum_\lambda^R a_\lambda N_\lambda^{l-1}(\mathbf{x}) \tag{27}$$

Here $l$ denotes the scale, $N_\lambda^{l-1}$ is a standard FE shape function at scale $l - 1$ and coefficient $a_\lambda$ is chosen from the condition: $\int_\Omega \varphi_\beta^{l-1}(\mathbf{x}) d\Omega = 0 \quad \forall \beta \in [1, p(l)]$. Each scale of wavelets represents a Reisz basis in $\Omega$. Adding $N_\lambda^{l-1}$

extends the compact support of the wavelet function $\varphi_\beta^{l-1}$ to the whole domain, i.e., $\bigcup_\beta^{p(l)} \text{supp}(\varphi_\beta^{l-1}) = \Omega$. The lifting scheme with $R = 2$ is sufficient for all the above properties.

## 5.2    Adaptive Solution Enhancement with Wavelet Basis Functions

The hierarchical wavelet-enhancement is based on the finite deformation crystal plasticity FE formulation summarized in Sect. 2. The solution in the Newton-Raphson algorithm corresponds to the $i$-th iterative correction $\mathbf{u}$ of the displacement increment $\triangle \mathbf{u}^i$ in a time step between $t$ and $t + \Delta t$. In the proposed algorithm (Azdoud et al. 2017), an adaptive enhancement is made to the first iterate of the solution, i.e., $\Delta \mathbf{u}^{i=1} = \mathbf{u}$. It is premised upon finding an optimal discretization space $V^{h(t)}(\Omega)$ for $\mathbf{u} = \Delta \mathbf{u}^{i=1}$ that will reduce the discretization error to within a prescribed tolerance. Assume that the approximate solution $\mathbf{u}^h$ at time $t$ has been evaluated on the discretized space $V^{h(t)}(\Omega) \subset V(\Omega)$ as:

$$\mathbf{u}^h(\mathbf{x}) = \sum_\alpha^m \mathbf{u}_\alpha^h N_\alpha(\mathbf{x}) + \sum_\beta^{m_{\text{enr}}(t)} \mathbf{w}_\beta^h \varphi_\beta^{(t)}(\mathbf{x}) \quad \forall \mathbf{x} \in \Omega \tag{28}$$

The standard finite element basis $N_\alpha$ corresponds to the approximation of $\mathbf{u}$ in the original coarse FE discretization space at time $t_0$ with $m$ as the number of nodes in this mesh. The adaptive method introduces a set of enrichment functions $\{\varphi\}^{m_{\text{enr}}}$ in the hierarchy, which expand the discretization space $V^h(\Omega)$ to an enriched space $V^{h_{\text{enr}}}(\Omega) \supset V^h(\Omega)$. $m_{\text{enr}}$ corresponds to the number of additional enrichment nodes that are hierarchically added to the initial number $m$. Assume that the set $\{\phi\}^n$ is an arbitrarily large ($n \to \infty$) and sufficient set of multi-scale hierarchical enrichment functions for the coarse discretization space $\{N\}^m$. The functions in the set $\{\phi\}^n$ are the standard $C^0$ hierarchical FEM shape functions obtained by uniform subdivision of the coarse mesh. For the increment $\Delta t \in t \to t + \Delta t$, the adaptive method finds an optimal set $\{\varphi\}^{m_{enr}(t+\Delta t)} \subset \{\phi\}^n$ such that:

$$\|\mathbf{u} - \mathbf{u}^{h_{enr}}\| \le \epsilon \text{ where } \mathbf{u}^{h_{enr}}(\mathbf{x}) = \sum_\alpha^m \mathbf{u}_\alpha^{h_{enr}} N_\alpha(\mathbf{x}) + \sum_\beta^{m_{enr}(t+\Delta t)} \mathbf{w}_\beta^{h_{enr}} \varphi_\beta^{t+\Delta t}(\mathbf{x}) \quad \forall \mathbf{x} \in \Omega \tag{29}$$

An iterative error estimation-solution enrichment algorithm is implemented with iteration steps denoted by $k$. The resulting algorithm for a time step from $t \to t + \Delta t$ has two iterative loops, viz., (i) iterations for the first estimate of $\mathbf{u}$, in which the enrichment functions $\{\varphi\}^{m_{\text{enr}}(t+\Delta t)}$ are sought, and (ii) the Newton-Raphson iterations for the constitutive update. The adaptive iterative scheme for an iteration step $(k + 1)$ to determine $\{\varphi\}^{m_{\text{enr}}(t+\Delta t)}$ is presented in Azdoud et al. (2017).

## 5.3    Results with Adaptive CPFEM for Polycrystals

The effectiveness of the adaptive, wavelet-enhanced hierarchical CPFE model is examined in this example. A polycrystalline microstructure of the *hcp* Ti6242 alloy, containing 208 grains in a computational microstructure of dimensions $124 \times 124 \times 124\,\mu$m is simulated under uniaxial displacement conditions. The $z$-axis misorientation distribution is shown in Fig. 10a. The loading is applied uniformly on the top surface ($z = 124\,\mu$m) with a displacement ramp from $u_z = 0$ to $u_z = 3\,\mu$m, while the surface ($z = 0$) is constrained with $u_x = u_y = u_z = 0$. The transversely

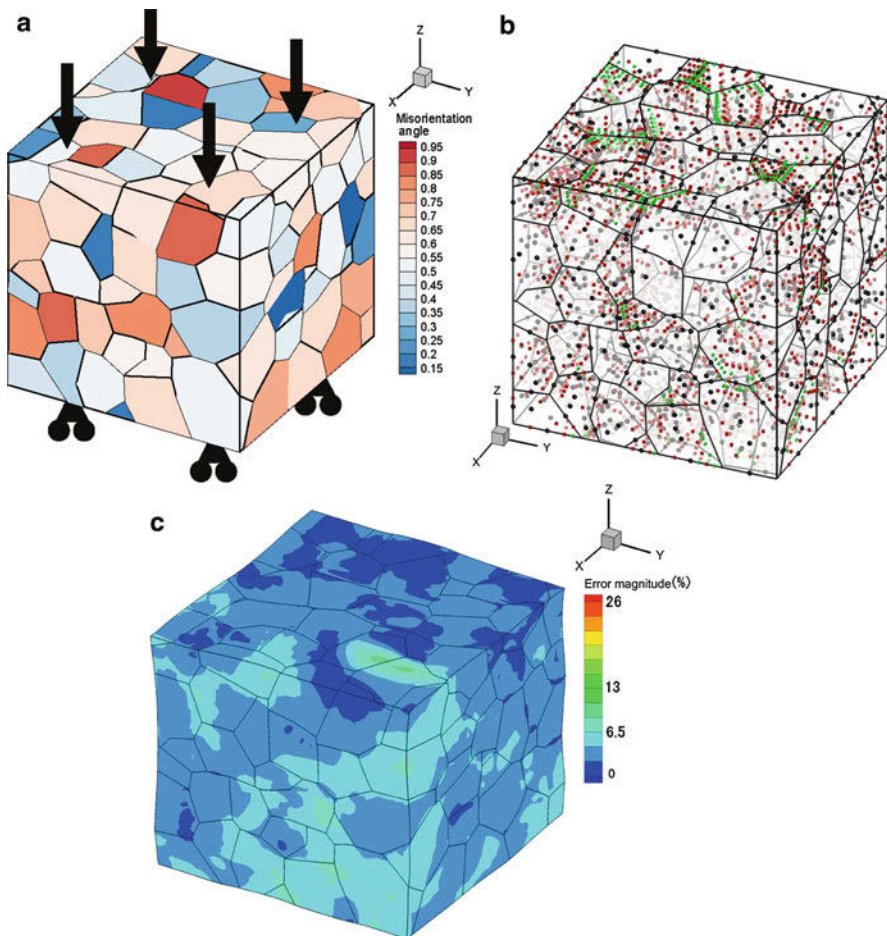

**Fig. 10**  (**a**) A 208 grain polycrystalline microstructure showing $z$-axis misorientation distribution, (**b**) node enrichment positions, where the black spheres, red cubes, and green octahedra denote the enrichment scales 1, 2, and 3, respectively, and (**c**) contour plot of error $e_l(\%)$ for the wavelet adapted model with 42,000 enrichment DoFs
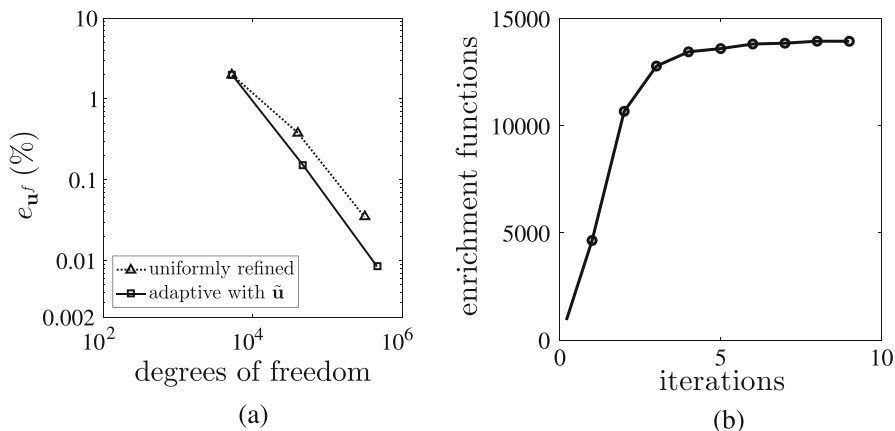

**Fig. 11** (**a**) Log-log plot of the $L_2$ norm of displacement error as a function of DoF and (**b**) evolution of the number of $\tilde{\mathbf{u}}^*$ enrichment functions as a function of the number of iterations

elastic stiffness coefficients and crystal plasticity parameters are given in Azdoud and Ghosh (2017) and Azdoud et al. (2017).

For the elasticity problem only, the wavelet adaptivity admits three scales of enrichment. The coarse-scale solution $\mathbf{u}^h$ is computed on a mesh composed of $N_e = 9485$ tetrahedral elements with $N_n = 1,778$ nodes. The mesh for the fine-scale reference FE solution $\mathbf{u}^f$, as well as the adapted FE model with three scales of enrichment, both have $N_e = 4,856,320$ tetrahedral elements and $N_n = 821,569$ nodes. A total of 14,000 enrichment functions are used, with 5568 functions at scale 1, 6730 functions at scale 2, and 1702 functions at scale 3. In Fig. 10b, nodal positions of the 14,000 enriched function $\{\varphi\}^{m_{\text{enr}}}$ are predominantly in regions of large error near highly misoriented grain boundaries. Figure 10c shows the magnitude of the displacement error $e_l = \sqrt{\frac{(\mathbf{u}^{henr} - \mathbf{u}^f)^T (\mathbf{u}^{henr} - \mathbf{u}^f)}{(\mathbf{u}^f)^T (\mathbf{u}^f)}} \times 100(\%)$ for the adapted solution $\mathbf{u}^{henr}$. The convergence rate of the solution with the adaptive hierarchical FE method is compared to that of a uniformly enriched FE method in Fig. 11a. The average convergence rate for the adaptive method is $\sim \mathcal{O}(N^{-1.22})$ compared to $\sim \mathcal{O}(N^{-0.99})$ for the standard FEM. The evolution of the number of enrichment functions with the number of iterations is depicted in Fig. 11b for a tolerance $\epsilon = 0.002$. Convergence is generally reached in under five iterations. The CPU time for different simulations show a significant gain in efficiency with reduced error for the adaptive method in comparison with a uniformly refined mesh.

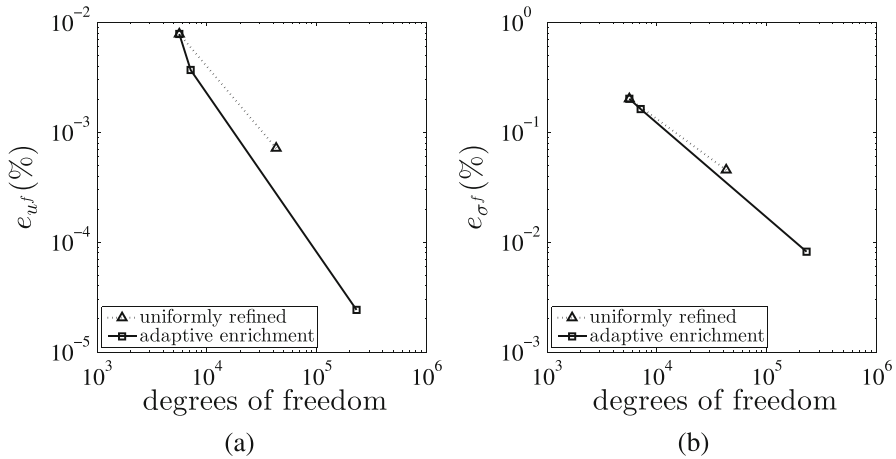
For crystal plasticity simulations, convergence rates of the wavelet-enriched adaptive method are compared with that for the uniformly refined hierarchical FEM solutions in Fig. 12a, b. The convergence rates are calculated from displacement and stress errors. The adaptive method converges faster than the uniformly refined hierarchical FEM simulations. For the adaptive method, the convergence rate is $\sim \mathcal{O}(N^{-1.509})$ for the displacement norm and $\sim \mathcal{O}(N^{-0.861})$ for the stress norm,


**Fig. 12**  Log-log plot of convergence rates of (**a**) displacement error $e_{\boldsymbol{u}f}$, (**b**) stress error $e_{\boldsymbol{\sigma}f}$ as a function of degrees of freedom at the end of simulation

while those for the uniformly refined model are $\sim\mathcal{O}(N^{-1.179})$ and $\sim\mathcal{O}(N^{-0.733})$, respectively. In conclusion, the proposed adaptive wavelet enrichment method is robust with reduced computational costs while preserving the accuracy of local fields. It is very efficient when a conforming mesh cannot be obtained, such as for heterogeneous materials.

## 6      Conclusions

This chapter emphasizes the need to explore novel methods and algorithms in computational mechanics to facilitate robust and efficient crystal plasticity FE-based modeling of deformation and failure in metals and alloys. Image-based CPFE models incorporate characteristic microstructural features, as well as under-lying physical mechanisms. The claim for such innovative developments is made through three challenging problems that are often bottlenecks in crystal plasticity modeling of extreme mechanisms such as twinning and localization. Remedies to these challenges are developed through methods of element stabilization, multi-time-domain subcycling, and efficiency enhancement through wavelet enhanced hierarchical adaptivity. Many other opportunities exist in the crystal plasticity FE modeling arena. For example, when modeling fatigue failure, it is necessary to conduct simulations for a large number of cycles with a high time resolution to reach local states of crack nucleation and growth. A powerful, multi-resolution wavelet transformation induced multi-time scaling (WATMUS) algorithm has been developed in Chakraborty and Ghosh (2013) and Joseph et al. (2010) for accelerated cyclic simulations. The WATMUS methodology introduces wavelet decomposition of displacements and all associated variables in the finite element formulation to

decouple the response into a monotonic cycle-scale behavior and oscillatory fine timescale behavior. In conclusion, this chapter provides motivation to look beyond available tools and make fundamental advances for effective predictive capabilities. Many of these codes will be hosted at the JHU Software Hub cited in Ghosh (2018).

**Abstract**

Recent years have seen the explosion of a field of research now commonly termed "materials informatics." Though the roots of this research can be traced back to the early 1970s, and mostly driven by the chemistry community, the last 20 years have seen the pioneering and then systematic application of deterministic or stochastic methods based on large data collections to design or discover novel materials, where the materials data themselves are the outcome of calculations, or exploit these in synergy with experimental databases. This chapter aims to provide an overview of some of the most successful and exciting efforts worldwide in this area, with a focus on materials science and condensed-matter physics, but also including notable contributions in chemistry and molecular science. Contributions can be broadly assigned to two different areas: efforts dedicated to producing and/or storing curated or raw computational or experimental data and associated materials properties, and machine-learning

e-mail: nicola.marzari@epfl.ch

efforts dedicated to leveraging those data to bypass the need of expensive, and typically first-principles, calculations. Both hold great promise in our quest to understand, predict, and design the properties of novel materials.

# 1    Introduction

Adamson and Bush (1973, 1974) noted how "some chemical information systems hold property data as well as structure diagrams in machine-readable forms," and suggested that "if structure-property relationships could be investigated easily within chemical information systems, then the usefulness of the systems would be considerably increased." In 1980, Marvin Cohen and collaborators (▶ Chap. 3, "Modeling Solids and Its Impact on Science and Technology") were able to show that computational condensed-matter physics and materials science had reached the capability to predict materials properties entirely from first-principles, i.e., without any experimental input. The roots of what is happening today are all here: calculations can predict materials data, and this materials data can be used to predict materials properties, which is almost a revolution. For all good revolutions, a cadre of revolutionaries is needed. I will list three in the vanguard that I found inspiring. Franceschetti and Zunger (1999) introduced the materials community to the concept of inverse design – by capturing a structure-property relationship in a model (something that had been done for quite some time, e.g., using cluster, Ising, or Heisenberg expansions to predict the energetics of alloys, or the phase transitions of magnetic materials), it becomes possible to focus on the inverse design problem – rather than predicting the properties of a structure, search for the structure that could deliver a target property. Jóhannesson et al. (2002) showed how first-principles calculations can be executed reliably in a high-throughput manner, allowing to explore and identify novel and promising metal alloys. Curtarolo et al. (2003) showed how one can leverage the calculation of large sets of first-principles materials data to extract heuristic rules that could then be applied to, e.g., crystal structure prediction. Therefore, inverse design, high-throughput, and data mining all make their appearance in the materials world.

The unsung heroes of this revolution are, of course, the computer codes that make it all possible. The calculation of complex materials properties from first-principles required, and requires, efforts that span decades and involved dedicated individuals and groups, albeit rewarded by the enormous impact that these tools have on the community. (*Nature* identified, in 2014, 12 papers dedicated to density-functional theory among the 100 most-cited papers ever in the field of science, engineering, and medicine/life sciences (Van Noorden et al. 2014).) Without these computer codes, it would not have been possible to translate the pioneering ideas mentioned earlier into an industrial revolution of computing farms incessantly and inexorably extending and refining databases of calculated materials properties, and of intelligent computer agents condensing that knowledge in parametric and nonparametric forms to predict even more, or even less expensively, the properties. Given the exponential growth of throughput capacity for the past 30 years, doubling every 14 months, the future

seems exceedingly predictable – less hype than reality, materials informatics is here to stay.

---

## 2    Contributed Chapters to "Materials Informatics"

Contributions presented in this chapter offer broad vistas for the field and highlight some of the most relevant efforts in producing, collecting, and curating computational data; in collecting and curating experimental data; and in leveraging either resource with machine learning.

Some of the early efforts in calculating and providing large amounts of computational data for materials, alluded to in the Introduction, are represented by the Materials Project (https://materialsproject.org/), based at LLNL; by the AFLOW consortium (http://aflowlib.org/), based at Duke University; by the Open Quantum Materials Database (OQMD, http://oqmd.org/), based at Northwestern University; by the Computational Materials Repository (CMR, https://cmr.fysik.dtu.dk/), based at DTU; and by the Materials Cloud (https://www.materialscloud.org/), based at EPFL and CSCS. All these are discussed in this section, and several are aggregated in the NoMaD repository (https://nomad-repository.eu/), based at the Fritz Haber Institute (for an overview, including chemical and molecular repositories, see the contribution in ▶ Chap. 88, "Machine Learning and Big-Data in Computational Chemistry"). All these repositories support an open-access model to the data, although the complexity of bulk retrieval may vary. Notable, in this respect, has been the creation of the OptiMaDe consortium (http://www.optimade.org), collecting all the above players, with the stated goal of making all the materials databases interoperational by developing a common REST API.

Of course, the field of materials repositories predates computational efforts, and a long-term visionary effort has been in place for decades to curate experimental structures and properties into the Pauling File (http://paulingfile.com/), together with its recent web frontend (https://mpds.io/). The Pauling File is also notable for having collected through the years an extensive and standardized dictionary of materials properties (http://paulingfile.com/index.php?p=physical%20properties) that could be very helpful for the ontologies being developed nowadays, spearheaded by the European Materials Modelling Council (https://emmc.info/) and the RDA Task Group for Semantic Assets for Materials Science. The Inorganic Crystal Structure Database (ICSD, http://www2.fiz-karlsruhe.de/icsd_home.html) provides also an extensive database of materials' structures, and has been used extensively as a starting point for the calculations in the Materials Project, AFLOW, and OQMD. At variance with these two previous efforts, where data are licensed, the Crystallography Open Database (COD, http://www.crystallography.net/cod/) is an open-access collection of crystal structures of organic, inorganic, and metal-organic compounds and minerals, freely accessible.

The effort to drive thousands of calculations (or even millions, as is the case of AFLOW) has had a second major benefit – i.e., it has driven the development of the infrastructure needed to execute, run, and monitor calculations in

fully automatic ways – this is implemented with different levels of complexity in ASE (https://wiki.fysik.dtu.dk/ase/), AiiDA (http://www.aiida.net), Atomate (https://atomate.org), AFLOWπ (http://aflowlib.org/src/aflowpi/), or Abipy (https://github.com/abinit/abipy), to name a few starting with A. Such capabilities will make it increasingly straightforward for other computational modeling groups or experimental teams to rapidly benefit from the usage of complex electronic-structure codes, with modeling services even available freely when open-source codes are used (e.g., the model of the Work section of the Materials Cloud).

Python has also emerged as the de facto standard for all these projects and has been adopted by the community following the early efforts of ASE and PyMatGen (http://pymatgen.org/) that have now become power tools for the analysis of the materials data produced by the simulations, leading to the automatic construction of complex materials relationships, such as phase or Pourbaix diagrams.

Several efforts are showcased here, with an extensive description of the computational infrastructure being developed in the Materials Project (▶ Chap. 81, "The Materials Project: Accelerating Materials Design Through Theory-Driven Data and Tools"), in the AFLOW consortium (▶ Chap. 82, "The AFLOW Fleet for Materials Discovery"), and in the Swiss and European Centres MARVEL (http://nccr-marvel.ch) and MaX (http://www.max-centre.eu/) through the AiiDA materials' informatics framework and the Materials Cloud dissemination platform (▶ Chap. 83, "Open-Science Platform for Computational Materials Science: AiiDA and the Materials Cloud").

The curation of experimental datasets is discussed in the two contribution from the Pauling File (▶ Chap. 84, "The PAULING FILE Project and Materials Platform for Data Science: From Big Data Toward Materials Genome") and COD (▶ Chap. 85, "Crystallography Open Database (COD)"), that often, together with ICSD and the chemistry databases, provide the starting point, the verification step, and the variety that is needed for the discovery or prediction projects.

Last, and most excitedly, the wealth of information becoming available makes it possible to data mine the current resources, to uncover unexpected correlations, or to provide novel suggestions for optimal materials, but especially to short-circuit the entire expensive electronic-structure framework by machine learning the simple or complex properties – from potential energy surfaces to NMR chemical shifts – that would otherwise be obtained with calculations that are several orders of magnitude more expensive. It can be envisioned that even the most expensive quantum chemistry and wave function methods in electronic-structure – providing the highest degree of reliability and predictive accuracy – could powerfully provide the baseline for machine learning, thus reaching what has been up to now the impossible dream of modeling complex properties or materials in complex environments with full quantum-mechanical accuracy.

The field is here extensively represented by contributions spanning the world of materials and of molecules, and bridging them. In ▶ Chap. 86, "Quantum Machine Learning in Chemistry and Materials," the fundamental mathematical formulations of quantum machine learning (i.e., of models which can be used in the context of quantum-mechanical training and testing data) are discussed, highlighting also

how up to now the primary focus has been on ground-state or local minimum properties, rather than more challenging excited states or properties that depend in an ill-conditioned manner on atomic coordinates. In ▶ Chap. 87, "Machine Learning of Atomic-Scale Properties Based on Physical Principles," a mathematical framework is presented, based on the concept of the atomic density, for building descriptors of atomic environments that preserve the geometric symmetries and chemically sensible limits. Coupled with kernel regression, this allows the fitting of complex models of physical properties on the atomic scale, both scalars such as interatomic potentials (force fields) and tensors such as multipole moments and quantum mechanical operators. In ▶ Chap. 88, "Machine Learning and Big-Data in Computational Chemistry", a broad perspective on current efforts in machine learning, and materials screening and discovery, is provided. Notably, it also underscores how computational modeling is becoming increasingly a high-velocity and high-volume field, but where variety is somewhat lacking, leading to the need to address heterogeneous, unstructured data to recover variety.

## 3 Final Concluding Remarks

Some considerations on data production, collection, and exploitation are then warranted. One might go as far as highlighting first a core difference in the world of data, and identify three broad data categories:

- Social data (harvested, most often in uncontrolled conditions)
- Experimental data (harvested, in largely controlled conditions)
- Computational data (generated, in controlled conditions)

The fact that in computational science the data are calculated, under controlled conditions, reminds us of a core difference with respect to other fields – i.e., putting squarely at the center of this effort the codes and workflows of different codes that are able to produce automatically, and on-demand, the desired quantity. And each of these quantities has its own pedigree – how expensive it is to calculate, how much intermediate data are needed; the balance between the cost of calculating and the cost of storing being property and material specific. But, of course, one needs data to begin with, and so right now there is a healthy and biodiverse ecosystem of curated, raw, and aggregated data that explore all the different models – all probably needed, and all useful in different ways. If one wanted a simplification, one could say that the most pressing needs in computational sciences are those of having the following:

1. Highly curated data (fully verified, with standardized protocols)
2. Data on demand (the capability of calculating new data on an automatic request)

The interplay of theory, algorithms, and workflows that are able to deliver these goals are able to produce the vast trove of simple or complex materials'

properties that can then be data mined or machine learned – these not only are great accelerators, but promise to direct searches in directions that would not have been intuitive to soft-matter intelligence.

These considerations bring us to underscore the power that machine learning will have in materials research. Here, three easy predictions are made. First, the emergence of parametric and non-parametric models, such as neural network and Gaussian approximation potentials, has delivered the remarkable recognition that it is possible to reproduce with great accuracy and at costs that are reduced by 4– 5 orders of magnitude of the potential energy surfaces of materials (Behler and Parrinello 2007; Bartók et al. 2010; Li et al. 2015). This has, and will have, a revolutionary impact in those fields where deterministic or stochastic sampling of materials relies on length and time scales a few orders of magnitude larger than current capabilities, and with an accuracy that only first-principles methods can deliver. This is very much the domain of metals' plasticity, or nucleation and growth – both fields underpin all our efforts in understanding and engineering synthesis and manufacturing of advanced materials – from vapor-liquid-solid growth of nanostructures to fast precipitation in additive manufacturing. Second, the capability to machine-learn properties that are very expensive to calculate – from thermodynamics with chemical accuracy to magnetic spectroscopies or transport properties – will provide a great accelerator in the direct, high-throughput discovery or the inverse design of materials. Last, harvesting and correlations can take place in the social domain – natural language processing aims to identify properties or even chatter in the editorial or social world – and in the experimental domain, so one can easily envision an ever-growing effort to leverage heterogeneous information from these domains, and combine with homogenous (but systematically biased, in mysterious ways) computed data to aim for that elusive, but most desirable, breakthrough of a novel material able to contribute, hopefully, to the growth and well-being of our society.

**Abstract**

The Materials Project (MP) is a community resource for theory-based data, web-based materials analysis tools, and software for performing and analyzing calculations. The MP database includes a variety of computed properties such as crystal structure, energy, electronic band structure, and elastic tensors for tens of thousands of inorganic compounds. At the time of writing, over 40,000 users have registered for the MP database. These users interact with this data either through the MP web site (https://www.materialsproject.org) or through a REpresentational State Transfer (REST) application programming interface (API). MP also develops or contributes to several open-source software libraries to help set up, automate, analyze, and extract insight from calculation results. Furthermore, MP is developing tools to help researchers share their data (both computational and experimental) through its platform. The ultimate goal of these efforts is to accelerate materials design and education by providing new data and software tools to the research community. In this chapter, we review the history, theoretical methods, impact (including user-led research studies), and future goals for the Materials Project.

# 1    History and Overview of the Materials Project

Materials scientists and engineers have always depended on materials property data to inform, guide, and explain research and development. Traditionally, such data originated almost solely from experimental studies. In the past 10–15 years, it has become possible to rapidly generate reliable materials data using scalable computer simulations of the fundamental equations of physics such as the Schrödinger equation. This paradigm shift was induced by a combination of theoretical advances, most notably the development of density functional theory (DFT), algorithmic improvements, and low-cost computing.

The Materials Project (MP, or "The Project") was founded in 2011 as a collaborative effort to leverage ongoing advances in theory and computing to accelerate the research and design of new materials. The Project rests on a comprehensive database of predicted properties of materials that is the result of executing millions of DFT simulations on supercomputing resources. At the time of writing, this database includes $>69,000$ inorganic materials with crystal structures and total energies, $>57,000$ materials with electronic band structures, $>48,000$ with electronic transport properties (Fig. 1) (Ricci et al. 2017), $>30,000$ with XANES k-edge spectra (Dozier et al. 2017), $>15,000$ with conversion battery properties, $>6000$ with elastic tensors (de Jong et al. 2015a), $>3,000$ with intercalation battery
**Fig. 1** Example of a large electronic transport data set in MP generated through computations. Each point represents one compound, with Seebeck coefficient versus electron conductivity (divided by $\tau$) plotted. The color represents the thermoelectric power factor ($S^2\sigma$), and the point size is proportional to the bandgap (Ricci et al. 2017). This data set is available through the MPContribs platform (see Sect. 6.2) at: https://materialsproject.org/mpcontribs/boltztrap

properties, >1,000 with piezoelectric tensors (de Jong et al. 2015b), >1,000 with dielectric tensors (Petousis et al. 2017), and > 1000 elemental surface energies (Tran et al. 2016). This database is continually expanding with more materials and more properties (see Fig. 2 for an example of properties listed in the current iteration).

The Project launched its publicly accessible web site in October 2011 and has since grown into a multi-institution collaboration as part of the US Department of Energy Office of Basic Energy Sciences (BES). The web site provides access to the database as well as applications (or "apps") that combine and visually present the data for specific analyses such as phase diagram generation or battery electrode evaluation. The MP web site hosts more than 40,000 registered users worldwide consisting of a diverse set of researchers and students from academia, industry, and educational institutions (Figs. 3 and 4). The diversity of the audience base highlights the usefulness of a theory-based materials database across the spectrum of education, research, and development activities.

Apart from the core data and web site, MP helps develop and maintain a set of open-source software libraries for setting up, executing, analyzing, and deriving insights from calculations. These libraries, which include pymatgen (Ong et al. 2013), custodian, FireWorks (Jain et al. 2015), and atomate (Mathew et al. 2017),

**Fig. 2** An example of a "materials detail" page for BaTiO$_3$ on the Materials Project web site. The information available includes crystal structure parameters, thermodynamic properties, electronic band structure and density of states, a simulated x-ray diffraction pattern, simulated x-ray absorption spectra, a substrate matcher, an elasticity tensor, a piezoelectric tensor, a table and links pertaining to calculation methodology details, and metadata regarding the crystal structure source
**Fig. 3** Total number of registered users since release of the MP web site and fraction of users belonging to various institution types

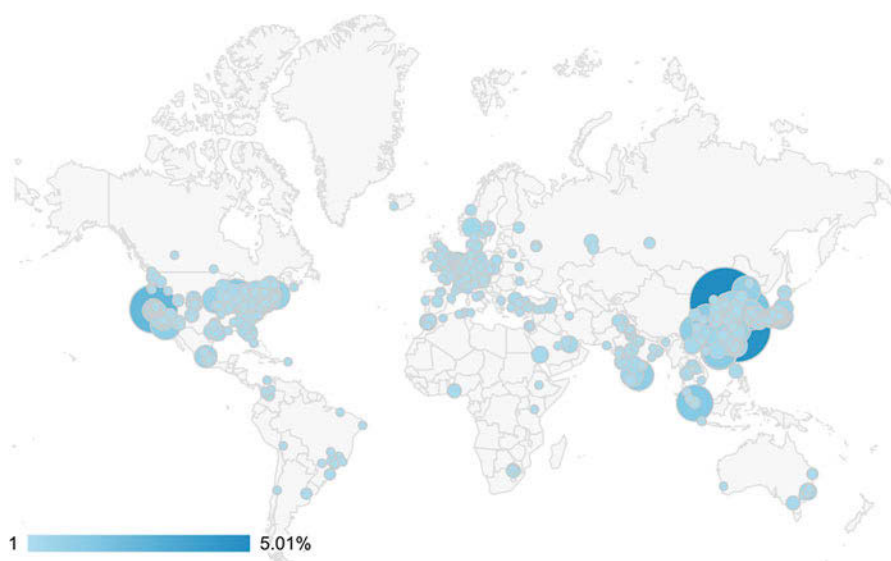

**Fig. 4** Amount of Materials Project user sessions by city for the month of October 2017. Sessions originated in 112 countries, 36 of which totaled >100 sessions

have been used by hundreds of researchers worldwide. The newest additions to MP allow users to suggest compounds for computation as well as contribute their own data (theoretical or experimental) to the database. Furthermore, MP hosts educational workshops focused on its online and programmatic infrastructure, and the MP web site has become an integral teaching tool in several materials science courses.

As the state of the art in theory and computing are bound to change, the specifics of MP's data, scope, capabilities, and infrastructure will no doubt change as well. Nevertheless, this chapter summarizes the current state of the Materials Project.

## 2 Underlying Theoretical Formalism and Development of Materials Design "Apps"

### 2.1 Theoretical Methods

The Materials Project's core data set consists of results obtained from density functional theory (DFT) calculations on a library of inorganic compounds. DFT is well suited for creating a database of materials properties because it has fewer parameters that require tuning for different materials systems and because the computational cost for small- to medium-sized (approximately 300 atoms or less) systems is manageable. DFT methods have become standardized to a large extent such that various software implementations with slightly different parameters (e.g., pseudopotentials) produce very similar results (Lejaeghere et al. 2016).

Nevertheless, selecting a robust set of parameters for high-throughput computations is still not trivial. It is important to emphasize there is currently no perfect DFT functional as they are all approximations to the complete set of physics that define materials phenomena. For example, strongly correlated systems remain challenging. It is typically possible to treat even complex systems with specialized methods in single studies. However, when constructing a large database with many compounds, such specialized treatment is difficult to achieve practically and would also lead to inconsistent and often incompatible results between various compounds. Additionally, one must more carefully balance computational costs with expected information gain. Whereas a single study may not be noticeably impacted if its calculations are over-converged numerically and use 50% more computing power than necessary, such a situation would severely slow down a high-throughput database project such as MP that consumes tens of millions of CPU hours of computing per year. Thus, MP must make practical compromises that try to maintain the accuracy of a specialized, precise calculation while being completely automatic and computationally efficient and maintaining clarity and consistency of procedure with other calculations.

One of the approaches used by the Materials Project to achieve this balance is to split materials into two classes and apply a different DFT functional to model each

class. The first class of compounds are transition metal oxides and sulfides. Standard DFT functionals such as the local density approximation (LDA) (Kohn and Sham 1965) and the generalized gradient approximation (GGA) (Perdew et al. 1996) are not accurate for these compounds due to more pronounced self-interaction error as well as errors in orbital occupation from lack of derivative discontinuity (Zhou et al. 2004; Cococcioni and de Gironcoli 2005). One computationally efficient way to treat these compounds is with the GGA+$U$ framework, in which a Hubbard-like correction is applied to localized $d$ orbitals. The specific $U$ corrections are fitted to formation energy data as described previously (Wang et al. 2006). It is important to note that these same $U$ values may not be optimal for accurately representing other properties such as the electronic band structure. The second class of compounds encompasses all other systems and is treated with the standard GGA-PBE functional (Perdew et al. 1996).

By allowing different compounds to be treated with two different functionals, it is possible to enhance accuracy of the resulting database compared to using only a single functional such as GGA for the entire database. However, one must then additionally design a scheme to mix results (e.g., total energies) obtained from different methods since these results are not directly compatible. In the Materials Project, these adjustments between results from different functionals are made by benchmarking to experimental formation enthalpy data (Jain et al. 2011b). Figure 5 depicts the effects of one instance of this by presenting Fe-P-O phase diagrams using the GGA only, GGA+$U$ only, and mixed GGA and GGA+$U$ total energies. Only the version of the diagram that uses two different functionals (with the mixing adjustment applied) reproduces all known stable phases in this system.

Another practical measure taken by the Materials Project pertains to molecular systems. Although molecular systems and solids can be modeled within the same density functional theory framework (e.g., PBE-GGA with plane-wave basis sets), computed reaction energies that include both molecules and solids typically exhibit high errors because self-interaction errors differ significantly between systems characterized by local (e.g., molecules or highly correlated systems) and nonlocal (e.g., metals) electrons (Grindy et al. 2013; Perdew et al. 1998). Similarly, intermolecular interactions present in gases, 2D materials, and liquids that are not well described by pure GGA functionals present further challenges for constructing a comprehensive thermodynamic framework derived from DFT that avoids such systematic errors.

Rather than calculating the liquid/gas energies directly, MP adjusts the energies of several elements that are liquid or gaseous at room temperature based on experimental reaction enthalpies such as the oxidation of metals (Wang et al. 2006). All of the following compounds have adjusted energies to better reproduce reaction energies with solid phases: $O_2$, $N_2$, $Cl_2$, $F_2$, and $H_2$.

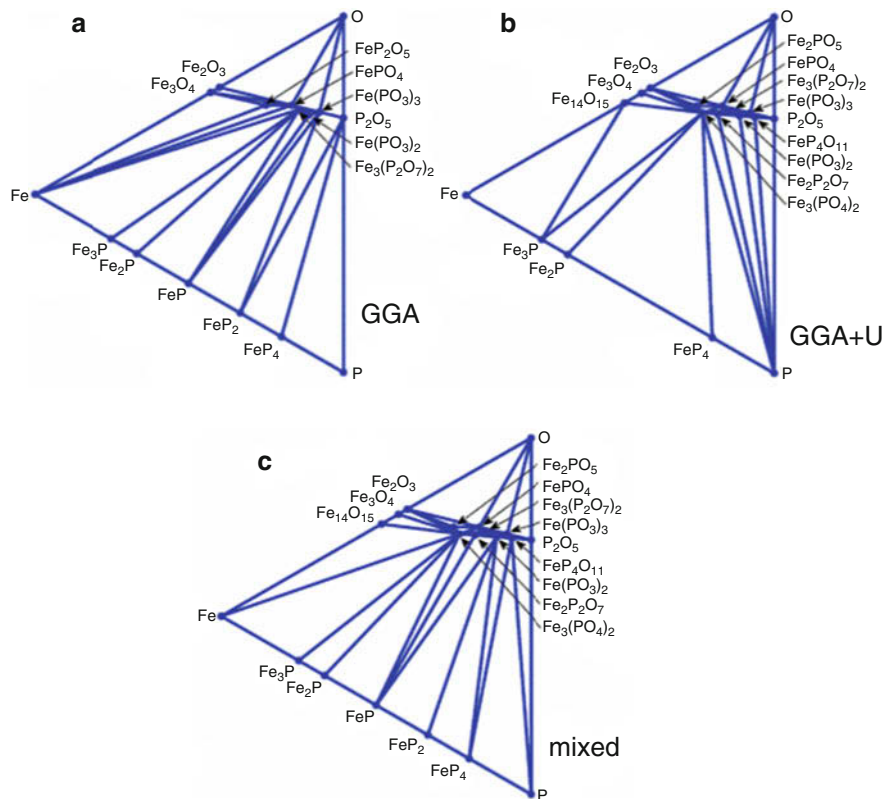
Finally, we mention that MP also adjusts certain numerical parameters based on the type of compound. For example, MP uses a denser k-point mesh when calculating metals (as determined from an initial, loose k-point mesh calculation) versus semiconductors and insulators. In addition, the numerical tolerances used by the Materials Project have been growing more precise over time. The parameters


**Fig. 5** Fe-P-O ternary phase diagrams built using total energy calculations from (**a**) only GGA, (**b**) only GGA+U, and (**c**) mixing GGA and GGA+U functionals. Only the mixed phase diagram reproduces all known phases as stable on the phase diagram. (Reprinted figure with permission from Jain et al. (2011b). Copyright 2011 by the American Physical Society)

used for each calculation are available via the Materials Project web site, and the most current description of parameter settings is provided at https://www.materialsproject.org/docs/calculations.

## 2.2 "Apps" for Data Exploration

Much of the value of the MP data set comes from secondary analyses that are performed on top of the raw data. These secondary analyses often combine multiple data points and can take the form of common diagrams used in materials science (e.g., phase stability diagrams or Pourbaix diagrams), application-specific materials design tools (e.g., evaluating MP compounds as battery electrodes), or simply as additional information (e.g., reporting potential substrates that might form coherent

lattices with a target material). Such tools are vital for helping users extract as much value as possible from the data sets.

The Materials Project develops the methodologies to perform many such secondary analyses and releases them both as open-source software implementations (through the pymatgen (Ong et al. 2013) package) and as web applications ("apps"). Apps provide a visual, user-friendly interface to these powerful and often complex analysis routines. In the following example, we describe the underlying methodology as well as the accompanying app for generating and manipulating phase diagrams.

### 2.2.1 Phase Diagram App

Phase diagrams have multiple applications in materials science. Traditional phase diagrams generated from experiments show not only stable phases but also delineate solubility limits and temperature dependence. In contrast, because MP currently only models materials at zero temperature and pressure and does not model solubility limits, the resulting phase diagrams might be more accurately referred to as phase *stability* diagrams (we use the terms interchangeably here). Nevertheless, such phase stability diagrams show the stable phases in a given chemical system as well as the relevant phase equilibria at various compositional ratios. One major application of such phase diagrams is to serve as a "reality check" for new hypothetical materials. If the energy of that proposed material is low enough to be on or nearly on the phase stability diagram, there is a higher probability that the material will be stable enough to be synthesized in the lab (Sun et al. 2016). Phase stability diagrams are also useful for identifying possible decomposition products that might compete with a target phase.

Generating such computational phase diagrams requires knowledge of the formation energies of all possible materials within a chemical system. For example, calculating a ternary phase diagram requires knowledge of the formation energies of all the relevant unary, binary, and ternary phases in that system. For a typical ternary system, calculating the energy for all known phases would require several dozen calculations. However, because the MP database already contains precomputed energies for most known inorganic compounds, one can now avoid running all these simulations and directly create reasonably complete phase diagrams using the MP data set.

Mathematically, the set of stable points on a phase diagram can be determined using the convex hull construction, which is a method of finding the minima as a function of $n$ degrees of freedom (Barber et al. 1996). By calculating the convex hull for the total energies of various calculated DFT energies, globally stable structures can be found as well as the various tie-lines that connect stable phases. The convex hull construction can be used to construct phase diagrams for an arbitrary number of components.

Many known compounds are not thermodynamically stable, i.e., they do not appear on phase stability diagrams (Sun et al. 2016). An additional metric is then necessary to distinguish the degree of metastability for these compounds. The construction of a convex hull provides an envelope of stability. Compounds

on the convex hull are stable, while compounds above the hull in energy are metastable. The energetic distance to the hull at the composition is thus a quantifiable metric and directly related to the metastability of that compound. A lower energy above the hull is typically desirable for synthesis because it implies less of an energy penalty to form the target compound compared to the known stable phase. Many of the known metastable compounds in the Materials Project are within 15 meV/atom of the hull, but depending on chemistry can extend past 60 meV/atom above the hull (Sun et al. 2016). While this analysis focuses on the metastability of known compounds, there is still work needed to quantify the limits of metastability.

Thus far we have described the formalism for closed systems, i.e., ones in which the stoichiometric ratio of elements is fixed, but the same formalism can be equally applied to open systems in which one or more elements are held at a fixed chemical potential rather than held to a fixed amount. For example, experiments may be carried out in air, which essentially serves as an infinite reservoir of atmospheric elements such as oxygen and nitrogen at particular chemical potentials. The same experiment under flowing argon gas would still represent an open system, but one in which the chemical potentials of those elements are greatly reduced. Thus, in environments that are open to a particular element, the relevant control variable is the chemical potential of that element ($\mu_i$) rather than its compositional value. The chemical potential is then treated as an external variable to obtain a grand potential phase diagram.

Users of MP need not be familiar with all the methodological details (Ong et al. 2008) of computational phase diagram construction to generate and use them. The MP web site allows users to simply type (or click on a visual periodic table) the elements for the system they are interested in. This will generate a phase diagram that will graphically display the phase diagram as well as a list of stable and metastable/unstable materials. Figure 6 shows a screenshot of the MP phase diagram app for a grand potential phase diagram for Li-Fe-P-O with an oxygen potential of $-5.288$ eV. Note that since the oxygen composition is prescribed by the potential, it doesn't exist as a degree of freedom in the phase diagram, collapsing the quaternary phase diagram into a ternary phase diagram (with a slider for controlling the oxygen chemical potential).

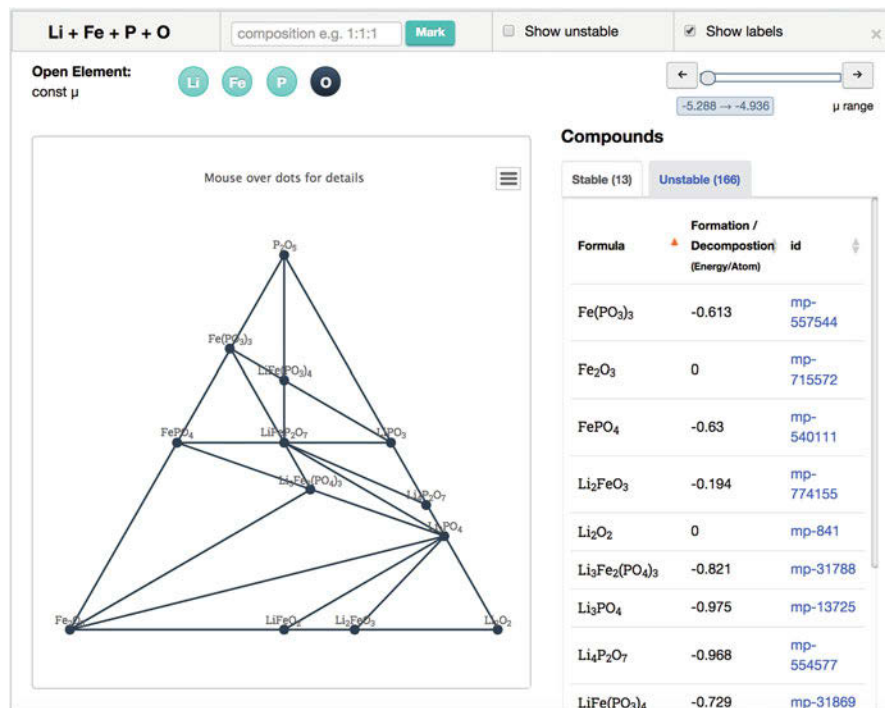
Other apps similarly make available powerful underlying methodologies to a broad audience. For example, similar to the grand potential phase diagram, Pourbaix diagrams are projections of global stability into potential-pH space to model electrochemical stability. A methodology for calculating such diagrams by utilizing experimentally measured free energies of aqueous ions and the calculated DFT energies for solid phases available in the Materials Project was previously developed (Persson et al. 2012). This methodology was incorporated into a "Pourbaix app" that allows users to simply select the chemical system of interest, elemental ratio, and concentration of ions in order to generate a familiar Pourbaix diagram that leverages the MP data set and that can be visually and interactively explored by the user. In addition, the stability of individual materials relative to the most stable decomposition product may be generated as a heatmap overlaid on the Pourbaix


**Fig. 6** The Li-Fe-P-O ternary grand potential phase diagram open to oxygen as generated by the Materials Project's "phase diagram" app

diagram, providing users with a tool to estimate metastability under aqueous conditions (Singh et al. 2017).

## 3    Computation Infrastructure and Software Tools

Developing and maintaining calculation databases such as the Materials Project requires considerable attention to computing and software infrastructure. At the time of this writing, the Materials Project is the result of over one million individual calculations that represent over 100 million central processing unit (CPU) hours of computing time invested. Setting up, executing, analyzing, and managing all these calculations are far from straightforward. Here, we describe the infrastructure of the Materials Project at the time of this writing. However, we note that the economics of computing as well as the optimal choice of software libraries can change very quickly. The Materials Project infrastructure is therefore constantly evolving to apply the latest developments and best practices in computer science and software engineering to the field of materials science.

## 3.1    Computing Resources

The Materials Project (MP) has employed high-performance computing (HPC) resources at the US National Energy Research Scientific Computing Center (NERSC) and elsewhere, consuming over 100 million of CPU hours to date. Many-task computing workflows (Raicu et al. 2008) are increasingly using HPC environments because these resources typically offer the potential for large amounts of total computing time, good hardware specifications (e.g., moderate to high memory), and adequate storage. However, HPC environments present several challenges for running high-throughput calculations because these environments were originally designed to serve the needs of a small number of large, highly parallel applications that run for predictable times and perform all input/output to disk. In contrast, high-throughput calculations are typically extremely numerous and limited in achievable parallelism and require unpredictable, often very long total run times. In addition, they are often more suited to management by external services rather than solely through flat files on disk. To overcome these challenges, the Materials Project has developed a software library for running high-throughput calculations called "FireWorks" (Jain et al. 2015) that solves many of the computing challenges associated with running high-throughput jobs on HPC resources.

## 3.2    Choice of Database Software

Many portions of a high-throughput calculation workflow require efficient storage, retrieval, and search of information, including:

- Managing the state of high-throughput calculations
- Storage of the raw calculation results, and
- A searchable set of processed data for data dissemination and analysis

The Materials Project has chosen to use a not-only-SQL (NoSQL) "document store" (Cattell 2011), MongoDB, as its main database technology for these tasks (raw output files are also preserved). We note that this represents a shift from a other SQL-based data management strategies used previously in high-throughput computational materials science (Jain et al. 2011a). This decision was made primarily because MongoDB accommodates both the data heterogeneity and rapid pace of data model development required by the Materials Project. For example, unlike typical SQL relational database management systems (RDBMS) such as MySQL and PostgreSQL, MongoDB does not require a pre-designed, normalized schema between all data types at the beginning of the project. The types of data being stored continually evolve as we add new types of calculations into the project. By choosing MongoDB, MP can adapt quickly to these changes with small changes in application code instead of refactoring complex relational schemata.

Among document-oriented datastores, MongoDB is notable for its simple but powerful query language, ease of administration, and good performance on read-heavy workloads where most of the commonly accessed data (the so-called working set) can fit into memory. Its relative weaknesses for linking disparate data (database "joins") and write-heavy workloads are a reasonable trade-off for MP. A productivity benefit of MongoDB is that both the query language and the native data model are JavaScript Object Notation (JSON) (Bray 2017), which is the standard data format for modern web applications and easily represented and manipulated as native data types in the Python programming language (Van Rossum et al. 2007) in which our other software libraries are written. Thus, users familiar with Python and in particular its "dict" object can adapt quickly to understanding and developing data models with MongoDB. Our experience is that these aspects have allowed many more members of our team to collaborate on database development compared to our historical use of RDBMS in which only one or two members of the team were familiar enough with the system to make changes. More details on our experiences and challenges encountered in deploying a centralized datastore of this type within a scientific HPC ecosystem are described in Gunter et al. (2012).

## 3.3    Software Stack

### 3.3.1    Software to Perform and Analyze DFT Calculations

At the time of this writing, the Materials Project primarily uses density functional theory as implemented by the Vienna Ab Initio Simulation Package (VASP) (Kresse and Hafner 1994; Kresse and Furthmüller 1996). However, it is likely that other software packages such as ABINIT (Gonze et al. 2016) will play a larger role in MP in the future. Regardless of the choice of DFT implementation, the procedure for performing calculations involves many steps outside the core simulation. These steps include:

- Setting up the geometry for the material or system of interest
- Defining a workflow of calculations to compute the properties of interest
- Executing the calculations and correcting possible errors
- Analyzing, storing, and organizing the output data

The Materials Project has developed a comprehensive suite of software tools to accelerate and assist in these steps (see Fig. 7 for an overview).

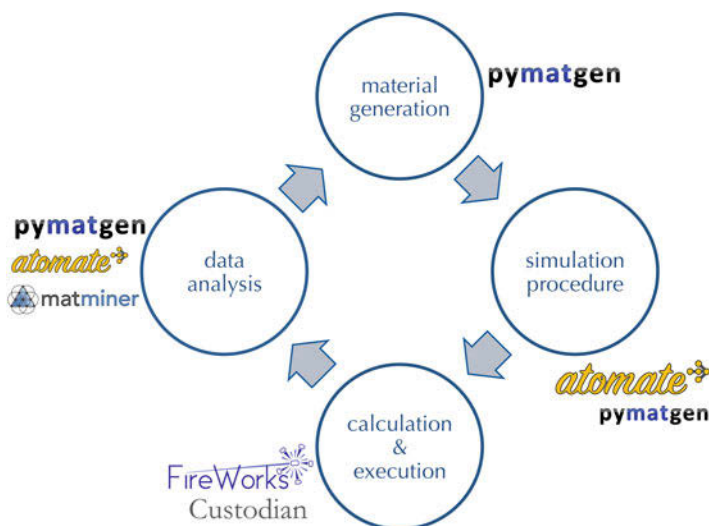
Most of the compounds currently in the Materials Project use bulk crystal structure geometries as reported in the Inorganic Crystal Structure Database (ICSD) (Belsky et al. 2002). However, the computation of many properties requires performing algorithmic operations on these geometries. Examples include determining an appropriate ordered cell for sites with partial occupancies, creating appropriate slabs for surface calculations, and performing a series lattice deformations for computing elastic tensors. We have implemented routines for such geometry modifications in Python as part of the pymatgen (Ong et al. 2013) open-source software


**Fig. 7** Various steps involved in data generation and analysis along with the relevant software stack for the Materials Project infrastructure

library. In many cases, these routines are directly implemented in pymatgen, whereas in others we provide an object-oriented Python wrapper to libraries released by the community such as spglib (Togo 2018) and enumlib (Hart and Forcade 2008). We note that the growth of web-based collaboration presents the opportunity for another method of generating new compounds: crowdsourced user suggestions. In this method, crystal structures designed by the user community (either offline or through Materials Project tools) are used as starting points for the calculation with the results reported back to the community. In its first three years of operation, this "MPComplete" service has been employed by over 800 unique users and has resulted in over 8,300 new materials added to MP's public database.

Depending on the property to be studied, a DFT "calculation" may in fact involve a series of individual computations that require data passing and modifications of geometry or input settings between computations. The set of calculations required for obtaining a desired output property, along with the dependencies and data passing requirements between these calculations, define a "workflow." The Materials Project has developed two software libraries in the Python programming language to manage such workflows. The first library, called "FireWorks" (Jain et al. 2015), is a general-purpose workflow library. FireWorks does not contain any materials science or DFT-specific code. Its scope is to provide a framework for users to define arbitrary sequences of calculations, store them in a database, execute them on various types of computing resource, and manage the status of potentially millions of workflows across systems. Thus, FireWorks is compatible with a broad class of scientific computing workflows (although it is best suited for high-throughput applications) and is frequently used outside the field of materials

science. The second library for workflow creation, "atomate" (Mathew et al. 2017), contains specific materials science workflows implemented in FireWorks and using pymatgen as a base library. The atomate package can be thought of as providing a library of materials science workflow implementations (e.g., standard workflows for electronic band structure, elastic properties, and piezoelectric, dielectric, and ferroelectric properties). Atomate users can specify an input geometry for a material and the desired workflow type, and atomate will provide a FireWorks-based implementation of that workflow that is ready to execute at supercomputing centers. Furthermore, atomate leverages the pymatgen library to automatically parse calculation outputs and create a database of materials properties that can be queried by the user. Various features in FireWorks and atomate allow for customization of behavior to specific situations, from low-level issues (such as interacting with various queueing systems) to high-level issues (such as running the same workflow with multiple DFT functional choices). Calculation workflows can also automatically adapt their procedure for later calculations based on the results obtained from earlier calculations.

When executing the calculation, it is possible to encounter various errors relating to calculation convergence. The Materials Project has developed a type of job wrapper to simulation software (e.g., VASP Kresse and Hafner 1994; Kresse and Furthmüller 1996 or QChem Kong et al. 2000) called "custodian" (Ong et al. 2014) that automatically monitors the output files of the calculation and automatically fixes errors (by stopping the job, changing the input files, and restarting the job) according to a set of rules. The custodian software can also be used to automate linear sequences of calculations (e.g., a convergence protocol that tightens numerical parameters until no change in output is achieved).

Once the calculation is executed, the results are parsed and stored in various database collections. Raw data is parsed by pymatgen as a component of atomate workflows. We note that pymatgen can parse output files (into structured data or as Python objects with callable functions) and can also perform high-level data analyses such as phase diagram creation or plotting. Separately, we employ code called "builders" that collect, reorganize, and post-process raw data into separate database collections that are more amenable to analysis than raw data collections. For example, a builder might collect together all calculated results on a single material to build a single summary report (a "material" document) for that compound. A builder might also collect together information from multiple compounds, perform an analysis, and store the results in a database. In service of such processes, we develop and use lightweight libraries to automate, simplify, and ultimately streamline the process of creating MongoDB databases. Our general "builder" code could be useful to any project that needs to perform extract-transform-load (ETL) operations with MongoDB. For example, they can be run in parallel without explicit coding of parallelism by the author. This allows CPU-intensive transformations of the data to run much faster on multi-core machines, which includes most modern hardware (integration with the Message Passing Interface (MPI) standard to enable parallelization across supercomputing resources is in development). Furthermore, facilities in our code for incremental building allow successive builds of source

MongoDB collection(s) to only operate on the records added since the last build, which can save significant amounts of computation time. Overall, the builder framework allows for efficient generation and reliable updating of multiple database collections that are tailored for different types of query and usage patterns.

### 3.3.2 Software for Data Dissemination: The Web Interface and RESTful API

The Materials Project places a strong emphasis on user experience, user interface design, and ensuring that data is efficiently disseminated so that a wide variety of users are able to apply the data for research, development, and education (Jain et al. 2016b). To this end, we have built an interactive web portal (https://www.materialsproject.org) focusing on the scientist as the end user. This web portal is built using the mature Django web framework (Dja 2015) due to its clean separation of front-end views from the back-end business logic. Django is written in the Python programming language, which eases integration with the pymatgen library and the growing scientific software ecosystem in Python. Django also provides a clear structure for organizing a so-called project into "apps," which maps well to our various interactive views across materials data such as compositional phase diagrams, Pourbaix diagrams, or domain-specific applications such as battery electrode searching. Additionally, Django features robust tools for user management, simplifying procedures for authentication (who someone is) and authorization (what a known someone can access/do). These tools are used, for example, to provide prepublication "sandboxes" for certain user groups within which to explore and perform analyses across private data sets prior to public release.

In order to tighten feedback loops for users searching data and using various functionalities that may not be applicable to all users, we organize our front-end code to asynchronously load both data and additional code using standard Asynchronous JavaScript And XML (AJAX) and Asynchronous Module Definition (AMD) protocols. Our choices of specific libraries for the web interface continue to evolve as trade-offs between established best practices (that are attractive for a system intended for continuous and reproducible use over many years) and emerging standards (that simplify ongoing maintenance and adding features).

Although many exploratory research studies are well suited to a graphical interface such as the one described above, other studies require programmatic access to this database. With this in mind, we have chosen to expose our data through an application programming interface (API) called the Materials API (MAPI) (Ong 2015). MAPI allows users to develop computer programs that can query, process, and download Materials Project data through a well-defined interface. To date, the MAPI has served more than 100 million requests for materials data for over 1500 distinct users.

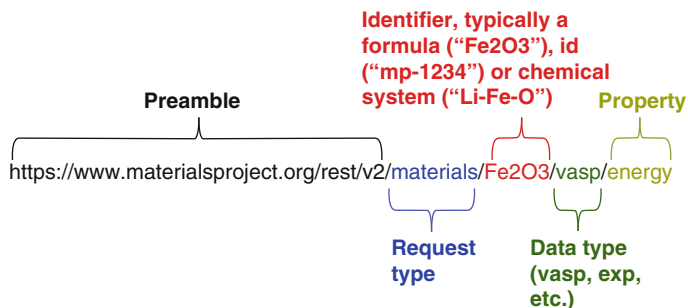
APIs are used extensively throughout technology and software development. They serve to clearly and explicitly define a protocol for communicating with a piece of software or other system that is accessed programmatically. At the time of this writing, the most common framework for APIs that operate over the Internet


**Fig. 8** An example of the URL structure for the Materials API. (Reprinted from Ong (2015) with permission from Elsevier)

is REpresentational State Transfer (most commonly referred to as REST). The most simple use case for REST APIs is to map web uniform resource identifiers (URIs) to data (similar to how a computer's file system maps data to directories and filenames). In RESTful systems, information is organized into resources, each of which is uniquely identified via a uniform resource identifier (URI). In the case of Materials Project, each document or object (such as a computational task, crystal structure, or materials property) is represented by a URI (see Fig. 8 for an example) and an HTTP verb that can act on that object (GET, POST, PUT, DELETE, etc.). In most cases, this action returns structured data that represents the object, e.g., in the JavaScript Object Notation (JSON) format. For example, to request energy data (as calculated using VASP) on all $Fe_2O_3$ compounds in the Materials Project database, the URL shown in Fig. 8 could be constructed according to the protocol specified in the MAPI. We note that since MAPI is a RESTful system, users can interact with the MP database regardless of their computer system or programming language (as long as it supports basic HTTP requests.)

REST APIs allow for more powerful behavior to be seamlessly integrated alongside such basic information retrieval. For example, unique strings of characters associated with specific users (called API keys) can be used to manage access to resources. This is done by implementing the API in such a way that requires users to include their API keys in requests they make to the system and then implementing controls on the back end of the system to handle permissions and activity logging. RESTful APIs can also accept filtering parameters or other variables within requests to give users greater control over what they send or receive from a database. Moreover, URLs can be linked to more than just static resources; they can also point to back-end functions that enable interaction between a user program and MP. An example might be linking a URL such as "https://www.materialsproject.org/rest/v1/materials/snl/submit" to a function registering a request to compute a desired structure embedded in an http POST parameter.

Use of such an API offers a number of advantages. First, users do not have to be concerned with the actual architecture of the database they are interacting with or the details of its implementation since the API serves as a kind of "middleman" in

the process. From a user's perspective, the procedure to interact with the database is consistent over time, freeing the development team to make back-end changes without impacting the user's mode of interaction with the data. In addition, access to the database is system-agnostic. Anyone can develop an application in whatever environment they wish on top of the API with the confidence that it will be compatible with the MP database. Moreover, the data that users receive is always up-to-date, with no extra effort on their part, and the capabilities of the API can be seamlessly improved over time to give users access to even more powerful queries and analyses without creating new procedures for their use.

Although RESTful APIs can be intimidating to novices, they can be made more user-friendly by making the URL scheme explorable and hiding complexity through intermediate software layers. For example, a high-level Python interface to the MAPI called the MPRester is provided in the pymatgen (Ong et al. 2013) code base that allows users to obtain properties like crystal structure or electronic band structure using Python functions rather than explicit HTTP requests. We note that, whenever possible, the main Materials Project web site front end also avoids direct database queries and uses MAPI to query and access data in a way that is more maintainable and less prone to failure than custom interactions with the back-end software.

## 4    User Applications of the Materials Project to Research and Design Problems

Since its release, users of the Materials Project have used its data and tools in several hundred research studies (as highlighted in a previous review Jain et al. 2016a). In this section, we describe several recent examples and outline general strategies that have emerged in the literature for screening and designing materials for specific applications. While several of these studies involve active MP collaborators (Dagdelen et al. 2017; Yan et al. 2017; Chen et al. 2016; Zimmermann et al. 2017), a large fraction of the most recent studies that we found through a Web of Science search are from users that are not involved in Materials Project (Sendek et al. 2017; Shi et al. 2017; Ashton et al. 2017; Cheon et al. 2017; Choudhary et al. 2017; Lau et al. 2017; Shandiz and Gauvin 2016). This latter class of users perhaps most clearly demonstrates that it is possible to accelerate the research and design of new materials by generating and sharing materials information with the research community.

### 4.1    Phase Diagrams and Compound Stability

In studies that aim to improve our understanding based on experimental evidence or to synthesize new materials for a given application (Bayliss et al. 2014; Krishnamoorthy et al. 2015; Martinolich and Neilson 2014), generating phase equilibrium data is among the most frequently used MP capabilities . For example, Bayliss et al. conducted a study on a sodium-doped strontium silicate material

that had been claimed to feature remarkably high oxide ion conduction (Bayliss et al. 2014). By combining experiments (neutron powder diffraction, two-point AC impedance spectroscopy, time-of-flight secondary ion mass spectrometry) and DFT calculations, they could show that the conductivity was lower than previously reported and that the high energetic cost of oxygen vacancy formation was the underlying reason. Data from MP was used to cross-check the study's results for the DFT-PBEsol-derived major limiting phases of the $SrSiO_3$ decomposition.

Shi and co-workers (Shi et al. 2017) employed a high-throughput DFT screening approach for stable delafossite and related layered phases of composition $ABX_2$, where A and B are any elements from the periodic table and X a chalcogen (O, S, Se, and Te). From the initial materials set of 15,624 compounds, 285 were found to be within 50 meV/atom from the convex hull. While the majority of these structures are contained within the Materials Project database, the authors highlight that 79 of these stable systems are absent. This underscores that crystal structure databases such as MP still have considerable growth potential in terms of compound completeness and highlights the role that user-based compound submissions (through the MPComplete service, cf., Sect. 6.1) could play in extending such databases.

A similar example is the work by Krishnamoorthy et al. (2015), who used a high-throughput DFT-based screening to identify lead-free germanium iodide perovskites that could be used for light harvesting. The researchers computed the PBE bandgaps of 360 $AMX_3$ compositions, uncovering 9 interesting candidates. MP phase equilibrium data were used to further reduce the list by requiring that the materials be thermodynamically stable against decomposition to simpler binary phases. Three materials were left from the computational screening, $RbSnBr_3$, $CsSnBr_3$, and $CsGeI_3$, of which the latter was successfully synthesized and characterized. We refer the interested reader to a previous review article Jain et al. (2016b) for further examples of experimental studies conducted using MP-calculated phase diagrams.

## 4.2 Crystal Structure Analysis, 2D Materials, and Machine Learning

The large corpus of data available in the Materials Project can serve as a test bed for the development of new algorithms for processing of crystallographic data. This is the case for Ashton and co-workers (Ashton et al. 2017) who developed a topology-scaling algorithm to identify the dimensionality of a given crystal structure. They used the algorithm to search the MP database for materials that could be prospective 2D materials; 826 stable layered materials were identified, of which 680 were predicted to be feasible 2D material candidates based on the calculated exfoliation energy.

Similarly, Cheon and co-workers (Cheon et al. 2017) present an algorithm that can identify the dimensionality of weakly bonded subcomponents of a three-dimensional crystal structure. They apply this algorithm to >50,000 MP materials and identify 1,173 two-dimensional layered materials as well as 487 weakly bonded one-dimensional molecular chains, representing an order of magnitude increase

in the number of identified materials. Furthermore, 325 of these materials were suggested to be piezoelectric monolayers.

Interestingly, by specifically exploiting a weakness in typical DFT calculations that the dispersion forces are not well accounted for and thus lattice parameters of layered materials are often significantly inaccurate, Choudhary and co-workers (Choudhary et al. 2017) were able to identify two-dimensional material candidates. To this end, the authors required that the deviation between lattice constants from experiments and (mainly) MP database be ≥5%. In order to validate their approach, the authors used an accepted criterion based on the exfoliation energy and found that 88.9% of their predictions met this test.

Many structure-property relationships that form the basis of design rules in materials science are based on information pertaining to the local coordination environment. Therefore, it is highly desirable to have tools that effectively and efficiently identify basic local structural motifs such tetrahedra, octahedra, bcc, fcc, and hcp environments. Zimmermann et al. provided classification criteria for these motifs that are based on local structure order parameters, which were used to automatically identify these motifs in the entire Materials Project database. Additionally, these tools may also lead the way to alternative structure matching avenues (Zimmermann et al. 2017).

The abundance of data in the Materials Project also provides an opportunity to develop new machine learning (ML) techniques for modeling materials properties and for better understanding structure-property relationships. One such example of this appears in work from Faber et al. (2015) aimed at developing representations of periodic systems adaptable to ML models. In this study, 4000 structures from the Materials Project were used to evaluate the generalization error in the predicted formation energy based on three different crystal structure representation schemes and using kernel ridge regression, revealing that a sine matrix approach intended to simulate an infinite Coulomb sum was superior in its efficiency and accuracy.

Similarly, de Jong et al. (2016) demonstrated a machine learning approach to predicting elastic moduli of k-nary compounds that was effective over a highly diverse set of chemistries. More specifically, this study used gradient boosting machine local polynomial regression (GBM-Locfit) over the MP elastic tensor data set to determine a set of relevant descriptors and to derive elastic modulus predictions. Ultimately, this model was leveraged to estimate the Vickers hardness of the entire MP materials library, enabling a rapid search for superhard materials.

In most cases, easily retrievable or computable data such as the space group, composition, and the density are used in order to predict more complex properties such as the formation energy or the elastic tensor. Shandiz and Gauvin pursued the inverse route (Shandiz and Gauvin 2016): the authors conducted a classification study of 339 materials from the MP database that are potential Li-ion silicate cathodes (general composition: Li-Si-(Mn, Fe, Co)-O). In particular, they tested whether or not they could predict the crystal system (monoclinic, orthorhombic, or triclinic) based on features that were derived from both the input crystal structure and DFT outputs: the unit cell volume, the bandgap, the number of sites in the unit

cell, the formation energy, and the energy above the convex hull. Pair correlation plots of these features indicated that there was no exploitable direct correlation between any of the features and the crystal system. Decision tree-based methods (random forest and extremely randomized trees) were shown to yield prediction accuracies of up to 75%, and these methods performed better than linear and shrinkage discriminant analysis, respectively, artificial neural networks, support vector machines, and $k$-nearest neighbor classification.

## 4.3   Screening Materials for Applications

Perhaps the most consistent materials screening strategy that has emerged from the data on the Materials Project is that of filtering materials on successively tighter criteria appropriate to a given application space. In this approach, a filter common to most applications is typically on stability via $\Delta E_{hull}$, which can provide an indicator of whether a compound will be experimentally feasible. As illustrated in Fig. 9, successive filters in turn reduce the number of materials to be considered until it reaches a tractable quantity for follow-up with either more sophisticated calculations or for experimental inquiry.

This was the approach taken by Sendek and co-workers (Sendek et al. 2017) who searched for new candidate materials that could be used as solid-state electrolytes for lithium-ion batteries. The authors screened 12,831 Li-containing compounds from the Materials Project to filter those with high structural and chemical stability, low electronic conductivity, and low cost, thus, eliminating 92.2% of their initial

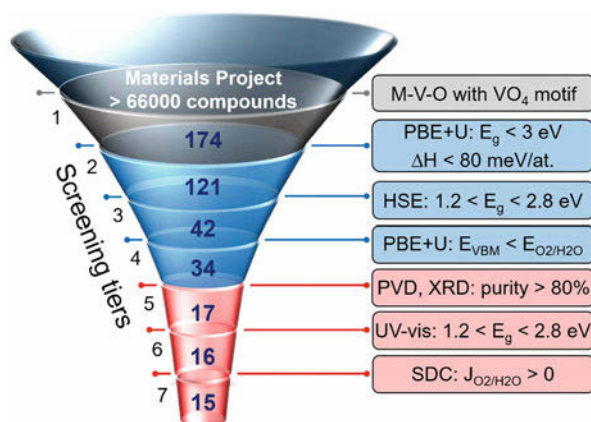

**Fig. 9** The "funnel" approach to materials screening through successive criterion filtering as applied to designing materials for solar fuel photoelectrocatalysis by Yan et al. (2017). Such approaches start with a large list of potential candidate materials and use a series of criteria (generally of increasing cost or complexity) to reduce the space of possibilities. (Reproduced from Yan et al. (2017); copyright 2017 National Academy of Sciences)

materials. Subsequently, an ionic conductivity classification model, which was trained on 40 crystal structures and associated measurements from literature, reduced the list of interesting candidates down to only 21 materials. In the latter step, the consideration of a multi-descriptor model over single-descriptor functions was critical to achieve predictive power. Many of the remaining 21 materials have not yet been studied experimentally, which hence offers new opportunities for experimental electrolyte research.

Identifying structurally similar compounds for the purpose of screening structure-sensitive properties and classifying materials has also begun to emerge as a screening strategy and design paradigm. Dagdelen and co-workers (Dagdelen et al. 2017) demonstrate such a screening procedure for predicting new auxetic materials (compounds with negative Poisson's ratios). The authors systematically screened the entire MP database via the Materials Project's REST API and compared each structure to $\alpha-$cristobalite $SiO_2$, one of the only inorganic crystalline materials previously known to exhibit a negative homogeneous Poisson's ratio. By coupling pymatgen's structure matching algorithm (which can match structures within a user-defined tolerance irregardless of crystal setting, supercell size, or composition) with more conventional screening strategies, 30 likely candidates were gleaned from over 65,000 structures. The full elastic tensor of each candidate was then calculated and their Poisson's ratios subsequently derived. Of these 30 structures, 3 were found to be homogeneously auxetic, and an additional 9 were found to exhibit near-zero homogeneous Poisson's ratio, with experimental confirmation ongoing.

An example of *in silico* screening with the Materials Project that has led to experimentally confirmed materials discovery was presented by Lau et al. (2017). These authors searched for promising chemical looping air separation (CLAS) materials in the MP database through successive criterion filtering ("funnel" approach). Specifically, the applied search filters included (i) restricting binary and ternary compounds, (ii) identifying compounds that can undergo oxidation reactions (at this step, the phase diagram app was employed), and (iii) restricting the temperature and oxygen partial pressure ranges in which the oxidation reactions would be carried out to sensible limits. The approach resulted in 5,501 tentative compounds and 20,861 relevant redox reactions. Since the reduction enthalpy and the gravimetric $O_2$ capacity (Fig. 10) did not reveal any exploitable trends, the authors had to employ a more heuristic route to reduce the candidate list. First, they required the reaction complexity and the total number of phases present in the reactions to be minimal, yielding 292 materials. Second, they decreased the number further to 108 by excluding compounds with expensive and toxic materials as well as reactions that involved non-oxides after reduction. From the remaining materials, they picked the $ABO_3$ perovskites because of their flexibility in oxygen stoichiometry without large structure changes and the ease of synthesizing perovskites in general. They subsequently synthesized and characterized $SrFeO_{3-\delta}$, which has emerged as a promising CLAS candidate due to its thermodynamic and excellent cycling stability as well as its resistance to carbonation over the temperatures of operation (Lau et al. 2017). Further examples of compound discovery with the Materials Project can be found in prior reviews (Hautier et al. 2012; Jain et al. 2016c).

**Fig. 10** An example of materials screening for chemical looping air separation application using MP data. Each data point represents a reduction reaction for each distinct compound with the largest $\mu_{O_2}$. The predicted reduction temperature at $p_{O_2} = 2.1 \times 10^4$ Pa for each reaction is plotted against $\Delta H_{reduction}$ (upper) and $O_2$ gravimetric capacity (lower). # 5 Outreach

Starting in 2016, the Materials Project has held annual workshops that have hosted more than 100 attendees from around the world. The workshops cover use of the Materials Project web site as well its software stack for performing and analyzing high-throughput calculations. Tutorials for the workshop utilized Jupyter (Ragan-Kelley et al. 2014) notebooks, which are a form of computer document that mixes formatted text, editable code, and interactive plots to illustrate a procedure. Participants were given the option to install the various codes to their own systems or to interact with a pre-installed environment configured using JupyterHub and Docker Swarm. The latter option allowed participants to focus on learning to use the software stack and left the details of individualized setup for later. All tutorials and course materials from these workshops are available online (Mathew et al. 2016; Winston et al. 2017).

Apart from the annual workshops, the Materials Project interacts with users in various ways. For example, MP has created YouTube videos with tutorials on all aspects of the web site, its various apps, and use of the API, which have had a total of over 30,000 views at the time of this writing. The Materials Project web site maintains a general-purpose discussion board

(https://discuss.materialsproject.org/) that has over 100 monthly active users, over 400 posts, and nearly 200 "likes" (whereby users quickly mark the helpfulness of posts) as of this writing. Finally, the MP software stack contains dedicated Google groups and Github issue pages where users and developers of the software can ask questions or get advice on software usage; hundreds of tickets have been resolved thus far.

# 6 Future of Materials Project

The advances in electronic structure theory, numerical algorithms, computing hardware, and software that have converged to make it possible to develop electronic structure databases are truly stunning. By leveraging these advancements, the Materials Project has computed millions of materials properties (e.g., electronic band structure, thermodynamic properties, mechanical properties, dielectric properties) across tens of thousands of materials, organized that information into searchable databases, and built rich web applications around the data in a way that would not have been possible a decade ago. The future efforts of the Materials Project will concentrate on further empowering the tens of thousands of scientists who design and develop new materials. Here, we describe some possible future developments to enhance property coverage, improve community data import capabilities, and provide an online materials design environment that leverages modern data analytics techniques.

## 6.1 Data Set Expansion

The Materials Project is continually generating new materials data at a rate of several tens of million CPU hours per year to expand the scope of its database. In the future, the Materials Project will expand in both breadth and depth: a greater variety of materials systems will be investigated, and more information will be calculated about individual materials. In terms of breadth, the Materials Project will expand to more completely encompass crystals with site disorder, i.e., partial site occupancies. The Materials Project will also continue its efforts and partnerships to expand its offerings of data on molecular, i.e., nonperiodic, systems. Finally, the Materials Project expects to play a more active role in not only computationally characterizing known materials but aiding experimentalists in the search for new materials yet to be discovered. In terms of depth, the Materials Project is expanding its library of computational workflows so that more information is available for each material in the database. Active areas of effort include phonon calculations and finite temperature properties, interfaces, spectroscopy, defects, and mapping relations between mechanical, thermal, and electrical effects. Furthermore, the Materials Project will leverage new advances in DFT functionals that make it possible to improve accuracy while still being computationally efficient for high-throughput computation.

This data set expansion will require orders of magnitude more computing resources than is currently employed. The Materials Project will continue to use "crowdsourcing," i.e., using input from the user community, as a method to prioritize various aspects of data set expansion. For example, the MPComplete service of Materials Project already allows users to both suggest new compounds for calculation and vote on compounds on which to prioritize more computationally expensive workflows. MPComplete then automatically integrates the results of each calculation with MP's core data set.

## 6.2    Beyond Simulations: Community-Contributed Materials Data

MP has become a worldwide resource for the materials sciences community, with over 40,000 users who rely on the portal as a trusted source to accelerate their research. This presents an opportunity to broaden the scope of MP's mission to also include assisting researchers disseminate their own data sets (whether computational or experimental) to the larger community of materials scientists. Thus, MP would serve not only as a hub for centrally generated computational data but would also host and distribute a variety of data sets generated by research groups worldwide. This will also give users of MP a more holistic picture of a compound because they would be presented with both computational and experimental information from a variety of techniques.

For this purpose, we soft-released our general contribution framework, MPContribs (Huck 2016b; Huck et al. 2015a, b, 2016), as a sustainable solution for well-curated data management, organization, and dissemination in the context of MP. Data as contributed through this framework as well as provenance and citation information for the contributors can be viewed on the MP web site. Early adopters are experimenting with MPContribs as a potential dissemination and hosting platform for their data, expanding the scope of data available through MP.

About a dozen early adopters have released landing pages to their contributed data sets on https://materialsproject.org/mpcontribs. Figure 11 highlights the landing pages for external studies of MnO2 phase selection, GLLB-SC bandgaps, dilute solute diffusion, and Fe-V-Co magnetic thin films. The last of these is based on data measured at the Advanced Light Source at Lawrence Berkeley National Laboratory, whereas the others are computationally derived. These landing pages can serve as interactive versions of the accompanying journal publications and allow research studies to be more easily reproduced and expanded upon.

## 6.3    MPCite: Citing Materials Data in Publications

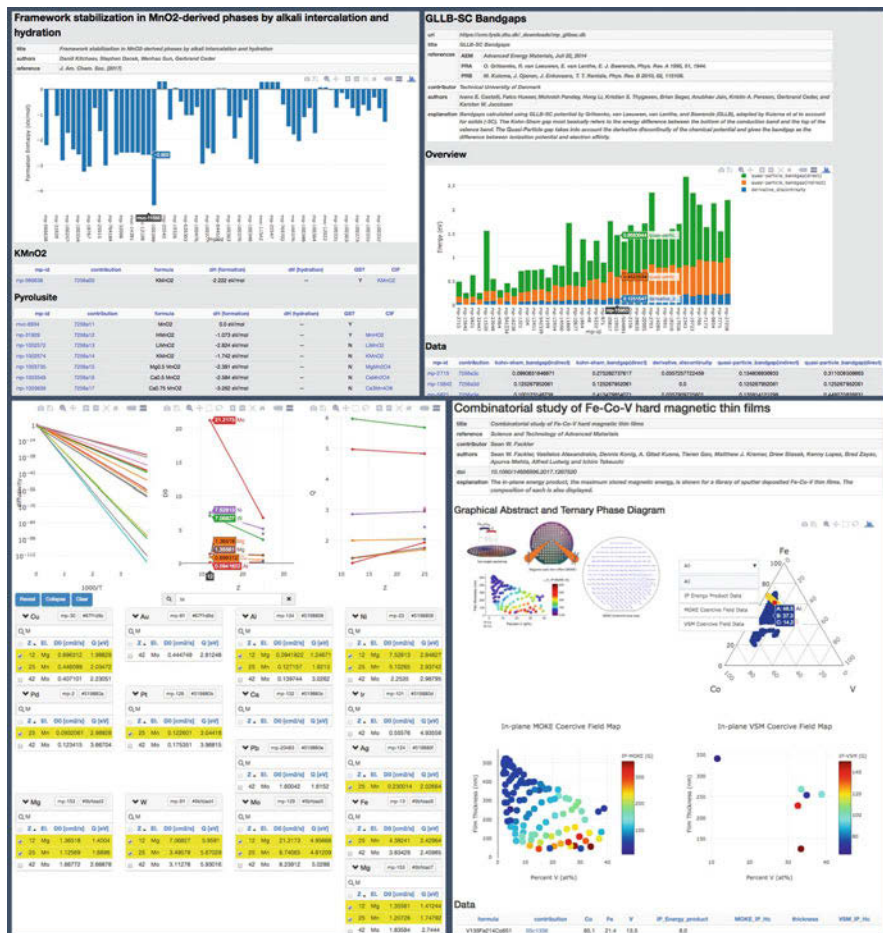
The US Department of Energy Office of Scientific and Technical Information (OSTI) (Elliot et al. 2016) provides the E-Link service, which allows researchers to submit information about OSTI products (in form of XML meta-data records) and


**Fig. 11** Examples of four different landing pages (representing different types of user-generated data sets) submitted to MPContribs

retrieve persistent digital object identifiers (DOIs) to identify it on the World Wide Web. DOIs are most commonly used for referencing and locating journal papers because they provide a unique URL linking to the journal's online landing page with more information about the publication. Our open-source software MPCite (Huck 2016a) enables the continuous request, validation, and dissemination of DOIs for all MP compounds. MPCite can also be employed for the assignment of DOIs to non-core database entries such as theoretical and experimental data contributed through MPContribs or user-generated analyses or structural data.

## 6.4    Data Analytics and Materials Design Environment

The Materials Project aims to not only generate raw data but also to empower users to make the best use of that data. For example, as described previously, we have found that many scientific studies conducted by users employ the "apps" built around the data such as phase diagram plots. As new data capabilities are established, we will continue to build additional apps to enable users to bridge the gap between a simple list of materials data and incorporating that data into a scientific analysis.

   The Materials Project will also place additional emphasis on helping users transform underlying data assets into new insights about structure-property relationships. In particular, new capabilities will allow users to formulate complex queries using visual interfaces and perform interactive data analysis and real-time filtering. Users will be able to rapidly iterate on materials design exploration with guidance provided by machine learning algorithms as well as traditional theory calculations. The four components of this vision for a materials design platform are Query, Process, Visualize, and Model/Compute (see Fig. 12). Next, we discuss these components in detail.

**Query**   Today, the Materials Project provides a visual web-based search interface to its underlying databases that is optimal for identifying a set of materials matching a series of constraints. However, many users require more sophisticated data pipelines in which one can visually add or remove filters and inspect the results at multiple points in the analysis or merge results from independent query streams. Such functionality is already possible for those that are capable of writing computer programs to fetch Materials Project data through MAPI, but remains difficult for others. New techniques of allowing users to fetch and interact with the data will be developed in the future so that one is able to call up exactly the desired data using a visual query interface.

**Process**   Once a user has compiled a data set of interest through the query tools, the Materials Project will make it easy for users to add descriptors/features to the data in a way that aids visualization, interpretation, and model building. We envision a system whereby a user can bring up any set of results (e.g., 100 materials of interest) and, by clicking a button, can rapidly generate a library of descriptors such as average electronegativity, local environment type, or polyhedral connection type for every material in the data set. Users will be able to use these descriptors to explore potential structure-property relationships through both conventional data analysis (e.g., visualization, statistical reports) and data mining and machine learning approaches.

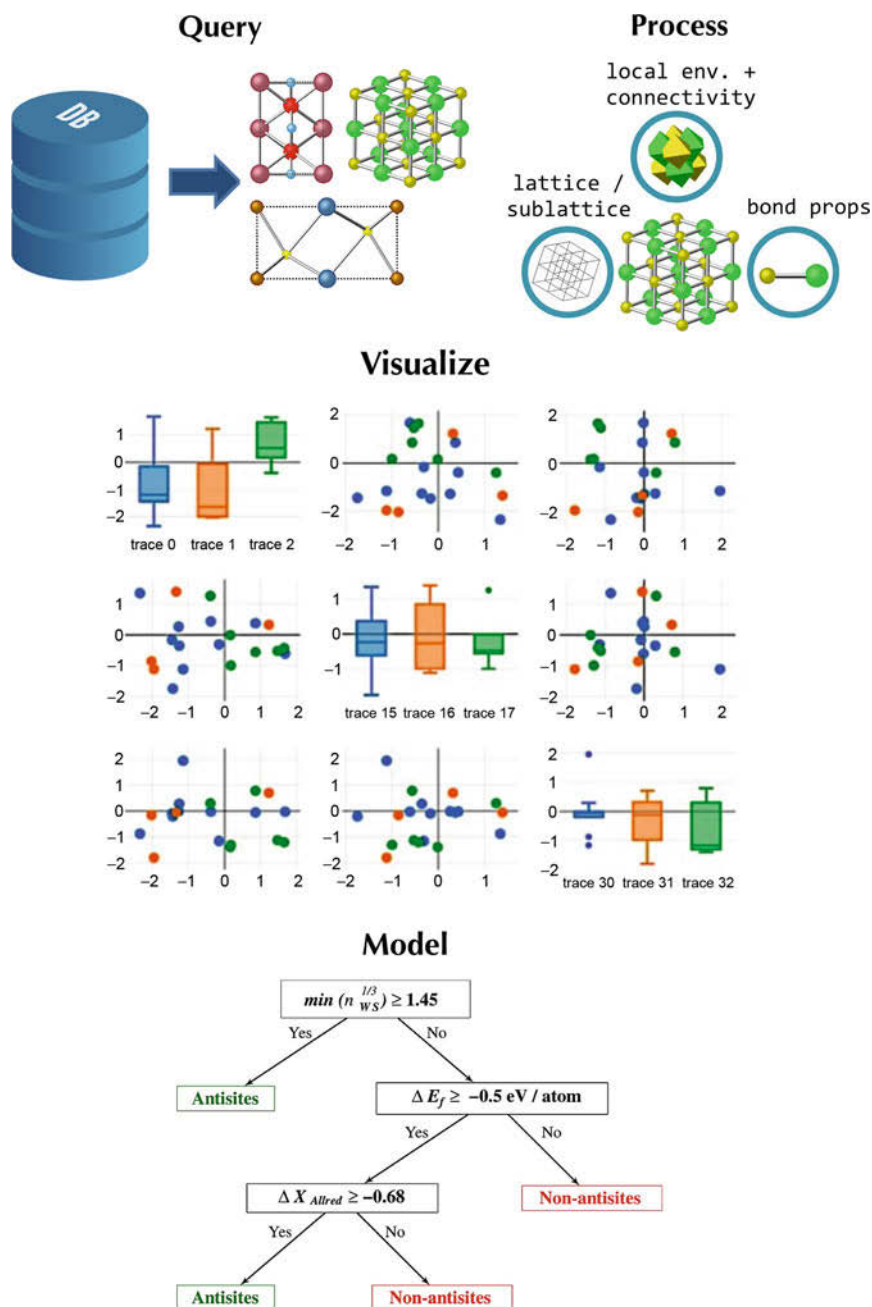
**Visualize**   New software libraries and web frameworks such as Dash by Plotly and Crossfilter are making it easier than ever to produce high-quality charts on the web that can be interactively explored and manipulated. Such libraries can enable users


**Fig. 12** Four steps in data exploration and modeling for which MP is currently developing new features to assist the user. For a detailed description of these steps, see the main text

to perform a greater fraction of their data exploration on the MP web site itself. As a simple example, a user may decide to produce a standard X-Y scatterplot between two user-chosen properties of interest that additionally allows hovering over specific points to display details of that material. A more complex example would be to include tools for interactive filtering of the data set, with each modification or addition of a filter displaying live histogram charts of the distribution of various materials properties for the materials remaining in the data set. This will allow users to obtain immediate feedback on the distribution of various properties in their data set and visualize how various constraints and filters change this distribution.

**Model/Compute** After data preparation and exploration, the next step is to take action on the data. One possible action is to produce a model describing the various relationships between materials properties. For example, one may attempt to build a model that relates a structural descriptor such as local environment and a compositional descriptor such as redox active species to a computed output such as battery voltage. Machine learning models are an interesting way forward because, once trained and validated, they can be used to obtain nearly instantaneous feedback on how materials might behave even before any simulations are performed. Thus, such models can serve as surrogates for more complex and time-consuming physics simulations for qualitative estimation and ranking purposes. One can also imagine using these models to guide decisions regarding the computation of new materials.

With these elements in place, a single interactive web session would allow a user to perform sophisticated queries on the data set, automatically generate descriptors that could be useful in forming structure-property relationships, visually explore (and, if necessary, further refine) the data set, produce models that describe the data, and use those models to drive further computations. Indeed, many of these elements are present on the Materials Project today. For example, for materials in which elastic moduli are not yet computed, users can instantaneously obtain an estimate based on machine learning models (de Jong et al. 2016) as well as upvote the full computation based on density functional theory. In the future, this type of mixed usage of both data mining and conventional theory models will become more prevalent and increasingly natural to users.

## 6.5 Concluding Thoughts

Ab initio simulations have long been powerful tools for understanding and designing materials. With advances in high-throughput computing, it is now possible to create libraries of simulation results that can produce information on materials at a rate far surpassing that possible in the past. Furthermore, advances in software frameworks and web technologies have enabled the dissemination of these results in a barrier-free fashion to thousands of researchers worldwide. The Materials Project is an effort to make use of these advancements to build a valuable resource of materials data as well as software tools that transform the way materials are designed. In addition, the Materials Project aims to make computational materials science a more

collaborative process through the development of open-source software and through feedback from experimental groups.

It is an exciting time for theory – never before has there been so much materials data available or the potential of computation to make an impact in materials design higher. Experimentalists and theorists alike have been able to use the Materials Project to conduct scientific and industrial studies in a way that bridges traditional knowledge gaps. These use cases are likely an early sign of a future in which theoretical techniques and large materials databases will be increasingly influential and help to create a new materials design paradigm.

the development and the deployment of new technologies, the AFLOW Fleet for computational materials design automates high-throughput first-principles calculations and provides tools for data verification and dissemination for a broad community of users. AFLOW incorporates different computational modules to robustly determine thermodynamic stability, electronic band structures, vibrational dispersions, thermomechanical properties, and more. The AFLOW data repository is publicly accessible online at `aflow.org`, with more than 1.8

million materials entries and a panoply of queryable computed properties. Tools to programmatically search and process the data, as well as to perform online machine learning predictions, are also available.

# 1    Introduction

The AFLOW Fleet is an integrated software infrastructure for automated materials design (Curtarolo et al. 2013) centered around the Automatic Flow (AFLOW) (Curtarolo et al. 2012a) framework for computational materials science. It features multiple scientific software packages, including the AFLOW high-throughput frame-

work, the AFLOW$\pi$ (Supka et al. 2017) medium-throughput framework, and the PAOFLOW (Buongiorno Nardelli et al. 2017) utility for electronic structure analysis, along with the AFLOW.org data repository (Curtarolo et al. 2012b), its associated representational state transfer application programming interface (REST-API)) (Taylor et al. 2014), and the AFLUX Search-API (Rose et al. 2017). These elements are well integrated with one another: a Python+JSON (JavaScript Object Notation) interface connects AFLOW, AFLOW$\pi$, and PAOFLOW; and all software packages access the AFLOW.org repository via the REST-API and the Search-API.

Similar infrastructure has been developed by initiatives such as the Materials Project (Jain et al. 2013), NoMaD (Scheffler et al. 2014), OQMD (Saal et al. 2013), the Computational Materials Repository (Landis et al. 2012), and AiiDA (Pizzi et al. 2016). The Materials Project uses the `pymatgen` (Ong et al. 2013) Python-language data generation software infrastructure, and their repository is available at `materialsproject.org`. The Novel Materials Discovery (NoMaD) Laboratory maintains an aggregate repository available at `nomad-repository.eu`, incorporating data generated by other frameworks including AFLOW. The Open Quantum Materials Database (OQMD) (Saal et al. 2013) uses tools such as `qmpy` to generate their database, which can be accessed at `oqmd.org`. The Atomic Simulation Environment (ASE) (Bahn and Jacobsen 2002) is used to generate the Computational Materials Repository, available at `cmr.fysik.dtu.dk`. The ASE scripting interface is also used by the Automated Interactive Infrastructure and Database (AiiDA) framework available at `aiida.net`, which revolves around relational databases for its overall design and data storage. Additional materials design utilities include the High-Throughput-Toolkit (HTTK) and the associated Open Materials Database, `httk.openmaterialsdb.se`, as well as the Materials Mine database available at `www.materials-mine.com`, while computationally predicted crystal structures can be obtained from the Theoretical Crystallography Open Database at `www.crystallography.net/tcod/`.

The AFLOW Fleet employs density functional theory (DFT) to perform the quantum mechanical calculations required to obtain materials properties from first principles. These DFT calculations are carried out by external software packages, namely, the Vienna Ab initio Simulation Package (VASP) (Kresse and Hafner 1993; Kresse and Furthmüller 1996) in the case of AFLOW and QUANTUM ESPRESSO (Giannozzi et al. 2009, 2017) in the case of AFLOW$\pi$. Results are stored in the AFLOW.org repository (Curtarolo et al. 2012b) and made freely available online via the `aflow.org` web portal, which is programmatically accessible and searchable via the AFLOW Data REST-API (Taylor et al. 2014) and AFLUX Search-API (Rose et al. 2017), respectively. The repository currently contains calculated properties for over 1.8 million materials entries, including both experimentally observed and theoretically predicted structures, and new results are continuously being added. This AFLOW data is successfully applied to (i) formulate descriptors for the formation of disordered materials such as metallic glasses (Perim et al. 2016), (ii) find new magnetic materials (Sanvito et al. 2017) and superalloys (Nyshadham et al. 2017), (iii) generate phase diagrams for alloy systems (Barzilai et al. 2016, 2017a; Lederer et al. 2018) and identify new ordered compounds (Levy et al. 2010a, b, c;

Barzilai et al. 2017b), and (iv) train machine learning models to identify potential superconductors (Isayev et al. 2015) and predict electronic and thermomechanical properties (Isayev et al. 2017).

## 2    AFLOW: Efficient Data Generation

The AFLOW framework for computational materials science automates the full workflow for materials properties calculations (Curtarolo et al. 2012a). Using a standard set of calculation parameters (Calderon et al. 2015), input files are automatically generated for the VASP (Kresse and Hafner 1993; Kresse and Furthmüller 1996) DFT software package with projector-augmented-wave pseudopotentials (Blöchl 1994) and the PBE parameterization of the generalized gradient approximation to the exchange-correlation functional (Perdew et al. 1996). Calculations are monitored as they run to detect and correct for errors without the need for any user intervention. Useful materials data is then extracted and processed for dissemination through the AFLOW.org repository. The entire framework is written in the C++ programming language (more than 400,000 highly integrated lines, as of version 3.1.153), providing a robust platform for continuous infrastructure development with reliable high performance.

### 2.1    AFLOW: Automated Workflows

AFLOW offers several automated workflows, each dedicated to a specific type of characterization yielding a set materials properties. For electronic properties, AFLOW performs four DFT calculations: two rounds of geometry relaxation (stage name: "RELAX") using the VASP conjugate gradient optimization algorithm, a static run (i.e., fixed geometry; stage name: "STATIC") with a denser $\mathbf{k}$-point mesh to obtain an accurate density of states, and a band structure calculation (stage name: "BANDS") following the AFLOW Standard path through the high-symmetry $\mathbf{k}$-points in the Brillouin zone (Setyawan and Curtarolo 2010).

Other workflows in AFLOW manage ensembles of DFT calculations, all offering the same automated error-correction procedures for high-throughput processing. For thermal and elastic properties, the Debye-Grüneisen model (Automatic GIBBS Library, AGL) (Toher et al. 2014) is combined with the Automatic Elasticity Library (AEL) (Toher et al. 2017) as described in Sect. 2.6. A more accurate thermal characterization can be resolved with the finite displacement method for phonon calculations (Automatic Phonon Library, APL) (Nath et al. 2016) and its associated extensions, i.e., the quasi-harmonic approximation (QHA-APL) (Nath et al. 2016) and Automatic Anharmonic Phonon Library (AAPL) (Plata et al. 2017), as described in Sect. 2.7. AFLOW also extends beyond ideal crystalline materials characterization, offering modules to investigate off-stoichiometric materials (AFLOW-POCC, Sect. 2.5) (Yang et al. 2016) and to predict metallic glass formation as a function of composition (Perim et al. 2016).

## 2.2    AFLOW: Prototype Library

The AFLOW framework uses decorated crystal structure prototypes for materials discovery (Mehl et al. 2017). Structural prototypes are specific arrangements of atoms which are commonly observed in nature, such as the rock salt, zinc blende, and wurtzite structures. The atomic sites in these prototypes are populated with different elemental species to generate materials structures, for which the properties and thermodynamic stability are then obtained from DFT calculations. An extensive list of the structural prototypes included in AFLOW has been published in Mehl et al. (2017) and is available online at `http://aflow.org/CrystalDatabase`.

   Pages within the website display a curated list of data for each structural prototype, including materials exhibiting this structure, various symmetry descriptions, the primitive and atomic basis vectors, and original references where the structure was observed. Accompanying these descriptions is an interactive `Jmol` visualization of the prototype, as described in Sect. 2.8. The page also contains a prototype generator, where the structural degree(s) of freedom and atomic species are defined to create new materials by leveraging the AFLOW prototypes module. This generates the corresponding input file for one of many ab initio software packages, including VASP (Kresse and Hafner 1993; Kresse and Furthmüller 1996), QUANTUM ESPRESSO (Giannozzi et al. 2009, 2017), ABINIT (Gonze et al. 2002), and FHI-AIMS (Blum et al. 2009).

## 2.3    AFLOW-SYM: Symmetry Analyzer

The AFLOW framework automatically analyzes the symmetry of materials structures and returns a complete symmetry description. To address numerical tolerance issues, AFLOW employs an atom mapping procedure that is reliable even for non-orthogonal unit cells and uses an adaptive tolerance scheme to ensure symmetry results are commensurate with crystallographic principles (see Fig. 1). These routines—referred to as AFLOW-SYM (Hicks et al. 2018)—are robust and have been used to successfully determine the symmetry properties of over 1.8 million materials in the AFLOW repository.

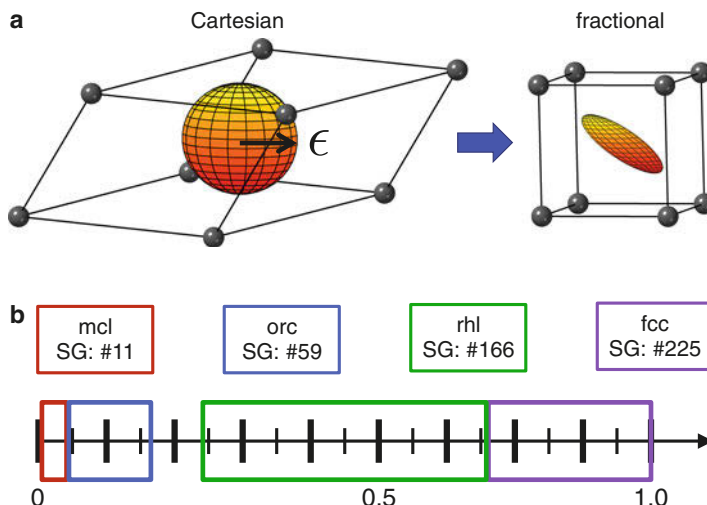
   Structural isometries are identified by determining the set of symmetry operators that lead to isomorphic mappings between the original and transformed atoms. The structure exhibits symmetry under a particular operation if the set of closest mapping distances are all below a tolerance threshold $\epsilon_0$. Periodic boundary conditions introduce complexity for finding the minimum mapping vector, necessitating the exploration of neighboring cells. This is achieved via the method of images through either (i) a unit cell expansion, yielding the globally optimal distance or (ii) a bring-in-cell method (generally performed in fractional coordinates) that reduces each component of the distance vector independently. While computationally inexpensive compared to the unit cell expansion, the bring-in-cell method is only exact for orthogonal lattices (i.e., described by a diagonal metric tensor), since it does not consider overlap between lattice vectors (see Fig. 1a). To safely exploit


**Fig. 1 Visualization of tolerance-sphere warping and adaptive tolerance method.** (**a**) Illustration of the warping of space when transforming from cartesian to fractional coordinates in the general case. (**b**) Spectrum of space groups identified by AFLOW-SYM with different tolerance choices

the bring-in-cell approach, AFLOW-SYM employs a heuristic maximum tolerance $\epsilon_{\max}$ based on the maximum lattice skewness with a threshold which guarantees consistent and accurate results (Hicks et al. 2018).

Given a particular tolerance value, different symmetry operations can be realized in or excluded from the description of a crystal. Figure 1b highlights how the tolerance value affects the possible space groups for AgBr (ICSD #56551 with a reported space group #11). The neighboring space group regions are consistent with non-isomorphic subgroup relations, namely, between space groups #59 and #11 and between #225 and #166. However, a gap or "confusion" tolerance region occurs between space groups #59 and #166 (with no direct subgroup relations). The problematic regions stem from noise in the structural data, impeding the identification of operations consistent with symmetry principles. This problem is solved by using a radial tolerance scan extending from the input tolerance $\epsilon_0$. Given a change in tolerance, the algorithm recalculates and verifies all symmetry properties until a globally consistent description is identified.

AFLOW-SYM is compatible with many established ab initio input files, including those for VASP (Kresse and Furthmüller 1996), QUANTUM ESPRESSO (Giannozzi et al. 2009, 2017), ABINIT (Gonze et al. 2002), and FHI-AIMS (Blum et al. 2009). From the structural information, AFLOW-SYM delivers the symmetries of the lattice, crystal (lattice + atoms), reciprocal lattice, superlattice (equally decorated sites), and crystal-spin (lattice + atoms + magnetic moment). This affords a multitude of symmetry descriptions to be presented, such as the space group number/symbol(s), Pearson symbol, point group symbol(s), Wyckoff positions, and Bravais lattice

type/variation (Setyawan and Curtarolo 2010). Moreover, the operators of the different symmetry groups—including the point groups, factor groups, space group, and site symmetries—are provided to users in rotation matrix, axis-angle, matrix generator, and quaternion representations for easy manipulation. All symmetry functions support the option to output in JSON format. This allows AFLOW-SYM to be leveraged from other programming languages such as Java, Go, Ruby, Julia, and Python—facilitating the incorporation of AFLOW-SYM into numerous applications and workflows.

## 2.4   AFLOW-CHULL: Convex Hull Analysis

Structure and energy data from the AFLOW.org repository are used to resolve the low-temperature/low-pressure thermodynamic stability of compound systems. For a given stoichiometry, the AFLOW.org repository provides the DFT energies of various crystal polymorphs. By exploring representative structures over the full range of stoichiometries, AFLOW-CHULL (Oses et al. 2018) constructs the minimum energy surface, i.e., the lower-half convex hull (Barber et al. 1996), defining thermodynamic stability for the system (at zero temperature and pressure). Structures on the hull are thermodynamically stable (ground state), while those far from the hull will decompose into a combination of stable phases, dictating synthesizability at these conditions. Any analysis of the hull requires sufficient statistics to ensure convergence, i.e., enough representative structures have been included in the alloy system calculations such that any additional entries are not expected to change the minimum energy surface.

The geometric construction offers several key properties critical for synthesizability. For a specific composition, the energetic distance to the hull quantifies the energy released during the decomposition, while the ground state phases defining the tie-line/facet below the compound are the products of the reaction. The distance from the hull also measures the "severity" of instability, i.e., structures near the hull may stabilize at higher temperatures or pressures. Similarly, a robust stability criterion can be quantified for ground state phases by removing the phase from the set and measuring the distance of the compound from the new hull. The larger the distance, the less likely the ground state phase will become unstable at higher temperatures/pressures (Sanvito et al. 2017). The generalized tie-lines (facet ridges) dictate which phases can coexist in equilibrium and play a role in determining the feasibility of synthesis/treatment techniques, such as precipitation hardening (Nyshadham et al. 2017).

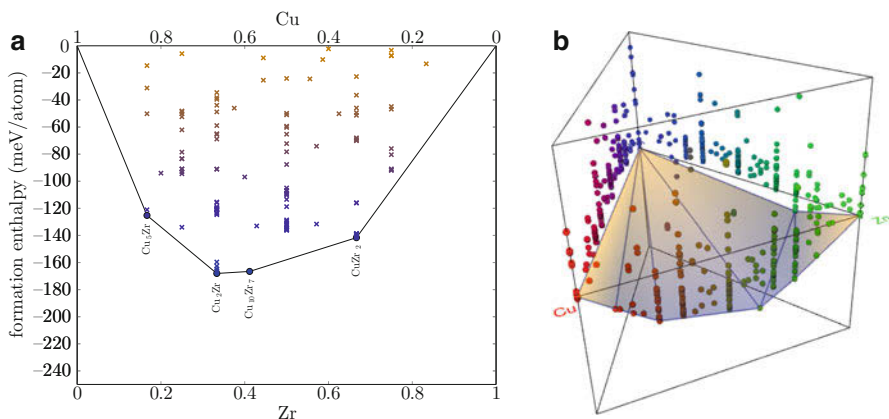
Given a compound system, AFLOW-CHULL automatically queries the AFLOW.org database, constructs the hull, calculates the aforementioned properties, and delivers the information in one of the following formats: PDF, plaintext, and JSON. AFLOW-CHULL can also visualize the 2D and 3D hulls, as illustrated in Fig. 2. In the case of the PDF output format, hyperlinks are included to allow for additional queries of the full properties set offered through the AFLOW.org repository. Links are also


**Fig. 2 Example convex hull illustrations offered by AFLOW.** (**a**) 2D convex hull of the CuZr system generated automatically by AFLOW. (**b**) 3D convex hull of the CuMnZn system presented through the AFLOW-CHULL application online: http://aflow.org/aflow-chull

added connecting the hull visualization to relevant properties for easy navigation of the full PDF document.

A separate online application, available at aflow.org/aflow-chull, has been created to showcase the results of AFLOW-CHULL and provides interactive binary and ternary convex hull visualizations. The application consists of four components: the periodic table, visualization viewport, selected entries list, and the comparison page. The periodic table component is the entry point of the application and provides the interface to search for convex hulls of different alloy systems. Elements within the periodic table respond when selected to display information to the user. As a selection is made, the color of each border will change to green, yellow, and red based on hull reliability. A reliability threshold of 200 compounds for a binary hull has been heuristically defined. Selections highlighted in green are well above this threshold, while those in yellow/red are near/below the cutoff.

When a hull is selected, the application transitions to the visualization viewport component. Depending on the number of elements selected, a 2D plot (binary) or 3D plot (ternary) will appear. Each plot is interactive, allowing points to be selected, where each point represents an entry in the AFLOW repository. Information for each point is displayed in the selected entries list component, which is accessible through the navigation bar. Selected hulls will appear on the comparison page as a grid of cards, and selected points are highlighted across all hulls containing those entries.

## 2.5    AFLOW-POCC: Partial Occupations

The AFLOW Partial Occupation module (AFLOW-POCC) (Yang et al. 2016) models configurational and structural disorder including substitutions, vacancies, and
**Fig. 3 Structure enumeration for off-stoichiometric materials modeling.** For the off-stoichiometric material $ZnS_{0.25}Se_{0.75}$, a superlattice of size $n = 4$ accommodates the stoichiometry exactly. By considering all possibilities of decorated supercells and eliminating duplicates by UFF energies, seven structures are identified as unique. These representative structures are fully characterized by AFLOW and VASP and are ensemble-averaged to resolve the system-wide properties

random lattice site occupation, by generating a set of representative configurations. First, a supercell size is determined that accommodates the fractional stoichiometry to within a user-defined tolerance. Given the supercell size, $n$, superlattices are generated using Hermite Normal Form matrices (Hart and Forcade 2008), which are then decorated in accordance with the stoichiometry to generate all possible configurations, as illustrated in Fig. 3. Duplicate configurations are rapidly identified and eliminated by estimating the energy of each structure using the Universal Force Field (UFF) model (Rappe et al. 1992). The properties of the remaining unique configurations are calculated with DFT, and ensemble-averaged to resolve system-wide properties of the disordered material. The ensemble-average employs a Boltzmann distribution weight which is a function of a disorder parameter (temperature), energy relative to the ground state configuration, and degeneracy as determined by the UFF model. Ensemble-average properties include the electronic band gap, density of states, and magnetic moment.

## 2.6    AEL and AGL: Thermomechanical Properties

The AFLOW Automatic Elasticity Library (AFLOW-AEL Toher et al. 2017) and the AFLOW Automatic GIBBS Library (AFLOW-AGL Toher et al. 2014) modules determine thermomechanical materials properties from calculations of strained primitive cells. These methods are generally computationally less costly than the phonon (APL and AAPL) calculations described in Sect. 2.7, although APL and AAPL generally give more quantitatively accurate results, particularly for properties where anharmonic effects are important. AEL and AGL have been combined into a single automated workflow, which has been used to calculate the thermomechanical properties for over 5000 materials in the AFLOW repository.

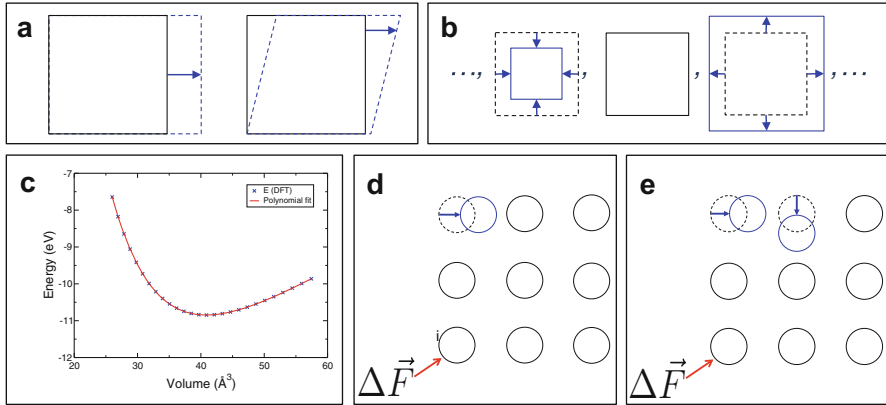
The AEL module applies a set of independent normal and shear strains to the primitive cell of a material (de Jong et al. 2015; Toher et al. 2017) as depicted in Fig. 4a and uses DFT to calculate the resulting stress tensors. This set of strain-stress data is used to generate the elastic stiffness tensor, i.e., the elastic constants:


**Fig. 4** **Ensembles of distorted geometries for the calculation of thermomechanical properties with AFLOW.** AEL uses the stresses from a set of (**a**) normal and shear strained cells to obtain the elastic constants. AGL calculates the energies of a set of (**b**) isotropically compressed and expanded unit cells and (**c**) fits the resulting $E(V)$ data by a numerical polynomial or by an empirical equation of state. APL obtains the (**d**) second-order harmonic IFCs from a set of single-atom displacements and the (**e**) third-order anharmonic IFCs from a set of two-atom displacements

$$
\begin{pmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{pmatrix} = \begin{pmatrix} c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\ c_{12} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\ c_{13} & c_{23} & c_{33} & c_{34} & c_{35} & c_{36} \\ c_{14} & c_{24} & c_{34} & c_{44} & c_{45} & c_{46} \\ c_{15} & c_{25} & c_{35} & c_{45} & c_{55} & c_{56} \\ c_{16} & c_{26} & c_{36} & c_{46} & c_{56} & c_{66} \end{pmatrix} \begin{pmatrix} \epsilon_{11} \\ \epsilon_{22} \\ \epsilon_{33} \\ 2\epsilon_{23} \\ 2\epsilon_{13} \\ 2\epsilon_{12} \end{pmatrix} \tag{1}
$$

written in the $6 \times 6$ Voigt notation using the mapping (Poirier 2000): $11 \mapsto 1$, $22 \mapsto 2$, $33 \mapsto 3$, $23 \mapsto 4$, $13 \mapsto 5$, $12 \mapsto 6$. These elastic constants are combined to calculate the bulk, $B$, and shear, $G$, elastic moduli in the Voigt, Reuss, and Voigt-Reuss-Hill (VRH, $B_{\mathrm{VRH}}$ and $G_{\mathrm{VRH}}$) approximations. The Poisson ratio $\nu$ is then given by:

$$
\nu = \frac{3B_{\mathrm{VRH}} - 2G_{\mathrm{VRH}}}{6B_{\mathrm{VRH}} + 2G_{\mathrm{VRH}}}. \tag{2}
$$

The AGL module is based on the GIBBS (Blanco et al. 1996, 2004) quasi-harmonic Debye-Grüneisen model and calculates the energy as a function of volume, $E(V)$, for a set of isotropically compressed and expanded strains of the primitive cell, as illustrated in Fig. 4b. The $E(V)$ data are fitted by either a numerical polynomial or an empirical equation of state to obtain the adiabatic bulk modulus $B_{\mathrm{S}}(V)$, as shown in Fig. 4c. The Debye temperature $\theta_{\mathrm{D}}(V)$ as a function of volume is then calculated using the expression:

$$\theta_D = \frac{\hbar}{k_B}[6\pi^2 V^{1/2} n]^{1/3} f(\nu) \sqrt{\frac{B_S}{M}}, \tag{3}$$

where $n$ is the number of atoms per unit cell, $M$ is the unit cell mass, and $f(\nu)$ is a function of the Poisson ratio $\nu$:

$$f(\nu) = \left\{ 3 \left[ 2 \left( \frac{2}{3} \cdot \frac{1+\nu}{1-2\nu} \right)^{3/2} + \left( \frac{1}{3} \cdot \frac{1+\nu}{1-\nu} \right)^{3/2} \right]^{-1} \right\}^{\frac{1}{3}}, \tag{4}$$

where $\nu$ can be obtained from Eq. 2 using AEL or set directly by the user. The vibrational contribution to the free energy, $F_{vib}$, is given by:

$$F_{vib}(\theta_D; T) = nk_B T \left[ \frac{9}{8} \frac{\theta_D}{T} + 3 \log\left( 1 - e^{-\theta_D/T} \right) - D\left( \frac{\theta_D}{T} \right) \right], \tag{5}$$

where $D(\theta_D/T)$ is the Debye integral:

$$D(\theta_D/T) = 3 \left( \frac{T}{\theta_D} \right)^3 \int_0^{\theta_D/T} \frac{x^3}{e^x - 1} dx. \tag{6}$$

The Gibbs free energy is obtained from:

$$G(V; p, T) = E_{DFT}(V) + F_{vib}(\theta_D(V); T) + pV. \tag{7}$$

The volume which minimizes $G(V; p, T)$ at a given pressure $p$ and temperature $T$ is the equilibrium volume $V_{eq}$, which is used to evaluate $\theta_D(V_{eq})$ and the Grüneisen parameter $\gamma$ as defined by:

$$\gamma = -\frac{\partial \log(\theta_D(V))}{\partial \log V}. \tag{8}$$

Finally, $\theta_D$ and $\gamma$ are used to calculate other thermal properties including $C_V$, $C_p$, $\alpha_V$, and $\kappa_L$ (Toher et al. 2014; Blanco et al. 2004).

## 2.7   AFLOW-APL: Phonons

The AFLOW Automatic Phonon Library (AFLOW-APL) (Curtarolo et al. 2012a) calculates the harmonic vibrational properties of a crystal using the finite displacement method. Computed properties include the phonon dispersion and density of states, vibrational entropy ($S_{vib}$), and the heat capacity (at constant volume, $C_V$) as a function of temperature. These features are determined through an analysis of the phonon modes, accessed through the Interatomic Force Constants (IFCs) (Maradudin et al. 1971). To first approximation, the harmonic (second-order)

IFC $C_{i,j;\alpha,\beta}$ is the negative of the force exerted in the $\alpha$ direction on the atom $i$ when the atom $j$ is displaced in the $\beta$ direction, with all other atoms maintaining their equilibrium position. To determine the forces, the atoms of the structure (supercell) are individually perturbed as illustrated in Fig. 4d. The forces are obtained with DFT from the derivative of the total energy using the Hellmann-Feynman theorem. Supercells are used to sufficiently capture/isolate the impact of the distortion on the structure; distortions on small cells create forces on all atoms as well as their periodic images.

Given an input structure, AFLOW creates the full set of distorted supercell structures for the calculation of the forces. To minimize the number of expensive DFT calculations (primary computational bottleneck), AFLOW-SYM (see Sect. 2.3) is employed to determine which distortions are symmetrically equivalent using the site symmetry. Only inequivalent distortions are applied and explicitly calculated. Symmetry is then used to appropriately construct the IFC matrix, from which the dynamical matrix is constructed and the phonon modes, energies, and group velocities are derived.

APL has been extended to include the calculation of quasi-harmonic (quasi-harmonic approximation APL, QHA-APL Nath et al. 2016, 2017) and anharmonic (Automatic Anharmonic Phonon Library, AAPL Plata et al. 2017) effects in order to obtain properties such as the heat capacity at constant pressure $C_p$, coefficient of volumetric thermal expansion $\alpha_V$, and lattice thermal conductivity $\kappa_L$.

QHA-APL performs harmonic APL calculations at multiple different volumes and extracts the Grüneisen parameter from the change of the phonon frequencies with respect to volume:

$$\gamma_i = -\frac{V}{\omega_i}\frac{\partial\omega_i}{\partial V}. \tag{9}$$

The Grüneisen parameter can be used in combination with harmonic properties such as $C_V$ to calculate $C_p$, $\alpha_V$ (Nath et al. 2016), and $\kappa_L$ (Nath et al. 2017).

AAPL obtains the third-order anharmonic IFCs by distorting two atoms in a supercell structure at a time as depicted in Fig. 4e and then calculating the change in forces on the other atoms (Plata et al. 2017). These IFCs are used to calculate the three-phonon scattering rates, and thus the scattering time and mean free displacement. These quantities are combined with the group velocities obtained from harmonic APL to solve the Boltzmann transport equation and calculate $\kappa_L$ with quantitative accuracy (Plata et al. 2017).

## 2.8    AFLOW: Visualization Tools

AFLOW leverages a panoply of visualization tools for materials data, including standard software such as `gnuplot`, `latex`, and `xmgrace` for plots of phonon dispersions, electronic band structures, electronic density of states, and convex hull visualization. These plots are served publicly through the AFLOW.org repository.
**Fig. 5 Side-by-size visualization of the crystal structure and Brillouin zone using Jmol.** The structure highlighted is $Ag_3KS_2$ (ICSD #73581): http://aflow.org/material.php?id=Ag6K2S4_ICSD_73581. The AFLOW Standard path of high-symmetry **k**-points is illustrated in the Brillouin zone (Setyawan and Curtarolo 2010)

To visualize crystal structures, AFLOW employs the Jmol software, which has incorporated substantial functionality for AFLOW-specific application. The JSmol branch of the software powers the online crystal structure visualizations in the AFLOW.org repository entry pages and AFLOW Prototype Library pages. With its recently added POSCAR reader, JSmol provides an assortment of capabilities ranging from different view perspectives, supercell expansions, and varying unit cell representations. A similar visualization application showing the AFLOW Standard high-symmetry paths in the Brillouin zone (Setyawan and Curtarolo 2010) is currently being incorporated, as illustrated in Fig. 5. Additionally, the Jmol desktop client offers a specialized macro (aflow) for visualization of alloy systems, which leverages the AFLUX Search-API.

## 3    AFLOW$\pi$: Minimalist High-Throughput

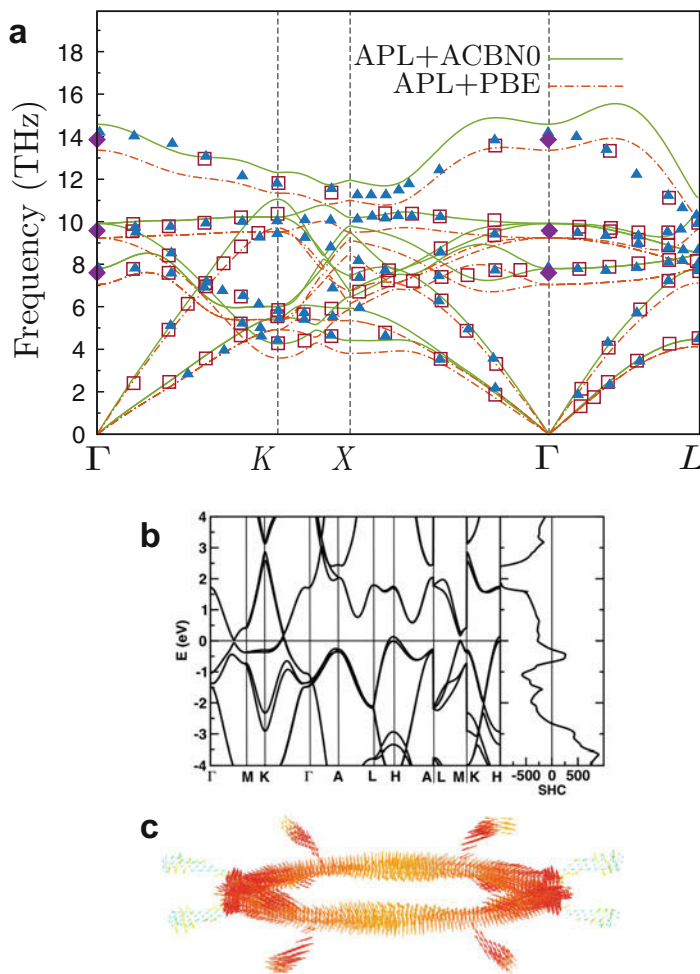
The AFLOW$\pi$ (Supka et al. 2017) framework has been originally implemented as a minimalist software to perform verification tasks (see Sect. 5.7) on data published on AFLOW.org. By design, AFLOW$\pi$ is easy to install and to extend to a variety of electronic structure codes (currently only the QUANTUM ESPRESSO (Giannozzi et al. 2009, 2017) DFT package is implemented). AFLOW$\pi$ builds on the versatility of Python, providing a module to prepare, run, and analyze large sets of first-principles calculations and includes tools for the automatic projection on pseudo-atomic orbitals (PAO; see Sect. 4) and the self-consistent calculation of Hubbard $U$ corrections within the Agapito, Curtarolo and Buongiorno Nardelli (ACBN0) approach (Agapito et al. 2015; Andrade et al. 2015). In addition, workflows for the calculation of elastic constants, diffusive transport coefficients, optical spectra, and phonon dispersions with DFT+$U$ (see Fig. 6a for assessing the


**Fig. 6 Vibrational spectrum calculated with AFLOW$\pi$ and AFLOW-APL (left) and electronic properties computed with PAOFLOW (right).** (**a**) Phonon dispersion of $CaF_2$ calculated with APL (Plata et al. 2017), using the ACBN0 method as implemented within AFLOW$\pi$ (green lines). The results obtained using PBE are shown by the broken orange lines for comparison. The blue triangles and red unfilled squares represent neutron scattering data from Schmalzl et al. (2003) and Elcombe and Pryor (1970), respectively, while the purple diamonds represent Raman and infrared data from Kaiser et al. (1962). (**b**) Electronic band structure, s̲pin H̲all c̲onductivity (SHC), and (**c**) spin texture of the nodal line and Weyl points in HfC, as calculated using the PAOFLOW utility

effect of the Hubbard $U$ corrections on the phonon dispersion calculated using APL) are included. When possible, AFLOW$\pi$ exploits the tight-binding hamiltonians as in D'Amico et al. (2016). Calculation results can be easily packaged and prepared for incorporation into the AFLOW.org data repository (see Sect. 5).

## 4      PAOFLOW: Fast Characterization

PAOFLOW (Buongiorno Nardelli et al. 2017) is a stand-alone tool to efficiently post-process standard DFT pseudo-potential plane-wave calculations to generate tight-binding (TB) Hamiltonians which faithfully reproduce the calculated electronic structure (eigenvalues and eigenvectors) with arbitrary precision in reciprocal space (Agapito et al. 2013, 2016a, b) (see Fig. 6b for PAOFLOW generated band structure for HfC (ICSD #169399, space group #187, AFLOW prototype: AB_hP2_187_d_a)). By exploiting the simplicity of the TB formalism and the efficiency of fast Fourier transforms, PAOFLOW interpolates the band structure and computes the matrix elements of the momentum operator, $\mathbf{p}_{m,n}$. These are used to improve the quality of integrated quantities such as the density of states (adaptive smearing), to compute electronic transport coefficients within the constant relaxation time approximation, and to compute the dielectric constants (D'Amico et al. 2016). In addition, the $\mathbf{p}_{m,n}$ matrix elements facilitate the calculation of the Berry curvature and related properties (anomalous Hall conductivity, spin Hall conductivity (see Fig. 6b), magnetic circular dichroism, spin circular dichroism; see spin texture of the nodal line and Weyl points in HfC shown in Fig. 6c). Starting from a well-interpolated band structure, it is also possible to compute topological invariants.

Because of the local representation of the electronic structure provided by the PAOFLOW software, surface-projected band structure and Landauer ballistic transport are also computable within PAOFLOW.

The software is implemented in Python, is portable and easy to install, and is parallel by design (on both CPUs and GPUs). PAOFLOW is also an integral part of the AFLOW$\pi$ framework.

## 5      AFLOW: Data Repository

The AFLOW data repository (Curtarolo et al. 2012b) contains the calculated properties for over 1.8 million materials entries, obtained using the AFLOW framework. These properties are available through the aflow.org web portal, which includes online search/sort and data analysis applications. The repository is programmatically accessible through the AFLOW Data REST-API (Taylor et al. 2014) and the AFLUX Search-API (Rose et al. 2017).

### 5.1      AFLOW: Web Portal

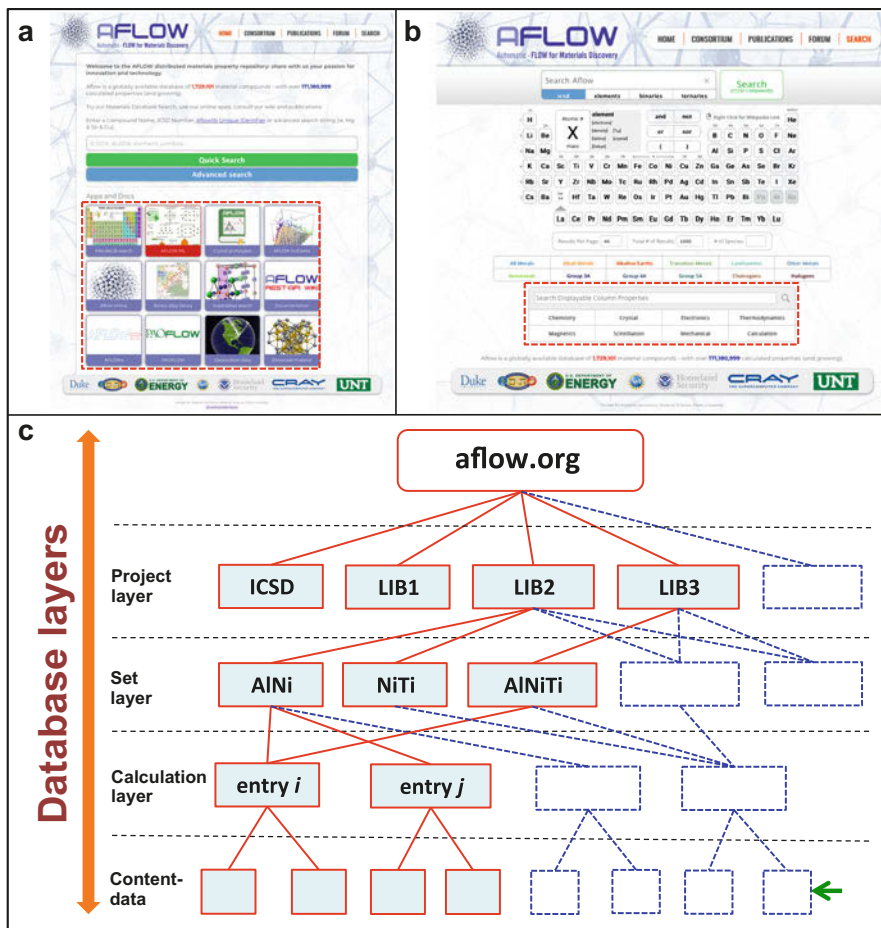
The AFLOW repository (Curtarolo et al. 2012b) is available online via the aflow.org web portal (Fig. 7a). It contains multiple online applications for data access, processing, and visualization, including the advanced "MendeLIB" search application at http://aflow.org/advanced.php which facilitates


**Fig. 7 AFLOW web portal and data repository.** (**a**) Online applications and documentation are accessible via the "Apps and Docs" set of buttons surrounded by the dashed red rectangle. (**b**) The advanced search application can be used to search for specific compositions and also includes property search filters, as highlighted by the dashed red rectangle. (**c**) The AFLOW data repository is organized into project, set (i.e., alloy system), and calculation (i.e., materials entry) layers

searching for materials entries with filters for elemental composition and calculated properties (see Fig. 7b), the interactive convex hull application at `http://aflow.org/aflow-chull` (see Sect. 2.4), the online machine learning model at `http://aflow.org/aflow-ml` (see Sect. 5.2), and the AFLOW online tool at `http://aflow.org/aflow_online.html` which gives access to AFLOW crystal structure analysis and processing functions. These applications and more are accessible from the main `aflow.org` web page, via the "Apps and Docs" set of buttons highlighted by the dashed red rectangle in Fig. 7a.

## 5.2      AFLOW-ML: Online Machine Learning

The AFLOW machine learning (AFLOW-ML) online application provides a user interface to leverage machine learning models trained on AFLOW data. It accepts a standard structure file (POSCAR or QE) and outputs predictions for properties such as the band gap, elastic moduli, heat capacity, Debye temperature, vibrational free energy, and thermal expansion coefficient. Additionally, structures within the AFLOW repository can be imported via the sidebar. This application provides an accessible medium to retrieve machine learning predictions without the need to install a software library or machine learning package.

Currently, AFLOW-ML supports two different machine learning models. The first model, property-labeled materials fragments (Isayev et al. 2017), plmf, has been trained using data from the AFLOW repository and predicts properties such as the electronic band gap, specific heat capacities, and bulk/shear moduli. The second method is the molar fraction descriptor model (Legrain et al. 2017), mfd, which predicts vibrational properties such as vibrational free energy and entropy and is based only on the chemical composition of the material.

The AFLOW-ML API (Gossett et al. 2018) offers programmatic access to the AFLOW-ML online application and provides a simplified abstraction that facilitates leveraging powerful machine learning models. This distills the prediction process down to its essence: from a structure file, return a prediction. Using the API is a two-step process: first a structure file, in POSCAR 5 format (structure input for version 5 of VASP), is posted (i.e., uploaded) to the endpoint /<model>/prediction on the aflow.org server using standard HTTP libraries or dedicated programs such curl or wget, where <model> specifies the machine learning model to use in the prediction (current options: plmf and mfd). When a prediction is submitted, a JSON response object is returned that includes a task id. The results of the prediction are then retrieved from the /prediction/result/ endpoint on the aflow.org server by appending the task id to the end of the URL, i.e., /prediction/result/{id}/. This endpoint monitors the prediction task and responds with a JSON object that details its status. When complete, the endpoint responds with the results of the prediction, represented as a JSON object containing a key-value pair for each predicted property.

## 5.3      AFLOW: Database Organization

The AFLOW data repository (Curtarolo et al. 2012b) is organized into project, set, and calculation layers as illustrated in Fig. 7c. At the project layer, the calculations are divided into different catalogs based on the origin and composition of the entries (Taylor et al. 2014; Rose et al. 2017). Within each catalog, entries are grouped into sets based on shared lattice type or alloy system. The entries within each set contain the results of DFT calculated properties for particular structures.

The AFLOW-ICSD catalog contains the DFT calculated properties for over 57,000 experimentally observed materials listed in the Inorganic Crystal Structure Database (ICSD) (Bergerhoff et al. 1983; Karen and Hellenbrandt 2002). Internally, this catalog is organized by lattice type and then by individual materials entry. Since the materials in this catalog are already known to exist, the primary interest is in accurately calculating electronic structure and thermomechanical properties. Therefore, calculations for this catalog are generally performed using the Hubbard $U$ correction to the DFT exchange-correlation functional (Liechtenstein et al. 1995; Dudarev et al. 1998) where appropriate, using a set of standardized $U$ values (Calderon et al. 2015). Within this catalog, entries are grouped by Bravais lattice type into 14 sets: "BCC", "BCT", "CUB", "FCC", "HEX'", "MCL'", "MCLC'", "ORC'", "ORCC'", "ORCF'", "ORCI'", "RHL'", "TET'" and "TRI'". The name of each materials entry is generated using the format `<composition>_ICSD_<ICSD number>`.

The entries in the other catalogs, such as "LIB1," "LIB2," and "LIB3", are generated by decorating crystal structure prototypes to predict new hypothetical compounds and contain unary, binary, and ternary materials, respectively. Additional catalogs, "LIB4," "LIB5," and "LIB6," are currently being generated for quaternary, quinary, and hexenary materials. Within each catalog, the entries are grouped by element and exchange-correlation functional in the case of "LIB1" and by alloy system in the cases of "LIB2" and "LIB3." "LIB1" contains a total of 3068 entries, while "LIB2" currently has 329,192 entries and "LIB3" has over 1.4 million. Within each alloy system, the individual materials entries are named according to the relevant crystal prototype. For these catalogs, the emphasis is on the discovery of new thermodynamically stable or metastable materials and on their use to generate the thermodynamic density of states for the prediction of the formation of disordered materials such as metallic glasses (Perim et al. 2016) or high-entropy alloys (Lederer et al. 2018). Therefore, calculations in these catalogs are performed using the GGA-PBE exchange-correlation functional (Perdew et al. 1996) without Hubbard $U$ corrections (Calderon et al. 2015) so as to produce consistent energy differences, enabling the calculation of accurate formation enthalpies.

## 5.4 AFLOW: Database Properties

Materials properties within the AFLOW repository (Curtarolo et al. 2012b) are indexed as keyword-value pairs which are programmatically accessible via the AFLOW Data REST-API (Taylor et al. 2014) and programmatically searchable via the AFLUX Search-API (Rose et al. 2017). Search filters for these properties are also available in the advanced search application of the aflow.org web portal as highlighted by the dashed red rectangle in Fig. 7b, where they are grouped into chemistry (e.g., chemical species, stoichiometry), crystal (e.g., space group, Bravais lattice type), electronic (e.g., band gaps), thermodynamic (energetic and thermal properties, e.g., formation enthalpies and Debye temperatures), magnetic, scintillation, mechanical (elastic moduli and pressure-related properties), and calculation (e.g., **k**-point mesh, AFLOW version) parameters. In total there are in excess of 170
**Fig. 8 Example band structure and density of states images automatically generated and served through the AFLOW.org data repository.** The structure highlighted is AlCo$_2$Fe (ICSD #57607): http://aflow.org/material.php?id=Al1Co2Fe1_ICSD_57607. The results of the spin-polarized calculation are differentiated by color on the band structure plot (black/red for majority/minority spin) and sign on the density of states plot (positive/negative for majority/minority spin). The band structure is calculated following the AFLOW Standard path of high-symmetry **k**-points (Setyawan and Curtarolo 2010)

million individual materials properties indexed in the AFLOW database ($\sim$100 per materials entry). Lists of the keywords corresponding to the materials properties are provided in Taylor et al. (2014), Rose et al. (2017), and Toher et al. (2017).

Systems for which the "STATIC" and "BANDS" calculations have been performed are supplemented with automatically generated images of the density of states, projected density of states, and band structure. Both low (PNG)- and high (EPS)-quality variants of the images are available for download. An example band structure and density of states image is displayed in Fig. 8.

## 5.5   AFLOW: Data REST-API

The full data set generated by the high-throughput AFLOW process (Curtarolo et al. 2012b) is backed by a disk store of (at this time) over 12 TB of input criteria, calculated results, and derivative output. The backing store is exposed via the AFLOW Data REST-API (Curtarolo et al. 2012b) in a hierarchical organization. This direct exposure of our results not only grants the end user a high degree of utility via direct access, but, more importantly, guarantees data provenance that promotes reproducibility. The hierarchy of the AFLOW Data REST-API categorizes this abundance of information into meaningful high-level classifications allowing

for exploration of self-similar materials that are related by stoichiometric and/or crystallographic properties. Once a selection of materials has been determined, the full range of available properties and procedural data are retrievable.

The organizational hierarchy of both the underlying data store and the REST-API is project dependent, as described in Sect. 5.3. Each project is equivalent to one of the catalogs listed in Sect. 5.3 and in the REST-API is denoted by the project layers "ICSD_WEB," "LIB1_RAW," "LIB2_RAW," and "LIB3_RAW." Each project layer contains multiple set layers, which correspond to specific alloy systems in the case of "LIB1_RAW," "LIB2_RAW," and "LIB3_RAW." For instance, `http://aflowlib.duke.edu/AFLOWDATA/LIB2_RAW/` exposes the set layer for binary entries, where each set corresponds to different binary alloy systems, allowing for pairwise atomic species examination. Within each set is the entry layer, consisting of decorated structural prototypes which provide stoichiometric and structural variation for each alloy system. Each entry contains the calculated results for a particular structure and composition, organized as keyword-value pairs. The calculated values of thermodynamical, mechanical, electronic, magnetic, chemical, and crystallographic properties can be directly accessed by querying a Uniform Resource Identifier (URI) of the form `<server>/<project>/<set>/<entry>/?<keyword>`, where `<server>` is `http://aflowlib.duke.edu/AFLOWDATA`, `<project>` is the appropriate project layer, `<set>` is the alloy system, `<entry>` is the structural prototype, and `<keyword>` corresponds to the materials property of interest. A full description of the REST-API keywords is provided in Taylor et al. (2014), along with additions in the appendices of Rose et al. (2017) and Toher et al. (2017).

The ability to explore related entries predicated on a multitude of properties leads directly to novel materials discovery and use. The AFLOW Data REST-API disseminates our methods and results, without restriction, to a global research audience in order to promote scientific and engineering advancement.

## 5.6    AFLUX: Search-API

The Automatic Flow of LUX or AFLUX Search-API (Rose et al. 2017) is a human usable remote data search API. LUX is designed to be a domain agnostic solution to the outstanding problem of programmatically searching remote data that typically is either exposed via a capriciously limited utility or requires a-priori knowledge of the internal organization of the remote repository. The LUX query concept flattens the exposed data, while simultaneously providing arbitrarily complex query capability, allowing an end user full freedom in constraining the requested data. LUX is designed to operate in the nearly ubiquitous web URI context while minimizing any potentially conflicting interactions with existing URI functionality.

AFLUX is the domain-specific implementation of LUX and is available at the `<AFLUX-URI>`: `http://aflowlib.duke.edu/search/API/?`. At this time, the AFLUX API freely exposes over 180 million keyword-value properties without any requirements or restrictions on the end user. Specific properties and

compositions can be searched for by appending the appropriate keywords to the `<AFLUX-URI>`. Search results can be restricted by including specific values or value ranges in parentheses after the appropriate keyword. For example, a search can be restricted to entries that contain both of the elements Na and Cl, and have a calculated electronic band gap in excess of 1.0eV, by including the search parameters `species(Na,Cl),Egap(1.0*)` in the query part of the URI. In LUX, "," corresponds to the logical AND operator, and "*" is the `loose` operator which extends the search to entries in a specified value range. If no parameters are provided for a particular keyword, then the values of that property are returned for all entries which satisfy the remaining search criteria. A full list of all LUX logical operators can be found in Rose et al. (2017), along with descriptions of their functionality and appropriate usage.

In addition to materials properties keywords, LUX also accepts directives, which behave as pseudo property keywords. They are used to provide additional information on LUX usage and control the format and quantity of the returned data. Note that any directives included in a search query must come after all of the materials properties keywords. In particular, the `schema` directive can be used to retrieve the most current and canonical list of keywords using the AFLUX summons: `<AFLUX-URI>schema,format(json)`.

## 5.7   AFLOW: Data Quality Control

Data quality control, including validation of methodologies and verification of calculated data, is vital when constructing large databases such as the AFLOW repository (Curtarolo et al. 2012b) in order to guarantee the reliability of the results. Methodological validation involves quantifying the accuracy of calculation models with respect to experiment, while data verification includes checking the robustness of calculation parameters and the satisfaction of convergence criteria.

Physical models incorporated into the AFLOW framework are validated by comparison to benchmark sets of experimental data. This helps determine the predictive accuracy of the methods for real materials, as well as the regimes in which they are reliable. For example, the AEL and AGL modules were validated by comparison to a benchmark set of ∼75 experimentally well-characterized compounds of various structural types (Toher et al. 2014, 2017), and the accuracy was quantified by the Pearson and Spearman correlations and the root-mean-square deviations. Similar validation analyses were performed for the QHA-APL (Nath et al. 2016, 2017) and AAPL methods (Plata et al. 2017), as well as the property labeled materials fragments machine learning model (Isayev et al. 2017).

The AFLOW-POCC methodology has been validated by comparing the band gap as a function of composition for $ZnS_{1-x}Se_x$ and $Mg_xZn_{1-x}O$, and the magnetic moment per atom as a function of composition for $Fe_{1-x}Cu_x$, to experimental values (Yang et al. 2016).

The ACBN0 functional (Agapito et al. 2015), implemented in AFLOW$\pi$ (see Sect. 3) and PAOFLOW (see Sect. 4), has been validated by comparing the lattice

parameters, bulk moduli, electronic band gaps, phonon modes, high-frequency dielectric constants, and Born effective changes it produces to the experimentally measured values for the Zn and Cd chalcogenides (Gopal et al. 2015).

The convergence of both the charge density optimization and the ionic structural relaxation are automatically verified for all AFLOW calculations prior to incorporation into the data repository. This includes, for example, checking that the charge density has converged in accordance with the AFLOW Standard settings (Calderon et al. 2015) and verifying the relaxation of the cell size and shape by ensuring that all elements of the stress tensor are less than 10kB. The convergence level for any individual calculation can be verified by querying appropriate keywords for the stress tensor: `stress_tensor`, Pulay stress: `Pulay_stress`, residual external pressure on the relaxed cell: `pressure_residual`, and the $\delta E$ value for the final electronic convergence step: `delta_electronic_energy_convergence`, using the AFLOW Data REST-API (Taylor et al. 2014) or the AFLUX Search-API (Rose et al. 2017). Initial calculation parameters can similarly be obtained using the appropriate keywords, such as the k-point grid, `kpoints`, or the electronic energy convergence threshold, `delta_electronic_energy_threshold`.

## Conclusion

The AFLOW Fleet for computational materials design automates first-principles calculations of materials properties. AFLOW incorporates a wide range of different modules, including applications for symmetry and thermodynamic stability analysis, generation of ordered and disordered materials structures, and calculation of thermomechanical properties, in a single integrated framework. AFLOW$\pi$ is a versatile minimalist framework that includes tools for projection onto pseudo-atomic orbitals (PAO) and the self-consistent calculation of Hubbard $U$ corrections using ACBN0. PAOFLOW generates tight-binding Hamiltonians which reproduce the electronic structure calculated using first-principles methods, facilitating the rapid calculation of electronic and magnetic properties such as transport coefficients and the Berry curvature. All results are stored in, and disseminated through, the AFLOW data repository, which is available online at aflow.org and is programmatically accessible via the AFLOW Data REST-API and the AFLUX Search-API.

**Abstract**

We discuss here our vision for an Open-Science platform for computational materials science. Such a platform needs to rely on three pillars, consisting of (1) open data generation tools (including the simulation codes, the scientific workflows, and the infrastructure for automation and provenance tracking), (2) an open integration platform where these tools interact in an easily accessible way and computations are coordinated by automated workflows, and (3) support for seamless code and data sharing through portals that are FAIR-compliant and compatible with data management plans. As a practical implementation, we show how such a platform can be achieved in a few examples and focusing in particular on the combination of the AiiDA infrastructure and the Materials Cloud web portal.

# 1    Introduction

In the field of atomistic materials science, computer simulations have become a key ingredient in materials design. The availability of accurate codes based on density-functional theory (DFT) and beyond-DFT methods and the ever-increasing speed of supercomputers make computational materials science more accessible. Indeed, computations have developed into an essential component to complement experiments in the study and optimization of materials properties. The current relevance of these techniques is also demonstrated by the fact that 12 out of the top-100 most-cited papers in the whole scientific literature are about DFT-related methods (Van Noorden et al. 2014). As a consequence, many groups have started computing materials properties for large sets of known and unknown materials, often starting from databases of crystal structures like the ICSD (Belsky et al. 2002), the COD (Gražulis et al. 2012), and the Pauling File (Villars et al. 2004). Many of these computed materials properties are available online; some of these portals are also described in this handbook and include the Materials Project (Jain et al. 2011), AFLOWlib (Curtarolo et al. 2012), OQMD (Saal et al. 2013), Nomad (The Nomad Repository 2018), and the CMR (Landis et al. 2012).

Furthermore, large sets of computations are nowadays being used as training data to predict materials properties more efficiently using machine-learning techniques (Ramakrishnan et al. 2014; Dragoni et al. 2018). In general, however, it is essential to have enough information on the data, including how it was generated (i.e., its provenance), which physical and numerical parameters were used, and in general be able to reproduce the results to validate them. This is even more important for machine-learning, where accurate predictions are possible only if the quality of the data used to train the algorithms is known and consistent across datapoints.

In addition to this, the availability of open data is beneficial to boost research and discovery because datasets can be repurposed for new studies and analyses not considered by the original authors. In principle, recording data with its full provenance and sharing it should be much easier for computer simulations with respect to, e.g., experiments. However, in practice there are a number of aspects that

hinder automatic computation of materials properties, calculation reproducibility, dissemination of data provenance, and sharing of open research data. In this chapter, we discuss our vision of a platform for Open Science that can lower these barriers, and we review the challenges that need to be addressed. We also present the two software infrastructures AiiDA (Pizzi et al. 2016) and Materials Cloud (Materials Cloud 2017) and show examples of how their combination makes it possible to create a fruitful Open Science ecosystem.

## 1.1    The Pillars of an Open-Science Platform

Before starting, we want to define the term Open-Science platform (OSP) and how it is used in this chapter. With Open Science, we refer to a combination of open tools and data that make it possible to run simulations and then share and reuse the results without barriers, with the aim to accelerate scientific discovery. While open data is definitely an essential ingredient of an OSP, we believe that the platform must have a strong focus on the tools to generate and share the data. Moreover, it should be composed by modular components, so as to cover a multitude of use-cases and to encourage researchers to use and expand it with contributions.

We think that an OSP should be based around the three following pillars: (1) open data generation tools, including open simulation codes, an open architecture to manage simulations, and open workflows to steer them; (2) an integration platform that makes these tools accessible and available in the form of automated solutions, not only to experienced computational researchers but also to experimentalists, students, or the industry; and (3) support for seamless data sharing through portals that make data not only findable (e.g., via DOIs) and openly available, but also interoperable and reusable, encouraging the use of open data and code licenses.

Moreover, in our vision an OSP should also include the availability of open libraries of curated input data, often needed for simulations (like crystal structures or pseudopotentials) and that can enable the creation of automated workflows, as well as of open learning and educational resources to ease the introduction of young researchers to the field.

## 2    Open Science Pillar 1: Open Data Generation

## 2.1    Open Simulation Tools

The first requirement to be able to generate data within an OSP is the availability of open simulation codes. In the field of materials science (and limiting to atomistic simulations using density-functional theory only), a number of open codes are available thanks to the developments that have happened in the past few decades. These include Quantum ESPRESSO (Giannozzi et al. 2017), SIESTA (Soler et al. 2002), YAMBO (Marini et al. 2009), FLEUR (Blügel and Bihlmayer 2006), CP2K (Hutter et al. 2014), and ABINIT (Gonze et al. 2016) just to mention a few.

This open licensing model makes the codes accessible to everybody. Moreover, it becomes possible to build simulation services on top of them that can also be beneficial to the code themselves, as these services can become financing channels for the code development.

There are also other codes that are widespread in the community and have commercial licenses, like, for instance, VASP (Kresse and Furthmüller 1996) or CASTEP (Clark et al. 2005). These might have benefits in term of additional features implemented, speed, robustness, more widespread adoption, or stronger user support (the latter is often very valued outside academia in industrial research and development environments). The challenge for an OSP becomes then to be able to integrate also these non-open tools while abiding by their license terms. Models can be devised that are beneficial both for the commercial codes and for the platform. An example could be to provide open interfaces and plugins for the codes to enable or facilitate their integration in the OSP, while keeping a commercial license for the codes. The latter can also benefit from this model because having interfaces ready can facilitate the code adoption by OSP users.

## 2.2    The ADES Model and the Implementation in AiiDA

In recent years, many research projects used a high-throughput computing (HTC) approach to scan hundreds of thousands of different systems and identify those with optimal materials properties. For this kind of projects, it is unrealistic to run all the simulations manually and even more to control the sequence of calculations needed to compute a given materials property. Tools are hence needed to help manage and store simulations, search through them, and at the same time steer their execution when calculation dependencies exist. Our experience showed that these tools can easily grow in complexity if they need to be reusable and modular. Therefore, there is a need to collect and develop them in an organized architecture.

In Pizzi et al. (2016), a model for such a computational science architecture to manage calculations and workflows has been discussed, based on the four ADES pillars of automation, data, environment, and sharing. These are at the foundation of AiiDA, a python platform introduced in the same paper. Here, we briefly describe the ADES model and how AiiDA implements its four pillars, and later we discuss why an ADES-compliant architecture is essential within an OSP.

The first ADES pillar, *Automation*, involves all those software components that aim at solving the issue of managing large numbers of HTC runs on supercomputers. AiiDA, in order to be independent of the supercomputer details, implements plugin interfaces to control the connection, transfer files, and execute commands (e.g., via SSH) or to interact with job schedulers. These plugins are used by a daemon that runs in the background and is responsible for creating new calculation inputs and uploading them to the supercomputers, submitting new simulations and managing their lifecycle on a job scheduler, and retrieving and parsing results when they finish.

The second ADES pillar, *Data*, is then needed to store and preserve all the generated data in a reproducible and searchable way. AiiDA uses a provenance

model based on directed acyclic graphs to keep track of all inputs and outputs and of the logical relationships between different calculations. The provenance is tracked automatically by AiiDA (see also Sect. 2.3) and can be browsed at any time to understand how data were generated or calculations were run. An example of a provenance graph as tracked by AiiDA is shown in Fig. 1. Moreover, it is also important to have the possibility to analyze results efficiently. To this aim, AiiDA stores the provenance graph in a database, whose schema is optimized to ensure that typical queries run fast.

The third ADES pillar, *Environment*, focuses on two aspects. The first consists in ensuring that AiiDA is simple to use and provides users with an effective research environment to help and facilitate them in their work. This happens thanks to user APIs and command-line tools that simplify the execution of typical tasks (management of computational resources and codes, inspection of calculation inputs and results, data analytics) and by extensive documentation of these features. Moreover, AiiDA provides a transparent access to the database that does not require knowledge of SQL or similar database languages, to perform queries and data analytics. This is implemented both via the use of object-relational mapping (ORM) classes to access directly the data stored in the database and via the QueryBuilder class to enable users to perform generic queries on the AiiDA graph by using standard python syntax, independent of the database backend. The other defining aspect of the environment pillar is the possibility to implement and manage complex, nested scientific workflows. These are a core ingredient of an OSP (see also Sect. 3.1) and are needed since the vast majority of materials properties are computed by a sequence of different calculations with nontrivial logic to control the choice of physical and numerical parameters, the dependencies, and the convergence loops and to perform error recovery. This logic is known to experienced computational scientists; encoding it in workflows not only simplifies the management of simulations when they must be repeated many times with different input choices but also enables automated computation of materials properties. The latter aspect is extremely beneficial first because these automatic workflows can be handed over to, e.g., experimentalists that can use them to quickly evaluate the properties they are interested to but also because it becomes possible to recompute the properties with different approximations or different codes for verification and validation purposes, to contribute to existing databases by adding new materials with their properties, and to validate the correctness of these new contributions automatically.

Finally, *Sharing* focuses on creating a social ecosystem to encourage data and workflows reuse and accelerate research discoveries. AiiDA can export all data stored, including the whole provenance graph and not only inputs and outputs. This information can be then imported in another AiiDA instance and used for new simulations or for further data analytics. AiiDA adopts common formats for typical data structures (like crystal structures, electronic bands, molecular-dynamics trajectories, … ) that are independent of the simulation codes. Thanks to the automatic tracking of the provenance, moreover, these can be converted in any other standard format at any time, as we discuss with an example in Sect. 4.3.
**Fig. 1** The provenance graph for the band structure of a 2D material (PtSe$_2$) from Mounet et al. (2018). AiiDA automatically records the provenance and can display it in graphical form with the `verdi graph generate` command. Here, calculations are shown as orange rectangles and data as ellipses. The codes used (binaries with their location, libraries) are also recorded in the provenance graph (green diamonds). We have highlighted with colors some specific data types: pseudopotentials in gray, the final band structure in blue, and crystal structures in purple. Data nodes in white are other input parameters for the calculations (e.g., k-point grids or input keywords). The graph makes it apparent that the final band structure for the 2D material was obtained starting from an initial 3D structure, in this case from the Crystallography Open Database (COD) (top purple node), first via a set of filtering steps, then via a Quantum ESPRESSO relaxation, followed by the geometrical exfoliation and a final relaxation and band structure calculation for the 2D structure

## 2.3    ADES in Open Science

We believe that one of the most effective approaches in the implementation of the ADES model, especially in the context of an OSP, is to couple automation and data storage. More specifically, AiiDA requires that all information needed to generate the calculation inputs is stored in the database even before the calculation is launched. The daemon is then responsible to create the actual input files, using only information already present in the database.

This coupling comes at a small cost for the researchers when new calculations are generated, as they must provide inputs using the AiiDA data structures and run them through the daemon (even if the additional barrier can be lowered by simplifying the user interface, as prescribed by the environment pillar). On the other hand, this approach ensures that common data structures are easily reusable even in different codes and that all calculations are reproducible and the provenance metadata is always correct. In fact, if the user had to add provenance information only after the execution of thousands of simulations, it would be a huge and tedious work, especially if calculations are not homogeneous. For this reason, in most cases researchers end up not adding complete provenance information to their data, unless strictly necessary. Moreover, this approach is error-prone as, e.g., the wrong inputs could be assigned to a given calculation.

The coupling of automation and data, simplified in a proper environment, is then strengthened (especially in view of our discussion on Open Science) by the sharing capabilities of data, provenance, and workflows. In the next sections, we will show with a number of examples how an ADES tool becomes an essential ingredient of an OSP and completes it when coupled with additional services.

## 3    Open Science Pillar 2: Making It Accessible

### 3.1    Not Only Data: Sharing of Workflows and Plugins

Sharing research data is one of the components of Open Science, as it allows other researchers to reproduce and reuse the results, perform new data analytics, and start new research using the data published. Hence, data sharing in an open and reusable format is essential. To this aim, recently, in the materials science community, a number of sharing portals have appeared, some of which are also discussed in this Handbook, like the Materials Project, AFLOWlib, OQMD, Nomad, and the CMR.

We emphasize, however, that sharing should not only be made easy and with appropriate open licenses, but also it is essential that the data is distributed together with sufficient metadata information to understand it and how it was generated. If simulations are run with an ADES tool like AiiDA that tracks data provenance, this aspect is simply addressed by always sharing data together with the corresponding provenance. Furthermore, data and metadata should be shared in a standard format.

Defining standard formats is a community effort and cannot be done by a single research group. Nevertheless, automatic provenance tracking makes it possible to export data after its generation in any other format, as discussed in Sect. 4.3, and hence any future standard can also be supported with very limited effort.

However, we believe that Open Science cannot be limited to open data sharing, as reproducibility is hindered if the tools used to generate the data are not available. These tools include the quantum simulation packages to compute materials properties as discussed already in Sect. 2.1 but also the pre- and post-processing tools to analyze the data and more generally the scientific workflows to obtain a set of materials properties from an initial minimal input, like a crystal structure. These are composed of a number of components: the infrastructure to run the workflows (like AiiDA), the plugins to interface AiiDA with the various codes adopted, and the logic that encodes the scientist's knowledge on the choice of numerical and physical parameters, on how to perform the sequence of calculations, and on how to deal with potential errors or convergence issues. Only if all these components are openly available, we can truly speak of reproducible Open Science. Indeed, we emphasize here that the availability of the provenance graph for a given dataset like the one shown in Fig. 1 is extremely useful but often allows only to reproduce that single result. In many cases, however, the graph is not enough to understand the sophisticated workflow logic used to select input data (like cutoffs or numerical parameters) or to filter relevant results (e.g., in a high-throughput study).

The challenge for Open Science, encoded in the second pillar discussed in Sect. 1.1, consists then in ensuring that all these components can be shared and reused with limited effort, that they can be interoperable and used together, and that contributions to them by third-parties with extensions or improvements are encouraged.

## 3.2 Encouraging Contributions

An OSP should be general and support a variety of simulation codes, data types, and workflows. Clearly, maintaining and supporting this ecosystem cannot be sustained by a single group, in particular for plugins to support specific simulation codes, because writing them requires in-depth knowledge of the code and of its typical usage patterns. Even more, this is true for workflows that are both coupled to the codes used and to the specific research field or topic.

As a consequence, in AiiDA we opted for a plugin interface. The main infrastructure, "AiiDA core," only contains the main logic that is independent of the codes, like dealing with external supercomputers, storing data and provenance in a database, or querying it. All the tools specific to codes, data, and workflows are implemented as plugins in independent repositories. A design based on plugins is essential, but an effective implementation can facilitate their installation and encourage contributions. For instance, in earlier versions of AiiDA, plugins had to be contributed to the code repository of AiiDA. Since version 0.9, the AiiDA plugin infrastructure has been improved: these can now be developed in independent repositories, and final users can easily choose which plugins to install. Once

installed, AiiDA automatically detects and uses them. The advantage is twofold: first, it encourages researchers to contribute their own code, as they do not lose control over it but maintain full authorship and can even decide a custom licensing scheme. Most importantly, if plugins live in different repositories, their development can occur independently without having to tie and synchronize their releases (e.g., if one code just needs a bugfix while another one is in the process of a big refactoring and is not ready for a new release).

During the design and improvement of the plugin interface, the AiiDA team soon recognized the need of a centralized repository to list existing plugins. In fact, in the past few years, it occurred that more than one researcher started to develop a plugin for the same code, driven by their needs. As a result, two very similar but essentially incompatible plugins were released. This results in work duplication with the additional risk that both plugins miss some important feature present in the other one. As a consequence, users that are faced with the choice of a plugin might get confused. Moreover, having multiple, slightly different formats also hinders sharing and reusability. To address this issue, the AiiDA plugin registry (AiiDA Team 2017a) has been created (see also Fig. 2), consisting in a centralized list of existing plugins, brief notes on how to use them, and links to their code repository and documentation. The plugin code is not copied or duplicated. Instead, the registry acts merely as an index to facilitate the discovery of existing plugins. Anybody can register a new plugin, and developers are encouraged to do so in the very early stages of development. Besides allowing them to reserve the plugin name (that needs to be unique among all plugins and should not be changed over time), this policy also reduces the risk that multiple researchers start independently to develop plugins for the same code. To describe the readiness of plugins, a "state" flag mentions if the plugin is stable and ready for production, under development, or only registered. Finally, a "plugin-template" repository is also provided (and is also available on the plugin registry) that can be copied and modified to start developing a new plugin very easily. To prove the effectiveness of this approach, we note that just 1 year after the creation of the registry, 22 different plugins are already available, including plugins for widespread simulation codes like Quantum ESPRESSO, VASP, CP2K, FLEUR, SIESTA, and YAMBO. Moreover, more than half of them provide detailed documentation websites, also in this case facilitated by the backbone documentation structure provided by the plugin template.

Finally, also in the spirit of facilitating usage and contributions and of increasing interoperability, AiiDA has been integrated and made compatible with other libraries and tools written in python that is becoming an extremely popular programming language in the materials science community. For instance, AiiDA can import and export structures between its internal format and the format of ASE (Larsen et al. 2017) and pymatgen (Ong et al. 2013), so that functionality present in these two libraries (crystal structure manipulation, comparison, processing) can be seamlessly integrated in any AiiDA workflow. Similarly, crystal symmetry can be analyzed using spglib (Togo and Tanaka 2018), and high-symmetry $k$-points in the Brillouin zone (together with suggested paths for band structures) can be automatically obtained via seekpath (Hinuma et al. 2017) and directly used as input to calculations.

**Fig. 2** Left, a screenshot of the homepage of the AiiDA plugin registry discussed in Sect. 3.2 and available at http://aiidateam.github.io/aiida-registry, that contains a list of all available plugins for AiiDA. Right, an example of a detail page for one of these plugins, containing general information on which functionality is provided by the plugin, how to install and use it, and where to find the code and the respective documentation

## 3.3 Documentation, Tutorials, and Open Learning Resources

The availability of open codes and tools for data generation and analysis is, as described in the previous section, an essential aspect of Open Science. If, however, these tools are not straightforward to use, their adoption is strongly hindered. We believe therefore that it is essential to invest resources in lowering the barrier for users. To achieve this goal, it is needed to have well-written and extensive documentation for the codes, describing how to install them and how to specify their inputs. In our experience, it is important to ensure that the documentation is easily searchable and indexed in web engines. Moreover, it is very effective to provide quick-start guides, example scripts or input files that can be copied and adapted by users, and a "cookbook" of useful recipes that are typically repeated by many users, like how to achieve a particular task or how to troubleshoot potential problems. In our experience, we found the use of a notebook-like format particularly effective (in particular with the use of jupyter, that we describe in more detail in Sect. 4.4 with some examples of its use in the Materials Cloud platform). On top of this, documentation specifically designed for developers is greatly useful for contributors to understand the code and be able to independently add new features and is therefore another tool to encourage contributions to the platform (as discussed in Sect. 3.2).

However, documentation alone (while essential) can easily become overwhelming for large codes and therefore might not lower enough the entrance barrier. Also tutorials and schools are extremely powerful tools for code dissemination. These events put researchers in direct contact with the developers of the tools, helping in creating a network and direct communication channels. The advantage is on both sides: users can get direct benefit by faster and more effective learning, and developers can profit from these events to know how their software is used, to collect useful feedback on common use-cases and to understand how to improve the code usability.

Finally, we also believe that it is important to provide access to educational resources like recordings of lectures, tutorials, and schools that cover both the basics of the science of the field as well as the code usage and applications. These resources should be disseminated in an open format, providing access to all students and young researchers. An example of this is shown in Sect. 4.4, where we discuss the learn section of Materials Cloud, a hub for educational videos and resources in the field of materials science.

## 3.4 Virtual Machines and the Quantum Mobile

Researchers often have a specific problem to address and look for a software that can solve it. A good documentation and effective tutorials can help convince them of the functionality of the code, and jupyter notebooks can facilitate its use, but the main initial barrier of installation and configuration remains. Unfortunately, the

potential issues that the users can experience are quite varied, are very dependent on their computer configuration, and are often related to code dependencies (need for C/fortran libraries, specific compilers or python packages; operating system incompatibilities; conflicts between multiple library versions; ... ). If the installation turns out to be too complex, the researchers might be discouraged (especially if they are not certain that the code can help them). The situation can be further complicated by the need of using more than on tool at the same time and making them interact.

To address this barrier, we suggest a few different approaches to reduce and almost remove the time required to start using a software (or a collection of softwares).

The simplest solution that does not require setting up any online server is the creation of virtual machines with useful software preinstalled. The distribution is very simple, consisting in sharing a single file (typically of a few GB in size) with the virtual machine image. Once this file is obtained, by just running the virtual machine, users find all codes preinstalled and preconfigured and can directly start to run simulations. A practical example of this is the Quantum Mobile (AiiDA Team 2017b) virtual machine. It contains a number of simulation codes preinstalled (including Quantum ESPRESSO, FLEUR, SIESTA, Yambo, CP2K, Wannier90) as well as AiiDA, preconfigured to run these codes within the virtual machine and coming already with a database preconfigured. This setup is ideal for education in computational materials science classrooms, where students can focus directly on the problem at hand and on understanding the results. This has been already proven in the 2018 "Molecular and Materials Modelling" course at ETH Zürich, in which the Quantum Mobile has been used as the platform to run the simulations, only after less than 4 months after its first release.

For larger simulations, running within the virtual machine is not ideal or even possible because of CPU or memory limitations, but researchers can still use it by configuring AiiDA to connect to the supercomputers they have access to. An alternative virtualization solution includes the use of Docker that can be thought as a tool to create lightweight virtual machines, where the Linux kernel and some resources are shared and not emulated. AiiDA now comes with a Docker image preconfigured, and this has pushed also many of the codes mentioned before to provide their own Docker images. The Docker setup provides a very similar level of containerization and code setup reproducibility of a virtual machine and is much more lightweight (for instance, in terms of disk usage when multiple similar machines are executed). Therefore, it is suited for tasks where many equivalent systems need to be automatically created. A typical use-case is in continuous testing platforms. On the other hand, however, it is worth noting that the use of Docker images is less indicated for educational purposes with respect to virtual machines. In fact, virtual machines are (still at the time of writing) much easier to start up without advanced knowledge of computer administration and of Docker and its related technologies. Additionally, a virtual machine provides seamless access to GUI applications (like text editors or file browsers), while with Docker one would need to access the instance through the command line, creating a potential additional barrier for students.

## 3.5    Supercomputer Centers

A second approach to facilitate users in the adoption of codes is to deploy them in supercomputer centers where the simulations are run. Already now most high-performance computing (HPC) centers have an application support team that compiles various versions of the codes used by their users and provides them as modules. The same could be done for tools to manage simulations like AiiDA. This might require, however, that these centers transition from a classical model of HPC providers to more general service providers for, e.g., virtual machines, database services, or long-term storage. A number of centers (like, in Europe, the Swiss CSCS, the Italian CINECA, or the German JSC) are already in the process of providing these new services and working together to federate access to them; we expect that this trend will be followed by even more centers in the next few years.

## 4    Open Science Pillar 3: Seamless Data Sharing and Preservation

### 4.1    Data Management Plans and FAIR Compliance

In the first phases of research, offline tools and codes are typically used to perform and organize research, as the data generated can be large and is typically confidential. However, when data must be shared, as described in the third pillar of an OSP described in Sect. 1.1, it becomes essential to employ suitably designed web portals. In addition to this, currently many funding agencies require to comply with data management plans (DMPs) for data dissemination and long-term preservation. Ideally, data should be compatible with the FAIR principles of sharing (Wilkinson et al. 2016) that require data to be findable, accessible, interoperable, and reusable. Findability can be achieved only if research data is associated with persistent handles like DOIs to make it citable. Free portals exists, like Zenodo (2018), that assign DOIs to datasets obtained from research projects and also guarantee long-term preservation. However, while files generated by the different codes can be uploaded on these services, this would still require that another researcher has a compatible software installed in order to open and analyze the results in the format uploaded by the original author. To remove this barrier, web portals need therefore to address also the other FAIR aspects to become effective OSPs.

In the next few sections, we show examples of how the goals of being DMP and FAIR-compliant can be conveniently achieved using a combination of suitable web portals together with an ADES tool like AiiDA to manage simulations and track provenance. We discuss in particular the integration of AiiDA with the Theoretical Crystallography Open Database (TCOD) in Sect. 4.3 that proves how the automatic tracking of data provenance makes it possible to tag results with standard metadata automatically and after the simulations have run; and the

Materials Cloud portal (Sect. 4.4) that provides tools encompassing all steps of computational research, from learning to generating data and curating the results, to finally publishing and sharing results, while being fully compliant with the FAIR principles.

## 4.2 Interoperability Between Different Databases: The OPTiMaDe API

Even if automated provenance tracking allows to store a posteriori the metadata information in any format, as we discuss in the next section, it is still extremely valuable that standards are defined. This, in fact, would allow easy interoperability between different existing databases. A community effort in the direction of database and web-portal interoperability is happening in the OPTiMaDe consortium that is working toward the definition of a common API specification to be implemented by the different partners. Many of the large databases in the community are already part of this consortium (including Materials Cloud that has the _mcloud_ prefix assigned to it). In the current version (0.9.5), OPTiMaDe already defines a REST API format that makes it possible to query, with the same format, for the existence of crystal structures in different databases, with common filters like number of atoms, presence or absence of a chemical element, as well as supporting database-specific fields.

## 4.3 Automatic a Posteriori Metadata Tagging: AiiDA and TCOD Integration

Ontologies and other standards for metadata tagging and sharing of research results in materials science are currently being discussed in the community, like, e.g., the TCOD dictionaries (Gražulis et al. 2014) and the Nomad metadata (Nomad Meta Info 2018), even if there is not an established standard yet. For this reason, it is difficult to enforce a given ontology. The lack of a single standard format in the community, however, is not a major issue if simulations are run with automatic provenance-tracking tools. Indeed, tracking of provenance (if complete and automatic) allows users, a posteriori, i.e., after all simulations have run, to convert the provenance information in any other format by just implementing a converter. An example of this is shown in Merkys et al. (2017), where methods and codes have been presented to convert the provenance as tracked by AiiDA to the format defined by the TCOD ontology. In this work the authors show in particular how Quantum ESPRESSO simulations managed via AiiDA are automatically tagged with metadata using to the TCOD ontology, with no user input required. Moreover, the implementation is modular and additional plugins can be developed to support other simulation tools or other metadata formats.

## 4.4   Materials Cloud

In Sect. 2 we have described how AiiDA addresses the challenges of data generation in an OSP, in Sect. 3 we have outlined how to make Open Science accessible, and in Sect. 4.1 we have emphasized how web portals tailored to comply with the FAIR principles are an essential ingredient to achieve seamless sharing.

For this reason, Materials Cloud has been designed, implemented, and deployed. It is a web portal for materials science that is coupled to AiiDA and, in combination with it, addresses all three OSP pillars introduced in Sect. 1.1. Materials Cloud is composed of different sections that aim at assisting researchers during the full lifecycle of a scientific project.

The first section, *Learn*, contains educational material like videos of schools, tutorials, and lectures in the field of materials science, together with the corresponding material to assist learning (like slides and exercises). The learn section uses the SlideShot technology, a software platform that makes it possible to show the video feed of the speaker together with the slides in high resolution, allowing viewers to quickly seek through the video via the slides thumbnails. This is coupled with a standard hardware setup to perform recordings and then import them into SlideShot.

The *Work* section then focuses on the task of data generation. This section addresses in particular the second pillar of Open Science to make the simulation tools available in the form of automated solutions, removing access barriers and making them available not only to experienced computational researchers but also to experimentalists or to students. Besides providing links to download various versions of the Quantum Mobile virtual machine (see Sect. 3.4), it provides access to computational tools with two different approaches, suitable for different use-cases that we briefly discuss here. The first approach of the work section of Materials Cloud is to provide a set of *online tools* to perform fast analysis of data, directly from the web browser, similar in the spirit to, e.g., the many tools of the Bilbao Crystallographic Server (Aroyo et al. 2011). This is particularly suited for computations that can run in real time (i.e., with a running time of up to a few seconds) and that can benefit from a graphical web interface. An example is seekpath (Hinuma et al. 2017), a tool that, given an input structure, computes a standardized primitive unit cell according to the standard definitions in the crystallography literature, like in the International Tables of Crystallography (Shmueli 2010) and in Parthé and Gelato (1984). The tool then returns also the labels of high-symmetry points in the Brillouin zone together with a suggested path for the computation of band structures. The only required input, in this case, is a crystal structure (accepted in a number of common formats) and, optionally, a few numerical parameters; interactivity happens mainly via to interactive 3D visualizers for the crystal structure and the Brillouin zone.

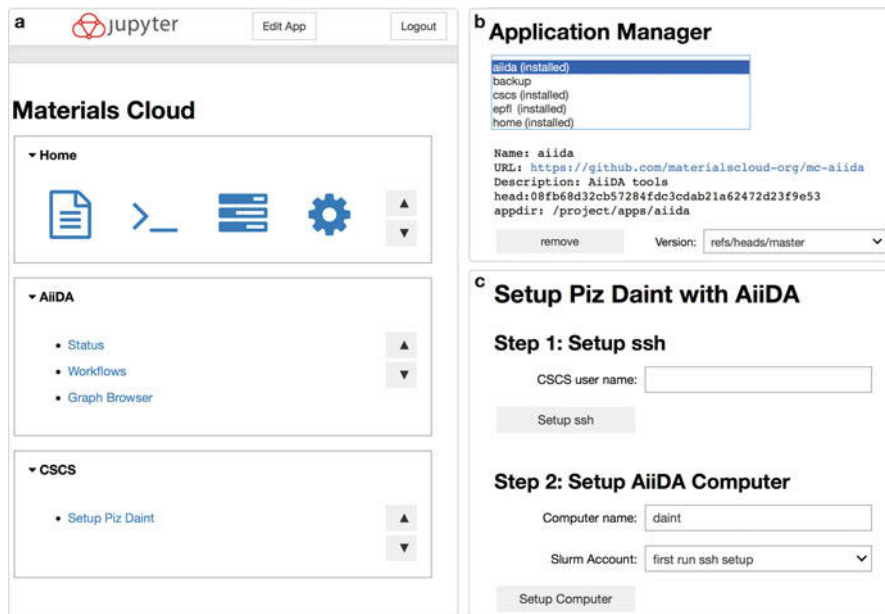
The second and more flexible approach for data generation in the Materials Cloud is based on the *jupyter* interface. Jupyter is a notebook-like web front end that allows to run any python code (and also supports many other programming languages) subdivided in cells with inputs and outputs. This is a very flexible interface, and in Materials Cloud it is further powered by the AppMode plugin that by default hides


**Fig. 3** Three screenshots of the jupyter interface of the Materials Cloud. Pages are customized with the AppMode plugin, to make the appearance very similar to a standard web page. (**a**) Home page, with the top panel with main tools to manage Materials Cloud applications, to show a terminal or to show the control panel. On the top, a "Edit app" button allows to go back to the standard jupyter notebook interface. (**b**) Application manager that allows to select existing apps from the Materials Cloud app registry and make them appear in the home page. (**c**) One of the apps to setup a new computer (in this case, the Piz Daint supercomputer at the Swiss Supercomputer Centre) with just a few clicks

the cells and just shows the outputs (including widgets like buttons, text boxes, and drop-down lists) in a format that resembles a standard interactive web page. The jupyter interface of the Materials Cloud is shown Fig. 3, providing a home page where contributed apps can be added directly via the web interface (panels a and b). Apps can be provided by anyone and just need to be registered in the Materials Cloud App registry. Users are provided with a working space already preconfigured with AiiDA and codes, removing any setup time. Additional configuration (e.g., setting up AiiDA to interact with custom computational clusters) is significantly simplified by apps with simple GUIs (see Fig. 3c). The only disadvantage of this section is that it requires a user login, because users can access a full computer with unrestricted access to code execution and internet access, but on the other hand, it is the ideal platform to create custom fully automated workflow solutions for the computation of materials properties.

Once the data has been generated (locally with AiiDA on in the jupyter section), it can be displayed in the two sections *Discover* (for curated data) and *Explore* (for the "raw" data as generated via AiiDA). The first section can be used by a

researcher to provide an accessible interface to understand a project and present its results with dynamic data filtering, as well as interactive views of the figures shown in the corresponding papers. Data can be linked to the corresponding AiiDA nodes in the explore section. In the latter, data is visualized together with its provenance (browsable via an interactive graph to inspect the calculation that generated it or to find out by which calculations it was used as input). Calculations are always displayed together with their full set of inputs and outputs that can also be directly viewed or downloaded. Materials Cloud has been designed as an extension of AiiDA so that, if the simulations are run with AiiDA, the explore section is filled in automatically by just importing an AiiDA export file. To make an analogy: AiiDA is a tool used to manage simulations and provenance locally on a computer and can be compared to Git, used locally for the organization and tracking of the history of files and source codes. Then, the Materials Cloud explore section plays the role of GitHub, GitLab, or similar web services, providing web browsing of the content of repositories and acting as a central server for sharing.

Finally, Materials Cloud has a fifth section, *Archive*, for the long-term storage and dissemination of research results. A DOI is assigned automatically to each submitted entry, and standardized metadata are exposed in the XML Open Archives Initiative Protocol for Metadata Harvesting (OAI-PMH) format (XML OAI-PMH 2018). Each entry can contain files with research results and can be linked to the corresponding discover and explore sections. An example screenshot of an entry of the Materials Cloud Archive is shown in Fig. 4.

By coupling the different sections, Materials Cloud realizes a FAIR-compliant platform as discussed in Sect. 4.1. In fact, the DOIs assigned to published research data in the archive section achieve findability. At the same time, if the data has been generated with AiiDA, each entry can be linked to a curated discover section and to an explore section, making it possible to visualize inputs and outputs of calculations and more generally to explore the data provenance. This real-time web interface makes data accessible (second FAIR pillar) and does not create any barrier due to authentication or to software installation. Interoperability (third FAIR pillar) is achieved since data that is common to different codes (e.g., crystal structures, electronic and phonon bands or $k-$point sets) are stored in a code-independent format and the outputs of a calculation can be used as the inputs for a different code. Finally, reusability (fourth FAIR pillar) is guaranteed by the possibility of getting all inputs and outputs of calculations and reproduce them, coupled with the large selection of licenses that the users can choose (with encouragement for those allowing for reuse, like the Creative Commons ones).

## 5    Examples of Open-Science Research Using AiiDA and the Materials Cloud

To better explain the ideas and tools described in the previous sections, we briefly discuss here two scientific projects, managed with AiiDA and hosted on the Materials Cloud, that demonstrate the concepts of an OSP discussed here.

A Standard Solid State Pseudopotentials (SSSP) library optimized for accuracy and efficiency (Version 1.0, data download)

Description

Despite the enormous success and popularity of density functional theory, systematic verification and validation studies are still very limited both in number and scope. Here, we propose a universal standard protocol to verify publicly available pseudopotential libraries, based on several independent criteria including verification against all-electron equations of state and plane-wave convergence tests for phonon frequencies, band structure, cohesive energy and pressure. Adopting these criteria we obtain two optimal pseudopotential sets, namely the Standard Solid State Pseudopotential (SSSP) efficiency and accuracy libraries, tailored for high-throughput materials screening and high-precision materials modelling. As of today, the SSSP accuracy library is the most accurate open-source pseudopotential library available. This archive entry contains the database of calculations (phonons, cohesive energy, equation of state, band structure, pressure, etc.) together with the provenance of all data and calculations as stored by AiiDA.

**Fig. 4** An entry of the Materials Cloud Archive, in this case version 1 of the SSSP pseudopotential library (Prandini et al. 2018a). Each entry, beside typical metadata like authors, affiliations, and a description, can also contain a number of files that are preserved in the long term. Moreover, entries can have direct link to respective discover or explore sections, where data is directly visualizable in the web browser. Materials Cloud assigns each entry a DOI (the prefix of Materials Cloud is 10.24435) and requires authors to choose a license

## 5.1   The SSSP Pseudopotential Library

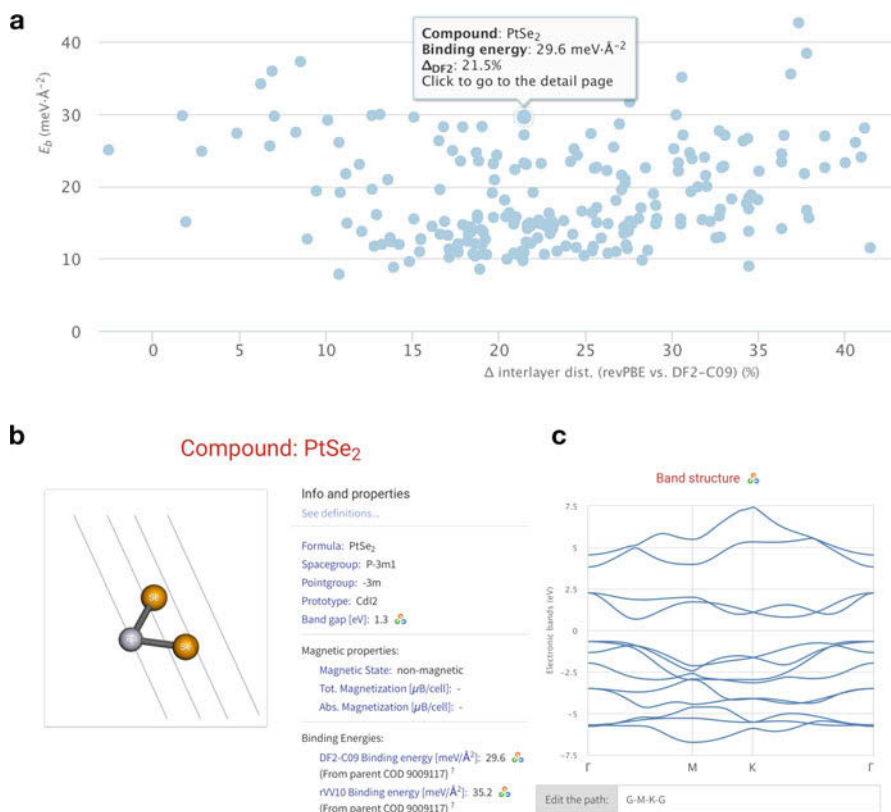
The Standard Solid State Pseudopotentials (SSSP) (Prandini et al. 2018b) library provides a curated selection of pseudopotentials for plane-wave density-functional theory (DFT) codes (in UPF format). SSSP is composed of two sublibraries, optimized, respectively, for *precision* and *efficiency* by means of a number of convergence studies on elemental solids, for various relevant physical properties including zone-boundary phonons, cohesive energy, pressure, and band structure.


**Fig. 5** Screenshots of the discover section for the exfoliable 2D materials section. (**a**) One of the three selection pages, allowing to select a 2D material based on its binding energy and the change in interlayer distance in the bulk when computed with a DFT energy functional including or not including van der Waals force contributions. Other selection views include a periodic table and a detailed table. (**b**) Top part of the detail view for one of the materials (in this case, $PtSe_2$). The view includes an interactive structure 3D visualizer, as well as the main properties computed for this material. (**c**) Another portion of the detail view showing the electronic band structure of $PtSe_2$. The plot is interactive and zoomable, and the default path (here $\Gamma-M-K-\Gamma$) can be changed by the user. Both here and in panel **b**, the small AiiDA icons are links that bring the user to the corresponding explore section, to browse the provenance of the corresponding data (the provenance of the band structure is the one shown in Fig. 1)

The pseudopotential library is available on the Materials Cloud Archive (Prandini et al. 2018a); see also Fig. 4.

In the respective discover section, a periodic table uses a color legend to indicate the optimal pseudopotential for each element and indicates the suggested cutoff values. Clicking on an element shows a detailed view containing all convergence studies and plots (equations of states, band structures, bands chessboards) for all the pseudopotentials compared in the study. Datapoints in the interactive plots are clickable and bring the user to the explore section, with browsable provenance for

all data. Simulations were run using Quantum ESPRESSO and managed by AiiDA that also tracked the provenance.

## 5.2 The Exfoliable 2D Materials Database

In Mounet et al. (2018), the authors performed a high-throughput search of novel two-dimensional (2D) materials by screening the ICSD and the COD databases. Starting from over 100,000 unique bulk experimentally known materials, they could first detect with a geometrical algorithm the ∼6000 that are composed by layers and then refine this list with DFT binding-energy calculations (using Quantum ESPRESSO and managed by AiiDA) to only include those held together by weak forces. With this approach they could identify a set of about 1800 potentially or easily exfoliable 2D materials. Furthermore, a subset of 254 materials (easily exfoliable with up to 6 atoms per unit cell) has been extensively studied to compute relevant electronic, vibrational, and magnetic properties. These results and calculations are available on the Materials Cloud Archive (Mounet et al. 2017). Also in this case, the archive section is coupled to a curated discover page (Fig. 5). In the filtering page, a 2D structure can be selected via a table, by selecting elements in a periodic table or by picking a material from a binding-energy plot. After having selected the material, a detailed view is presented, showing data and results that include the binding energy of the 2D layer, the interlayer distance computed with different van der Waals functionals, the magnetic ground state (also including antiferromagnetism in larger supercells), the electronic band structure, and the phonons. These were computed with the correct 2D physics that properly considers electrostatic screening in low-dimensional systems, reproducing correctly the behavior of longitudinal and transverse optical phonons near $\Gamma$ (Sohier et al. 2017). Final results (plot and numerical values) are accompanied by small AiiDA icons, as shown in Fig. 5b, c. These are links to the corresponding explore page, where users can check how the results have been computed by browsing their AiiDA provenance.

## 6 Conclusions

In this chapter we have introduced our vision for an Open-Science platform. Such a platform should rest on three main pillars, namely: open data generation tools, open integration platform, and seamless data sharing. We have discussed the challenges set up by these requirements, and we have shown how a combination of the AiiDA code and the Materials Cloud platform can achieve the goals defined by these three pillars. These aspects have furthermore been demonstrated with two examples of projects that used the two tools, namely, the SSSP pseudopotential library and the database of exfoliable 2D materials. Indeed, if simulations are run with AiiDA, the generated data is reproducible and its provenance (i.e., how it was generated) is automatically tracked and stored. AiiDA also helps creating and steering automatic workflows for the calculation of materials properties. Combined with the Materials

Cloud work section (and in particular with the jupyter subsection), advanced workflows can be exposed with an intuitive and easy interface, minimizing the barrier to access and use them. The other sections of Materials Cloud, furthermore, enable sharing of computed data in a FAIR-compliant format. DOIs are assigned to data entries (that are preserved in the long term) to make them findable, as required by data management plans. These entries, moreover, are made accessible by a tight coupling with interactive views to present curated data. The latter is linked to browsable graphs to access and explore the data provenance automatically tracked by AiiDA as well as the raw input and output files. AiiDA and Materials Cloud, therefore, implement our Open-Science vision with the aim of making science accessible to everybody and of encouraging reuse of results to promote and support scientific discovery.

# The PAULING FILE Project and Materials Platform for Data Science: From Big Data Toward Materials Genome

# 84

Evgeny Blokhin and Pierre Villars

## Contents

**Abstract**

One of the oldest initiatives in materials informatics, the PAULING FILE project, is described. It includes the comprehensive database for inorganic crystalline compounds, their atomic structures, intrinsic physical properties and phase

diagrams. On top of that, the powerful online retrieval software is introduced, called MPDS, the Materials Platform for Data Science. The practical recipes of storage, exchange, and analysis of the large amounts of materials data are given. The focus is made on the modern information technologies and software engineering. As a result, from the large heterogeneous data, holistic conclusions about the entire set of known materials are drawn. They can be regarded as a guideline for the systematic large-scale predictions.

## 1  Introduction

The PAULING FILE project is the materials database with nearly 25 years history, grouping crystallographic data, phase diagrams, and physical properties of inorganic crystalline substances under the same frame. Its focus is put on the experimental observations. Each individual crystal structure, phase diagram, or physical property originates from a particular peer-reviewed publication. The world's scientific literature in materials science, engineering, physics, and inorganic chemistry is covered from 1891 to the present date. The Materials Platform for Data Science is an online edition of the PAULING FILE project, created in 2016. It presents all the PAULING FILE data in two online interfaces: graphical user interface and application programming interface. The former is intended for the materials scientists; the latter is intended for the software engineers and data scientists. An intersection of the research interests of these groups falls into the scope of the novel discipline of materials informatics.

## 2  Materials Big Data and the PAULING FILE Project

### 2.1  Modern Challenges Ahead of the Materials Community

Counterintuitively, empirical traditions are widespread in the fundamental science and particularly in materials science. The pioneer in chemoinformatics, Peter Murray-Rust (Cambridge, UK), called the materials science as one of the most conservative precise disciplines, the least transparent and open to collaboration and crowd-sourcing, compared to the other sciences, as biochemistry, astronomy, mathematics, and computer and environmental sciences (Murray-Rust 2013) – not counting paywalls. Interesting to note, the field of materials informatics is less established and younger, compared to chemo- and bioinformatics (Gasteiger and Engel 2003, here *informatics* assumes an *information exchange*). Among the novel distributed computing projects, where anyone may volunteer computing time from their personal computers to a specific cause, only a very little part is concerned with materials science. The following not exhaustive explanation can be given. Materials science and engineering are maximally tightly bound to the industries, e.g., aerospace, automotive, electronics, military industry, etc. Considerable part of materials research and development is privately funded. A know-how in materials

science costs on average higher, than in other precise disciplines. These costs can be compared to high energy physics or astronomy. However an influence of such know-hows on the technological progress is also higher, and the lag between investment and innovation is relatively moderate (about 15 years or less, Obama 2011). Further, due to its widespread and extreme complexity, materials science is also very segmented ("feudal"). Consequently, the level of competition is very high, both in academia and industry (government grants, staff positions, etc.). In terms of complexity, even mastering the basic formalism of the modern solid-state physics presents a nontrivial task. The multidisciplinary specialists are generally rare in materials science. These reasons may give an idea, why the materials science community is inherently very conservative.

Moreover, until the recent years the culture of sharing the basic research outcome (e.g., raw measurement or simulation logs, in contrast to the articles) was totally absent and sometimes even tabooed in materials science. Concerning the publications, still there is no way to obtain scientific information in machine-readable format from journals for further reuse and repurposing. However with the technical progress the modern academics are sinking in the "ocean of data." Today there is a common complaint that researchers are publishing too much and too fast. To estimate this growth, it is wrong to cite the growth of academic databases, as no database captures everything. The bibliometric analysts from the Max Planck Society and Swiss Federal Institute of Technology (Bornmann and Mutz 2015) estimated that the global scientific output roughly doubles every 9 years. Moreover, with the increase in popularity of the modern data-intensive approaches, commonly denoted as "materials design" or "materials genome," there is an evidence that the amount of raw big data in materials science generated by experiments or simulations will continue to grow exponentially. Speaking about the *big data*, the computer science community has appropriately defined this phenomenon as the data amounts governed by four metrics: volume, velocity, variety, and veracity. In materials science *volume* refers to the big sizes, exceeding personal computer facilities, and *velocity* refers to harnessing real-time data acquisition (e.g., from dynamics experiments). *Variety* is concerned with the fact that the data takes all forms in materials science, ranging from discrete numerical values to qualitative descriptions of materials behavior and imaging data. *Veracity* acknowledges the practical reality about uncertainties and a lot of "missing" data (Rajan 2015). Nowadays is the epoch of big data in materials science. Yet in this epoch of big data, materials science is still not doing enough to encourage and enable the sharing, analysis, and interpretation of the vast swatches of data that researchers are collecting. The traditional means of exchange of scientific information in materials science community are deeply imperfect. In such conditions a natural diversity appears, with the principles of the natural selection guiding the shape of the cutting-edge research. And in the last several years with the high penetration of the Internet and modern information technologies, the situation has started to change slowly. Here the ability to digest information, drawing the correct conclusions, is crucial. This is where the data science tools (e.g., machine learning) need to be linked to the foundations of materials science: theory, modeling, and experiments. The aim is to

make the *laboratories* for generating the new information and not just *repositories* for retrieving the known or expected information (Ghiringhelli et al. 2017).

## 2.2 PAULING FILE Background

There are a number of initiatives in the world trying to overcome the above-mentioned challenges in materials science (Pizzi et al. 2016). The main idea is either to systematically collect the materials data or generate and process them in a high-throughput manner. One of the notable initiatives is the PAULING FILE project, launched in 1995. Its main focus is put on the critical evaluation of the published experimental materials data. Historically, it was a joint venture of the Japan Science and Technology Corporation, Material Phases Data System company in Switzerland, and the University of Tokyo, RACE. Now it is managed solely by the Swiss company. Three steps were planned from the beginning. The first goal was to create and maintain a comprehensive database for inorganic crystalline substances, covering crystallographic data, diffraction patterns, intrinsic physical properties, and phase diagrams. The data should be checked with the extreme care. The term "inorganic substances" was defined as compounds containing no C-H bonds. In parallel to the database creation, the second goal was to develop an appropriate retrieval software to make the data accessible in a single-user interface. In longer term, as the third goal, the new tools for materials design should be created, to search the database for correlations automatically. This is known as intelligent design of the new inorganic materials with predefined intrinsic physical properties. The pilot version PAULING FILE Binaries Edition was released as a desktop software in 2002. Now the selected parts of the PAULING FILE data are included in several printed, offline and online products. Today the PAULING FILE project is quite well-known. There are already thousands of publications referring it. Its foundations, database design, and data-centric observations are published (e.g., Villars 2004; Villars et al. 2008; Xu et al. 2011; Kong et al. 2012; Villars and Iwata 2013 etc.). The recent implementation of the PAULING FILE retrieval software and the materials design tools is an online product called Materials Platform for Data Science.

Now a minimum of required definitions must be given. A *database* is a collection of interrelated stored data that serves the needs of the multiple users. In the so-called relational paradigm, these stored data are organized in the *tables*. The motivations for using databases rather than files include greater availability to a diverse set of users, integration of data for easier access to and updating of complex transactions, and less redundancy of data. A *database management system* (DBMS) is a generalized software for manipulating the databases. A DBMS supports a logical view (*database schema*), physical view (access methods, data clustering), data definition and manipulation language, and utilities, such as transaction management and concurrency control, data integrity, crash recovery, and security (Teorey et al. 2005). For example, Oracle is used as an internal DBMS for PAULING FILE. The PAULING FILE database has the following structure. The standard unit of data is called an *entry*. All the entries are subdivided into three kinds: crystalline structures,

physical properties, and phase diagrams. They are called S-, P-, and C-entries, correspondingly. Entries have persistent identifiers, analogous to digital object identifiers (DOIs), e.g., S377634, P600028, and C100027. Another dimension of the PAULING FILE data is the *distinct phases*. The three kinds of entries are interlinked via the distinct materials phases they belong. A tremendous work has been done by PAULING FILE editors in the past 25 years to manually distinguish more than 150,000 inorganic materials phases, appearing in the world scientific literature. Each phase has a unique combination of (*a*) chemical formula and (*b*) modification. These are defined using the structure prototype, Pearson symbol, and space group. Each phase has an integer identifier called *phase id*. In the next three sections, each of the entry types (S-, P-, and C-) together with their interlinkage will be covered in details.

## 2.3   Physical Properties

The P-entries of PAULING FILE include the experimental and to a limited extent simulated data for a broad range of intrinsic physical properties of inorganic compounds in the solid, crystalline state. The considered physical properties belong to one of the following seven general domains: (*a*) electronic and electrical properties, (*b*) optical properties, (*c*) magnetic properties, (*d*) mechanical properties, (*e*) phase transitions, (*f*) superconductivity, and (*g*) thermal and thermodynamic properties. The taxonomy consists of three levels: the mentioned general domains, sub-domains, and the particular physical properties. For instance, the domain "electronic and electrical properties" contains the sub-domain "electron energy band structure," which in turn contains the "Fermi energy" property, etc. Currently there are about 100 sub-domains and nearly 2000 particular physical properties. The taxonomy was compiled by Fritz Hulliger (Swiss Federal Institute of Technology in Zurich, Switzerland), Roman Gladyshevskii (Ivan Franko National University of Lviv, Ukraine), and Karin Cenzual (University of Geneva, Switzerland). To a certain degree, it reflects the development of the solid-state physics during the last century.

The physical properties are stored in four different ways: numerical values, figure descriptions, property classes (such as ferromagnet, piezoelectric, etc.), and indications of existence of the particular data in a source publication, e.g., different spectra. The symbols for the most common physical properties have been standardized, mainly based on the *CRC Handbook of Chemistry and Physics* (Lide 1997–1998). The numerical values are stored in the published units and converted to the standard SI units. For certain properties at the atomic level, other units such as eV or $\mu B$ are used. Properties expressed with respect to a defined quantity of substance (per kg, per mole) are converted to per atom-gram. Each numerical property value is accompanied by information about the experimental conditions for the particular measurement. A great flexibility is provided via the links to the reference tables. Thanks to that, the new properties may be selected, and their symbols, units, and ranges of magnitude can be controlled.

All the data are taken from the primary literature. Each P-entry corresponds to a particular data source and can contain several numerical values, figure

descriptions, and keywords. For an investigation of a compound through a temperature- or pressure-induced structural phase transition, there will be two P-entries, for instance, one for the room-temperature modification and one for the low-temperature modification. By default, ferroelectric transitions are assumed to be accompanied by structural changes and will justify the creation of two P-entries, whereas magnetic, electric, or superconducting transitions are not. Data for the phases with a certain homogeneity range are grouped under a representative chemical formula. The actual composition for a particular measurement, when differing from the composition representing the P-entry, is specified among the parameters. As for the crystal structure part, there will be three database entries for a continuous solid solution between two ternary compounds: one for each ternary boundary compositions and a third one grouping samples containing four chemical elements. Some simulated data from the ab initio calculations are also included, in particular energy band structures, but focus is on experimentally measured data and values directly derived from measurements.

In addition to the physical properties (in the form of numerical values, figure descriptions, or keywords), and compulsory items such as the chemical formula, large amounts of information concerning the sample preparation and experimental conditions are stored. The following database fields may be present in a physical properties P-entry: (*a*) compound, such as chemical system, published chemical formula (investigated samples), representative standardized chemical formula, modification; (*b*) bibliographic data, such as reference, authors, language, title etc.; (*c*) preparation, such as starting materials and method of synthesis; (*d*) sample description, such as form, chemical analysis, stability with respect to temperature, pressure, and composition, elastic behavior, density, color, chemical reactivity; (*e*) crystallographic data, such as structure prototype, space group, and cell parameters.

The PAULING FILE data are checked for consistency using the original software package ESDD (evaluation, standardization, derived data), containing more than 100 different modules (Cenzual et al. 2000). The checking is carried out progressively level by level, also on the individual database fields. These include formatting of numerical values, units and symbols for physical properties, Hermann-Mauguin symbols, Pearson symbols, consistency of journal code, year and volume, pages for literature references, formatting of chemical formulae, usual order of magnitude, spelling, etc. Consistency checks within the individual datasets include atom coordinates, Wyckoff letters, site multiplicity, comparison of chemical elements in chemical system, chemical formula, and comparison of computed and published values. Further quantities for checking are cell volume, density, absorption coefficient, interplanar spacings, Pearson symbol, space group, cell parameters, refined composition, chemical formula, units, symbols for physical properties, Bravais lattice, diffraction conditions, site symmetry, anisotropic displacement parameters, and so on. Special checking of the crystallographic data includes comparison of the interatomic distances with the sum of the atomic radii, comparison of interatomic distances within chemical units, checks on charge balance, search for missed symmetry elements, and comparison with the type-defining entry (cell parameter ratios, atom coordinates). Consistency checks within

the entire database include comparison of densities, comparison of cell parameter ratios for isotypic compounds, check for compulsory data, check of database links, and so forth. Wherever possible, misprints detected in the original publications are corrected. Since editing mistakes can never be completely avoided, all modifications of the originally published data and interpretations of ambiguous data are stored in remarks. The ESDD software further computes the following parameters: at.% of the different elements, molar mass, refined composition and formula, computed density, interplanar spacings from functions of Bragg angle, equivalent isotropic displacement parameters, linear absorption coefficient, Miller indices referring to the published space group setting. It converts compositions expressed in wt.% to at.% and values expressed in various published units to standard units, including units per mole or wt.% to units per gram-atom, respecting the number of significant digits. As seen, an extreme care is taken to provide maximal quality of the stored data.

## 2.4   Crystalline Structures

Currently, PAULING FILE contains more than 350,000 crystalline structure S-entries. The minimal requirement for an S-entry in the PAULING FILE is a complete set of published cell parameters, assigned to a compound of well-defined composition. Whenever the published data are available, the crystallographic data also include atom coordinates, displacement parameters, and experimental diffraction lines and are accompanied by information concerning preparation, experimental conditions, characteristics of the sample, phase transitions, and dependence of the cell parameters on temperature, pressure, and composition. In order to give an approximate idea of the actual structure, a complete set of atom coordinates and site occupancies is proposed for S-entries where a prototype could be assigned. The crystallographic data are stored as published but also have been standardized according to the method proposed by Parthé and Gelato, using the program STRUCTURE TIDY (Gelato and Parthé 1987). When relevant, they are further adjusted so that the data for isotypic S-entries can be directly compared. Derived data include atomic environments of the individual atomic sites, based on the maximum gap method (Brunner and Schwarzenbach 1971; Daams et al. 1992), and the Niggli-reduced cell. The S-entries are checked for inconsistencies within the S-entry and by comparing different S-entries, using the program package ESDD mentioned in the previous section. For 5% of the S-entries, one or more misprints in the published crystallographic data are detected and corrected. Warnings concerning remaining short interatomic distances, deviations from the nominal composition, etc. are added in remarks. SI units are used everywhere, and the crystallographic terms follow the recommendations by the International Union of Crystallography.

Similarly to the physical properties, all the data are extracted from the primary literature. When available, supplementary materials deposited as CIF files or in the other formats are used as data source. Approximately 10% of the processed documents exist in an original version (e.g., Russian) and a translated version

(English); duplicates are avoided, and both references are stored. Crystallographic data, simulated by the ab initio calculations or optimized by the other methods, are only considered being confirmed by experimental observations. Distinct S-entries are created for all the complete refinements reported in a particular paper. For cell parameters without published atom coordinates, an S-entry is prepared for each chemical system and crystal structure. For example, for a continuous solid solution between two ternary compounds, there will be three S-entries: one for each ternary boundary composition and one for the quaternary system. The latter may contain a remark describing the composition dependence of the cell parameters. For the choice of the retrievable cell parameters, preference is given to values determined under ambient conditions.

All the S-entries are subdivided into different categories, according to the level of investigation: complete structure determined, coordinates of non-H atoms determined, cell parameters determined and prototype with fixed coordinates assigned, cell parameters determined and prototype assigned, only cell parameters determined, etc. In addition to the crystallographic data, large amounts of information concerning the sample preparation and experimental investigation are also included in the PAULING FILE. Basic data are stored as published (for rapid comparison with the original paper) and standardized (for efficient data checking and retrieval and for a homogeneous presentation). The following database fields may be present in a crystal structure S-entry: (*a*) classification, such as chemical system, published and standardized chemical formula, modification, colloquial name, structure prototype, Pearson symbol, space group number, Wyckoff sequence, mass per formula unit, computed density, level of structural investigation etc.; (*b*) bibliographic data, such as reference, authors, language, title; (*c*) published and standardized crystallographic data, including detailed information on the atom coordinates, etc. and transformation from published to standardized data; (*d*) Niggli-reduced cell, including transformation from published to Niggli-reduced cell; (*e*) isotropic, anisotropic displacement parameters; (*f*) published diffraction lines, Bragg angle or equivalent parameter, interplanar spacing, intensity, Miller indices, radiation, and remarks; (*g*) preparation, such as starting materials (purity, form), method of synthesis, etc.; (*h*) mineral name, and locality; (*i*) compound description, such as chemical analysis, stability, color, sample form, chemical reactivity, measured density, etc.; (*j*) determination of cell parameters and structure determination, such as sample, experimental method, radiation, and conditions; (*k*) figure descriptions, such as number in the original publication, title, parameters, and ranges; and, finally, (*l*) editor's or general remarks.

As said, each S-entry gets the structure prototype assigned. The structure prototype is a well-known concept in inorganic chemistry, where a large number of compounds often crystallize with very similar atom arrangements. The compilation Strukturbericht (Ewald and Hermann 1931) started already in the beginning for the twentieth century to classify crystal structures into prototypes, named by codes such as *A2*, *B2*, or *G1*. Though these notations are still in use, structure prototypes are nowadays generally referred to by the name of the compound for which this particular atom arrangement was first identified. The PAULING FILE uses a longer notation, which includes also the Pearson symbol (a lowercase

letter for the crystal system, an uppercase letter for the Bravais lattice, sum of multiplicities of all, fully or partially occupied atom sites) and the number of the space group from the *International Tables for Crystallography* (Hahn 1983). All datasets with the published atomic coordinates are classified into the structure prototypes. Each structure prototype is defined based on the first experimentally determined compound with the respective geometrical arrangement of atoms within the unit cell. More than 36,000 different structure prototypes have been identified and assigned to the S-entries. When not published, the editor also assigns the space group setting of the published cell parameters.

There exist an infinite number of ways to select the crystallographic data (cell parameters, space group setting, representative atomic coordinates) that define a crystal structure. The number remains high even when the basic rules recommended by the *International Tables for Crystallography* (Hahn 1983) are respected, due to the allowed symmetry operations such as permutations, origin shifts, etc. It follows that even identical or very similar atom arrangements may not be recognized as such. The classification of crystal structures into structure prototypes is largely facilitated by the use of standardized crystallographic data. The crystallographic data in the PAULING FILE are stored as published but also standardized. This second representation of the same data is such that compounds crystallizing with the same prototype (isotypic compounds) can be directly compared. It is prepared in a three-step procedure. First, the published data are checked for the presence of overlooked symmetry elements and, if found, converted into a space group of higher symmetry. Second, the resulting data are standardized with the program STRUCTURE TIDY. Third, the resulting data are compared with the standardized data of the type-defining database entry (Villars et al. 2018).

The atomic environments, also called coordination polyhedra, are defined for each S-entry using the method of Brunner and Schwarzenbach (Brunner 1971; Daams et al. 1992). One hundred different polyhedral types have been identified in the PAULING FILE data. In most structures, the coordination numbers vary from 1 to 22. It should be noted that this purely geometrical approach was developed for the intermetallic compounds and does not distinguish bonding types. As a consequence, the selected atomic environment may include both cations and anions. However, the method is simple to apply and useful in the majority of cases. Also, this approach offers an additional possibility to check the crystal structure data for geometrical correctness. The atomic environments can be used as the second independent structure classification. For instance, one can easily find geometrically similar prototypes. Notably, the PAULING FILE database supports geometrical restraint criteria for retrieval. That is, one may request information for the crystal structures containing, e.g., tetrahedra and octahedra.

## 2.5   Phase Diagrams and Distinct Phases

The phase diagram section of the PAULING FILE contains temperature-composition phase diagrams for binary systems, as well as the horizontal and vertical sections and liquidus or solidus projections for ternary, quaternary, and

other high-order systems. Both experimentally determined and calculated diagrams are processed. Primary literature is considered in the first priority. Also the diagrams from a few well-known compilations, such as the compendium of binary phase diagrams (Massalski et al. 1990) and the series of books on ternary phase diagrams (Petzow and Effenberg 1988–1995), have been included. All the diagrams have been converted to at.% and °C and redrawn in a single scale, so that the different reports for the same chemical systems can easily be compared. Single-phase fields are colored in blue and three-phase fields in yellow. The phases identified on the diagrams are named according to the PAULING FILE conventions, but also the original names are stored. Each phase diagram is linked to a C-entry, which usually contains the following database fields: (*a*) classification, such as chemical system and type of the diagram; (*b*) investigation, such as experimental or calculation technique, APDIC standardization; (*c*) bibliographic data, such as reference, authors, affiliation, language, and title; (*d*) original diagram details, such as figure number in the publication, borders, scales, sizes, etc.; (*e*) redrawn diagram details, such as concentration range, temperature, and conversion of concentration; and (*f*) list of the phases present on the diagram, standardized phase name, name used in the original publication, structure prototype assigned by the editor, structural information given in the original publication, and link to a representative crystal structure S-entry. For binary systems also the temperature and reaction type for the upper and (or) lower limit of existence of the phase are stored.

The physical property, crystal structure, and phase diagram entries are related via the distinct phases concept. At the database level, all three different types of data (P-, S-, and C-entries) are linked to the distinct phases table. To prepare this table, each chemical system has been evaluated. For example, the three major distinct phases reported for $TiO_2$ crystal (rutile, anatase, and brookite) are separated with respect to the temperature or pressure. Then the reported physical properties or crystalline structures of $TiO_2$ are associated only with the corresponding distinct phase. Finally, each C-entry (phase diagram) is formed by a particular set of the known distinct phases. Thus the unique interlinkage of data is achieved. A certain number of characteristics, attributed to the phases (compound classes, mineral names, etc.), are stored in the distinct phases table. Each distinct phase obtains a unique name containing a representative chemical formula, when necessary followed by a specification such as "ht," "rt," "cub," etc. There are the following special cases. *First*, the phases that crystallize in the same structure prototype, but are separated by a two-phase region in phase diagrams, are distinguished. The same is true for the temperature- or pressure-induced isostructural phase transitions where a discontinuity in the cell parameters is reported. *Second*, the structures with different degrees of ordering have in some cases been considered separately, in others not, depending on the possibility to assign unambiguously one or the other modification. Structure refinements considering, for instance, split atom positions are often grouped under the parent prototype. *Third*, the structure proposals, stated to be incorrect in the later literature, have been grouped under a single phase in agreement with the more recent reports. That is, e.g., an S-entry reporting a hexagonal cell may in such a case be grouped under an orthorhombic phase. *Fourth*,

the definition of a structure prototype used here suggests that a continuous solid solution may smoothly shift from one prototype to another. Refinements considering one or the other prototype are then grouped together. *Fifth*, the physical properties reported ignoring the crystal structure, and in principle referring to ambient conditions, are assigned to the "rt" modification, or, if the temperature dependence is not known, to the most commonly observed modification. *Sixth*, by default the paraelectric-ferroelectric phase transitions are assumed to be accompanied by a structural transition, and different phases are considered above and below the transition temperature. On the contrary, magnetic ordering is assumed not to modify the nuclear structure to a significant extent, therefore not leading to the new phases. Still there exist the chemical systems that are little explored, so that the reports in the literature are contradictory. The phase assignment becomes here very difficult, and the list of distinct phases will sometimes contain more phases than there exist in reality. It should be noted that there is a certain amount of subjectivity when assigning a phase identifier. Nevertheless, this approach represents a substantial advantage.

## 2.6   Applications

Thanks to the large amount of information stored in dozens of tables and hundreds of distinct database fields, the PAULING FILE offers almost unlimited possibilities for retrieval. It can of course be used for all kinds of trivial search, based on the chemical system, or literature data, but also much, much more. The conversion to standard units facilitates the search for properties within a particular numerical range, and the assignment of distinct phases plays an essential role, making it possible to combine searches on data stored in the three parts of the database: crystal structures, phase diagrams, and physical properties. The hundreds of interconnected database fields can be used to create different products. The PAULING FILE data are included in various printed products, as well as offline and online software, such as desktop catalogs, simulation environments, materials investigation toolkits, etc. Some of these products contain only structure data, others phase diagrams and crystallographic data, and others the three groups of data. Following the preference of the producers, some products contain only the published cell parameters, others only the standardized cell parameters, and yet others both published and standardized crystallographic data. Some of the products are limited to the PAULING FILE data, whereas others also contain data from other sources.

The Materials Platform for Data Science (MPDS) is a recent online infrastructure, presenting all the three parts of the PAULING FILE data. It contains nearly 70,000 phase diagrams, over 350,000 crystalline structures, and nearly 700,000 physical property entries. About 300,000 scientific publications in materials science, chemistry, and physics serve as source for these data. About 80% of the data can be requested remotely in a mass manner (via the so-called MPDS application programming interface) in a developer-friendly format, ready for any external modern data-intensive applications. Next sections give an overview of this

PAULING FILE implementation, its technical details and usage scenarios, as well as ongoing work in this field in general.

## 3    Materials Genome and Materials Platform for Data Science

### 3.1    Materials Genome Background

The concept of materials genome was taken from bioinformatics, referring to the Human Genome Project, publicly funded initiative started in 1990 and successfully ended in 2003 (Schmutz et al. 2004). In June 2011 the US President announced the multiagency Materials Genome Initiative to help US businesses and universities to discover, develop, and deploy new materials twice as fast, at a fraction of the cost. In 2012, Materials Genome Initiative commitments include $12 million of research at the Department of Energy and $17 million in materials research at the Department of Defense. To the end of 2014 several dozens of universities were participating. The oldest and, probably, the most recognized participant is the Materials Project, an undertaking of the groups of Gerbrand Ceder and Kristin Persson (Lawrence Berkeley National Laboratory). The Materials Project team had identified hundreds of new compounds, several of which now function as lithium battery electrode materials. The software toolkit for materials design, development of the Materials Project, simplifying routine computational tasks, is actively used by about 100 scientists in different organizations around the world, and approximately every second user contributes in the open-source code. Additionally, there exists an open database, prepared using this toolkit (approx. 100,000 compounds). Importantly, the Materials Project team on a half consists of the experimental scientists, who deal with lab synthesis. This leads to an incredibly strong collaboration of theory, modeling, software development, and experiment.

The first European counterpart of the Materials Project was the NoMaD Project, started in 2013 from the collaboration of Fritz Haber Institute (FHI) of the Max Planck Society, Berlin, and Humboldt University of Berlin (HU) with the aim to create an international ab initio materials science data repository. In the end of 2014, the first version of NoMaD user interface was publicly launched, and in 2015 NoMaD Project was successfully funded by European Union's infrastructure call for Centers of Excellence (CoE) in computational sciences. As of 2017, the NoMaD data repository contains more than three million ab initio simulation files (more than 10 Tb disk space on estimate), contributed by the community and taken from the other repositories. In total, more than ten data formats for all the major well-known quantum simulation packages are supported. Based on these data volumes, the online materials science encyclopedia and the software analytics toolkit are publicly released. A possible disadvantage of NoMaD is the focus on the community's data centralization, which is currently not very well accepted in the materials science community.

Speaking about the publicly funded projects of materials genome, an ongoing commercial activity should also be mentioned. The notable product with the long

history (since 1998) is MedeA scientific software environment (Christensen et al. 2017), which presents one of the most advanced and sophisticated simulation desktop toolkits. The MedeA employs computational workflows and allows to manage high-throughput database-driven simulations. Also there are two prominent materials informatics startups in the San Francisco Bay Area, USA: Exabyte and Citrine. The focus of the *Exabyte* software platform is the high-throughput ab initio simulations of the materials, performed in the cloud, i.e., at the commodity hardware cluster infrastructure, rented at one of the public vendors. As a simulation engine, the well-known VASP package is employed. In two recent years the team was able to perform a comparative analysis of about a thousand different materials by utilizing extensive on-demand scalability of the developed cloud platform (Bazhirov et al. 2017). The total costs of the runs ended up not exceeding a few thousand US dollars. The *Citrine*'s online data platform is called Citrination (O'Mara et al. 2016). It was launched in 2015 and now houses over several millions of data points. So far the platform has received various contributions from about 2000 different institutions worldwide, including universities, government laboratories, and companies. The disposed data are completely free and opened. Citrine itself contributes to its platform, searching and disposing the datasets from the opened online sources. The platform provides a free mass access interface for all its data. Citrine also claims to develop the artificial intelligence-based tools that enable new insights from the collected materials data.

It is seen that all the abovementioned initiatives have one main feature in common, namely, they build their own software infrastructures to process information efficiently and tackle the challenge of materials big data. They also develop the novel data-intensive analysis methods. The development of such tooling is mostly conducted within the *open-source* paradigm. This means, the program code of the complex tools is provided for free, and anyone can adopt it for own aims. This has a strong rationale. After a certain complexity threshold, the software product becomes practically unusable, because only a very limited group of professionals are able to deal with it. Often such people are not motivated by money, but they can be attracted by chances and challenges of the possible technological breakthrough. Thus, open-sourcing the parts of the code is great advertising, which allows to attract such talents that could hardly financially be attracted. If the code is popular enough for the outside contributions, a force multiplier is created that helps to get more work done faster and cheaper. More contributors mean more use cases being explored and, finally, the more robust software. Importantly, the user community must be grown around the open-source tooling. Normally such community is fairly amorphous and requires guidance and patronage. The expenses for the development are well covered by the talented contributions from outside, reputation and acknowledgment, which, in turn, can be converted to the other means of profit. It is also planned to open-source the certain parts of the software of Materials Platform for Data Science. And a part of the PAULING FILE data is now already opened online under the Creative Commons Attribution 4.0 International license. These are (*a*) all entries found by keywords "cell parameters – temperature diagrams" and "cell parameters – pressure diagrams," (*b*) all data for compounds containing both Ag and K, and (*c*)

all data for binary compounds of oxygen. In total, (*a–c*) present quite a rich dataset, suitable for educational data-mining purposes.

## 3.2    Development of the PAULING FILE Materials Infrastructure

As of today, materials informatics is a collection of recipes taken from computer science and adopted for the modern materials science. The main difficulty is purely technical from an academic point of view – how to handle materials big data efficiently. Here some recipes are discussed. All they were considered while development and maintenance of the PAULING FILE online retrieval software – MPDS (Materials Platform for Data Science).

One of the possible ways to tackle complexity is the unified modeling language (UML), general-purpose, developmental, modeling language for software engineering (see e.g., Miles and Hamilton 2008). From a bird's eye view, UML is a convention of drawing concepts in a human-understandable manner. Although it cannot be interpreted by a computer, UML provides formal description of the problematic field, which is then much easier to encode in a computer programming language. Another UML advantage is its standardization and high popularity in the field of software engineering (suited for collaborative work). The concepts in UML must be related with the defined relationship types.

The PAULING FILE concepts as implemented in the MPDS platform are represented in Fig. 1, with the very short UML legend at the bottom. Notably, UML provides a clear formal way to understand, how a certain problem domain is organized. Namely, it is seen at Fig. 1 that (*a*) any data-mining tool (e.g., visualization) is based on the MPDS PAULING FILE data; (*b*) data are subdivided into three parts: crystalline structure part (S), physical properties part (P), and phase diagrams part (C); (*c*) each part is represented by entries; and (*d*) each entry is concerned with the relevant phase and scientific publication. Also, there are users with the different data access permissions. Thus, the UML presents the important guideline for the further development.

The MPDS is an online software, working according to a client-server architecture. There are many advantages of the online products over the offline products: absence of installation, cross platform operation, no special requirements to the client PC, transparent updates, enhanced security and reliability, and more. With the ubiquitous penetration of the Internet and the wide availability of the server resources, the online model becomes clearly preferable. The details are presented in Fig. 2.

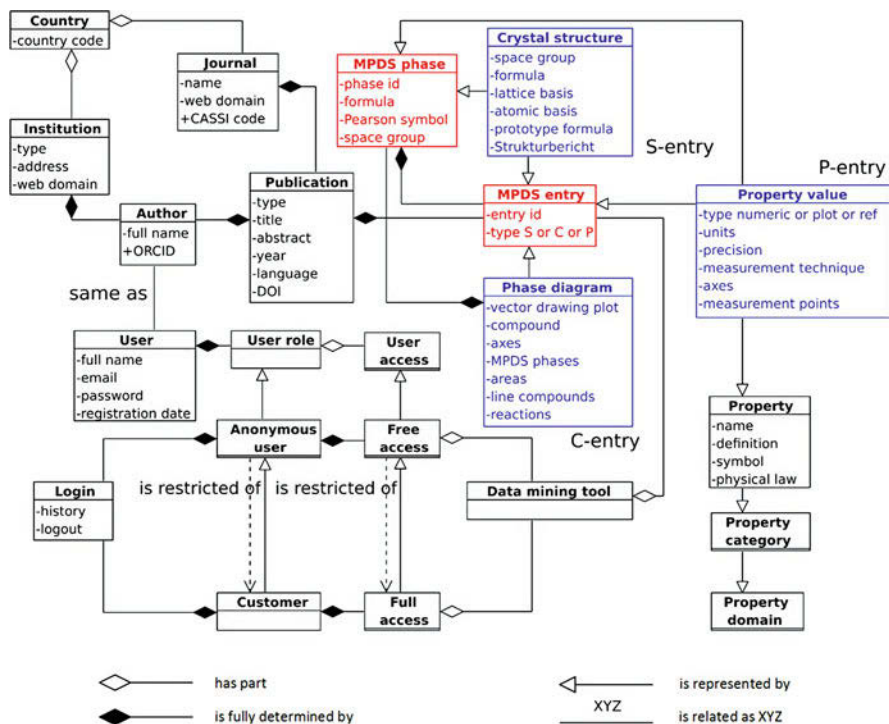
Generally, the World Wide Web is based on the idea of interconnection. Indeed, in a modern environment no isolated software per se makes sense, and each application communicates with the others. In order to provide fast and efficient interaction experience and not to develop a new access interface for each case, the application programming interfaces (APIs) are commonly used. The API regulates communications between any kind of the software (be it a complex of data-mining programs, simulation platform, or any other big data consumer). The main idea is


**Fig. 1** UML diagram for PAULING FILE concepts, as implemented in the MPDS

that the functionalities are collected in a single place and exposed (encapsulated) via the online API. The APIs in the online medium normally adhere to the principle of representational state transfer or REST (Fielding 2000). The REST presents guiding constraints for client-server software architecture and could be called as meta-API. It is also employed for the MPDS API (see Fig. 2), which presents all the PAULING FILE data in a developer-friendly, machine-readable way, using the opened formats, such as CIF, JSON, and MIF (see below). Importantly, the API is not only how the clients communicate with the server. In a wider sense, online API is a software architecture, declaring the way of all the communications. This way the audience is not bound to the existing human-oriented graphical user interfaces (irrespective of their convenience) and able to use the service provider maximally efficient for their aims.

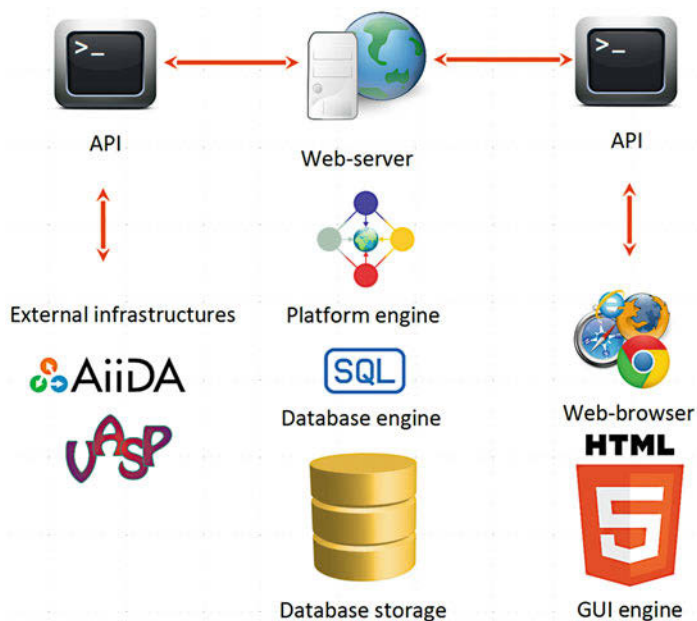
Nevertheless, much attention at the MPDS is given to its graphical user interface. The search input field allows to type different combinations of basic search terms seamlessly at once, so that they are correctly recognized and the matching entries are shown. The algorithm, responsible for treatment of such seamless searches, works as follows. First, the stop-words ("the," "and," "about," etc.) are filtered. Then, the words are checked to belong to the one-term categories: chemical formulae, chemical elements, and crystalline lattices. These categories cannot contain more


**Fig. 2** Client-server architecture of the MPDS

than a single word. The found words are interpreted and excluded. Then, the remaining words are checked to belong to the materials classes and physical property categories. The matches of the longest combinations of words are checked in the beginning, and then the shorter combinations are checked. Unrecognized words are marked as "ignored."

From the very beginning of MPDS development performance of all the sub-systems was a cornerstone. This is especially important for the centralized online software, when the server is a single point of failure. Generally, for any online project it is always recommended to focus on the operation speed. It should be noted that the software designed for 5 simultaneous users differs considerably from that designed for 50 or 500 simultaneous users. There are two approaches to scaling the performance: vertical and horizontal (Michael et al. 2007). *Vertical scaling* means the more powerful server is deployed with the increased loads, but the software architecture remains the same. This solution is a quick and efficient, although limited. First, the more powerful, the more expensive is the server, and the dependence is not linear. Second, there is a limit of computational capacity per a single server. And the database performance is normally saturated much lower this limit. So for a database after a certain tolerance vertical scaling makes no sense. The solution in this situation is the *horizontal scaling*, when the software architecture is changed in such a way to distribute the increased loads evenly among the server cluster, consisting of inexpensive commodity hardware. The idea is that the new replicas with the MPDS software are added to the server cluster by

simple quick copying. A new replica joins the server cluster and starts accepting the incoming HTTP requests. Furthermore, if a replica fails by whatever reason, it can be automatically replaced by a new one. This way the server cluster stays highly available, and even the huge loads cannot influence the performance, since more cheap replicas could be added. However while the server price remains under control, the development is complex and requires time.

## 3.3 Storage and Exchange of Materials Data

Similar to any other scientific data, materials data are commonly stored in the files and databases. The files usually present raw data (simulation or measurement logs, compressed archives, etc.) Reusable processed data are normally stored in the databases. It should be noted although that such subdivision is very conditional, moreover a file could be a database and vice versa (e.g., HDF5 container, SQLite, etc.). A database model is a type of data model that defines the logical structure of a database and fundamentally determines in which manner data can be stored, organized, and manipulated.

The MPDS employs several database models, in particular, relational and semantic graph model. Additionally, the document-oriented model is used as an intermediate step while preparing data. In the document-oriented model each PAUL-ING FILE entry is treated as a *document*. Such documents may have varying number of properties and are all stored in a single giant database table. All the document properties are searchable. The model is implemented using the PostgreSQL DBMS. Being very simple, this model allows unique flexibility (single table, arbitrary data queries). The cost of such flexibility is very low access speed. Being inappropriate for production, it suits very well for development. Being robust and mature, the relational model is a core of the MPDS production system. It is also supported by the PostgreSQL DBMS, in addition to the intermediate document-oriented model. The standard data manipulation language within the relational model is called structured query language (SQL) and based upon the relational algebra. Eventually, the single table from the document-oriented model is taken, refined, and split into many simpler tables related to each other. This process is called normalization (Teorey et al. 2005). This way much greater access speed is achieved. The refined table structure is however tightly bound to the chosen usage scenario and does not provide extra flexibility.

The disadvantage of the relational model is that the data must obey the strict rules, defined as the database schema. Normally, these rules do not imply an existence of other terms at the database level outside an application business logic. However, the expert systems and artificial intelligence applications must act in an opened world, making inferences and determining new facts, basing on the newly collected information. Their databases must be able to include the new terms and to follow the new logic dynamically and therefore do not fit into the traditional relational paradigm. Usually, such databases employ the so-called semantic Web approach (DuCharme 2013). The data in such model are represented as a *graph*. Such graph

is comprised by a set of statements in the form "subject-property-object," called triples. Using the semantic graph database model, the unprecedentedly flexible and expressive queries on top of the knowledge graph become possible. The MPDS currently uses the semantic graphs only indirectly, complementary to the relational model; however much wider adoption of this model is planned. As a back end for the semantic graph model, the Virtuoso DBMS is employed.

As mentioned, the development of the single data exchange format in materials science is an extremely complex task. Nowadays computer science suggests a very convenient paradigm, when a specific information container is accompanied with the rules definition, i.e., an automatic validation tooling. There are various examples following this idea: SQL and schemata for the relational databases, A-Box and T-Box for the semantic graphs, XML and XSD for the machine-readable data transfer and markup, JSON and schemata for the human-readable data transfer, etc. In this respect, two successful achievements in developing the common exchange format in materials science should be mentioned: Crystallographic Information File (Hall et al. 1991) and Materials and Physical Information File (Michel and Meredig 2016). Both of them are supported at the MPDS and partially at the other mentioned materials informatics infrastructures.

The Crystallographic Information File (CIF) was established in the 1990s by the International Union of Crystallography (IUCR). CIF is based on a text container called STAR (Self-Defining Text Archive and Retrieval), where the physical properties, obtained, e.g., as a result of X-ray diffraction or theoretical modeling, are labeled by the standard tags. The standard tags determine the parameters of the unit cell, symmetry, atomic positions, relevant scientific publication metadata, etc. These tags are defined in the external CIF dictionaries (cf. XSD schemata for the XML documents), so it is possible to validate a CIF file against a CIF dictionary and even to infer the new physical properties from those available. The difference is that the CIF format allows the arbitrary tags. They are ignored by CIF parser but later can become the part of standard CIF dictionaries, according to IUCR. Furthermore, CIF format supports the relational data model, so one can refer to the specific atom in the crystalline structure by its identifier. The drawback is the absence of a convenient multilevel hierarchy support, so here the STAR container concedes to XML. CIF format is used for the online crystal structure visualization at the MPDS, and no other proprietary or self-made formats are employed. Only the Web browser is needed for visualization, and no plugins, applets, or other software is required. Normally, structure rendering is done on the GPU (i.e., graphical card). However, if the GPU is outdated or not available, rendering is done on the CPU (central processor). In this case the quality of rendering is reduced. The total size of the code served online for the rendering is only about 150 Kb, and after the code is loaded, no further Internet connection is required. The CIF visualization at the MPDS is based on the open-source technologies.

The JSON format is simpler, more flexible, and more permissive. Historically, it is much more common for the software development than a narrow-purpose CIF. The container of the Materials and Physical Information File (MIF), introduced by a Citrine startup, is built on top of JSON, taking all its advantages. JSON

also provides its own schema approach, used for validation, documentation, and interaction control, i.e., a contract for the JSON data required by a given application, and how that data can be modified. JSON schemata for all types of the PAULING FILE data, including MIF specifications, were developed in 2016 and now are publicly available. The JSON format, including MIF, is the most widely adopted within the mentioned materials infrastructures.

## 3.4   Computer-Assisted Data Analysis

Undoubtedly plotting and visualizations are extremely helpful for data analysis. One of the interesting plotting features of the MPDS is the semantic graphs of terms. Generally, all the MPDS data are a giant semantic graph of the structured knowledge in materials science, accumulated by the humankind. Unfortunately, no human being may observe this graph as a whole. The online interactive visualizations attempt to show only tiny portions of a giant MPDS semantic graph, related to the particular user's input, in a very simplified form. Fortunately, modern semantic technologies (DuCharme 2013) are able to comprehend a giant MPDS graph all at once. This is the planned direction of the MPDS platform development in future. Another type of visualizations, the dynamically rendered phase diagrams (C-entries), displayed online at the MPDS, are fully digitized, programmatically drawn plots. The rendering engine works in all the modern Web browsers, requires no plugins, and is based on the open-source Web technologies. The phases at the phase diagram are associated with the parametric equations in the form $x = x(t)$, $y = y(t)$, $0 <= t <= 1$, where $x$ stands for the composition and $y$ for the temperature.

Recently the MPDS has launched the first version of its machine-learning predictions. To demonstrate some practical usage scenarios of the materials data-mining using MPDS API, a relatively unsophisticated yet powerful predictive machine-learning algorithm, the decision tree regression, was chosen. A decision tree is a statistical model, which describes the data going from the observations about some item (e.g., a crystalline structure) to the conclusions about the item's target value (e.g., a corresponding physical property). The MPDS data contain crystal structures with the corresponding physical properties, so it is feasible to train a model on this dataset. The following physical properties were chosen: isothermal bulk modulus, enthalpy of formation, heat capacity at constant pressure, and melting temperature. Multiple decision trees were built by repeatedly resampling training data with replacement and voting for the trees yielding a consensus prediction. This algorithm is known as a "*random forest*" regressor. The "random forest" is a statistical estimator that fits a number of classifying decision trees on various subsamples of the dataset and use averaging to improve the predictive accuracy (Breiman 2001). Its presently used state-of-the-art open-source implementation is very efficient and takes seconds to train a model from MPDS data on an average desktop PC (McKinney 2010).

The evaluation process was repeated at least 30 times to achieve a statistical reliability. The results of a randomly chosen evaluation process are shown in Fig. 3.
**Fig. 3** Formation enthalpy, kJ g-at.$^{-1}$: *predicted* versus *factual* values; mean absolute error is 42 kJ g-at.$^{-1}$, comparable with the results of the ab initio simulations

The prediction quality is acceptable and on average may even compete with the ab initio simulation results. The difference is that the simulation normally requires hours or days of computation time, whereas the machine-learning model yields the results in milliseconds on the same hardware. Another difference is that the ab initio simulations in practice require careful fine-tuning of the method, whereas the chosen method of machine learning is a black box, where no initial setup is needed. The disadvantage of the machine-learning model is that no physical meaning of predictions is implied. The underlying complex physical phenomena, as well as the lack of training data, may lead to the poor prediction quality. The size of the training dataset should not be necessarily huge, but there is some minimal threshold. For example, predictions using the smaller dataset of the open MPDS data demonstrate worse quality. Here it is important to note that nowadays more accurate machine-learning techniques exist, such as deep learning neural networks, and the quality of predictions may be further increased.

In the search for the new technological opportunities in the materials data mining, the end point of the route is the artificial intelligence techniques. This is an understandable fact, since the more sophisticated technology, the more similar its intellectual output to the human's one. Historically, there are two approaches to the construction of the intelligent agents (Jones 2008): statistic ("bottom-up" or connectionist) and deterministic ("top-down" or symbolic). The statistic approach is known as "machine learning," i.e., the machine is expected to discover the world on its own, as the humans do. The deterministic approach is known as "inference engine," i.e., the facts are prepared in advance and considered logically. This

approach will be shortly reviewed below. The so-called *ontologies* are employed. The language for ontology expression is called OWL (ontology Web language) and based on the logical calculus, used in mathematics, philosophy, linguistics, and computer science (Baader et al. 2007). Applied to materials science, the ontologies are almost unknown, although this term appears in the publications last two decades from time to time. Conceptually, the ontologies and databases look similar. A database consists of the schema and data (i.e., arrangement of tables plus their content). An ontology consists of the axioms and facts (called T-Box and A-Box). There is however an important difference compared to databases. A database schema acts as constraints on structure of data, whereas ontology axioms act as implications or inference rules. The logical expressiveness of the ontology axioms can be much higher (richer) than any database schema. Currently the schema of the MPDS platform database is quite carefully tuned to meet the designed usage scenarios. On the other hand, this is also a potential limitation. Being highly optimized to satisfy online searches, the MPDS platform database does not however perform very well for nonstandard complex queries and hierarchical data manipulations. In this sense, the ontologies fit the MPDS data model very well. Nonetheless, currently the most important drawback of the ontologies compared to the databases is that the performance cannot be unfortunately even theoretically guaranteed, as the OWL logical calculus is extremely complex mathematically. Apparently, all the successful production deployments of the ontologies somehow overpass this limitation (Cuel and Young 2015). Notably, the ontologies per se do not present much practical sense. In fact, they are just logical constructions attached to the data. Only the whole set of accessory technologies and implementations (called the *semantic web stack*) is able potentially to shed more light to the laws of nature, enclosed in the materials data.

## 3.5    Data-Centric Observations

Following Dmitri Mendeleev and Lothar Meyer, who observed periodical patterns in the properties of the chemical elements in the 1860s, one may try to find similar patterns in the whole range of the known materials and make a step toward hypothetical periodic table of materials. Based on the observations across the PAULING FILE database, the 12 empirical principles were formulated (Villars 1995; Villars et al. 2008; Villars and Iwata 2013). These principles can be called the cornerstones of nature, and all they can be explained using the modern electronic structure theory. They define (*a*) the compound formation, (*b*) the ordering of chemical elements within a structure prototype, and (*c*) the linkage between the position of a chemical element in the periodic table and its occupied sites in the structure prototype.

*First*, compound formation: the atomic size, electrochemical, valence-electron, and cohesion energy factors are governing compound formation. For example, one can observe that about 30% of all chemical element combinations form no compounds within the binary, ternary, and quaternary systems.

*Second,* correlation of the number of chemical elements and atomic environment type: the maximal diversity of the atomic environments is achieved within the binary and ternary inorganic compounds. The quaternary, quinary, and other higher-order compounds strongly prefer the atomic environment types with the low coordination number. One may also call this observation as a surprising reduction of geometrical diversity with the increasing element count.

*Third*, active concentration ranges: there is the systematic occurrence of daltonide inorganic phases for binary, ternary, and quaternary inorganic systems within the certain rather limited (active) concentration ranges.

*Fourth*, stoichiometric ratio condition: there are highly preferred stoichiometric ratios for the vast majority of daltonide compounds.

*Fifth*, compound simplicity: the vast majority of the inorganic compounds have on average only ten atoms per unit cell, thus showing only three or fewer atomic environment types within the crystal structures. One may note here that the nature indeed prefers simplicity.

*Sixth*, compound symmetry: 10% of the space groups cover nearly 70% of the inorganic compounds. The most frequent 11 space groups are 12, 62, 63, 139, 166, 191, 194, 216, 221, 225, and 227. As seen, the high symmetry is preferred.

*Seventh*, atomic environments arrangement: 18 out of about 100 possible atomic environment types are highly preferred and were found for 90% of all the PAULING FILE compounds. In particular, the most frequent types of polyhedra are tetrahedron, octahedron, cube, tri-capped trigonal prism, four-capped trigonal prism, icosahedron, cubooctahedron, bi-capped pentagonal pyramid, and anti-cubooctahedron.

*Eighth*, chemical element ordering tendency: only about 30 structure prototypes have more than 1000 representatives, and the 1000 most populous prototypes and their representatives cover the majority of the crystalline structures of the PAULING FILE.

*Ninth*, correlation of the structure prototype and the periodic system: the vast majority of the crystalline structures show a very strict regularity between the position of the chemical element in the periodic system and its Wyckoff position occupation. This is confirmed on an example of the 1000 most populous prototypes.

*Tenth*, linking of structure and stability: the atomic size, electrochemical, valence-electron, and atomic number factors determine the crystalline structures of the intermetallic compounds. Again, this is applicable to binary, ternary, and quaternary systems. One may reveal clear patterns for, e.g., former versus non-former systems, iso-stoichiometric structure stability maps, and complete solid solubility between binary compounds within the same prototype.

*Eleventh*, generalized atomic environment type stability: using the periodic number (from Lothar Meyer's periodic table), one may subdivide different atomic environment types into distinct stability domains. It was found that the chemical elements with the periodic number more than 54 control the atomic environment types, independently of whether they act as the central or coordinating atoms. Thus, there exists a clear separation between the possible and impossible atomic environment types. Interestingly, the diversity of atomic environment types is very much reduced for quaternaries, as compared to binaries and ternaries.

*Twelfth*, complete solid solution stability: the atomic size, electrochemical, and valence-electron factors control solid solubility. For example, in a ternary system, where two of the binary boundary systems have the same structure prototype, one may predict whether a complete or limited solid solution is formed. Similarly, for a given chemical element, either a limited or extended solid solubility can be predicted.

As seen, all intrinsic physical properties of a single-phase inorganic solid are strongly linked to its crystal structure, emphasizing the importance of the crystal structure classification. And the 12 principles outlined above can only be discovered by the examination of a large amount of critically evaluated experimentally determined data. They ultimately lead to the restraints, which are a requirement for the development of a practicable and trustworthy computational materials design approach.

## 3.6   Applications

A trustworthy linkage between the published experimental inorganic solids and the high-throughput DFT calculations opens the new perspectives of the database-driven, data-intensive research and discovery of the new materials. At the moment two such high-throughput computational initiatives in China and Switzerland are starting to employ the MPDS API with the PAULING FILE data.

The majority of nowadays' practical materials science problems (clean energy sources, energy storage, superconductivity, etc.) are concerned with the big amounts of the complex knowledge to be assimilated, if not by the gifted humans then by the artificial intelligence agents. With the progress of the neuroscience and medicine, shedding the light on the nature of the human brain, new powerful computer science techniques emerge and later find their application in materials science. However, development of the complex tools in a closed (proprietary) environment is extremely difficult and even inefficient. This is why an academic tradition of openness and free exchange of the ideas realizes in an open-source strategy, showcasing the economically advantageous altruism.

## 4   Summary

The PAULING FILE, a unique and probably the oldest effort on organizing the materials data, was reviewed. Starting from the foundations of materials science, such as the taxonomy of physical properties, concepts of the structure prototypes, phases, phase diagrams, etc., it spans to the modern data-intensive science, employing the novel data storage and analysis techniques and providing high-quality materials insights, as implemented in the MPDS online platform. This is important while the efficient and quick knowledge exchange in materials science is obstructed, ahead of today's big data challenge. The other efforts and their contributions to the materials informatics are also noted. An importance of

fostering the emerging ecosystem of today's materials informatics is emphasized. It is based on the standards of JSON, MIF, and CIF, supporting the databases, virtual laboratories, connected with the online REST APIs, which tend to become the software infrastructure backbones. A conceptual UML modeling of the PAULING FILE at the highly abstraction level was showcased. Three types of the PAULING FILE scientific data are highly interlinked, therefore, inseparable within the MPDS online platform. The rich data structure assumes combination of storage approaches, in order to benefit of their advantages and mitigate deficiencies at the same time. Exploring the large amounts of different materials data, a holistic view on inorganic substances may be presented. Coupled with the high-throughput ab initio simulations, it can provide a key to the discovery of materials genome, playing a role of periodic table for entire set of materials. There are certain hopes for the artificial intelligence techniques, automatically generating the new materials discovery ideas, and, citing Linus Pauling, the best way to have a good idea is to have lots of ideas.

# Crystallography Open Database (COD)

# 85

Saulius Gražulis, Andrius Merkys, and Antanas Vaitkus

## Contents

### Abstract

The Crystallography Open Database (COD, http://crystallography.net/) is as of the time of writing the largest open-access collection of mineral, metal organic, organometallic, and small organic crystal structures, excluding biomolecules that are stored separately in the Protein Data Bank (http://wwpdb.org/). Unlike other existing chemical crystal structure databases, the COD is fully open – all its structures may be downloaded, used, and re-disseminated without restriction, along with the results derived from them. Currently, the COD contains >385,000 records and is growing constantly, encompassing most structures published in peer-reviewed academic press and donations by individual researchers. This

e-mail: grazulis@ibt.lt

article describes how data are organized in the COD and how the database can be queried, downloaded, and processed for various purposes.

# 1    Introduction

X-ray crystallography is an extremely powerful method for determining inner structure of the condensed matter. Soon after the discovery of X-rays (Röntgen 1896) and the first records of their diffraction on crystalline samples (Friedrich et al. 1912a, b), the number of structures determined by this technique started to grow. An explanation of the X-ray scattering using first principles (Bragg and Bragg 1913; Bragg 1913) allowed determination of structural models for a vast variety of solid materials in a uniform way, from simple inorganics to very large biomolecules. As more and more crystal structures were appearing, it became evident that the numbers (such as crystal unit cell parameters, atomic coordinates) in their descriptions, made uniform by the availability of the common scattering theory, possess a great value themselves and efforts to collect them systematically were started. The first collections were in paper form (Hermann and Ewald 1931; IUCr 2017c; Kitaigorodsky 1955), and numeric data were accompanying crystallographic publications in journals dedicated for this field from the very first publications (for instance, in the Acta Crystallographica journal started by the IUCr in 1948 (Clews and Cochran 1948).

Growing availability and power of electronic computers allowed crystallographers to use them for structure determination and prompted the idea that crystal structure data can also be handled automatically (Brown and McMahon 2002). A first dedicated crystallographic database, the CSD, was established by the CCDC in 1965 (Groom and Allen 2014) to collect structures of small organic molecules and embraced computer-assisted methods for information storage and retrieval (Allen et al. 1979). Data about inorganic crystals (Kaduk 2002), alloys (White et al. 2002) and powder diffraction data (Kabekkodu et al. 2002) were historically kept in separate archives. Today, we have a whole range of databases, differing by their scope, size and licensing model, covering various aspects of crystallographic data (Table 1).

As seen in from the Table 1, various licensing models were employed to support operations of the databases. About a third of all resources, and some of the oldest and the largest ones, use a subscription-based model, where a user of these databases must agree to a license and is restricted with respect of what he or she may do with the data obtained from the resource. As long as the main vehicle of database dissemination were paper editions or magnetic tape reels that could be used only in computer centers, such situation seemed fairly acceptable. In the epoch of ubiquitous computer access and with the advent of the Internet, however, researchers expressed concerns that certain licensing clauses are overly restrictive. So, the restriction to disseminate derived results was mentioned as an impediment for scientific work (Baldi et al. 2011; Andronico et al. 2011). As a result, several modern databases were created anew, following an open-access dissemination model, and

in certain cases can be used in situations where licensing requirements are too restricting (Sadowski and Baldi 2013). Among them, the Crystallography Open Database (COD) is currently the largest and the oldest open resource of small molecule crystal structures, providing access to data in mineralogy and chemical crystallography and placing all its collection in public domain.

## 2   A Short History of COD

The COD project started as a community initiative, when crystallographers on the SDPD (Structure Determination by Powder Diffraction) discussed possible modes of crystallographic data dissemination. It was 2003, computers were becoming cheap, Internet connections widely available and free/libre open source software (F/LOSS) ubiquitous. Armel Le Bail raised a question whether it is possible to build an entirely open and free for everyone to use crystallographic database by joining community efforts. Answering that question, Michael Berndt (1964–2003) listed three conditions that were necessary and sufficient for community resource creation and curation: "A small team of engaged scientists with some experience in database and software design to coordinate the project; the authors (i.e., the scientific community = you) who provide the project with database entries /.../; free software (a) for maintaining the database, (b) for data evaluation and calculation of derived data." With this plan in mind, the COD project started and turned out to be a viable alternative to the top-down, heavy-funded database projects. From 2003 to 2007, the COD database master copy was maintained by Armel Le Bail at the Le Mans University in France. In 2007 its collection of 50,000 records was ported to the Institute of Biotechnology in Vilnius, Lithuania, the software development for the COD, and database maintenance was continued. When the Institute of Biotechnology was merged with the Vilnius University in 2011, the COD development continued by the joint team from the Vilnius University Institute of Biotechnology and the Faculty of Mathematics and Informatics.

Despite the several transfers of maintainership, the COD is governed by an international COD Advisory Board (AB), listed on the COD Web site and operating via the mailing list. The COD AB establishes the COD data management policies and sets inclusion criteria for the COD data. In this way, a continuity of database quality is maintained.

During the period of 10 years since 2007, the COD was growing constantly and attained >385,000 records in 2017 (Fig. 1). This was possible with the introduction of the new data deposition Web site (Fig. 2) that allowed both manual and automatic uploads of data to the COD and after development of automated data collection and deposition software that deposits available structures to the COD automatically. This automation in turn is highly facilitated by the introduction of the Crystallographic Interchange Framework (CIF) (Hall et al. 1991; IUCr 2017b). The CIF framework was initially used to facilitate crystallographic paper publication and to reduce typing errors in data by providing automated means of crystallographic data processing (Brown and McMahon 2002). Introduction of electronic data handling
**Fig. 1** Growth of the COD database by year

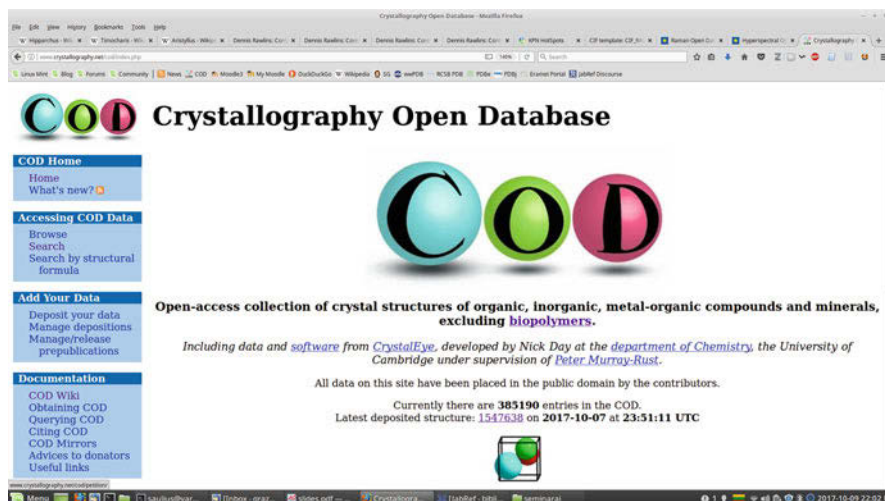

**Fig. 2** The Crystallography Open Database Web site

in the publication process significantly reduced typing errors in data publication, a significant step towards reliable data reuse. Not only that: availability of crystal structure descriptions in a standardized, machine readable form as supplementary material for scientific publications greatly facilitated reuse of that data. As a result the COD data acquisition subsystem can ingest automatically all necessary values and formulate structure description records, using information publicly available with the IUCr publications and from journals of some other publishers that make the necessary information publicly available. The same CIF framework makes

it possible for the COD to present all its data collection in a widely accepted, standardized form, so that researchers can use the same software to process the COD CIFs as for the outputs of structure determination programs or from journal Web pages.

The data collection procedure conducted by the COD is not completely straight-forward, though. Virtually all structures, even though represented in standard CIF format next to the publications, lack essential metadata such as publication bibliography; sometimes computed items such as cell volumes or space group names are missing or presented in a non-standardized form. Such information is automatically inserted by the COD data processing pipeline (Gražulis et al. 2009). Moreover, a non-negligible part of supplementary files, although it does contain necessary data in a form similar to the CIF, does not strictly follow the CIF syntax. Since the number of such cases was too large to be corrected manually, an error-correcting CIF parser was implemented (Merkys et al. 2016). The same procedure is followed when data is deposited by researchers into the COD using the Web deposition interface (Gražulis et al. 2012). In this way the COD ensures that all structure descriptions that enter its collection are syntactically correct, i.e., conform to the syntax defined by the IUCr (2017a).

With this setup, the COD is ready to grow further, to provide open access to crystal structure data for researchers and all interested parties, and to evolve to meet challenges of the new millennium. Computing landscape changes rapidly, with new techniques, languages, formats and protocols coming and going every day, and computer architectures changing fast enough so that any reasonable scientific archive must outlive many generations of computer software and hardware. The basic principles of the COD design and the successful operation of the COD for more than a decade hint that the methods chosen by the COD founders were sound and that the COD will successfully evolve into the future.

## 3    Scope and Contents of the COD

The COD collects machine-readable descriptions of crystal structures for inorganic compounds, minerals, small organic molecules, metal-organic and organometallic compounds. Proteins, nucleic acids and their complexes, glycoproteins and the like are as a rule excluded from the COD, since they are systematically collected in an open-access database, the Protein Data Bank (PDB) (Berman et al. 2012). Most of the "small molecule" structures in the COD are refined using assumption of independent atom parameters (using full-matrix least squares refinement), and a spherical atom model. This makes the COD suitable, for example, to generate restraints on molecular geometries and to refine larger molecules or molecular assemblies (Long et al. 2017a, b). We must note, however, that this assumption does not necessarily hold for all COD entries. For larger entries, or when disorder is present, restraints can be put the by authors on the thermal displacement parameters. For structures solved using powder diffraction techniques, restraints on bond lengths and angles can be also used. Finally, some structures in the COD are solved by

hybrid methods, using powder diffraction to carry out Rietveld refinement and to use DFT to further refine atomic parameters; some structures are reported entirely based on DFT calculations. Obviously, determining bond length and angle parameters from restrained structures would result in circular reasoning, since the same restraints were already used during the structure refinement process. Thus, the user is advised to inspect structure determination parameters and to select those structures that are suitable for his or her work.

## 4    COD Data Semantics and Selection

To facilitate structure selection, the COD maintains a set of flags that describe experimental and refinement techniques used for structure determination. In the COD SQL table, the "`method`" column of the '`data`' table describes the experimental technique which can be "`single crystal`", "`powder diffraction`" or "`theoretical`". If the value of this column is `NULL`, the method is most probably single crystal diffraction. Unfortunately, in many structures the most popular method, "`single crystal`", is not mentioned explicitly, so this assumption is a certain guess; but the structures solved by "`powder diffraction`" or "`theoretical`" methods are usually marked more accurately and are less numerous, so the guess should be reasonably safe. Structures marked as "`theoretical`" are in fact solved by DFT computations without using any structure-specific experimental data. These structures are of course more appropriate to a different database, the TCOD, which is dedicated to theoretical structures, and are in fact also most likely deposited there. They ended up in the COD since they were provided as supplementary material to some papers and were not marked as being theoretical and only later data curation revealed their determination method. Several important theoretical structures, e.g., from the DFT method error estimate studies (Lejaeghere et al. 2014), were deposited to the COD before the TCOD was fully operational but were deemed important enough so that permanent storage in a database for these data records is necessary. Since the COD policy is not to delete any records, so that once assigned COD IDs remain stable, the policy of the COD is to mark its entries with appropriate flags, but not to remove them.

Further the COD database tables contain several fields describing experimental techniques, taken from the IUCr Core CIF dictionary. The "`radiation`", "`radType`" and "`radSymbol`" columns of the "`data`" table are derived directly from the CIF data items `_diffrn_radiation_probe`, `_diffrn_radiation_type` and `_diffrn_radiation_xray_symbol`, respectively. These data items allow distinguishing between structures obtained from X-ray, neutron and electron diffraction data (the "`radiation`" column can have values "`x-ray`", "`neutron`" or "`electron`" for the respective radiation types). Again, like with the "`single crystal`" value, the most popular radiation type, "`x-ray`", is often not marked and thus represented as a `NULL`

value. We can expect that authors are more attentive when they submit a structure made by a less common method, but certain caution is of course appropriate.

When selecting records from the COD, one must keep in mind certain book-keeping data items. Certain structures are deposited to the COD that are deliberately worse than the best possible interpretation; this is usually done in publications to demonstrate that the main interpretation of data offered by authors is correct or indeed the best one. COD policy is to include such structures (so that the paper claims can be easily verified) but to mark them as "suboptimal." In COD CIFs, such structures are marked with `_cod_suboptimal_structure yes` and `_cod_related_optimal_struct` data items, and in the COD `data` table it has a non-NULL value in the "`optimal`" column pointing the related optimal structure. Unless explicit comparison of suboptimal and optimal structures is sought, only structures with NULL "`optimal`" values should be selected.

Another issue is structures that contain known problems. Again, the COD policy is not to remove such structures, once they were included in the COD, but to flag them appropriately. This flag is recorded in the COD database `data` table "`status`" column. Possible values for this column are "`warnings`", "`errors`", and "`retracted`". The "`warnings`" level indicates that the structure might be after all correct but there are strange features, unusual description, or wrong metadata in it. The "`errors`" mark structures that either have been proven wrong by subsequent published observations, authors' corrigenda or contain serious data consistency problems that prevent correct interpretation of the structure. In all cases, `_cod_error_description` gives a human readable description of the problem. Finally, the "`retracted`" in the "`status`" column indicates that the structure was retracted and should not be used under any circumstances. The reasons for retraction may vary, but usually this flag indicates very serious problems up to the outright scientific fraud, as was the case discovered in one IUCr investigation (Harrison et al. 2010); in such cases, the original publications are retracted as well.

The last thing to take care about is the presence of duplicated entries in the COD. Unfortunately, due to less stringent admission procedures in the earliest days of the COD, or due to programming or data encoding errors, sometimes the same structure is deposited more than once to the COD. Once again, when such situation is detected, neither entry is removed from the COD; instead, one entry, usually the most complete one, is declared to be the "main" entry describing this structure, and the others are marked as "duplicates" using the `_cod_duplicate_entry` data item. If the main entry is missing some information that is present in the duplicates, this information is merged into the main entry and committed as a new revision. Duplicate entries are marked by a non-NULL "`duplicateof`" column in the `data` table. Thus, to select only those entries that are not marked as duplicates, one needs to select entries that have "`duplicateof`" column set to NULL.

It must be noted that only technical duplicates are flagged as such in the COD, i.e., only structures that are originating from the same original description and from the same publication. Two structures of the same compound reported in different publications are not considered duplicates and are stored as different COD records.

Even when the same data file is published as supplementary material to two different publications, it is deposited under two different COD identifiers. The rationale here is that a COD record reports an instance of the crystal structure solution reported somewhere, and all such cases must be represented in the database. Further reduction of the multiple records is the responsibility of the COD user, and, indeed, different tasks will require different uniqueness criteria – in some cases these will be based in chemical identity, in other cases on crystal structure identity, and the COD must provide sufficient data for all such queries.

Collecting all above considerations into one SQL query, we can select all non-retracted experimental structures that are not marked as duplicates and have atomic coordinates with a query displayed in Listing 1; the query there reports number of such entries in the current COD SQL database and can be used for further narrowing down the selection based on crystal parameters.

**Listing 1** Number of non-retracted experimental structures with coordinates in the COD that are not marked as duplicates

```bash
#!/bin/bash

mysql -h sql.crystallography.net cod -u cod_reader -t -e \
    'select count(*), current_timestamp() from data
     where duplicateof is null
       and flags like "%has_coordinates%"
       and (status is null or status != "retracted")
       and (method is null or method != "theoretical")'
```

```
+----------+---------------------+
| count(*) | current_timestamp() |

+----------+---------------------+
```

## 5  Accessing the COD

### 5.1  Web Access to the COD

The COD offers several methods to access its structure collection. The one that requires least effort to learn is probably to use query forms (see Fig. 3). Multiple parameters can be specified, most of which should be self-explanatory; their exact meaning, however, is the same as in the RESTful query fields and can be looked up in the Table 2.

Results from a Web query are displayed in a separate browser page as a HTML table (Fig. 4); in addition to that, options are provided to download the list of resulting structures as a list of COD identifiers, download URLs or as a CSV format table. For a small number of hits, a ZIP archive of all found CIFs is offered, but for a larger number of structures (typically more than several thousands), this option is

**Fig. 3**  The Web query form of the Crystallography Open Database

**Table 2**  RESTful interface search parameters and their descriptions

| Parameter | Description |
| --- | --- |
| format | The format in which the results will be returned |
| formula | The empirical chemical formula of the crystal. Chemical element symbols in the formula must be ordered according to the Hill notation and separated by a space symbol, i.e., "C8 H10 N4 O2" |
| el1, el2, …, el8 | Chemical element symbols that must appear in the chemical formula |
| nel1, nel2, …, nel4 | Chemical element symbols that must not appear in the chemical formula |
| strictmin, strictmax | The minimum/maximum number of distinct chemical elements that must appear in the chemical formula |
| amin, amax | The minimum/maximum value of the lattice parameter a |
| bmin, bmax | The minimum/maximum value of the lattice parameter b |
| cmin, cmax | The minimum/maximum value of the lattice parameter c |
| minZ, maxZ | The minimum/maximum Z value of the lattice |
| year | The year of publication of the crystal structure |

not available in order to avoid excessive stress on the COD servers, and instead a user is advised to download the COD structures in full and pick the desired CIFs using the COD identifier list resulting from the search.

## 5.2    Using the RESTful Interfaces

The COD offers a RESTful interface that allows one to retrieve information about COD entries based on certain criteria as well as the crystal structure files themselves. The REST (REpresentational State Transfer) is an architectural style of network-based programs that was outlined in the doctoral dissertation of Roy Fielding (2000). The main ideas of this architecture relevant for the COD are to use a client-

**Fig. 4** An example result page from a Crystallography Open Database Web query

server design (the COD server serves multiple clients), to make the COD server stateless as much as possible (thus the same request to the COD server should yield identical results if repeated several times), to use standard connections based on HTTP protocol and stable Web URIs, and to use standard formats (CIF, HTML) to exchange information. An interface based on the ideas of REST, a so-called RESTful interface, has the benefit of not requiring a specialized client program since the queries can be executed by any piece of software capable of resolving URIs including, but not limited to, most Internet browsers.

COD RESTful search query URIs adhere to the HTTP GET query format taking http://www.crystallography.net/cod/result as the basis URI. For example, a query that returns a list of COD IDs associated with structures that contain the Li and O atoms and were published in 2017 would take a form of: http://www.crystallography.net/cod/result?el1=Li&el2=O&year=2017&format=lst

As mentioned above, specialized software is not required, but it can, however, ease the construction of the query strings. An example of the same request rewritten to use the cURL program is given in Listing 2.

**Listing 2** Querying the RESTful interface using cURL

```bash
#!/bin/bash

curl 'http://www.crystallography.net/cod/result' \
-d 'el1=Li' \
-d 'el2=O' \
-d 'year=2017' \
-d 'format=lst'
```

Several more examples of COD RESTful interface queries using cURL are given in listings Listings 3, 4, 5, and 6. Description of the used query parameters is given in Table 2. The full list of supported parameters and formats can be acquired at http://wiki.crystallography.net/RESTful_API/.

**Listing 3**   Count of structures that contain Fe atoms, but no O atoms

```
#!/bin/bash

curl 'http://www.crystallography.net/cod/result' \
-d 'el1=Fe' \
-d 'nel1=O' \
-d 'format=count'
```

**Listing 4**   Information about entries that contain only Fe and N atoms in JSON format

```
#!/bin/bash

curl 'http://www.crystallography.net/cod/result' \
-d 'el1=Fe' \
-d 'el2=N' \
-d 'strictmin=2' \
-d 'strictmax=2' \
-d 'format=json'
```

**Listing 5**   Text file with URLs of entries that have the "C O2" chemical formula

```
#!/bin/bash

curl 'http://www.crystallography.net/cod/result' \
-d 'formula'='C O2'
-d 'format=urls'
```

**Listing 6**   ZIP archive containing CIF files of entries that have cell length between 30 Å and 35 Å and Z number between 3 and 4

```
curl 'http://www.crystallography.net/cod/result' \
-d 'amin=30&amax=35' \
-d 'bmin=30&bmax=35' \
-d 'cmin=30&cmax=35' \
-d 'minZ=3&maxZ=4' \
-d 'format=zip'
```

## 5.3   Querying SQL Database

SQL (Structure Query Language) is arguably the most powerful method of interrogating relational databases and offers more features than the COD Web page or even

than the COD RESTful interface. The Crystallography Open Database offers a read-only access to its data tables so that SQL queries can be carried out by user or by third-party software. Covering SQL language syntax and its use is beyond the scope of this chapter, but numerous textbooks and on-line references of SQL exist, as well as excellent documentation of several F/LOSS implementations of SQL (MySQL is one of them). In this text we provide just a few examples that demonstrate how SQL queries can be used for querying the COD out of the box.

The COD SQL tables are constructed automatically from the COD CIF collection. Tables are updated by the post-commit hooks of the Subversion repository; thus the SQL tables should be always in sync with the CIF collection. In the COD, the dataflow is always from CIFs to the SQL database; thus all changes in tables must be first recorded and versioned in the main repository. Thus, MySQL acts essentially as a fast search cache for the COD, making use of index tables and query optimizer. The COD MySQL `data` table contains also the "svnrevision" column that records Subversion revision from which each row is produced. In addition to that, all COD MySQL tables are dumped nightly in text form and committed to the same Subversion repository as the CIF collection. These archives provide means to reproduce queries that were run some time ago, should this necessity arise for scientific computation reproducibility.

The simplest query counts number of records in the current revision of the COD (Listing 7). A more elaborate form of this query which filters structures that are usually unwanted is provided in the Listing 1. Further examples (Listings 8, 9, and 10) demonstrate how various chemical features can be queried. Specifically, the Listing 9 shows how the COD MySQL server can be queried using regular expressions, an extension of the SQL language. These queries permit selections based on atom chemical types, among other possibilities.

**Listing 7** Number of entries in the COD

```
#!/bin/bash

mysql -h sql.crystallography.net cod -u cod_reader -t -e \
    'select count(*), current_timestamp() from data'
```

```
+----------+---------------------+
| count(*) | current_timestamp() |
+----------+---------------------+
|   387948 | 2017-12-04 14:07:02 |
+----------+---------------------+
```

**Listing 8** DOIs and publication years of structures of cucurbituril

```
#!/bin/bash

mysql -h sql.crystallography.net cod -u cod_reader -t -e \
    'select file, doi, year from data
     where chemname like "%cucurbituril%"'
```

```
+---------+--------------------------+------+
| file    | doi                      | year |
+---------+--------------------------+------+
| 2200062 | 10.1107/S1600536800019498 | 2001 |

| 7032762 | MOF-205-NH2 |  27846 |
+---------+-------------+--------+
```

# 6 COD Applications

Even though the COD is not as large as some older crystallographic databases, it has numerous applications due to its open nature. One immediate possibility where the COD excels is teaching. Using the COD one can give students some real-life data search and crystallographic applications, illustrate structures of various compounds, and provide insights into modern chemical research areas (Gražulis et al. 2015). Advantages of the COD are its extremely rapid release cycle (the database is updated daily), permissive license that allows students to download arbitrary parts or even the whole database to their computers, and its availability on the Internet where it can be accessed from or outside the classroom.

Another widely accepted application of the COD is its use for material identification with the help of powder diffraction method and search-match procedure. Largest diffractometer vendors (among them Bruker, PANalytical, Rigaku) have adapted the COD collection for their software and ship it with their equipment, providing regular updates on the COD Web site or on their own pages. Since the COD is an open database, these updates are free of charge for the end users. The COD has currently accumulated enough mineral structures so that it can be used for the SOLSA project (http://solsa-mining.eu), where the database is used, together with other information sources, as a tool for material identification and data dissemination.

In bioinformatics and drug design, the COD is used as a source of open data for restraint libraries (Long et al. 2017a, b). It is also used in DataWarrior (Sander et al. 2015) as one of the sources of chemical information and in the OpenMolecules Web site (http://www.openmolecules.org/). Software testing benefits from large collection of COD data, where different cases need to be examined and data needs to be stored in regression tests. Finally, the COD is used in fundamental research to answer different questions about matter (see, e.g., recent works on MOFs (First and Floudas 2013), hydrogen storage (Breternitz and Gregory 2015), or characterization of 2D materials (Mounet et al. 2018).

# 7 Conclusions

The more than decade-long history of the COD has demonstrated that it is possible to build a lasting, high-quality scientific database using an open-access licensing model. At its current state, the COD is useful for a range of academic and industrial applications. Most importantly, this open database provides everyone with the access to knowledge in its own field of small molecule crystallography. At the same time, there are a lot of obvious improvements that can be done. Clearly the COD needs a more comprehensive data collection. More community organization effort should be done, to involve more people in data correction, collection, and ensuring quality of the COD records. More links with the rest of the Internet data resources should be made, integrating the COD more closely into the Linked Open Data

Cloud. None of these tasks seems to be outside the reach of current possibilities, and so one can expect that in due time, the COD is expanded to include all these features.

# Quantum Machine Learning in Chemistry and Materials

# 86

Bing Huang, Nadine O. Symonds, and O. Anatole von Lilienfeld

## Contents

**Abstract**

Within the past few years, we have witnessed the rising of quantum machine learning (QML) models which infer electronic properties of molecules and materials, rather than solving approximations to the electronic Schrödinger equation. The increasing availability of large quantum mechanics reference

B. Huang · N. O. Symonds · O. A. von Lilienfeld (✉)

e-mail: bing.huang@unibas.ch; nsnadinesymonds@gmail.com; anatole.vonlilienfeld@unibas.ch

datasets has enabled these developments. We review the basic theories and key ingredients of popular QML models such as choice of regressor, data of varying trustworthiness, the role of the representation, and the effect of training set selection. Throughout we emphasize the indispensable role of learning curves when it comes to the comparative assessment of different QML models.

# 1    Introduction

Society is becoming increasingly aware of its desperate need for new molecules and materials, be it new antibiotics or efficient energy storage and conversion materials. Unfortunately, chemical compounds reside in, or rather hide among, an unfathomably huge number of possibilities, also known as chemical compound space (CCS). CCS is the set of stable compounds which can be obtained through all combinations of chemical elements and interatomic distances. For medium-sized drug-like molecules, CCS is believed to exceed $10^{60}$ (Kirkpatrick and Ellis 2004). Exploration in CCS and locating the "optimal" compounds are thus an extremely difficult, if not impossible, task. Typically, one needs to constrain the search domain in CCS and obtain certain pertinent properties of compounds within the subspace and then choose the compounds with properties which come closest to some preset criteria as potential candidates for subsequent updating or validation. Of course, one can conduct experiments for each compound. Alternatively, one can also attempt to estimate its properties using modern atomistic simulation tools which, within one approximation or the other, attempt to solve Schrödinger's equation on a modern powerful computer.

The latter approach is practically more favorable and referred as high-throughput (HT) computational screening (Greeley et al. 2006). In spite of its popularity, it is inherently limited by the computational power accessible considering that (1) the number of possible compounds is much larger than what HT typically is capable of dealing with ($\sim 10^3$) and (2) often very time-consuming explicitly electron correlated methods are necessary to reach chemical accuracy (1 kcal/mol for energies), with computational cost often scaling as $O(N^6)$ ($N$ being the number of electrons, a measure of the system size). Computationally more efficient methods generally suffer from rather weak predictive power. They range from force fields and semiempirical molecular orbital methods, density functional theory (DFT) methods to so-called linear scaling methods which assume locality by virtue of fragments or localized orbitals (Kitaura et al. 1999). It remains an outstanding challenge within conventional computational chemistry that efficiency and accuracy apparently cannot coexist.

To tackle this issue, Rupp et al. (2012) introduced a machine learning (ML) Ansatz in 2012, capable of predicting atomization energies of out-of-sample molecules fast and accurately for the first time. By now many subsequent studies showed that ML models enable fast and yet arbitrarily accurate prediction for *any* quantum-mechanical property. This is no "free lunch"; however, the price to pay

consists of the acquisition of a set of pre-calculated training datasets which must be sufficiently representative and dense.

So what is machine learning? It is a field of computer science that gives computers the ability to learn without being explicitly programmed (Samuel 2000). Among the broad categories of ML tasks, we focus on a type called supervised learning with continuous output, which infers a function from labeled training data. Putting it formally, given a set of $N$ training examples of the form $\{(x_1, y_1), (x_2, y_2), \cdots, (x_N, y_N)\}$ with $x_i$ and $y_i$ being, respectively, the input (the representation) and output (the label) of example $i$, a ML algorithm models the implicit function $f$ which maps input space $X$ to label space $Y$. The trained model can then be applied to predict $y$ for a new input $x$ (belonging to the so-called test set) absent in the training examples. For quantum chemistry problems, the input of QML (also called representation) is usually a vector/matrix/tensor directly obtained from composition and geometry $\{Z_I, \mathbf{R}_I\}$ of the compound, while the label could be *any* electronic property of the system, notably the energy. The function $f$ is implicitly encoded in terms of the nonrelativistic Schrödinger equation (SE) within the Born-Oppenheimer approximation, $\hat{H}\Psi = E\Psi$, whose exact solution is unavailable for all but the smallest and simplest systems. To generate training data, methods with varied degrees of approximation have to be used instead, such as the aforementioned DFT, QMC, etc.

Given a specific pair of $X$ and $Y$, there are multiple strategies to learn the implicit function $f : X \rightarrow Y$. Some of the most popular ones are artificial neural network (ANN, including its various derivatives, such as convolutional neural network) and kernel ridge regression (KRR, or more generally Gaussian process regression).

Based on a recent benchmark paper (Faber et al. 2017), KRR and ANN are competitive in terms of performance. KRR, however, has the great advantage of simplicity in interpretation and ease in training, provided an efficient representation is used. Within this chapter, we therefore focus on KRR or Gaussian processes exclusively (see Sect. 2 for more details.).

Often, each training example is represented by a pair $(x_i, y_i)$. However, multiple $\{y_j\}_i$ can also be used, e.g., when multiple labels are available for the same molecule, possibly resulting from different levels of theory. The latter situation can be very useful for obtaining highly accurate QML models with scarcely available accurate training data and coarse data being easy to obtain. Multi-fidelity methods take care of such cases and will be discussed in Sect. 3.

Once the suitable QML model is selected, be it either in terms of ANN, KRR, or in terms of a multi-fidelity approach, two additional key factors will have a strong impact on the performance: The material representation and the selection procedure of the training set. The representation of any compound should essentially result from a bijective map which uses as input the same information which is also used in the electronic Hamiltonian of the system, i.e., compositional and structural information $\{Z_I, \mathbf{R}_I\}$ as well as electron number. The representation is then typically formatted into a vector which can easily be processed by the computer. Some characteristic representations, introduced in the literature, are described in Sect. 4, where we will see how the performance of QML models can be

enhanced dramatically by accounting for more of the underlying physics. In Sect. 5, further improvements in QML performance are discussed resulting from rational training set selection, rather than from random sampling.

Having introduced the basics of ML, we are motivated to point out two aspects of ML that may not be obvious for better interpretation of how ML works: (1) ML is an inductive approach based on rigorous implementation of inductive reasoning and it does not require *any* a priori knowledge about the aforementioned implicit function $f$ (see Sect. 2), though some insight of what $f$ may look like is invaluable for rational design of representation (see Sect. 4); (2) ML is of interpolative nature, that is, to make reasonable prediction, the new input must fall into the interpolating regime. Furthermore, as more training examples are added to the interpolating regime, the performance of the ML model can be systematically improved for a quantified representation (see Sect. 4).

## 2    Gaussian Process Regression

In this section, we discuss the basic idea of data-driven prediction of labels: the Gaussian process regression (GPR). In the case of a global representation (i.e., the representation of any compound as a single vector, see Sect. 4 for more details), the corresponding QML model takes the same form as in kernel ridge regression (KRR), also termed the global model. GPR is more general than KRR in the sense that GPR is equally applicable to local representations (i.e., the representation of any compound as a 2D array, with each atom in its environment represented by a single vector, see Sect. 4 for more details). Local GPR models can still successfully be applied when it comes to the prediction of extensive properties (e.g., total energy, isotropic polarizability, etc.) which profit from nearsightedness. The locality can be exploited for the generation of scalable GPR-based QML models which can be used to estimate extensive properties of very large systems.

### 2.1    The Global Model

Here we review the Bayesian analysis of the nonlinear regression model (Rasmussen and Williams 2006) with Gaussian noise $\varepsilon$:

$$\mathbf{y} = \phi(\mathbf{x})^\top \mathbf{w} + \varepsilon, \tag{1}$$

where $\mathbf{x} \in \mathbf{X}$ is the representation, $\mathbf{w}$ is a vector of weights, and $\phi(\mathbf{x})$ is the basis function (or kernel) which maps a $D$-dimensional input vector $\mathbf{x}$ into an $N$ dimensional feature space. This is the space into which the input vector is mapped, e.g., for an input vector $\mathbf{x}_1 = (x_{11}, x_{12})$ with $D = 2$, its feature space could be $\phi(\mathbf{x}_1) = (x_{11}^2, x_{11}x_{22}, x_{22}x_{11}, x_{22}^2)$ with $N = 4$. $\mathbf{y}$ is the label, i.e., the observed property of target compounds. We further assume that the noise $\varepsilon$ follows an independent, identically distributed (iid) Gaussian distribution with zero mean

and variance $\lambda$, i.e., $\varepsilon \sim \mathcal{N}(0, \lambda)$, which gives rise to the probability density of the observations given the parameters $\mathbf{w}$, or the likelihood:

$$p(\mathbf{y}|\mathbf{X}, \mathbf{w}) = \prod_{i=1}^{n} \mathcal{N}(\phi(\mathbf{x}_i)^\top \mathbf{w}, \lambda I) = \mathcal{N}(\phi(\mathbf{X})^\top \mathbf{w}, \lambda I), \tag{2}$$

where $\phi(X)$ is the aggregation of columns $\phi(\mathbf{x})$ for all cases in the training set. Now we put a zero mean Gaussian prior with covariance matrix $\Sigma_p$ over $\mathbf{w}$ to express our beliefs about the parameters before we look at the observations, i.e., $\mathbf{w} \sim \mathcal{N}(0, \Sigma_p)$. Together with Bayes' rule

$$p(\mathbf{w}|\mathbf{y}, \mathbf{X}) = \frac{p(\mathbf{y}|\mathbf{X}, \mathbf{w})p(\mathbf{w})}{p(\mathbf{y}|\mathbf{X})} \tag{3}$$

$$p(\mathbf{y}|\mathbf{X}) = \int p(\mathbf{y}|\mathbf{X}, \mathbf{w})p(\mathbf{w})d\mathbf{w}, \tag{4}$$

distribution of $\mathbf{w}$ can be updated as

$$p(\mathbf{w}|\mathbf{X}, \mathbf{y}) \sim \mathcal{N}(\bar{\mathbf{w}} = \lambda^{-1} A^{-1} \phi(\mathbf{X})\mathbf{y}, A^{-1}) \tag{5}$$

where $A = \lambda^{-1}\phi(\mathbf{X})\phi(\mathbf{X})^\top + \Sigma_p^{-1}$. The updated $\mathbf{w}$ is called the posterior with mean $\bar{\mathbf{w}}$. Thus, similar to Eq. (4), the predictive distribution for $\mathbf{y}_* = f(\mathbf{x}_*)$ is

$$p(\mathbf{y}_*|\mathbf{x}_*, \mathbf{X}, \mathbf{y}) = \int p(\mathbf{y}_*|\mathbf{x}_*, \mathbf{w})p(\mathbf{w}|X, \mathbf{y})d\mathbf{w}. \tag{6}$$

Substituting Eqs. (2) and (5) into Eq. (6),

$$p(\mathbf{y}_*|\mathbf{x}_*, \mathbf{X}, \mathbf{y}) = \mathcal{N}(\lambda^{-1}\phi(\mathbf{x}_*)^\top A^{-1}\phi(\mathbf{X})\mathbf{y}, \phi(\mathbf{x}_*)^\top A^{-1}\phi(\mathbf{x}_*)), \tag{7}$$

which can be further simplified to $p(\mathbf{y}_*|\mathbf{x}_*, \mathbf{X}, \mathbf{y}) = \mathcal{N}(\bar{\mathbf{y}}_*, \bar{\lambda})$ with $\bar{\mathbf{y}}_*$ and $\bar{\lambda}$ being, respectively,

$$\bar{\mathbf{y}}_* = K(\mathbf{x}_*, X)(K(\mathbf{X}, \mathbf{X}) + \lambda I)^{-1}\mathbf{y}, \tag{8}$$

$$\bar{\lambda} = K(\mathbf{x}_*, \mathbf{x}_*) - K(\mathbf{x}_*, \mathbf{X})(K(\mathbf{X}, \mathbf{X}) + \lambda I)^{-1}K(\mathbf{X}, \mathbf{x}_*), \tag{9}$$

where $I$ is the identity matrix and $K(\mathbf{X}, \mathbf{X}) = \phi'(\mathbf{X})^\top \phi'(\mathbf{X})$ $(\phi'(\mathbf{X}) = \Sigma_p^{1/2}\phi(\mathbf{X}))$ is the kernel matrix (also called covariance matrix, abbreviated as Cov). It's not necessary to know $\phi$ explicitly; their existence is sufficient. Given a Gaussian basis function, i.e., $\phi'(x) = \exp(-(x - x_0)^2/(2l^2))$ with $x_0$ and $l$ being some fixed parameters, it can be easily shown that the $(i, j)$-th element of kernel matrix $K$ is

$$k(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\frac{1}{2}\frac{||\mathbf{x}_i - \mathbf{x}_j||_2^2}{\sigma^2}\right), \tag{10}$$

where $|| \cdot ||_p$ is the $L_p$ norm and $\sigma$ is the kernel width determining the characteristic length scale of the problem. Note that we have avoided the infeasible computation of feature vectors of infinite size by using some kernel function $k$. This is also called the kernel trick. Other kernels can be used just as well, e.g., the Laplacian kernel, $k(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\frac{||\mathbf{x}_i - \mathbf{x}_j||_1}{\sigma}\right)$.

Rewriting Eq. 8, we arrive at a more concise expression in matrix form,

$$\mathbf{y}_* = K(\mathbf{X}_*, \mathbf{X})\mathbf{c}, \tag{11}$$

where $\mathbf{c}$ is the regression coefficient vector,

$$\mathbf{c} = (K(\mathbf{X}, \mathbf{X}) + \lambda I)^{-1}\mathbf{y}. \tag{12}$$

Note that this expression can also be obtained by minimizing the cost function $C(\mathbf{w}) = \frac{1}{2}\sum_i (y_i - \mathbf{w}^\top \phi(\mathbf{x}_i))^2 + \frac{\lambda}{2}||\mathbf{w}||_2^2$ with respect to $\mathbf{w}$

Note that $L_2$ regularization is used, together with a regularization parameter $\lambda$ acting as a weight to balance minimizing the sum of squared error (SSE) and limiting the complexity of the model. This eventually leads to a model called kernel ridge regression (KRR) model.

All variants of these global models, however, suffer from the scalability problem for extensive properties of the system such as energy, i.e., the prediction error grows systematically with respect to query system size (predicted estimates will tend toward the mean of the training data while extensive properties grow). This limitation is due to the interpolative nature of global ML models, that is, the predicted query systems and their properties must lie within the domain of training data.

## 2.2 The Local Version

The scalability problem can be overcome by working with local, e.g., atomic, representations. This relies on the idea that one can decompose a global extensive property of the system into local contributions. Among the many ways to partition systems into building blocks, we select the atom-in-molecule (AIM) idea, put forth many years ago by Bader (1990). For the total energy ($E$) of the system, it is usually expressed as a sum over atomic energies ($e$):

$$E = \sum_I e^I = \sum_I \int_{\Omega_I} \langle \Psi | \hat{H} | \Psi \rangle d^3 r \tag{13}$$

where $\Omega_I$ is the atomic basin determined by the zero-flux condition of the electron density,

$$\nabla \rho(\mathbf{r_s}) \cdot \mathbf{n}(\mathbf{r_s}) = 0, \quad \text{for every point } \mathbf{r_s} \text{ on the surface } S(\mathbf{r_s}) \tag{14}$$

where $\mathbf{n}(\mathbf{r_s})$ is the unit vector normal to the surface at $\mathbf{r_s}$. The advantage of using Bader's scheme is that the total energy is exactly recovered and that, at least in principle, it includes all short- and long-ranged bonding, i.e., covalent as well as non-covalent (e.g., van der Waals interaction, Coulomb interaction, etc.). Furthermore, due to nearsightedness of atoms in electronic system (Prodan and Kohn 2005), atoms with similar local chemical environments contribute a similar amount of energy to the total energy. Using the notion of alchemical derivatives, this effect, a.k.a. chemical transferability, has recently been demonstrated numerically (Fias et al. 2017). Thus it is possible to learn effective atomic energies based on a representation of the local atoms. Unfortunately, the explicit calculation of local atoms is computationally involved (the location of the zero-flux plane is challenging for large molecules), making this approach less favorable. Instead, we can also assume that the aforementioned Bayesian model is applicable to atomic energies as well, i.e.,

$$e^I = \phi(\mathbf{x}^I)^\top \mathbf{w} + \varepsilon \tag{15}$$

where $\mathbf{x}^I$ is an atomic representation of atom $I$ in a molecule. By summing up terms on both sides in Eq. 15, we have

$$E = \sum_I \phi(\mathbf{x}^I)^\top \mathbf{w} + \varepsilon. \tag{16}$$

Following Bartók et al. (2010), the covariance of the total energies of two compounds can be expressed as

$$K_{ij} = \text{Cov}(E_i, E_j) = \text{Cov}\left(\sum_I e_i^I, \sum_J e_j^J\right) = \sum_I \sum_J \text{Cov}\left(e_i^I, e_j^J\right)$$
$$= \sum_I \sum_J k\left(\mathbf{x}_i^I, \mathbf{x}_j^J\right) \tag{17}$$

where $I$ and $J$ run over all the respective atomic indices in molecule $i$ and $j$ and where $\mathbf{x}_i^I$ is the representation of atom $I$ in molecule $i$.

By inserting Eq. (17) in Eq. (11), we arrive at the formula for the energy prediction of a molecule $*$ out-of-sample:

$$E_* = \sum_i c_i \sum_{I \in i} \sum_{J \in *} k\left(\mathbf{x}_i^I, \mathbf{x}_*^J\right) \tag{18}$$

where $c_i = \sum_j ([K + \lambda I]^{-1})_{ij} E_j$. This equation can be rearranged:

$$E_* = \sum_{J \in *} \sum_i c_i \sum_{I \in i} k\left(\mathbf{x}_i^I, \mathbf{x}_*^J\right) = \sum_{J \in *} e_*^J, \tag{19}$$

where the atomic contribution of atom $J$ to the total energy can be decomposed into a linear combination of contributions from each training compound $i$, weighted by its regression coefficient,

$$e_*^J = \sum_i c_i \tilde{e}_{*i}^J. \tag{20}$$

The "basis function" $\tilde{e}_{*i}^J$ in this expansion simply consists of the sum over kernel similarities between atom $J$ and atoms $I \in i$, where the contribution of atom $I$ grows with its similarity to atom $J$:

$$\tilde{e}_{*i}^J = \sum_I k\left(\mathbf{x}_i^I, \mathbf{x}_*^J\right). \tag{21}$$

We note in passing that the value of the covariance matrix element (i.e., Eq. (17)) increases when the size of either system $i$ or $j$ grows, indicating that the scalability issue can be effectively resolved.

## 2.3 Hyper-Parameters

Within the framework of GPR or KRR, there are two sets of parameters: (1) parameters that are determined via training, i.e., the coefficients $\mathbf{c}$ (see Eq. (12)), whose number grows with the training data, and (2) hyper-parameter whose value is set before the learning process begins, i.e., the kernel width $\sigma$ in Eq. (11) and $\lambda$ in Eq. (2).

As defined in Sect. 2.1, $\lambda$ measures the level of noise in the training data in GPR. Thus, if the training data is noise free, $\lambda$ can be safely set to zero or a value extremely close to zero (e.g., $1 \times 10^{-10}$) to reach optimal performance. This is generally true for datasets obtained by typical quantum chemical calculations, and the resulting training error is (almost) zero. Whenever there is noise in the data (e.g., from experimental measurements), the best $\lambda$ corresponds to some finite value depending on the noise level. The same holds for the training error. In terms of KRR, $\lambda$ seems to have a completely different meaning at first glance: the regularization parameter determining the complexity of the model. In essence, they amount to the same, i.e., a minute or zero $\lambda$ corresponds to the perfectly interpolating model which connects every single point in the training data, thus representing the most faithful model for the specific problem at hand. One potential risk is poor generalization to new input data (test data), as there could be "overfitting" scenarios for training sets. A finite $\lambda$ assumes some noise in the training data, and the model can only account for this in an averaged way; thus the model complexity is simplified to some extend by

lowering the magnitude of parameters $\mathbf{w}$ so as to minimize the cost function $C(\mathbf{w})$. Meanwhile, some finite training error is introduced. To recap, the balance between SSE and regularization is vital and reflected by a proper choice of $\lambda$.

Unlike $\lambda$, the optimal value of $\sigma$ ($\sigma_{\text{opt}}$) is more dataset specific. Roughly speaking, it is a measure of the diversity of the dataset and controls the similarity (covariance matrix element) of two systems. Typically $\sigma_{\text{opt}}$ gets larger when the training data expands into a larger domain. The meaning of $\sigma$ can be elaborated by considering two extremes: (1) when $\sigma$ approaches zero, the training data will be reproduced exactly, i.e., $c_i = y_i$, with high error for test data, i.e., with deviation to mean, and (2) when $\sigma$ is infinity, all kernel matrix elements will tend toward one, i.e., a singular matrix, resulting in large errors in both training and test. Thus, the optimal $\sigma$ can be interpreted as a coordinate scaling factor to render the kernel matrix well-conditioned. For example, Ramakrishnan and von Lilienfeld (2015) selected the lower bound of the kernel matrix elements to be 0.5. For a Gaussian kernel, this implies that $K_{\text{min}} = \exp\left(-D_{\text{max}}^2/2\sigma_{\text{opt}}^2\right) \approx 0.5$, or $\sigma_{\text{opt}} \approx D_{\text{max}}/\sqrt{2\ln 2}$, where $D_{\text{max}}$ is the largest distance matrix element of the training data. Following the same reasoning, $\sigma_{\text{opt}}$ can be set to $D_{\text{max}}/\ln 2$ for a Laplacian kernel.

The above heuristics are very helpful to quickly identify reasonable initial guesses for hyper-parameters for a new dataset. Subsequently, the optimal values of the hyper-parameters should be fine-tuned through $k$-fold cross-validation (CV). The idea is to first split the training set into $k$ smaller sets, and (1) for each of the $k$ subsets, a model is trained using the remaining $k-1$ subsets as training data; the resulting model is tested on the remaining part of the data to calculate the predictive error); this step yields $k$ predictions, one for each fold. (2) The overall error reported by $k$-fold cross-validation is then the average of the above $k$ values. The optimal parameters will correspond to the ones minimizing the overall error. This approach can become computationally demanding when $k$ and the training set size are large. But it is of major advantage in problem such as inverse inference where the number of samples is very small, and its systematic applications minimize the likelihood of statistical artifacts.

## 2.4   Learning Curves

To assess the predictive performance of a ML model, we need to know not only the prediction error ($\varepsilon$, which can be characterized by the mean absolute error (MAE) or root mean squared error (RMSE) of prediction) for a specific training set but also predictive errors for varied sizes of training sets. Therefore, we can monitor how much progress we have achieved after some incremental changes to the training set size ($N$) so as to extrapolate to see how much more training data is needed to reach a desirable accuracy. The plot of $\varepsilon$ versus $N$ relationship is called the learning curve (LC), and examples are shown in Fig. 1 (note that only test error, i.e., MAE for the prediction of new data in test set, is shown; training errors are always zero or minute for noise-free training data).

**Fig. 1** Three representative learning curves with distinguished relative performance
Multiple factors control the shape of learning curve, one of which is the choice of representation. If the representation cannot uniquely encode the molecule, i.e., there may exist cases that two different molecules share the same input vector $\mathbf{x}_i$ but with different molecular properties, then it causes ambiguity to the ML algorithm (see more details in Sect. 4.1) and may consequently lead to no learning at all, as illustrated by the dashed curve in Fig. 1, with distinguishable flattening out behavior at larger training set sizes, resulting in poor ML performance.

In the case of a unique representation, according to Fasshauer and McCourt (2016), it can be proved that for kernel-based approximation, when the training set size $N$ is sufficiently large, the predictive error is proportional to the so-called "fill distance" or *mesh norm* $h_{\mathbf{X}}$, defined as

$$h_{\mathbf{X}} = \sup_{\mathbf{x} \in \Omega} \min_{\mathbf{x}_j \in \mathbf{X}} ||\mathbf{x} - \mathbf{x}_j||_2 \tag{22}$$

where "sup" stands for the supremum (or the least upper bound) of a subset, $\mathbf{x}$ is again the representation of any training instance as an element of the training set $\mathbf{X}$, and $\Omega$ represents the domain of studied systems (i.e., potential energy surface domain for chemistry problems). Clearly from the definition, fill distance describes the geometric relation of the set $\mathbf{X}$ to the domain $\Omega$ and quantifies how densely $\mathbf{X}$ covers $\Omega$. Furthermore, fill distance intrinsically contains a dimension dependence $d$, that is, $h_{\mathbf{X}}$ scales roughly as $N^{-1/d}$ if $\mathbf{x}$ are uniform or random grid points in a $d$ dimensional space.

Apart from the exponent, there should also be a prefactor; thus the leading term of the overall predictive error can be described as $b * N^{-a/d}$, where $a$ in the exponent is a constant. Therefore, to visualize the error vs. $N$, a log-log scale is the most convenient for which the learning curve can be represented by a linear

relationship: $\log(\varepsilon) \approx \log(b) - \frac{a}{d} \log(N)$; thus $a/d$ quantifies the rate of learning, while the prefactor $\log(b)$ is the vertical offset of the learning curve. Through a series of numerical calculations of learning a 1D Gaussian function as well as ground state properties of molecules with steadily improving physics encoded in the representation, it has been found (Huang and von Lilienfeld 2016) that the offset $\log(b)$ is a measure of target property similarity, which is defined as the deviation of proposed model (corresponding to the representation used) from the true model (Huang and von Lilienfeld 2016). While, in general, we do not know the true function (machine learning would be meaningless if we did), we often do have considerable knowledge about relative target similarity of different representations.

Applying the findings above to chemistry problems, we can thus obtain some insight in how learning curves will behave. Several observations can be explained: First, the learning rate would be almost a constant or changes very little when different unique representations are used, as the rate depends primarily on the domain spanned by molecules considered in the potential energy surface. Secondly, for a series of isomers, it is much easier to learn their properties in their relaxed equilibrium state than in a distorted geometry.

The limitation that the learning rate will not change much for random sampling with unique representations seems to be a big obstacle toward more efficient ML predictions, meaning that developing better representation (to lower the offset) can become very difficult even if substantial effort has been invested. However, is it possible to break this curse, reaching an improved learning curve as illustrated by the pink line in Fig. 1? We believe that this should be possible. Note how the linear (log-log) learning curve is obtained for *statistical* models. This implies that there must be "redundancy" in the training data; and if we were able to remove those redundancies a priori, we might very be able to boost the performance and observe superior LCs, such as the pink line in Fig. 1 with large learning rates. In such a case, statistics is unlikely to hold, and the LC may be just a monotonically decreasing function, possibly also just a damped oscillator, rather than a line. Strategies for rational sampling will be elaborated in detail in Sect. 5.

## 3   Multilevel Learning

By default, we assume for each $\mathbf{x}_i \in \mathbf{X}$, there exists one corresponding $y_i \in Y$ in the training examples. It makes perfect sense if $Y$ is easy to compute, i.e., in the circumstance that a relatively low accuracy of $Y$ suffices (e.g., PBE with a medium-sized basis set). It is also possible that a highly accurate reference data is required (e.g., CCSD(T) calculations with a large basis set) so as to achieve highly reliable predictions. Unfortunately, we can only afford few highly accurate $\mathbf{x}$ and $y$'s for training considering the great computational burden. In this situation, one can take great advantage of the $y$'s with lower levels of accuracy which are much easier to obtain. Models which shine in this kind of scenario are called multi-fidelity, where reference data based on a high (low) level of theory is said to have high (low) fidelity.

The nature of this approach is to explore and exploit the inherent correlation among datasets with different fidelities. Here we employ Gaussian process as introduced in Sect. 2 to explain the main concepts and mathematical structure of multilevel learning.

### 3.1 Multi-fidelity

For the sake of clarity and simplicity, we focus only on two levels of fidelity, the mathematical formulation stated below can be easily generalized to more fidelities. We consider two datasets with different level of fidelity: $\{\mathbf{X}, \mathbf{y}^{(1)}\}$ (in which the pairs of data are $(\mathbf{x}_1, y_1^{(1)})$, $(\mathbf{x}_2, y_2^{(1)})$, $\dots$) and $\{\mathbf{X}, \mathbf{y}^{(2)}\}$, where $\mathbf{y}^{(2)}$ has a higher level of fidelity. The number of data points in the two sets is, respectively, $N_1$ and $N_2$ and $N_1 > N_2$, reflecting the fact that high-fidelity data are scarce. We consider the following autoregressive model proposed by Kennedy and O'Hagan (2000):

$$\mathbf{y}^{(2)} = \rho \mathbf{y}^{(1)} + \delta^{(2)} \tag{23}$$

where $\mathbf{y}^{(1)}$ and $\delta^{(2)}$ are two independent Gaussian processes, i.e.,

$$\mathbf{y}^{(1)} \sim \mathcal{N}(0, K_1(\mathbf{X}, \mathbf{X})) = \mathcal{N}(0, \text{Cov}(\mathbf{y}^{(1)}, \mathbf{y}^{(1)})) = \mathcal{N}(0, K_1) \tag{24}$$

$$\delta^{(2)} \sim \mathcal{N}(0, K_2(\mathbf{X}, \mathbf{X}) = \mathcal{N}(0, \text{Cov}(\delta^{(2)}, \delta^{(2)})) = \mathcal{N}(0, K_2). \tag{25}$$

That $\mathbf{y}^{(1)}$ and $\delta^{(2)}$ are independent (notated as $\mathbf{y}^{(1)} \perp \delta^{(2)}$) indicates that the mean of $\mathbf{y}^{(1)}\delta^{(2)}$ satisfies $\mathbf{E}[\mathbf{y}^{(1)}\delta^{(2)}] = \mathbf{E}[\mathbf{y}^{(1)}]\mathbf{E}[\delta^{(2)}]$, and thus the covariance between $\mathbf{y}^{(1)}$ and $\delta^{(2)}$ is zero, i.e., $\text{Cov}(\mathbf{y}^{(1)}, \delta^{(2)}) = \mathbf{E}[\mathbf{y}^{(1)}\delta^{(2)}] - \mathbf{E}[\mathbf{y}^{(1)}]\mathbf{E}[\delta^{(2)}] = 0$. Therefore, $\mathbf{y}^{(2)}$ is also a Gaussian process with mean 0 and covariance:

$$\text{Cov}(\mathbf{y}^{(2)}, \mathbf{y}^{(2)}) = K_{22} = \text{Cov}(\rho \mathbf{y}^{(1)} + \delta^{(2)}, \rho \mathbf{y}^{(1)} + \delta^{(2)}) \tag{26}$$

$$= \rho^2 \text{Cov}(\mathbf{y}^{(1)}, \mathbf{y}^{(1)}) + \text{Cov}(\delta^{(2)}, \delta^{(2)}) = \rho^2 K_1 + K_2 \tag{27}$$

that is, $\mathbf{y}^{(2)} \sim \mathcal{N}(0, \rho^2 K_1 + K_2)$.

The most important term in multi-fidelity theory is the covariance between $\mathbf{y}^{(1)}$ and $\mathbf{y}^{(2)}$, which represents the inherent correlation between datasets with different levels of fidelity and is derived as $\text{Cov}(\mathbf{y}^{(1)}, \mathbf{y}^{(2)}) = K_{12} = \rho \text{Cov}(\mathbf{X}, \mathbf{X}) = \rho K_1$ due to the same independence restriction. Now the multi-fidelity structure can be written in the following compact form of a multivariate Gaussian process:

$$\begin{pmatrix} \mathbf{y}^{(1)} \\ \mathbf{y}^{(2)} \end{pmatrix} \sim \mathcal{N}\left(0, \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix}\right), \tag{28}$$

where $K_{11} = K_1$, $K_{22} \neq K_2$, $K_{12} = K_{21}$ due to symmetry. The importance of $\rho$ is quite evident from the term $K_{12}$; specifically, when $\rho = 0$, the high-fidelity and

low-fidelity models are completely decoupled, and there will be no improvements of the prediction at all by combining the two models.

The next step is to make prediction of $\mathbf{y}_*^{(2)}$ given the corresponding input vector $\mathbf{x}_*$, two levels of training data $\{\mathbf{X}, \mathbf{y}^{(1)}\}$ and $\{\mathbf{X}, \mathbf{y}^{(2)}\}$. To this end, we first write down the following joint density:

$$
\begin{pmatrix} \mathbf{y}_*^{(2)} \\ \mathbf{y}^{(1)} \\ \mathbf{y}^{(2)} \end{pmatrix} \sim \mathcal{N}\left( 0, \begin{pmatrix} K_{**} & K_{*1} & K_{*2} \\ K_{1*} & K_{11} & K_{22} \\ K_{2*} & K_{21} & K_{22} \end{pmatrix} \right),
\tag{29}
$$

where $K_{**} = \rho^2 K_1^* + K_2^*$, $K_{*1} = \rho K_1^*$ with $K_1^* = K_1(\mathbf{X}_*, \mathbf{X}_*) = \mathrm{Cov}(\mathbf{y}_*^{(1)}, \mathbf{y}_*^{(1)})$ and $K_2^* = K_2(\mathbf{X}_*, \mathbf{X}_*) = \mathrm{Cov}(\delta_*^{(2)}, \delta_*^{(2)})$; then following similar procedures as in Sect. 2.1, the final predictive distribution of $\mathbf{y}_*^{(2)}|\mathbf{X}_*, \mathbf{X}, \mathbf{y}^{(1)}, \mathbf{y}^{(2)}$ is again a Gaussian $\mathcal{N}(\bar{\mathbf{y}}_*^{(2)}, \mathrm{Var})$, where

$$
\bar{\mathbf{y}}_*^{(2)} = K_* K^{-1} Y, \ \ \mathrm{Var} = K_* K_*^\top - K_* K^{-1} K_*^\top,
\tag{30}
$$

$$
Y = \begin{pmatrix} \mathbf{y}^{(1)} \\ \mathbf{y}^{(2)} \end{pmatrix}, \ \ K_* = \begin{pmatrix} K_{*1} & K_{*2} \end{pmatrix}, \ \ K = \begin{pmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \end{pmatrix}.
\tag{31}
$$

We note in passing that since there are two correlation functions $K_1$ and $K_2$, two sets of hyper-parameters regarding the kernel width and an extra scaling parameter $\rho$ have to be optimized following the similar approach as explained in Sect. 2.4. This algorithm has already successfully been applied to the prediction of band gaps of elpasolite compounds with high accuracy (Pilania et al. 2017). But it can be naturally extended to other properties. So far, not much work has been done using this algorithm; its potential to tackle complicated chemical problems has yet to be unraveled by future work.

## 3.2   Δ-Machine Learning

A naive version of multi-fidelity learning is the so-called $\Delta$-machine learning model. Its performance is useful for the prediction of various molecular properties (Ramakrishnan et al. 2015a). In this model, $N_1$ is equal to $N_2$, the low- and high-fidelity models are, respectively, called baseline and target. The baseline property $(y^{(b)})$ is associated with baseline geometry as encoded in its representation $(\mathbf{x}^{(b)})$, and target property $y^{(t)}$ is associated with target geometry $\mathbf{x}^{(t)}$, respectively. The workhorse of this model is

$$
y_*^{(t)} = y_*^{(b)} + \sum_{i=1}^{N} c_i k(\mathbf{x}_*^{(b)}, \mathbf{x}_i^{(b)})
\tag{32}
$$

Note that we did not use the target geometry at all for the reason that (1) it is expensive to calculate and (2) it is not necessary for the test molecules.

The $\Delta$-ML model has been shown to be capable of yielding highly accurate results for energies if a proper baseline model is used. Other properties can also be predicted with much higher precision compared to traditional single fidelity model (Ramakrishnan et al. 2015a). What is more, this approach can save substantial computational time. However, the $\Delta$-machine learning model is not fully consistent with the multi-fidelity model. The closest scenario is that we set $K_1 = K_2$ when evaluating kernel functions in Eq. (31), but this will result in something still quite different. There are further issues one would like to resolve, including that (i) the coupling between different fidelities is not clear and that the correlation is rather naively accounted for through the $\Delta$ of the properties from two levels, assuming a smooth transition from one property surface (e.g., potential energy surface) from one level of theory to another. This is questionable and may fail terribly in some cases; (ii) it requires the same amount of data for both levels, which can be circumvented by building recursive versions.

## 4 Representation

The problem of how to represent a molecule or material has been a topic dating back to many decades ago, and the wealth of information (and opinions) about this subject is well manifested by the collection of descriptors compiled in Todeschini and Consonni's Handbook of molecular descriptors (Todeschini and Consonni 2008). According to these authors, the molecular descriptor is defined as "the final result of a logic and mathematical procedure which transforms chemical information encoded within a symbolic representation of a molecule into a useful number or the result of some standardized experiment." While the majority of these descriptors are graph-based and used for quantitative structure and activity relationships (QSAR) applications (typically producing rather rough correlation between properties and descriptor), our focus is on QML models, i.e., physics-based, systematic, and universal predictions of well-defined quantum-mechanical observables, such as the energy von Lilienfeld (2018). Thus, to better distinguish the methods reviewed here-within from QSAR, we prefer to use the term "representation" rather than "molecular descriptor." Quantum mechanics offers a very specific recipe in this regard: A chemical system is defined by its Hamiltonian which is obtained from elemental composition, geometry, and electron number exclusively. As such, it is straightforward to define the necessary ingredients for a representation: It should be some vector (or fingerprint) which encodes the compositional and structural information of a given neutral compound.

### 4.1 The Essentials of a Good Representation

There are countless ways to encode a compound into a vector, but what representation can be regarded as "good"? Practically, a good representation should lead to

a decent learning curve, i.e., error steadily decreases as a function of training set size. Conceptually, it should fulfill several criteria, including primarily uniqueness (non-ambiguity), compactness, and being size-extensive (von Lilienfeld et al. 2015).

Uniqueness (or being nonambiguous) is indispensable for ML models. We consider a representation to be unique if there is no pair of molecules that produces the same representation. Lack of uniqueness would result in serious consequences, such as ceasing to learn at an early stage or no learning at all from the very beginning. The underlying origin is not hard to comprehend. Consider two representation vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ for two compounds associated with their respective properties $y_1$ and $y_2$. Now suppose $\mathbf{x}_1 = \mathbf{x}_2$ while $y_1 \neq y_2$ (no degeneracy is assumed). One extreme case is that only these two points are used when training the ML model; obviously we will encounter a singular kernel matrix with all elements being 1; huge prediction errors will result, and basically there is no learning. Even if molecules like these are not chosen for training, it should be clear that such a representation introduces a severe and systematic bias. Furthermore, when trying to predict $y_1$ and $y_2$ after training, the estimate will be the same as the input to the machine is the same. The resulting test error is therefore directly proportional to their property difference.

The compactness requires atom index permutation and rotational and translational invariance, i.e., all redundant degrees of freedom of the system should be removed as much as possible while retaining the uniqueness. This can lead to a more robust representation, meaning (1) the size of training set needed may be significantly reduced and (2) the dimension of the representation vector (thus the size) is minimized, a virtue which becomes important when the necessary training set size becomes large.

Being size-extensive is crucial for prediction of extensive properties, among which the most important is the energy. This leads to the so-called atomic representation or local representation of an atom in a compound. The local unit atom can also consist of bonds, functional groups, or even larger fragments of the compound. As pointed out in Sect. 2.2, this type of representation is the crucial stepping stone for building scalable machine learning models. Even intensive properties such as HOMO-LUMO gap, which typically do not scale with system size, can be modeled within the framework of atomic representations, as illustrated using the Re-Match metric (De et al. 2016). For specific problems, such as force predictions, an analytic form of representation is desirable for analysis and rapid evaluation and for subsequent differentiation (with respect to nuclear charges and coordinates) so as to account for response properties.

## 4.2   Rational Design

It is not obvious how to obtain an optimal representation. In order to obtain a good representation, one has to gain intensive knowledge about the system and structure-property relationship. The use of simplified approximations to solutions of Schrödinger's equation is particularly powerful. The most approximative, yet atomistic, models of SE are universal force fields (FF) which typically reproduce the essential physics for certain system classes, such as bioorganic molecules,

reasonably well. Namely, the atom-pairwise two-body interactions in force fields typically decay as $1/R^n$ ($R$ being the internuclear distance and $n$ being some integer), while 3- and 4-body parts behave as periodic functions of angle and dihedral angle (modern force field approaches also include 2- to $(n-1)$-body interaction in $n$-body interactions). FFs are essentially a special case of the more general many-body expansion (MBE) in interatomic contributions, i.e., an extensive property of the system (e.g., total energy) is expanded in a series of many-body terms, namely, 1-, 2- and 3-body terms, $\cdots$, i.e.,

$$E(\{\mathbf{R}_I\}) = \sum_I^{[Z]} E^{(1)}(R_I) + \sum_{J>I}^{[Z]} E^{(2)}(R_{IJ}) + \sum_{K>J>I}^{[Z]} E^{(3)}(R_{IJ}, R_{IK}, \theta_{IJK}) + \cdots$$

(33)

where $E^{(n)}$ is the $n$-body interaction energy, $R_{IJ}$ is the interatomic distance between atom $I$ and $J$, and $\theta_{IJK}$ is the angle spanned by two vectors $\mathbf{R}_{IJ}$ and $\mathbf{R}_{IK}$. Other important properties can also be expressed in a similar fashion.

By utilizing the basic variables in MBE, including distance, angles, and dihedral angles in their correct physics-based functional form (e.g., the aforementioned $1/R^n$ dependence of 2-body interaction strength), one can already build some highly efficient representations such as BAML and SLATM (*vide infra*). This recipe relies heavily on preconceived knowledge about the physical nature of the problem.

## 4.3 Numerical Optimization

It is possible that for some systems and properties, one does not know which features are of primary importance. And it is not an option to try all features one-by-one considering that there are so many possibilities. In such a situation, the least absolute shrinkage and selection operator (LASSO) can offer suitable relief. LASSO is basically a regression analysis method. Consider a simple linear model: the property of a system is a linear functions of its features, i.e., $\mathbf{y} = \mathbf{X}\mathbf{c}$, where $\mathbf{X}$ is a matrix with each of the $N$ rows being the descriptor vector $\mathbf{x}_i$ of length $D$ for each training data points, $\mathbf{c}$ is the $D$-dimensional vector of coefficients, and $\mathbf{y}$ is the vector of training properties with the $i$-th property being $y_i$. Our task is to find the tuple of features that yields the smallest sum of squared error: $||\mathbf{y} - \mathbf{X}\mathbf{c}||_2^2$. Within LASSO, it is equivalent to a convex optimization problem, i.e.,

$$\underset{\mathbf{c} \in \mathbb{R}^D}{\operatorname{argmin}} ||\mathbf{y} - \mathbf{X}\mathbf{c}||_2^2 + \lambda ||\mathbf{c}||_1$$

(34)

where the use of $L_1$ norm of regularization term is pivotal, i.e., smaller $L_1$ norm can be obtained when larger $\lambda$ is used, thereby purging features of lesser importance. This approach has been exemplified for the prediction of relative crystal phase stabilities (rock-salt vs. zinc-blende) in a series of binary solids (Ghiringhelli et al. 2015). Unfortunately, this approach is limited in that it works best for rather low-

dimensional problems. Already for typical organic molecules, the problem becomes rapidly intractable due to coupling of different degrees of freedom. Under such circumstances, it appears to be more effective to adhere to the aforementioned rational design based heuristics, as manifested by the fact that almost all of the ad hoc representations in the literature are based on manual encoding.

## 4.4   An Overview of Selected Representations

Over the years, numerous molecular representations have been developed by several research groups working on QML. It's not our focus to enumerate all of them but to list and categorize the popular ones. Two categories are proposed; one is based on many-body expansions in vectorial or tensorial form, such as Coulomb matrix (CM), Bag of Bonds (BoB), Bond, Angle-based Machine Learning (BAML), Spectrum of London and Axilrod-Teller-Muto potential (SLATM), and the alchemical and structural radial distribution-based representation introduced by Faber, Christensen, Huang, and von Lilienfeld (FCHL). The other category is an electron density model-based representation called smooth overlap of atomic positions (SOAP).

### 4.4.1   Many-Body Potential-Based Representation

The Coulomb matrix (CM) representation was first proposed in the seminal paper by Rupp et al. (2012). It is a square atom-by-atom matrix with off diagonal elements corresponding to the nuclear Coulomb repulsion between atoms, i.e., $CM_{IJ} = Z_I Z_J / R_{IJ}$ for atom index $I \neq J$. Diagonal elements approximate the electronic potential energy of the free atom, which is encoded as $-0.5 Z_I^{2.4}$. To enforce invariance of atom indexing, one can sort the atom numbering such that the sum of $L_2$ and $L_1$ norm of each row of the Coulomb matrix descends monotonically in magnitude. Symmetrical atoms will result in the same magnitude. A slight improvement over the original CM can be achieved by varying the power low of $R_{IJ}$ (Huang and von Lilienfeld 2016). Best performance is found for an exponent of 6, reminiscent of the leading order term in the dissociative tail of London dispersion interactions. Thus, the resulting representation is also known as London matrix (LM). The superiority of LM is attributed to a more realistic trade-off between the description of more localized covalent bonding and long-range intramolecular non-covalent interactions (Huang and von Lilienfeld 2016).

In spite of the great virtue of uniqueness encoded in CM, it generally suffers from a high offset of learning curve (see Fig. 3). In contrast, the bag-of-bond (BoB) representation (Hansen et al. 2015), a bagged (vectorial) stripped down version of the CM, turns out to result in learning curves with lower offset than CM (see Fig. 3). The BoB representation is a 1-D array, constructed as the concatenation of a series of bags (1-D arrays as well); each corresponds to a specific type of atomic pair, e.g., all C-O pairs (covalently and non-covalently bonded) in the molecule are grouped into the bag labeled as CO, similarly for all other combinations of elemental pairs. Each bag thus includes a set of nuclear Coulomb repulsion values. Each bag is then sorted in descending order. In cases that the same type of bag for two molecules has not the
**Fig. 2** Two-body interaction is not enough to capture the physics of a pair of homometric molecules. In the figure, the energy of the two molecules is approximated as summation of LJ potentials with (dashed lines) or without three-body ATM potentials (solid line) and plotted as a function of $f$, the scaling factor of all coordinates of the two molecules. LJ and ATM stand for Lennard-Jones and Axilrod-Teller-Muto vdW potential, respectively. The letters $s$ and $l$ label the two existing different bond lengths, standing for "short" and "long." The atom represented by a yellow-filled circle with cross means out of plane

same size, the smaller bag is padded with zeros. Through bagging the performance is improved in comparison to the CM matrix. But inevitably, crucial higher-order information, such as the angular part, is missing. Due to its exclusive reliance on sorted two-body terms, BoB is not a unique representation, as also manifested by the deterioration of its slope in the learning curve for large training set sizes (see Fig. 3). This loss of information can also be illustrated for a pair of homometric molecules (same atom types, same set of interatomic distances) as displayed in Fig. 2. If we make a plot of the potential energy (approximated as a sum of Lennard-Jones potentials) curve of both planar and tetrahedral molecules as a function of the scaling factor $f$ of all coordinates, we will end up with the same curve due to a spurious degeneracy imposed by lack of uniqueness. The BoB representation would not distinguish between these two molecules. Only after addition of higher-order many-body potential terms (e.g., the 3-body Axilrod-Teller-Muto potential), the spurious degeneracy is lifted.

Based on this simple example, an important lesson learned is that collective effects which go beyond pairwise potentials are of vital importance for the accurate modeling of fundamental properties such as energies. While adhering to the ideas of bagging for efficiency, a representation consisting of extended bags can be constructed; each may contain interatomic interaction potentials up to three- and four-body terms. BAML was formulated in this way, where (1) all pairwise nuclear
**Fig. 3** Comparison of the learning curves for different representations for three typical datasets (QM7b (Rupp et al. 2012), QM9 (Ramakrishnan et al. 2014; Ruddigkeit et al. 2012), and 6k isomers from QM9). Note that the size and composition for molecules in all the three datasets are comparable, i.e., the dimensionality $d$'s of these systems is similar; hence almost the same learning rates are observed for all representations with no (or less) suffer from uniqueness issue. For QM7b dataset, a much lower offset is shown as the relevant molecules are much more relaxed than those in QM9 and 6k isomers; thus given any representation, its target similarity is larger for this dataset compared to others

repulsions are replaced by Morse/Lennard-Jones potentials for bonded/nonbonded atoms, respectively, and (2) the inclusion of three- and four-body interactions of covalently bonded atoms is achieved using periodic angular and torsional terms, with their functional form and parameters extracted from the universal force field (UFF) (Huang and von Lilienfeld 2016; Rappe et al. 1992). BAML achieves a noticeable boost of performance when compared to BoB or CM. Interestingly, the performance is systematically improving upon inclusion of higher and higher-order many-body terms, as the proposed energy model is getting more and more realistic, i.e., increasing similarity to target. Meanwhile and not surprisingly, the uniqueness issue, existing in two-body representations such as BoB, is also resolved (see Fig. 3). The main drawback of BAML, however, is that it requires pre-existing force fields, implying a severe bias when it comes to new elements or bonding scenarios. It would therefore be desirable to identify a representation which is more compact and ab initio in nature.

The so-called SLATM representation (Huang and von Lilienfeld 2017) enjoys all these attributes. It has two variants: a local and a global one. The basic idea of SLATM is to represent an atom indexed $I$ in a molecule by accounting for all possible interactions between atom $I$ and its neighboring atoms through many-body potential terms multiplied by a normalized Gaussian distribution centered on the

relevant variable (distance or angle). So far, one-, two-, and three-body terms have been considered. The one-body term is simply represented by the nuclear charge, while the two-body part is expressed as

$$\frac{1}{2}Z_I \sum_{J \neq I} Z_J \delta(\mathbf{r} - \mathbf{R}_{IJ}) g(\mathbf{r}) \tag{35}$$

where $\delta(\cdot)$ is set to normalized Gaussian function $\delta(x) = \frac{1}{\sigma\sqrt{2\pi}}e^{-x^2}$ and $g(r)$ is a distance-dependent scaling function, capturing the locality of chemical bond and chosen to correspond to the leading order term in the dissociative tail of the London potential $g(R) = \frac{1}{R^6}$. The three-body distribution reads

$$\frac{1}{3}Z_I \sum_{J \neq K \neq I} Z_J Z_K \delta(\theta - \theta_{IJK}) h(\theta, \mathbf{R}_{IJ}, \mathbf{R}_{IK}) \tag{36}$$

where $\theta$ is the angle spanned by vector $\mathbf{R}_{IJ}$ and $\mathbf{R}_{IK}$ (i.e.,$\theta_{IJK}$) and treated as a variable. $h(\theta, \mathbf{R}_{IJ}, \mathbf{R}_{IK})$ is the three-body contribution depending on both internuclear distance and angle and is chosen in form to model the Axilrod and Teller (1943) and Muto (1943) vdW potential:

$$h(\theta, \mathbf{R}_{IJ}, \mathbf{R}_{IK}) = \frac{1 + \cos\theta \cos\theta_{JKI} \cos\theta_{KIJ}}{(R_{IJ} R_{IK} R_{KJ})^3} \tag{37}$$

Now we can build the atomic version aSLATM for an atom $I$ through concatenation of all the different many-body potential spectra involving atom $I$ as displayed in Eqs. (35) and (36). As for the global version SLATM, it simply corresponds to the sum of the atomic spectra.

SLATM and aSLATM outperforms all other representations discussed so far, as evidenced by learning curves shown in Fig. 3. This outstanding performance is due to several aspects: (1) almost all the essential physics in the systems is covered, including the locality of chemical bonds as well as many-body dispersion; (2) the inclusion of 3-body terms significantly improves the learning; and (3) the spectral distribution of radial and angular feature now circumvents the problem of sorting within each feature bag, allowing for a more precise match of atomic environments.

Most recently, the FCHL representation has been introduced (Faber et al. 2018). It amounts to a radial distribution in elemental and structural degrees of freedom. The configurational degrees of freedom are expanded up to three-body interactions. Four-body interactions were tested but did not result in any additional improvements. For known datasets, FCHL-based QML models reach unprecedented predictive power and even outperform aSLATM and SOAP (see below). In the case of the QM9 dataset, for example, FCHL-based models of atomization energies reach chemical accuracy after training on merely ~1'000 molecules.

### 4.4.2  Density Expansion-Based Representation

Within the smooth overlap of atomic positions (SOAP) (Bartók et al. 2013) idea of a representation, an atom $I$ in a molecule is represented as the local density of atoms around $I$. Specifically, it is represented by a sum of Gaussian functions with variance $\sigma^2$ within the environment (including the central atom $I$ and its neighboring atoms $Q$'s), with the Gaussian functions centered on $Q$'s and $I$:

$$\rho_I(\mathbf{r}) = \sum_Q \exp\left(-\frac{(\mathbf{r} - \mathbf{R}_Q)^2}{2\sigma^2}\right) \tag{38}$$

where $\mathbf{r}$ is the vector from the central atom $I$ to any point in space, while $\mathbf{R}_Q$ is the vector from atom $I$ to its neighbor $Q$. The overlap of $\rho_I$ and $\rho_J$ then can be used to calculate a similarity between atoms $I$ and $J$. However, this similarity is not rotationally invariant. To overcome this, we can integrate out the rotational degrees of freedom for all three-dimensional rotations $\hat{R}$, and thus the SOAP kernel is defined:

$$\tilde{k}(I, J) = \int d\hat{R} \left| \int d\mathbf{r} \rho_I(\mathbf{r}) \rho_J(\hat{R}\mathbf{r}) \right|^2, \tag{39}$$

To enforce the self-similarity to be normalized, the final SOAP similarity measure takes the form of

$$k(I, J) = \frac{\tilde{k}(I, J)}{\sqrt{\tilde{k}(I, I)\tilde{k}(J, J)}} \tag{40}$$

The integration in Eq. (39) can be carried out by first expanding $\rho_I(\mathbf{r})$ in Eq. (38) in terms of a set of basis functions composed of orthogonal radial functions and spherical harmonics and then collecting the elements in the rotationally invariant power spectrum, based on which $k$ can be easily calculated. The interested reader is referred to Bartók et al. (2013).

SOAP has been used extensively and successfully to model systems such as silicon bulk or water clusters, each separately with many configurations. These elemental or binary systems are relatively simple as the diversity of chemistries encoded by the atomic environments is rather limited. A direct application of SOAP to molecules where there are substantially more possible atomic environments, however, yields learning curves with rather large offsets. This is not such a surprise, as essentially the capability of atomic densities to differentiate between different atom pairs, atom triples, and so on is not so great. This shortcoming remains even if one treats different atom pairs as different variables, as was adopted in De et al. (2016); averaging out all rotational degrees of freedom might also impede the learning progress due to loss of relevant information. To amend some of these problems, a special kernel, the RE-Match kernel (De et al. 2016), was

introduced. And most recently, combining SOAP with a multi-kernel expansion enabled additional improvements in predictive power (Bartók et al. 2017).

## 5     Training Set Selection

The last section of this chapter deals with the question of how to select training sets. The selection procedure can have a severe effect on the performance. The predictive accuracy appears to be very sensitive on how we sample the training molecules for any given representation (or better ones). Training set selection can actually be divided into two parts: (1) How to create training set. The general principle is that the training set should be representative, i.e., it follows the same distribution as all possible test molecules in terms of input and output. This will formally prevent extrapolation and thereby minimize prediction errors. (2) How to optimize the training set composition.

The majority of algorithms in literature deal with (2) assuming the existence of some large dataset (or a dataset trivial to generate) from which one can draw using algorithms such as ensemble learning, genetic evolution, or other "active learning"-based procedures (Podryabinkin and Shapeev 2017). All of these methods have in common that they select the training set from a given set of configurations based only on the unlabeled data. This is particularly useful for "learning on the fly"-based ab initio molecular dynamics simulations Csányi et al. (2004), where expensive quantum-mechanical calculation is carried out only when the configurations are sufficiently "new."

Step 1 stands out as a challenging task and few algorithms are competent. The most ideal approach is of course an algorithm that can do both parts within one step; the only competent method we know is the "amons" approach. We will elaborate on all these concepts below.

## 5.1     Genetic Optimization

To the best of our knowledge, the first application of a GA for generation and study of optimal training set compositions for QML model was published in Browning et al. (2017). The central idea of this approach is outlined as follows. For a given set ($S_0$) containing overall $N$ molecules, the GA procedure consists of three consecutive steps to obtain the "near-optimal" subset of molecules from $S_0$ for training the ML model (Browning et al. 2017): (a) Randomly choose $N_1$ molecules as a trial training set $s_1$; repeat $M$ times. This forms a population of training sets, termed the parent population and labeled as $\hat{s}^{(1)} = \{s_1, s_2, \ldots, s_M\}$. (b) An ML model is trained on each $s_i$ and then tested on a fixed set of out-of-sample molecules, resulting in a mean prediction error $e_i$, which is assigned to $s_i$ as a measure of how fit $s_i$ is as the "near-optimal" training set and dubbed "fitness." Therefore, the smaller $e_i$ is, the larger the fitness is. (c) $\hat{s}^{(1)}$ is consecutively evolved through selection (to determine which $s_i$'s in $\hat{s}^{(1)}$ should remain in the population to produce a temporarily refined

smaller set $\hat{t}^{(1)}$; a set $s_i$ with larger fitness means higher probability to be kept in $\hat{t}^{(1)}$), crossover (to update $\hat{s}^{(1)}$ from $\hat{t}^{(1)}$ and the new $\hat{s}$ is labeled as $\hat{s}^{(2)}$ with each set $s_i$ in $\hat{s}^{(2)}$ obtained through mixing the molecules from two $s_i$'s in $\hat{t}^{(1)}$), and mutation (to change molecules in some $s_i$'s in $\hat{s}^{(2)}$ randomly to promote diversity in $\hat{s}^{(2)}$, e.g., replace -$CH_2$- fragment by -NH- for some molecule. (d) Go to step (b) and repeat the process until there is no more change in the population and the fitness ceases to improve . We label the final updated trial training set as $\hat{s}$.

It's obvious that the molecules in $\hat{s}$ should be able to represent all the typical chemistry in all molecules in $S_0$, such as linear, ring, cage-like structure, and typical hybridization states ($sp, sp^2, sp^3$) if they are abundant in $S_0$. Once trained on $\hat{s}$, the ML model is guaranteed to yield typically significantly better results as the fitness is constantly increasing. This is not useful since the GA "tried" this already; the usefulness has to be assessed by the generalizability of $\hat{s}$ as training set to test on a new set of molecules is not seen in $S_0$. Indeed, as shown in Browning et al. (2017), significant improvements in offsets can be obtained when compared to random sampling. While the remaining out-of-sample error is still substantial, this is not surprising due to the use of less advantageous representations. One of the key findings in this study were that upon genetic optimization, (i) the distance distributions between training molecules were shifted outward and (ii) the property distributions of training molecules were fattened.

## 5.2    Amons

We note that the naive application of active learning algorithms will still result in QML models which suffer from lack of transferability, in particular when it comes to the prediction of larger compounds or molecules containing chemistries not present in the training set. Due to the size of chemical compound space, this issue still imposes a severe limitation for the general applicability of QML. These problems can, at least partially, be overcome by exploring and exploiting the locality of an atom in molecule (Huang and von Lilienfeld 2017), resulting from the nearsightedness principle in electronic systems (Prodan and Kohn 2005; Fias et al. 2017).

We consider a valence saturated query molecule for illustration, for which we try to build an "ideal" training set. As is well known, any atom $I$ (let us assume a $sp^3$ hybridized C) in the molecule is characterized by itself and its local chemical environment. To a first-order approximation, we may consider its coordination number ($CN$ for short) to be a distinguishing measure of its atomic environment, and we can roughly say that any other carbon atom with a coordination number of 4 is similar to atom $I$, as their valence hybridization states are all $sp^3$. Another carbon atom with $CN = 3$ in hybridization state of $sp^2$ would be significantly different compared to atom $I$. It is clear, however, that $CN$ as an identifier of atomic environment type is not enough: An $sp^3$ hybridized C atom in methane molecule (hereafter we term it as a genuine C-$sp^3$ environment) is almost purely

**Fig. 4** Comparison of the learning curves obtained for one molecule (see the inset) from random selection of training set and amons, respectively. For each red scatter point, errors were averaged over 100 random samplings
covalently bonded to its neighbors, while in $CH_3OH$, noticeable contributions from ionic configurations appear in the valence bond wavefunction due to the significant electronegativity difference between C and O atoms. Thus one would expect very different atomic properties for the $sp^3$-C atoms in these two environments as manifested, for instance, in their atomic energy, charge, or $^{13}$C-NMR shift. Alternatively, we can say that oxygen as a neighboring atom to $I$ has perturbed the ideal $sp^3$ hybridized C to a much larger extent in $CH_3OH$ than the H atom has in methane. To account for these differences, we can simply include fragments which contain $I$ as well as all its neighbors. Thus we can obtain a set of fragments, for each of which the bond path between $I$ and any other atom is 1.

Extending this kind of reasoning to the second neighbor shell, we can add new atoms with a bond path of 2 relative to atom $I$ in order to account for further, albeit weaker, perturbation to atom $I$. As such, we can gradually increase the size of included fragments (characterized by the number of heavy atoms) until we believe that all effects on atom $I$ have been accommodated. The set of unique fragments can then be used as a training set for a fragment-based QML model. Note that we saturate all fragments by hydrogen atoms. These fragments can be regarded as effective quasi-atoms which are defined as a̲tom in mo̲lecule, or "amon." Since amons repeat throughout chemical space, they can be seen as the "words" of chemistry (target molecules being "sentences") or as "DNA" of chemistry (target molecules being genes and properties their function). Given the complete set of amons, any specific, substantially larger, query molecule can be queried. Used in conjunction with an atomic representation such as aSLATM or FCHL, amons enable a kind of chemical extrapolation which holds great promise to more faithfully and more efficiently explore vast domain chemical space (Huang and von Lilienfeld 2017).

To demonstrate the power of amons, we show the example of predicting the potential energy of a molecule present as an inset in Fig. 4. With amons as the

training set, chemical accuracy (1 kcal/mol) is reached after training on only 40 amons (with amons being not larger than 6 heavy atoms). Sampling amons at random, the slope of the learning curve is substantially worse.

# 6    Conclusion

We have discussed primarily the basic mathematical formulations of all typical ingredients of quantum machine learning (QML) models which can be used in the context of quantum-mechanical training and testing data. We explained and reviewed why ML models can be fast and accurate when predicting quantum-mechanical observables for out-of-sample compounds. It is the authors' opinion that QML can be seen as a very promising approach, enabling the exploration of systems and problems which hitherto were not amenable to traditional computational chemistry methods.

In spite of the significant progress made within the last few years, the field QML is still very much in a stage of infancy. This should be clear when considering that the properties that have been explored so far are rather limited and relatively fundamental. The primary focus has been on ground state or local minimum properties. Application to excited states still remains a challenge (Ramakrishnan et al. 2015b), just as well as conductivity, magnetic properties, or phase transitions. We believe that new and efficient representations will have to be developed which properly account for all the relevant degrees of freedom at hand.

train from linear functionals of the potential energy, such as the total energy and atomic forces. We then give a detailed account of the smooth overlap of atomic position (SOAP) descriptor and kernel, showing how it arises from an abstract representation of smooth atomic densities and how it is related to several popular density-based descriptors of atomic structure. We also discuss recent generalizations that allow fine control of correlations between different atomic species, prediction, and fitting of tensorial properties and also how to construct structural kernels – applicable to comparing entire molecules or periodic systems – that go beyond an additive combination of local environments.

# 1    Introduction

There has been a surge of activity during the last couple of years in applying machine learning methods to materials and molecular modeling problems that was largely fueled by the evident success of these techniques in what can loosely be called artificial intelligence. These successes have followed from the collective experience that the scientific community has gained in fitting high volumes of data with very complex functional forms that involve a large number of free parameters while still keeping control of the regularity and thus avoiding catastrophic over-fitting. In the context of molecular modeling, empirical fitting of potential energy surfaces has of course been used for many decades. Indeed it is generally held that this is the only practical way to simulate very large systems (many thousands of atoms) over long time scales (millions of time steps) (Finnis 2004).

Traditionally, when fitting empirical models of atomic interactions, regularity was ensured by writing functional forms that are expressed in terms of one-dimensional functions, e.g., pair potentials, spherically symmetric atomic electron densities, bond orders (as a function of number of neighbors), etc. Such functions are easy to inspect visually to ensure that they are physically and chemically meaningful, e.g., that pair potentials go to zero at large distances and are strongly repulsive at close approach, that atomic electron densities are decreasing with distance, that electron density embedding functions are convex, etc. Moreover, these natural properties are easy to build into the one-dimensional functional forms or enforced as constraints in the parameter optimization. It is widely held that employing such "physically meaningful" functional forms is the key to achieving good *transferability* of the empirical models (Brenner 2000).

It is also recognized, however, that the limited functional forms that can be built from these one-dimensional functions ultimately limit the accuracy that these empirical models can achieve. In trying to replace them by high-dimensional fits using much more flexible functional forms, two things immediately have to change. The first is the target data. When fitting only a few parameters, it is natural to demand that important observables that are deemed to be central to the scientific questions being addressed are reproduced correctly, and it is easiest to do this if they are part of the fit, e.g., melting points and other phase boundaries, radial distribution functions, etc. But in the case of very many parameters, their optimization also takes a significant

number of evaluations, and it becomes impractical to use complex observables as targets. Moreover, there is a drive toward using a "first principles" approach, i.e., that the potentials should actually reproduce the real Born-Oppenheimer potential energy surface with sufficient accuracy *and therefore* the scientifically relevant observables also. So it is natural to take as target data values of the potential energy surface, as computed by the electronic structure method of choice. The large number of free parameters can then easily be counterbalanced by a large amount of calculated input data.

The second thing that has to change is how the smooth physically meaningful behavior of the potential is controlled. It is not practical to inspect manually high-dimensional functions to ensure that their predictions are physically and chemically meaningful for all possible configurations. Therefore it becomes even more important to build into the functional forms as much prior information as possible about limiting behavior and *regularity* (the technical word for the kind of smoothness we are interested in). Reviewing the recent work, this paper sets out an example framework for how to do this. The key goals are to create functional forms that preserve the (i) invariance of the properties over permutation of like atoms, (ii) invariance of scalar and covariance of tensorial properties with three-dimensional rotations, and (iii) continuity and regularity with respect to changes in atomic coordinates, including compact support of atomic interactions by including finite cutoffs.

Evidence is accumulating showing that enforcing these physically motivated properties strictly is enormously beneficial, and several of the most successful machine learning schemes for atomic-scale systems are built around symmetry arguments. One possible approach is to describe the system in terms of internal coordinates that satisfy automatically rotational invariance and then symmetrize explicitly the vector of descriptors or the functional relation between the descriptors and the properties. Permutationally invariant polynomials are an example that has been very effective to model the potential energy surfaces of small molecules (see, e.g., the work of Braams and Bowman 2009). Sorting the descriptors according to interatomic distances has also been used as a way of obtaining permutation invariance at the cost of introducing derivative discontinuities (Rupp et al. 2012; Faber et al. 2015; Zhang et al. 2018). Another possibility, which we will focus on in this paper, starts from a representation of each structure in terms of atomic densities – which are naturally invariant to atom permutations – and then builds a descriptor that is further invariant to translations and rotations also.

Either way, once an appropriate description of each structure has been obtained, further regularization can be achieved at the level of the regression scheme. To this end, two prominent techniques are the use of artificial neural networks and kernel ridge regression (Bishop 2016). We use the latter formalism here, and many further details about these techniques can be found in the rest of this volume. The kernel approach starts with the definition of a kernel function, which will be combined with a set of representative atomic configurations to construct basis functions for the fit. It is a scalar function – at least when learning scalar quantities – with two input arguments and in the present case two atomic structures. Its value should quantify

the similarity of the atomic configurations represented by its two arguments, and it can (but does not have to) be defined starting from their associated descriptors. The value should be the largest when its two arguments are equal (or equivalent up to symmetry operations) and smallest for maximally different configurations. The degree to which the kernel is able to capture the variation of the function when varying the atomic configuration will determine how efficient the fit is. The better the correspondence, the fewer basis functions that are needed to achieve a given accuracy of fit.

## 2    Kernel Fitting

We start by giving a concise account of the kernel regression fitting approach, for more details see Bishop (2016), Rasmussen and Williams (2006), and Schölkopf and Smola (2002). A function defined on an atomic structure is represented as a linear sum over kernel basis functions,

$$f(\mathcal{A}) = \sum_{\mathcal{B} \in M} x_{\mathcal{B}} K(\mathcal{A}, \mathcal{B}), \tag{1}$$

where the sum runs over a *representative set* of configurations $M$, selected from the total set $N$ of input configurations. The set of coefficients, combined into a vector $\mathbf{x}$, are determined by solving the linear system that is obtained when the available data (e.g., values of the target function evaluated for a set of structures) are substituted into Eq. (1). In the simplest case, there is one input data value corresponding to each atomic configuration. Let $\mathbf{y}$ be the vector of all available input data and $\mathbf{K}$ be the kernel matrix with rows and columns corresponding to atomic structures, so that the element of $\mathbf{K}$ with row and column corresponding to structures $\mathcal{A}$ and $\mathcal{B}$, respectively, is $K(\mathcal{A}, \mathcal{B})$. The fit is then obtained by solving a linear system in the least squares sense, i.e., minimizing the quadratic loss function:

$$\ell(\mathbf{x}) = \|\mathbf{K}\mathbf{x} - \mathbf{y}\|^2. \tag{2}$$

The textbook case is when the set of all configurations for which we have target data available is used in its entirety as the representative set (i.e., $N = M$), $\mathbf{K}$ is square, and as long as it is invertible, the optimal solution is:

$$\mathbf{x} = \mathbf{K}^{-1}\mathbf{y}. \tag{3}$$

In practice, for large data sets, using all the configurations in the data set as representatives is unnecessary. In this case, $M \subset N$, the solution is given by the pseudoinverse,

$$\mathbf{x}_M = (\mathbf{K}_{MN}\mathbf{K}_{NM})^{-1}\mathbf{K}_{MN}\mathbf{y}_N, \tag{4}$$

where we used subscripts to emphasize the set that the vector elements correspond to, e.g., $\mathbf{y} \equiv \mathbf{y}_N$ is the data vector with one element for each input data structure and $\mathbf{x} \equiv \mathbf{x}_M$ is the vector of coefficients, one for each representative configuration. The subscripts on the kernel matrix denote array slices, i.e., $\mathbf{K}_{MN} = \mathbf{K}_{NM}^{\top}$ is the rectangular matrix whose elements correspond to the kernel values between the representative configurations and the input configurations.

Using a representative set much smaller than the total number of structures has significant advantages in terms of computational cost, often with no reduction in fitting accuracy. The training cost is dominated by computing the pseudoinverse, which scales as $O(NM^2)$, which is linear in the size of the training data, $N$, evaluating the model scales as $O(M)$, now independent of the size of the training data. These cost scalings are analogous to those of artificial neural networks with a fixed number of nodes.

While the above solutions are formally correct, it is widely recognized that they lead to numerical instability and *overfitting*, i.e., they are solutions that attempt to maximize the fit to the input data, even when this might not be desirable, which is almost always the case. At first sight, this might sound surprising, since electronic structure calculations can be made deterministic, with precise convergence behavior in terms of its parameters, such as k-point sampling, SCF tolerance, etc. However, practical calculations are never converged to machine precision, and the resulting inconsistencies between the potential energy values for different configurations are not something that is desirable to propagate to a fitted potential energy surface. The magnitude of such inconsistencies can be easily assessed before the fit is made. Previous experience (Szlachta et al. 2014; Dragoni et al. 2018) suggests that in large databases for materials applications, the error due to k-point sampling is dominant and difficult to reduce below a meV/atom due to the associated computational cost.

In case we are fitting a potential energy surface with a representation that does not characterize the atomic positions of the whole system completely due to, e.g., a finite cutoff, or some other choices made to gain computational efficiency, the fit is not expected to be exact, irrespective of the amount of input data. Sometimes, such *model error* can also be assessed a priori, e.g., in the case of a finite cutoff by measuring the contribution made to forces on an atom by other atoms beyond the cutoff (Bernstein et al. 2009; Deringer and Csányi 2017; Fujikake et al. 2018).

These two considerations suggest that allowing some "looseness" in the linear system might be beneficial, because it can be exploited to allow smaller linear coefficients, making the fit more regular and thus better at extrapolation. We collect the errors we expect in the fit of each target data value on the diagonal of an $N \times N$ matrix, $\mathbf{\Lambda}$. The common procedure to regularizing the problem is due to Tikhonov et al. (1995). Specifically, in "kernel ridge regression" (and the equivalent "Gaussian process regression," a Bayesian view of the same), the Tikhonov matrix is chosen to be the kernel matrix between the $M$ representative points, $\mathbf{K}_{MM}$. With highly regular ("smooth") kernel functions, this regularization leads to smooth fits, and the sizes of the elements of $\mathbf{\Lambda}$ control the trade-off between the accuracy of the fit and smoothness. The corresponding solutions are

$$\mathbf{x} = (\mathbf{K} + \mathbf{\Lambda})^{-1}\mathbf{y}. \tag{5}$$

for the square problem, and

$$\mathbf{x}_M = (\mathbf{K}_{MM} + \mathbf{K}_{MN}\mathbf{\Lambda}^{-1}\mathbf{K}_{NM})^{-1}\mathbf{K}_{MN}\mathbf{\Lambda}^{-1}\mathbf{y}_N, \tag{6}$$

for the rectangular problem, where we again emphasized the index sets. This solution is equivalent to minimizing

$$\|\mathbf{K}\mathbf{x} - \mathbf{y}\|_{\mathbf{\Lambda}^{-1}}^2 + \|\mathbf{x}\|_{\mathbf{K}}^2, \tag{7}$$

which shows that the inverse of the tolerances in $\mathbf{\Lambda}$ are equivalent to weights on the different data points.

With the solution of the linear system in hand, the value of the fitted function for a new structure $\mathcal{C}$ can be written as

$$f(\mathcal{C}) = \mathbf{K}_{\mathcal{C}M}\mathbf{x}_M. \tag{8}$$

Note that the $\mathbf{K}_{\mathcal{C}M}$ slice is just a vector, with elements given by the kernel between the new structure $\mathcal{C}$ and the structures in the representative set $M$.

## 2.1 Selection of a Representative Set

Next we describe some ways to choose the set of representative environments over which the sum in Eq. (1) is taken. This can be done by simple random sampling, but we find it advantageous to use this freedom to optimize interpolation accuracy. Among the many strategies that have been proposed to this end (Hartigan and Wong 1979; Prabhakaran et al. 2012), we discuss two that have been used successfully in this context. One approach to this is to maximize the dissimilarity between the elements of the representative set. A greedy algorithm to select the configurations for the representative set is "farthest point sampling," in which we start with a randomly selected structure and then iteratively pick as the next structure the one which is farthest away from any of the structures already in the set (Gonzalez 1985; Ceriotti et al. 2013; Bartók et al. 2017). The distance between two structures is measured in the "kernel metric," defined as (Schölkopf and Smola 2002):

$$d^2(\mathcal{A}, \mathcal{B}) = K(\mathcal{A}, \mathcal{A}) + K(\mathcal{B}, \mathcal{B}) - 2K(\mathcal{A}, \mathcal{B}). \tag{9}$$

This algorithm performed well for selecting molecules in regression tasks, enabling the significant reduction of the data set sizes for a given level of accuracy (De et al. 2016).

Another technique that has been successfully used is based on matrix factorization, which is particularly appealing when the kernel function is linear or a low-order

polynomial of the descriptor vector. Consider the matrix of descriptor vectors, $\mathbf{D}$, in which each row is the descriptor vector of an input atomic configuration, such that a linear kernel is $\mathbf{K} = \mathbf{D}\mathbf{D}^\top$. We are looking to select rows, many fewer than the total number, which span as much of the space as all rows span. This is a problem of matrix representation, specifically that the representative set should serve as a low-rank approximation of $\mathbf{K}$ and/or $\mathbf{D}$. One solution to this is called CUR matrix decomposition (Mahoney and Drineas 2009), which can be applied to either $\mathbf{K}$ or $\mathbf{D}$, the latter being much cheaper if the length of the descriptor vectors is less than the number of data points.

To determine the optimal set of representative configurations, we start with a singular value decomposition of $\mathbf{D}$,

$$\mathbf{D} = USV^\top. \tag{10}$$

For each data point, a *leverage score* is calculated, essentially the weight that the top singular vectors have on that configuration.

$$\pi_{\mathcal{A}} = \frac{1}{k}\sum_{\xi=1}^{k}\left(u_{\mathcal{A}}^{\xi}\right)^2 \tag{11}$$

where $u_{\mathcal{A}}^{\xi}$ is the element of the $\xi$-th left singular vector that corresponds to structure $\mathcal{A}$. The sum runs over the first $k$ singular vectors, e.g., $k = 20$ is typical. The configuration $\mathcal{A}$ is included in the representative set with a probability that is proportional to its leverage score, $\pi_{\mathcal{A}}$. A deterministic variant is to select one structure $\mathcal{A}$ at a time – the one with the highest leverage score – delete the associated row from the descriptor matrix, and orthogonalize the remaining rows of $\mathbf{D}$ relative to it. The next data point can then be selected repeating the same procedure on the now smaller descriptor matrix (Imbalzano et al. 2018).

Note that in the Gaussian process literature, using a subset of the data to construct the basis is called *sparsification* (Quinonero-Candela and Rasmussen 2005; Snelson and Ghahramani 2006), even though the approximation relies on a low-rank matrix reconstruction rather than the kernel matrix being sparse.

## 2.2     Linear Combination of Kernels

When fitting interatomic potentials for materials, a model is constructed for the *atomic energy*, sometimes called the "site energy." This is both for computational efficiency and to reduce the complexity of the functional relation between structures and properties: each atomic energy is only a function of a limited number of degrees of freedom corresponding to the coordinates of the neighboring atoms and can therefore be evaluated independently from any other atomic energy. In fact this is the defining characteristic of an interatomic potential, in contrast to a quantum mechanical model that explicitly includes delocalized electrons. Going from atomic

energies to the total energy is trivial, the latter being the sum of the former. However, going in the other direction is not unambiguous. The total energy can be calculated from a quantum mechanical model, but the atomic energies are not defined uniquely, and it becomes part of the fitting task to find the best possible separation of the total energy into atomic energies. Treating these two transformations on the same footing helps. Suppose we want to predict the sum of function values for two (or more) configurations. For the simple case of the sum of two energies for structures $\mathcal{A}$ and $\mathcal{B}$, the prediction is, trivially, just the sum of the individual function value predictions, e.g.:

$$E_{\text{tot}} = E(\mathcal{A}) + E(\mathcal{B}) = \mathbf{K}_{\mathcal{A}M}\mathbf{x}_M + \mathbf{K}_{\mathcal{B}M}\mathbf{x}_M. \tag{12}$$

If we define a new "sum-kernel" to be the sum of kernel values between a number of new configurations and the representative set, the expression for the above total energy prediction takes the same form as the prediction of the individual function values. For some set $I$ of new configurations, let

$$^{\Sigma}\mathbf{K}_M = \sum_{\mathcal{A} \in I} \mathbf{K}_{\mathcal{A}M}, \tag{13}$$

where $^{\Sigma}\mathbf{K}_M$ is the *vector* of sum-kernel values, each element of which is the sum of the kernel between all the configurations in $I$ and a given configuration in the representative set $M$. The predicted total energy of the configurations in $I$ is then

$$E_{\text{tot}} = {}^{\Sigma}\mathbf{K}_M\mathbf{x}_M. \tag{14}$$

This same sum-kernel can be used to fit the model to sum data, rather than to individual function values. This is critical for the case of fitting interatomic potentials for materials systems, since only total energies, and not the atomic energies themselves, are available from electronic structure calculations. At the same time, in order to enforce a finite short range in the interatomic potential, we must express the potential as an atomic energy. Using the sum-kernel, this is straightforward, the original functional form in (1) can be retained, and then we now minimize:

$$\|{}^{\Sigma}\mathbf{K}\mathbf{x} - \mathbf{E}_{\text{tot}}\|^2, \tag{15}$$

where $^{\Sigma}\mathbf{K}$ is a matrix containing the sum-kernel values for all configurations in the input database and the representative set and the vector $\mathbf{E}_{\text{tot}}$ is the collection of corresponding total energy data.

## 2.3    Derivatives

The explicit analytic functional form of Eq. (1) leads to analytic derivatives with respect to the atomic coordinates, e.g., forces in the case of fitting an energy. Considering for the moment the simpler case in which we are computing the derivatives of an atom-centered quantity $f(\mathcal{A})$, we define $\nabla_{\mathcal{A}}$ as the vector of derivatives with respect to all the atomic coordinates in structure $\mathcal{A}$. We use the notation $\overleftarrow{\nabla}$ to indicate a derivative operator that applies to the first argument of the kernel and $\overrightarrow{\nabla}$ to indicate a derivative that applies to the second argument. The derivatives of $f(\mathcal{A})$ are nonzero only for atoms that belong to the structure $\mathcal{A}$ and are then given by differentiating Eq. (1):

$$\nabla_{\mathcal{A}} f(\mathcal{A}) = \sum_{\mathcal{B} \in M} x_{\mathcal{B}} \overleftarrow{\nabla}_{\mathcal{A}} K(\mathcal{A}, \mathcal{B}) = \mathbf{K}_{\nabla \mathcal{A} M} \mathbf{x}_M, \tag{16}$$

where we introduced the notation $\mathbf{K}_{\nabla \mathcal{A} M}$ to indicate the matrix that contains the derivatives of the kernels relative to all the relevant atomic coordinates. Similarly to the case of sums above, the gradient of the kernel function can also be used for fitting the model not to target values, but to *gradient data* (Solak et al. 2003). This is especially useful when the target represents a potential energy surface. When using typical electronic structure methods, the cost of computing the gradient with respect to all atomic positions is only a little bit more than the cost of computing the energy but yields much more information, $3n$ pieces of data for an $n$-atom structure. There are two approaches one can take to incorporate gradient information. In the first one, used in Bartók et al. (2010) and subsequent work of that group (Bartók et al. 2013a, 2017; Szlachta et al. 2014; Bartók and Csányi 2015; Deringer and Csányi 2017; John and Csányi 2017; Fujikake et al. 2018; Dragoni et al. 2018; Deringer et al. 2018; Caro et al. 2018; Rowe et al. 2018; Nguyen et al. 2018), the functional form for the energy is again retained to be the same as in Eq. (1). The corresponding loss function is

$$\| \mathbf{K}_{\nabla N M} \mathbf{x}_M - \mathbf{y}_{\nabla N} \|^2, \tag{17}$$

where $\mathbf{y}_{\nabla N}$ refers to the concatenated vector of gradients on all atoms in the set of input structures and $\mathbf{K}_{\nabla N M}$ to the corresponding matrix of kernel derivatives. The form of the solution for the coefficients is unchanged from (5) or (6) with $\mathbf{K}_{\nabla N M}$ taking the role of $\mathbf{K}_{N M}$.

In the second approach, used recently in Chmiela et al. (2017), derivatives of the kernel are the basis functions in the functional form of the fit,

$$f(\mathcal{A}) = \sum_{\mathcal{B} \in M} \mathbf{x}_{\nabla \mathcal{B}} \cdot \overrightarrow{\nabla}_{\mathcal{B}} K(\mathcal{A}, \mathcal{B}), \tag{18}$$

where $\mathbf{x}_{\nabla B}$ contains one weight for each of the derivatives relative to the atoms in structure $B$. The number of basis functions and corresponding coefficients is now much larger, $3nM$, for $n$-atom structures. Since the model is fitted to the derivatives, given by gradients of (18), the loss is

$$\|\mathbf{K}_{\nabla N \nabla M}\mathbf{x}_{\nabla M} - \mathbf{y}_{\nabla N}\|^2, \tag{19}$$

the target properties can be computed as

$$f(\mathcal{A}) = \mathbf{K}_{\mathcal{A}\nabla M}\mathbf{x}_{\nabla M}, \tag{20}$$

and their derivatives as

$$\nabla_{\mathcal{A}}f(\mathcal{A}) = \mathbf{K}_{\nabla \mathcal{A}\nabla M}\mathbf{x}_{\nabla M}. \tag{21}$$

The original motivation for this approach is apparent from Eq. (19) in which the matrix can be understood as a kernel directly between atomic forces (and in case of $M = N$, between the input data forces).

Both approaches constitute valid ways of learning a function from data representing its gradients, differing only in the choice of the kernel basis. The kernel-derivative basis functions could also be used in conjunction with a reduced representative set, and it is not yet clear which approach is better or indeed a combination: one could choose different basis functions (kernels or their derivatives) depending on the amount and kind of data available and on the size and choice of the representative set.

## 2.4  Learning from Linear Functionals

We can combine the sum-kernel and the derivative kernel naturally and write a single least squares problem for the coefficients in (1) that is solved to fit an interatomic potential to all available total energy, force, and virial stress data (the only condition being that the input data has to be expressible as a linear operation on function values). We define $\mathbf{y}$ as the vector with $L$ components containing all the input data: all total energies, forces, and virial stress components in the training database, $\mathbf{y}'$ as the vector with $N$ components containing the *unknown* atomic energies of the $N$ atomic environments in the database, and $\hat{\mathbf{L}}$ as the linear differential operator of size $L \times N$ which connects $\mathbf{y}$ with $\mathbf{y}'$ such that $\mathbf{y}' = \hat{\mathbf{L}}^{\top}\mathbf{y}$ (note that the definition of $\hat{\mathbf{L}}$ we use here is the transpose of that in Bartók and Csányi 2015). The least squares problem is now to minimize:

$$\|\hat{\mathbf{L}}\mathbf{K}\mathbf{x} - \mathbf{y}\|^2, \tag{22}$$

and the expression for the coefficients is given by:

$$\mathbf{x} = \left[\mathbf{K}_{MM} + (\hat{\mathbf{L}}\mathbf{K}_{NM})^\top \boldsymbol{\Lambda}^{-1} \hat{\mathbf{L}}\mathbf{K}_{NM}\right]^{-1} (\hat{\mathbf{L}}\mathbf{K}_{NM})^\top \boldsymbol{\Lambda}^{-1}\mathbf{y}. \tag{23}$$

It is instructive to write down the above matrices for the simple case when the system consists of just two atoms, $A$ and $B$, with position vectors $\mathbf{r}_A$, $\mathbf{r}_B$, target total energy $E$, and target forces $\mathbf{f}_A \equiv (f_{Ax}, f_{Ay}, f_{Az})$ and $\mathbf{f}_B \equiv (f_{Bx}, f_{By}, f_{Bz})$. The data vector is then given by

$$\mathbf{y} = [E \ f_{Ax} \ f_{Ay} \ f_{Az} \ f_{Bx} \ f_{By} \ f_{Bz}]^\top. \tag{24}$$

The aim of the fit is to determine two unknown atomic energy functions $\varepsilon_A$ and $\varepsilon_B$ as a function of the atomic environments centered around the two atoms, $\mathcal{A}$ and $\mathcal{B}$, respectively. The total energy is their sum, $E = \varepsilon_A + \varepsilon_B$, and the forces need to include the cross terms,

$$
\begin{aligned}
\mathbf{f}_A &= \frac{\partial \varepsilon_A}{\partial \mathbf{r}_A} + \frac{\partial \varepsilon_B}{\partial \mathbf{r}_A}, \\
\mathbf{f}_B &= \frac{\partial \varepsilon_A}{\partial \mathbf{r}_B} + \frac{\partial \varepsilon_B}{\partial \mathbf{r}_B}.
\end{aligned}
\tag{25}
$$

The representative set in this case consists of the same two atoms, so $N = M$, and the kernel matrix is square,

$$\mathbf{K} = \begin{bmatrix} K(\mathcal{A}, \mathcal{A}) & K(\mathcal{A}, \mathcal{B}) \\ K(\mathcal{B}, \mathcal{A}) & K(\mathcal{B}, \mathcal{B}) \end{bmatrix}, \tag{26}$$

and the linear operator $\hat{\mathbf{L}}$ is a $7 \times 2$ matrix and is given by

$$\hat{\mathbf{L}} = \begin{bmatrix} 1 & 1 \\ \overleftarrow{\nabla}_{\mathbf{r}_A} & \overleftarrow{\nabla}_{\mathbf{r}_A} \\ \overleftarrow{\nabla}_{\mathbf{r}_B} & \overleftarrow{\nabla}_{\mathbf{r}_B} \end{bmatrix}, \tag{27}$$

so the $\hat{\mathbf{L}}\mathbf{K}$ matrix to be substituted into Eq. (23) is

$$\hat{\mathbf{L}}\mathbf{K} = \begin{bmatrix} K(\mathcal{A}, \mathcal{A}) + K(\mathcal{A}, \mathcal{B}) & K(\mathcal{B}, \mathcal{A}) + K(\mathcal{B}, \mathcal{B}) \\ \overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{A}, \mathcal{A}) + \overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{B}, \mathcal{A}) & \overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{A}, \mathcal{B}) + \overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{B}, \mathcal{B}) \\ \overleftarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{A}, \mathcal{A}) + \overleftarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{B}, \mathcal{A}) & \overleftarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{A}, \mathcal{B}) + \overleftarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{B}, \mathcal{B}) \end{bmatrix} \tag{28}$$

Note that terms such as $\overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{B}, \mathcal{B})$ or $\overleftarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{A}, \mathcal{B})$ are not zero because atom $A$ is present in the environment $\mathcal{B}$ of atom $B$, and so $K(\mathcal{B}, \mathcal{A})$, and also $K(\mathcal{B}, \mathcal{B})$ depend on $\mathbf{r}_A$ explicitly.

Using the approach of Chmiela et al. (2017) for the dimer, the kernel matrix is $6 \times 6$ and is given by:

$$\mathbf{K}_{\nabla \mathcal{A} \nabla \mathcal{B}} = \begin{bmatrix} \overleftarrow{\nabla}_{\mathbf{r}_A} \overrightarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{A}, \mathcal{A}) & \overleftarrow{\nabla}_{\mathbf{r}_A} \overrightarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{A}, \mathcal{B}) \\ \overleftarrow{\nabla}_{\mathbf{r}_B} \overrightarrow{\nabla}_{\mathbf{r}_A} K(\mathcal{B}, \mathcal{A}) & \overleftarrow{\nabla}_{\mathbf{r}_B} \overrightarrow{\nabla}_{\mathbf{r}_B} K(\mathcal{B}, \mathcal{B}) \end{bmatrix}. \tag{29}$$

In practice it is always worth using *all* available data, even though once the fit is converged in the limit of infinite amount of data, the information from derivatives (forces) is the same as from energies. With finite amount of data, however, choosing the weights corresponding to energies and forces via the diagonal regulariser allows control of the fit, in the sense of its relative accuracy in reproducing energies and forces.

## 3 Density-Based Representations and Kernels

Having summarized the algorithms that can be used to perform kernel ridge regression using atomic-scale properties and their derivatives as inputs, we now proceed to describe a framework for defining physics-based descriptors of local atomic environments and the kernels built from them. In kernel ridge regression, the descriptors do not necessarily need to be expressed explicitly but can also be defined implicitly by means of the kernel function $K(\mathcal{A}, \mathcal{B})$ that corresponds to the scalar product of descriptor vectors that span a (possibly infinite-dimensional) Hilbert space (Schölkopf and Smola 2002). Vectors $|\mathcal{A}\rangle$ in this "reproducing kernel Hilbert space" do correspond to atomic structures, and one can write formally $K(\mathcal{A}, \mathcal{B}) \equiv \langle \mathcal{A}|\mathcal{B} \rangle$ even if the kernel might be computed without ever determining the vectors explicitly.

The reader trained in quantum mechanics will recognize an isomorphism between descriptors and the state vectors on one hand and kernels and expectation values on the other. This analogy suggests that it may be beneficial to formulate atomic-scale descriptors using a formalism that mimics Dirac notation. Whereas in a quantum mechanical setting the physical symmetries of the problem are built into the Hamiltonian, in a machine learning setting, they are more conveniently included in the representation itself that should be made invariant to basic symmetries such as atom labeling, rigid translations, and rotations. In this section we show how starting from these intuitions one can build a very abstract description of a molecular structure that is naturally invariant with respect to the physical symmetries, based on a representation of the atom density.

Translational and rotational symmetries can be included by decomposing the structure into a collection of local environments and by explicit symmetrization over the $SO(3)$ group. This construction is reminiscent of methods that have been applied to the comparison of solid objects (Kazhdan et al. 2003) and leads naturally to the SOAP descriptor and kernel (Bartók et al. 2013b) and to several other popular choices of density-based descriptors – from Behler-Parrinello symmetry functions (Behler and Parrinello 2007) to voxel density descriptors (Kajita et al. 2017) to the binning of the pair correlation function (Schütt et al. 2014) – that

can be regarded as different projections of the same smooth atomic amplitude. A peculiarity of the SOAP framework is that it allows one to explicitly compute the descriptors whose scalar product constitutes the kernel function, which allows one to go back and forth between a kernel and a descriptor language. The atomic environmental descriptors can then be modified to generate nonlinear kernels, as well as combined into global structural kernels. We will briefly discuss different possible approaches to the latter, either by simple linear combination of the local descriptors, or by a more sophisticated procedure that takes into account the most effective matching between pairs of environments in the two structures that are being compared.

## 3.1  A Dirac Notation for Structural Descriptors

Let us introduce an abstract notation to describe atomistic structures in terms of the positions and chemical nature of the atoms that compose them. Taking inspiration from Dirac notation for quantum mechanical states, we associate a ket $|\mathcal{A}\rangle$ with each configuration. Let us start with a simple example to see how such a formalism can be introduced and used. Much like in the case of quantum states, we can define a concrete representation of the ket associated with a structure in terms of positions and chemical species, e.g.:

$$\langle \mathbf{r}|\mathcal{A}\rangle = \sum_i g_i(\mathbf{r} - \mathbf{r}_i)\,|\alpha_i\rangle, \tag{30}$$

where the position of each atom is represented by a smooth density $g_i$ (that in principle could depend on the nuclear charge and the position of atom $i$) and the kets $|\alpha_i\rangle$ contain the information on the nuclear charge of each atom.

The Dirac notation lends itself naturally to the definition of overlap kernels between structures, $\langle \mathcal{A}|\mathcal{B}\rangle$. To compute such an integral, one can use the position representation and assume that the kets associated with different elements are orthonormal:

$$
\begin{aligned}
\langle \mathcal{A}|\mathcal{B}\rangle &= \int d\mathbf{r}\,\langle \mathcal{A}|\mathbf{r}\rangle\,\langle \mathbf{r}|\mathcal{B}\rangle \\
&= \sum_{ij} \int d\mathbf{r}\, g_i^A(\mathbf{r} - \mathbf{r}_i^A)^\star g_j^B(\mathbf{r} - \mathbf{r}_j^B)\left\langle \alpha_i^A \middle| \alpha_j^B \right\rangle \\
&= \sum_\alpha \sum_{i,\,j \in \{\alpha\}} \int d\mathbf{r}\, g_i^A(\mathbf{r} - \mathbf{r}_i^A)^\star g_j^B(\mathbf{r} - \mathbf{r}_j^B).
\end{aligned}
\tag{31}
$$

This density-based representation would not be in itself very useful, as the kernel is not invariant to relative rotations of the structures, and not even to the absolute

position of the two structures in space, or their periodic representation. Nevertheless, it can be taken as the starting point to introduce many of the most successful feature descriptors that have been used in the recent years for machine learning of materials and molecules. To see how, one can take inspiration from linear-scaling electronic structure methods and the nearsightedness principle for electronic matter (Yang 1991; Galli and Parrinello 1992; Goedecker 1999; Prodan and Kohn 2005). We then shift the attention from the description of complete structures to that of spherical atomic environments that one can conveniently center on top of each atom. This is also consistent with the atom-centered potentials that have been discussed in the previous section as an obvious application of this framework. We will use the notation $\left|\mathcal{X}_j\right\rangle$ to indicate an environment centered around the $j$-th atom in a structure and express it in the position representation as:

$$\left\langle \mathbf{r} \middle| \mathcal{X}_j \right\rangle = \sum_i f_c(r_{ij}) g_{ij}(\mathbf{r} - \mathbf{r}_{ij}) \left| \alpha_i \right\rangle \tag{32}$$

where $f_c(r_{ij})$ is a cutoff function that restricts the environment to a spherical region centered on the atom for the sake of computational efficiency and/or localization of the density information. The atom-centered smoothing functions are typically taken to be uniform-width Gaussians, but it would be easy to generalize the expression to include a dependency on the atomic species and/or the distance of an atom from the center of the environment, which could be used to, e.g., reduce the resolution of the descriptor at the periphery of the environment or adapt the smoothing length scale to each atomic species.

Note that one could also combine the density contributions from atoms of the same species into a species-dependent atomic amplitude,

$$\left\langle \alpha \mathbf{r} \middle| \mathcal{X}_j \right\rangle = \psi_{\mathcal{X}_j}^\alpha(\mathbf{r}) = \sum_{i \in \alpha} f_c(r_{ij}) g_{ij}(\mathbf{r} - \mathbf{r}_{ij}), \tag{33}$$

and then write

$$\left\langle \mathbf{r} \middle| \mathcal{X}_j \right\rangle = \sum_\alpha \psi_{\mathcal{X}_j}^\alpha(\mathbf{r}) \left| \alpha \right\rangle. \tag{34}$$

This notation is very useful to reveal how different descriptors can be seen as alternative representations of the same abstract ket. For instance, one can expand the atom density in orthogonal radial functions $R_n(r)$ and spherical harmonics. The coefficients in such an expansion can be written as

$$\left\langle \alpha n l m \middle| \mathcal{X}_j \right\rangle = \int d\mathbf{r} \left\langle n l m | \mathbf{r} \right\rangle \left\langle \alpha \mathbf{r} \middle| \mathcal{X}_j \right\rangle$$

$$= \int dr \, d\hat{\mathbf{r}} \, r^2 R_n(r) Y_m^l(\hat{\mathbf{r}}) \psi_{\mathcal{X}_j}^\alpha(r\hat{\mathbf{r}}). \tag{35}$$

As another example, Behler-Parrinello atom-centered symmetry functions that have been used in the construction of artificial neural network-based interatomic potentials for materials (Behler and Parrinello 2007; Eshet et al. 2012; Morawietz et al. 2016; Cheng et al. 2016) and molecules (Smith et al. 2017) can be written by setting the basis functions to be delta distributions $g_{ij}(\mathbf{r} - \mathbf{r}_{ij}) = \delta(\mathbf{r} - \mathbf{r}_{ij})$ and averaging the atom density with an appropriate pair weighting function $G_2$, e.g.:

$$
\begin{aligned}
\langle \alpha \beta G_2 | \mathcal{X}_j \rangle &= \langle \alpha | \alpha_j \rangle \int d\mathbf{r}\, G_2(r) \langle \beta \mathbf{r} | \mathcal{X}_j \rangle \\
&= \delta_{\alpha_j \alpha} \sum_{i \in \{\beta\}} f_c(r_{ij}) G_2(r_{ij})
\end{aligned}
\tag{36}
$$

The basis functions of the spectral neighbor analysis potential (Thompson et al. 2015) also start with the same density and expands it in hyperspherical harmonics as introduced in Bartók et al. (2010).

## 3.2   Smooth Overlap of Atomic Positions

It is clear that a density-based representation such as Eq. (32) is invariant to translations of the entire structure, but not to rotations that would change the orientation of the atomic neighbor amplitude. This reflects the fact that scalar products of the form $\langle \mathcal{X}_j | \mathcal{X}_k \rangle$ depend on the relative orientation of the environments being compared. In the smooth overlap of atomic positions (SOAP) framework, we define a symmetrized version of the overlap kernel, using the Haar integral (Haar 1933) of the rotation group:

$$
K^{(\nu)}(\mathcal{X}_j, \mathcal{X}_k) = \int d\hat{R}\, |\langle \mathcal{X}_j | R \rangle | \mathcal{X}_k \rangle|^{\nu} = \left\langle \mathcal{X}_j^{(\nu)} \middle| \mathcal{X}_k^{(\nu)} \right\rangle
\tag{37}
$$

where the integral is performed over all possible rotation matrices. If the base kernel is raised to the $\nu$-th power, the average preserves information on the correlations between atoms up to the $(\nu + 1)$-th order (Glielmo et al. 2018). As we will show below, a crucial feature of the SOAP framework is that an explicit expression for the symmetrized descriptor vectors $|\mathcal{X}_j^{(\nu)}\rangle$ can be given, which is quite manageable for $\nu = 1, 2$, but becomes increasingly cumbersome for higher $\nu$. An effective description of higher-order interactions that does not increase too much the complexity of the analytical evaluation of (37) can be obtained by manipulating the $\nu = 2$ kernel, e.g., by taking a nonlinear function of it. In practice it has been found that raising it to a power $\zeta$ and normalizing it to 1:

$$
\left\langle \mathcal{X}_j^{(2)} \middle| \mathcal{X}_k^{(2)} \right\rangle_{\zeta} = \frac{\left\langle \mathcal{X}_j^{(2)} | \mathcal{X}_k^{(2)} \right\rangle^{\zeta}}{\sqrt{\left\langle \mathcal{X}_j^{(2)} | \mathcal{X}_j^{(2)} \right\rangle^{\zeta} \left\langle \mathcal{X}_k^{(2)} | \mathcal{X}_k^{(2)} \right\rangle^{\zeta}}}
\tag{38}
$$

are sufficient to include many-body contributions in the final kernel.

Using the Dirac notation, it is easy to see how one can give an explicit representation of the $SO(3)$ symmetrized ket for the case with $\nu = 1, 2$. Using a spherical harmonics expansion of $|\mathcal{X}_j\rangle$, it is very natural to perform the rotational average analytically by introducing the Wigner matrix associated with the rotation: $\langle lm| \hat{R} |l'm'\rangle = \delta_{ll'} D^l_{mm'}(\hat{R})$

$$\int \mathrm{d}\hat{R} \sum_{\alpha nlm} \langle \mathcal{X}_j|\alpha nlm\rangle \langle \alpha nlm| \hat{R} |\mathcal{X}_k\rangle = \sum_{\alpha nlmm'} \langle \mathcal{X}_j|\alpha nlm\rangle \langle \alpha nlm'|\mathcal{X}_k\rangle \int \mathrm{d}\hat{R}\, D^l_{mm'}(\hat{R}) \tag{39}$$

which simplifies greatly due to the properties of the Wigner matrices. Only the term with $l = 0$ survives, which makes it possible to write explicitly the $\nu = 1$ symmetrized SOAP descriptors in terms of the spherical harmonics coefficients

$$\left\langle \alpha n \middle| \mathcal{X}_k^{(1)} \right\rangle = \sqrt{8\pi^2}\, \langle \alpha n00|\mathcal{X}_k\rangle, \tag{40}$$

which corresponds to the simple kernel

$$\left\langle \mathcal{X}_j^{(1)} \middle| \mathcal{X}_k^{(1)} \right\rangle = \sum_{\alpha n} \left\langle \mathcal{X}_j^{(1)} \middle| \alpha n \right\rangle \left\langle \alpha n \middle| \mathcal{X}_k^{(1)} \right\rangle. \tag{41}$$

A position representation of the $\nu = 1$ descriptor $\langle r|\mathcal{X}_k^{(1)}\rangle$ yields naturally the rotational average of $\langle \mathbf{r}|\mathcal{X}_k\rangle$. This can be seen by expressing $K^{(1)}(\mathcal{X}_j, \mathcal{X}_k)$ in a position basis

$$\left\langle \alpha \mathcal{X}_j^{(1)} \middle| \alpha \mathcal{X}_k^{(1)} \right\rangle = \int \mathrm{d}\hat{R} \int \mathrm{d}\mathbf{r}\, \psi^\alpha_{\mathcal{X}_j}(\mathbf{r}) \psi^\alpha_{\mathcal{X}_k}(\hat{R}\mathbf{r})$$
$$= 32\pi^3 \int \mathrm{d}r\, r^2 \bar{\psi}^\alpha_{\mathcal{X}_j}(r) \bar{\psi}^\alpha_{\mathcal{X}_k}(r) \tag{42}$$

where we have defined the rotationally average atom density:

$$\bar{\psi}^\alpha_{\mathcal{X}_j}(r) = \frac{1}{4\pi} \int \mathrm{d}\hat{\mathbf{r}}\, \psi^\alpha_{\mathcal{X}_j}(r\hat{\mathbf{r}}) = \frac{1}{\sqrt{32\pi r^3}} \left\langle \alpha r \middle| \mathcal{X}_j^{(1)} \right\rangle, \tag{43}$$

which is thus closely related to the pair correlation function around the tagged atom. Similar descriptors have been used for machine learning of molecules and materials (Schütt et al. 2014; Faber et al. 2015), revealing once more the intimate relationships between different atom density-based descriptors.

The $\nu = 1$ descriptor integrates away all angular correlations and therefore does not provide a unique representation of an environment. The descriptors with $\nu = 2$ provide information on three-body correlations and can also be obtained relatively

easily in closed form. The Haar integral now contains the product of two Wigner matrices. Exploiting their orthogonality relations, one obtains

$$
\int d\hat{R} \left| \sum_{\alpha n l m} \langle \mathcal{X}_j | \alpha n l m \rangle \langle \alpha n l m | \hat{R} | \mathcal{X}_k \rangle \right|^2 = \sum_{\alpha n \alpha' n' l} \left\langle \mathcal{X}_j^{(2)} \middle| \alpha n \alpha' n' l \right\rangle \left\langle \alpha n \alpha' n' l \middle| \mathcal{X}_k^{(2)} \right\rangle
$$

(44)

where the $\nu = 2$ symmetrized SOAP descriptors read

$$
\left\langle \alpha n \alpha' n' l \middle| \mathcal{X}_j^{(2)} \right\rangle = \sqrt{\frac{8\pi^2}{2l+1}} \sum_m \langle \mathcal{X}_j | \alpha n l m \rangle \langle \alpha' n' l m | \mathcal{X}_j \rangle .
$$

(45)

This notation corresponds to the power spectrum components introduced in Bartók et al. (2013b) and De et al. (2016), $\left\langle \alpha n \alpha' n' l \middle| \mathcal{X}_j^{(2)} \right\rangle \equiv p_{nn'l}^{\alpha\alpha'}(\mathcal{X}_j)$. Note also that, while the representation of the symmetrized kets in terms of the $nlm$ expansion is very convenient, it is not the only possibility. Similar to Eq. (43), an explicit position representation can be obtained for $\left\langle \alpha \mathbf{r}_1 \alpha' \mathbf{r}_2 \middle| \mathcal{X}_k^{(2)} \right\rangle$ that provides a complete representation of the three-body rotationally invariant correlations. The three-body symmetry functions of the Behler-Parrinello kind can be seen as projections of this representation, similar to the case of two-body functions in Eq. (36).

The case of $\nu = 3$ leads to an explicit representation of the ket that is proportional to the bispectrum of the environment (Bartók et al. 2013b)

$$
\left\langle \alpha_1 n_1 l_1 \alpha_2 n_2 l_2 \alpha n l \middle| \mathcal{X}_j^{(3)} \right\rangle \propto \sum_{m m_1 m_2} \langle \mathcal{X}_j | \alpha n l m \rangle
$$

$$
\times \left\langle \alpha_1 n_1 l_1 m_1 \middle| \mathcal{X}_j \right\rangle \left\langle \alpha_2 n_2 l_2 m_2 \middle| \mathcal{X}_j \right\rangle \langle l_1 \, m_1 \, l_2 \, m_2 | l \, m \rangle .
$$

(46)

While the dimensionality of this descriptor makes it impractical unless somehow sparsified, it does give direct access to higher-order correlations. An interesting detail is that $\left| \mathcal{X}_j^{(3)} \right\rangle$, contrary to the $\nu = 1, 2$ cases, is not invariant to mirror symmetry, which makes it capable of distinguishing enantiomers.

Finally, one should note that the normalization of the kernel Eq. (38) can be achieved by normalizing the SOAP vector, so that an explicit representation of the normalized descriptor is possible. While in principle one could write out an explicit representation that yields the kernel for $\zeta > 1$, it would contain an exponentially increasing number of terms. As in the case of $\left| \mathcal{X}_j^{(3)} \right\rangle$, this only makes sense if combined with a sparsification procedure.

## 3.3   λ-SOAP: Symmetry-Adapted Gaussian Process Regression

When building a machine learning model for a tensorial property **T**, one should consider that the target is not invariant under the action of a symmetry operation (e.g., a rotation) but transforms covariantly. The most effective strategy to encode

the appropriate covariance properties in the model involves the decomposition of the tensor into its irreducible spherical components, i.e., combinations of the elements of the tensor that transform as the spherical harmonics of order $\lambda$ (Varshalovich et al. 1988). For these irreducible components,

$$T_{\lambda\mu}(\hat{R}\mathcal{X}_j) = \sum_{\mu'} D^\lambda_{\mu\mu'}(\hat{R}) T_{\lambda\mu'}(\mathcal{X}_j) \tag{47}$$

As shown in Glielmo et al. (2017) for the case of vectors and in Grisafi et al. (2018) for tensors of arbitrary order, one has to consider a matrix-valued kernel that describes the geometric relationship between the different components of $\mathbf{T}_\lambda$, which can be obtained by including an additional Wigner matrix $D^\lambda_{\mu\mu'}(\hat{R})$ in the Haar integral

$$\left\langle \mathcal{X}^{(v)}_{j,\lambda\mu} \middle| \mathcal{X}^{(v)}_{k,\lambda\mu'} \right\rangle = \int d\hat{R} \, D^\lambda_{\mu\mu'}(\hat{R}) \left| \langle \mathcal{X}_j | R \rangle | \mathcal{X}_k \rangle \right|^v. \tag{48}$$

For the case with $v = 2$, the symmetrized kets can be written explicitly based on a $\alpha nlm$ expansion of the atom density:

$$\left\langle \alpha n l \alpha' n' l' \middle| \mathcal{X}^{(2)}_{j,\lambda\mu} \right\rangle = \sqrt{\frac{8\pi^2}{2l+1}} \sum_{mm'} \langle \mathcal{X}_j | \alpha n l m \rangle$$
$$\times \langle \alpha' n' l' m' | \mathcal{X}_j \rangle \langle l \, m \, l' \, -m' | \lambda \, -\mu \rangle \tag{49}$$

We write Eq. (49) in this form because it is somewhat symmetric, but the properties of the CG coefficients require that $m' = m + \mu$, so the expression can be evaluated with a single sum. Furthermore, the expression evaluates to 0 whenever $|l - l'| < \lambda$, which reduces the number of elements that must be evaluated and stored and makes it clear that Eq. (49) reduces to the scalar SOAP Eq. (45) when $\lambda = 0$.

When using a linear model, each of the symmetry-adapted descriptors Eq. (49) can be used to represent tensorial components that transform as $Y^\lambda_\mu$. Linearity, in this case, is necessary for preserving the symmetry properties of the $\lambda$-SOAP. A nonlinear model, however, can be obtained by scaling each $\left\langle \alpha n l \alpha' n' l' \middle| \mathcal{X}^{(2)}_{j,\lambda\mu} \right\rangle$ by a (in principle different) nonlinear function of some $\lambda = 0$ descriptors. In the kernel language, a high-order version of the $\lambda$-SOAP kernel can be introduced with an expression analogous to (38):

$$\left\langle \mathcal{X}^{(2)}_{j,\lambda\mu} \middle| \mathcal{X}^{(2)}_{k,\lambda\mu'} \right\rangle_\zeta = \frac{\left\langle \mathcal{X}^{(2)}_{j,\lambda\mu} \middle| \mathcal{X}^{(2)}_{k,\lambda\mu'} \right\rangle \langle \mathcal{X}_j^{(2)} | \mathcal{X}_k^{(2)} \rangle_{\zeta-1}}{\left\| \left\langle \mathcal{X}^{(2)}_{j,\lambda\boldsymbol{\mu}} \middle| \mathcal{X}^{(2)}_{j,\lambda\boldsymbol{\mu}^\top} \right\rangle \right\|_F \left\| \left\langle \mathcal{X}^{(2)}_{k,\lambda\boldsymbol{\mu}} \middle| \mathcal{X}^{(2)}_{k,\lambda\boldsymbol{\mu}^\top} \right\rangle \right\|_F}, \tag{50}$$

where $\|\cdot\|_F$ indicates the Frobenius norm and $\left\langle \mathcal{X}_j^{(2)} \middle| \mathcal{X}_k^{(2)} \right\rangle_{\zeta-1}$ is a (scalar) SOAP kernel. This second term makes the overall kernel nonlinear, without affecting the symmetry properties of the overall tensorial kernel.

## 3.4   Kernel Operators and Descriptor Optimization

Provided one takes a long-range environmental cutoff and chooses a kernel that can represent high orders of many-body interactions, a density-based representation of atomic structures should provide a complete description of any atomic structure and – given a sufficiently complete training set – predict any atomistic property with arbitrary accuracy. In practice, obviously, the accuracy of a model depends on the details of the representation, which is why different descriptors or kernels provide different levels of accuracy for the same training and test set (Faber et al. 2017). The performance of a set of descriptors can be improved by modifying them so that they represent more efficiently the relations between structure and properties.

The relation between structures, properties, and kernels can be encoded in a Hermitian operator $\hat{W}$ bracketed between the translationally invariant environmental kets:

$$\langle \mathcal{X}_j | \mathcal{X}_k \rangle_{\hat{W}} \equiv \langle \mathcal{X}_j | W \rangle | \mathcal{X}_k \rangle. \tag{51}$$

When the kernel is averaged over rotations to obtain the SOAP kernel and the associated descriptors,

$$\left\langle \mathcal{X}_j^{(v)} \middle| \mathcal{X}_k^{(v)} \right\rangle_{\hat{W}} = \int d\hat{R} \left| \langle \mathcal{X}_j | W \rangle \hat{R} | \mathcal{X}_k \rangle \right|^p \tag{52}$$

it becomes clear that if we want to be able to write the "operator-adapted" $SO(3)$ descriptors explicitly, the operator $\hat{W}$ must commute with rotations. This additional requirement means that the most general form of $\hat{W}$, written in the $\{|\alpha nlm\rangle\}$ basis, is

$$\langle \alpha nlm | W \rangle | \alpha'n'l'm' \rangle = \delta_{ll'}\delta_{mm'}\hat{W}_{\alpha\alpha'nn'll'}. \tag{53}$$

This operator can be used, for instance, to scale the density as a function of distance or to introduce an "alchemical kernel" that couples the descriptors associated with different elements and in principle to realize an even more subtle tuning of the SOAP descriptors, in which radial, angular, and alchemical channels are mixed to provide a more efficient representation of complex chemical environments.

## 3.5  Computing SOAP Descriptors Efficiently

A practical calculation of both scalar and tensorial $\nu = 2$ SOAP descriptors $\left\langle \alpha n l \alpha' n' l' \middle| \mathcal{X}_{j,\lambda\mu}^{(2)} \right\rangle$ requires the evaluation of the expansion coefficients $\langle \alpha n l m | \mathcal{X}_j \rangle$. Let us start with the atom density written in the position representation, according to Eq. (35), and consider the case in which $\psi_{\mathcal{X}}^{\alpha}(\mathbf{r})$ is written as a superposition of spherical Gaussian functions of width $\sigma$ placed at the positions of the atoms of type $\alpha$. Then, the spherical harmonic projection in Eq. (35) can be carried out analytically, leading to:

$$
\langle \alpha n l m | \mathcal{X}_j \rangle = \sum_{i \in \alpha} Y_{lm}(\hat{\mathbf{r}}_{ij})\, e^{-\frac{r_{ij}^2}{2\sigma^2}} \times
$$
$$
\times \int_0^\infty \mathrm{d}r \; r^2 \; R_n(r) e^{-\frac{r^2}{2\sigma^2}} \iota_l\left(\frac{r r_{ij}}{\sigma^2}\right) \tag{54}
$$

where the sum runs over all neighboring atoms of type $\alpha$ and $\iota_l$ indicates a modified spherical Bessel function of the first kind. It is convenient to choose a form for the orthogonal radial basis functions $R_n(r)$ that makes it possible to perform the radial integration analytically.

One possible choice starts by using Gaussian type orbitals as non-orthogonal primitive functions $\tilde{R}_k(r)$

$$
\tilde{R}_k(r) = \mathcal{N}_k \, r^k \exp\left\{ -\frac{1}{2}\left(\frac{r}{\sigma_k}\right)^2 \right\}, \tag{55}
$$

where $\mathcal{N}_k$ is a normalization factor, such that $\int_0^\infty dr\, r^2 \tilde{R}_k^2(r) = 1$. The set of Gaussian widths $\{\sigma_k\}$ can be chosen to span effectively the radial interval involved in the environment definition. Assuming that the smooth cutoff function approaches one at a distance $r_{\text{cut}} - \delta r_{\text{cut}}$, one could take $\sigma_k = (r_{\text{cut}} - \delta r_{\text{cut}}) \max(\sqrt{k}, 1)/n_{\max}$ that gives functions that are peaked at equally spaced positions in the range between 0 and $r_{\text{cut}} - \delta r_{\text{cut}}$.

While the $\tilde{R}_k(r)$ are not themselves orthogonal, they can be used to write orthogonal basis functions $R_n(r) = \sum_k S_{nk}^{-1/2} \tilde{R}_k(r)$, where the overlap matrix $S_{kk'} = \int dr\, r^2 \tilde{R}_k(r) \tilde{R}_{k'}(r)$ can be computed analytically. The full decomposition of the translationally invariant environmental ket can then be obtained without recourse to numerical integration.

Once the spherical decomposition of the atomic density has been obtained, the coefficients can be combined to give the SOAP descriptors of orders 1 and 2. Particularly in the presence of many different chemical species, the number of components can become enormous. Ignoring for simplicity a few symmetries, and the fact that if all species do not appear in every environment, it is possible

to store a sparse representation of the descriptor, the power spectrum contains a number of components of the order of $n_{\text{species}}^2 n_{\text{max}}^2 l_{\text{max}}$, which can easily reach into the tens of thousands. In the case of the tensorial $\lambda$-SOAP, the number increases further to $\lambda^2 n_{\text{species}}^2 n_{\text{max}}^2 l_{\text{max}}$. It is however not necessary to compute and store all of these descriptors: each of them, or any linear combination, is a spherical invariant (covariant) description of the environment and can be used separately as a descriptor. This can be exploited to reduce dramatically the computational cost and the memory footprint of a SOAP calculation, determining a low-rank approximation of the descriptor. One can use dimensionality reduction techniques similar to those discussed in Sect. 2.1 to identify the most suitable reference structures. As shown in Imbalzano et al. (2018), both CUR decomposition and a greedy selection strategy based on farthest point sampling make it possible to reduce by more than 95% the number of SOAP descriptors that are needed to predict the energy of small organic molecules with chemical accuracy.

## 3.6    Back to the Structures

Whenever one is interested in computing properties that are associated to individual atoms (for instance, their NMR chemical shieldings or the forces), one can use directly the descriptors corresponding to each environment or the kernel between two environments, as the basis for a linear or nonlinear regression model. As discussed in Sect. 2, it is often the case that one is interested in using as structure labels some properties that are instead associated with the entirety of a structure, e.g., its cohesive energy, its dielectric constant, etc. In these cases a ridge regression model should be used that is based on "global" kernels between the structures, $K(\mathcal{A}, \mathcal{B})$, rather than those between individual atom-centered environments. This is reflected in how the kernels between environments should be combined to give a kernel that is suitable to represent the relation between local environments and the overall property of a structure. When the target property can be seen as an additive combination of local, atom-centered contributions, the most natural (and straightforward) choice, that is consistent with Eq. (13), is

$$K(\mathcal{A}, \mathcal{B}) = \sum_{j \in \mathcal{A}, k \in \mathcal{B}} K(\mathcal{X}_j, \mathcal{X}_k). \tag{56}$$

It is worth stressing that in the case where the environment kernel is a linear kernel based on SOAP descriptors, this sum-kernel can be written in terms of a global descriptor associated with the entire structure,

$$K(\mathcal{A}, \mathcal{B}) = \left\langle \mathcal{A}^{(\nu)} \middle| \mathcal{B}^{(\nu)} \right\rangle, \tag{57}$$

where we introduced

$$\left|\mathcal{A}^{(\nu)}\right\rangle = \sum_{j \in \mathcal{A}} \left|\mathcal{X}_j^{(\nu)}\right\rangle. \tag{58}$$

An alternative way to combine the information from individual environments in a symmetrized global kernel corresponds to averaging the Fourier coefficients of each environment,

$$\langle \alpha nlm | \mathcal{A} \rangle = \sum_{j \in \mathcal{A}} \langle \alpha nlm | \mathcal{X}_j \rangle \tag{59}$$

and then taking the Haar integral of the resulting sum. For instance, for $\nu = 2$,

$$\left\langle \alpha n\alpha'n'l \middle| \bar{\mathcal{A}}^{(2)} \right\rangle = \sum_m \langle \alpha nlm | \mathcal{A} \rangle \langle \mathcal{A} | \alpha'n'lm \rangle. \tag{60}$$

The form Eq. (56) is more general, and one can readily introduce nonlinear kernels such as $\left\langle \mathcal{X}_j^{(\nu)} \middle| \mathcal{X}_k^{(\nu)} \right\rangle_\zeta$ for which an explicit expression for the descriptors would be too cumbersome. Equation (56) also suggests that the combination of environment kernels could be generalized by introducing a weighting matrix

$$K_W(\mathcal{A}, \mathcal{B}) = \sum_{j \in \mathcal{A}, k \in \mathcal{B}} W_{jk}(\mathcal{A}, \mathcal{B}) K(\mathcal{X}_j, \mathcal{X}_k). \tag{61}$$

One could, for instance, determine the importance of each environment within a structure and set $W_{jk}(\mathcal{A}, \mathcal{B}) = w_j(\mathcal{A}) w_k(\mathcal{B})$. Alternatively, one can use techniques from optimal transport theory (Cuturi 2013) to define an entropy-regularized matching (REMatch) procedure (De et al. 2016), in which $W_{jk}$ is a doubly stochastic matrix that matches the most similar environments in the two structures, disregarding the environmental kernels between very dissimilar environments

$$\mathbf{W}(\mathcal{A}, \mathcal{B}) = \operatorname*{argmin}_{\mathbf{W} \in \mathcal{U}(N_\mathcal{A}, N_\mathcal{B})} \sum_{jk} W_{jk} \left[ d^2(\mathcal{X}_j, \mathcal{X}_k) + \gamma \ln W_{jk} \right], \tag{62}$$

where $d^2$ indicates the kernel-induced squared distance Eq. (9). The parameter $\gamma$ weights the entropy regularization and makes it possible to interpolate between strict matching of the most similar pairs of environments ($\gamma \to 0$) to an average kernel that weights all pairs equally ($\gamma \to \infty$). Although this construction complicates considerably the combination of local kernels, it provides a strategy to introduce an element of non-locality in the comparison between structures. Given the cost of computing the REMatch kernel and the fact that it prevents using some sparsification strategies that act at the level of individual environments, this method should be used when the target property is expected to exhibit very strong nonadditive behavior,

e.g., when just one portion of the system is involved, for instance, when determining the activity of a drug molecule, a problem for which REMatch has been shown to improve dramatically the accuracy of the ML model (Bartók et al. 2017).

## 3.7    Multi-kernel Learning

We have shown that SOAP descriptors can be seen as just one possible embodiment of a general class of rotationally symmetrized density-based descriptors that also encompasses other popular descriptors for atomic-scale machine learning, and that can be tuned to a great extent, e.g., by changing the way different components are weighted. The fact that different descriptors can be computed within the same formalism does not imply they are fully equivalent: each expression or kernel emphasizes different components of the structure/property relations. For instance, kernels with varying radial scaling or cutoff distance focus the machine learning model on short-, mid-, or long-range interactions. It is then natural to consider whether a better overall model can be constructed by combining descriptors that are associated with different cutoff distances or different levels of body order expansions. This can be achieved by a weighted combination of kernels of the form

$$K_{\text{tot}}(\mathcal{A}, \mathcal{B}) = \sum_{\aleph} w_{\aleph} K_{\aleph}(\mathcal{A}, \mathcal{B}), \tag{63}$$

where each $K_{\aleph}$ corresponds to a distinct model.

This is equivalent to an additive model for a property, similar to the construction of an atom-centered decomposition of the total energy in Eq. (12). In this case, instead, the property $y$ associated with each structure is written as the sum of contributions $y_{\aleph}(\mathcal{A})$ that are associated with the various kernels $K_{\aleph}$

$$y(\mathcal{A}) = \sum_{\aleph} y_{\aleph}(\mathcal{A}) = \sum_{\aleph, \mathcal{B}} x_{\mathcal{B}} w_{\aleph} K_{\aleph}(\mathcal{A}, \mathcal{B}) \tag{64}$$

where $x_{\mathcal{B}}$ are the kernel regression weights for each of the representative structures $\mathcal{B}$. The weights $w_{\aleph}$ correspond to the estimated contribution that each model will give to the final property and can be obtained by cross-validation or by physical intuition. For instance, in the case of multiple radial cutoffs, it is found that much smaller weights should be associated with long-range kernels, consistent with the fact that distant interactions contribute a small (although often physically relevant) contribution to the total energy (Bartók et al. 2017). It should also be noted that, provided that the descriptors corresponding to the kernels are linearly independent, Eq. (63) effectively corresponds to a feature space of increased dimensionality, obtained by concatenating the descriptors that are – implicitly or explicitly – associated with each kernel.

# 4    Conclusions

We have laid out a mathematical framework, based on the concept of the atomic density, for building descriptors of atomic environments that preserve the geometric symmetries and chemically sensible limits. Coupled with kernel regression, this allows the fitting of complex models of physical properties on the atomic scale, both scalars like interatomic potentials (force fields) and tensors such as multipole moments and quantum mechanical operators. We discuss in general terms how kernel regression can be extended to include a sparse selection of reference structures and to predict and learn from linear functionals of the target property. To leverage the many formal similarities between kernel regression and quantum mechanics, we use a Dirac bra-ket notation to formulate the main results concerning the SOAP descriptors. This notation also helps in making apparent the relationship between SOAP descriptors and other popular density-based approaches to represent atomic structures. The framework can be extended and tuned in many different ways to incorporate insight about the relations between properties, structures, and descriptors. With physical principles such as symmetry and nearsightedness of interactions at its core, we believe this formulation is ideally suited to provide a unified framework to machine learn atomic-scale properties.

# Nomenclature

| | |
|---|---|
| $\mathcal{A}$ | An item – structure, or atomic environment for which one wants to predict a property |
| $K(\mathcal{A}, \mathcal{B})$ | The kernel function computed between items $\mathcal{A}$ and $\mathcal{B}$ |
| $N$ | Number of input structures in the training set |
| $M$ | Number of structures in the representative set |
| $\mathbf{x}$ | The vector of KRR weights, also written as $\mathbf{x}_M$; the weight associated with a structure $\mathcal{B}$ is indicated as $x_{\mathcal{B}}$ |
| $\mathbf{y}$ | The vector containing the values of the target property, also written as $\mathbf{y}_N$. $y_{\mathcal{B}}$ indicates the value for the item $\mathcal{B}$ |
| $\mathbf{K}$ | Kernel matrix |
| $\mathbf{K}_{MN}$ | Slice of the kernel matrix $\mathbf{K}$, corresponding to rows in set $M$ and columns in set $N$ |
| $^{\Sigma}\mathbf{K}$ | Sum-kernel, defined as the sum of the regular kernel over a set of configurations |
| $\overleftarrow{\nabla}$ | Derivative operator applying to the first argument of the kernel matrix |
| $\overrightarrow{\nabla}$ | Derivative operator applying to the second argument of the kernel matrix |
| $\mathbf{K}_{\nabla_{\mathcal{A}}\mathcal{B}}$ | Derivative of the kernel matrix, applying to its first argument, with respect to the coordinates of atoms in structure $\mathcal{A}$, with structure $\mathcal{B}$ as its second argument |

| | |
|---|---|
| $\hat{\mathbf{L}}$ | Linear operator connecting the observed values $\mathbf{y}$ with the unobserved atomic energies $\mathbf{y}'$ |
| $\|\mathcal{A}\rangle$ | An abstract vector that describes the input $\mathcal{A}$ |
| $\langle\mathcal{A}\|\mathcal{B}\rangle$ | The scalar product between the features associated with $\mathcal{A}$ and $\mathcal{B}$. Could be either an explicit scalar product, or an abstract notation equivalent to $K(\mathcal{A}, \mathcal{B})$ |
| $g_i(\mathbf{r})$ | A smooth function – typically a Gaussian that is used to represent the density associated with atom $i$ |
| $\|\alpha\rangle$ | An abstract vector that represents the chemical species $\alpha$ |
| $\mathbf{r}$ | Position in 3D Cartesian coordinates. |
| $r$ | The modulus of the vector $\mathbf{r}$ |
| $\hat{\mathbf{r}}$ | The unit vector $\mathbf{r}/r$ |
| $\mathbf{r}_i$ | Position of the $i$-th atom. |
| $\mathbf{r}_{ij}$ | Displacement vector $\mathbf{r}_i - \mathbf{r}_j$ between the $i$-th and $j$-th atoms |
| $\psi^{\alpha}_{\mathcal{X}_j}(\mathbf{r})$ | The atom density of species $\alpha$ centered around the $j$-th atom |
| $Y^l_m(\hat{\mathbf{r}})$ | The $l, m$-th spherical harmonic |
| $R_n(r)$ | The $n$-th orthogonal radial basis function |
| $\left\|\mathcal{X}_j^{(\nu)}\right\rangle$ | The spherically-averaged SOAP descriptor of order $\nu$ |
| $\left\langle\mathcal{X}_j^{(\nu)}\middle\|\mathcal{X}_k^{(\nu)}\right\rangle_{\zeta}$ | The normalized SOAP kernel of order $\nu$ and nonlinear exponent $\zeta$. |
| $D^l_{mm'}(\hat{R})$ | The Wigner rotation matrix associated with the rotation $\hat{R}$ |
| $\left\langle\alpha n\alpha'n'l\middle\|\mathcal{X}_j^{(2)}\right\rangle$ | The radial/spherical representation of the SOAP $\nu = 2$ vector, corresponding to the power spectrum between species $\alpha$ and $\alpha'$ |
| $\langle l_1\, m_1\, l_2\, m_2\|l\, m\rangle$ | A Clebsch-Gordan coefficient |
| $T_{\lambda\mu}$ | The $\mu$-th component of the irreducible spherical component of order $\lambda$ for the tensorial quantity $\mathbf{T}$ |
| $\left\|\mathcal{X}_{j,\lambda\mu}^{(\nu)}\right\rangle$ | The $\lambda$-SOAP descriptor of order $\nu$, corresponding to the irreducible spherical component $\lambda\mu$ centered on atom $j$ |
| $\left\langle\mathcal{X}_j\middle\|\mathcal{X}_k\right\rangle_{\hat{W}}$ | A kernel transformed by the Hermitian operator $\hat{W}$ |

automation and digitization. Computational chemistry is seemingly on the verge of a big-data revolution.

In this chapter, we discuss how many of these data-driven paradigms are part of long-term trend and data have long been at the heart of many chemical problems. Historical repositories of chemical data where the modern cheminformatician can mine high value curated training data are reviewed. Modern automation tools and datasets available for high-data computational chemistry are described. Current applications of computer-driven discovery of molecular materials in optoelectronics (photovoltaics and light-emitting diodes) and electrical energy storage are discussed. Finally, the impact of machine learning approaches to computational chemistry areas of structure-property relationships and chemical space, with an emphasis on generative models, are analyzed.

## 1    Introduction

Chemistry has been a *big-data* enterprise for multiple decades. Long before the term was popularized, chemists strived to wield chemical datasets whose volume, variety, and velocity exceeded the ability of tools available to them. For one, chemists have long struggled to address the immensity of chemical space. Since the arrival of computers, chemists have been creators and early adopters of digital technologies for the storage, processing, and retrieval of chemical data. Along those same lines, the advent of the Internet set off a new era of accelerating knowledge creation and sharing in the chemical sciences.

In fields such consumer analytics, advertising, transportation, healthcare or finance, the clearest gains from big-data, and machine learning approaches have come from subareas that combine as many favorable features as possible: data is inexpensive to generate, digital in origin or easy to digitize, highly organized and consistent, and extremely abundant. While abundant, chemical data tends to be expensive to generate, heterogeneous, hand-made, and sparse. Chemical data entry and curation is generally done manually; these tasks require significant expertise because of the heterogeneous sources and reporting criteria, and the technical complexity of chemical reports. In recent years, as chemical instruments, such as microscopes or spectrometers, produce digitized data, very large datasets can be generated by a single device. This very much opens the door to leverage *local* big data, but one still faces similar barriers when attempting to consolidate results from different groups or apparatuses.

Computational chemistry approaches share a series of features that make them very amenable to this data-driven paradigm and are proving to be the perfect testing ground for realizing the big-data vision in chemistry. The output of computational chemistry software is digitized from beginning to end. Even if it relies on custom-formatted input and output files, automating the creation and processing of these files is a simple task. Computational results are replicable to floating point precision when using the same computer code, and with extreme accuracy even among different programs as long as they use the same underlying algorithms. Because compute

is essentially a commodity, results can be generated in arbitrary amounts with linear scaling in cost – or even sublinear, thanks to machine learning approaches. Finally, there is a well-understood tradeoff between computational cost and accuracy that can be leveraged through data-driven techniques.

In this chapter, we will analyze how computational chemistry has embraced big-data for accelerated discovery of much needed new molecules and how these newly generated datasets have allowed to apply, and develop, machine learning techniques that make them even more powerful.

## 2 Repositories of Chemical Data

The initial development of big-data approaches in chemistry was historically focused on consolidating, curating, and indexing literature and empirical data. Tackling these tasks was one of the first applications of computers in chemistry and remains a key driver in the development of new computational tools for chemistry.

The Chemical Abstracts Service (CAS) was created in 1907 to keep complete records of the chemical literature and reported substances, following the idea of previous abstracts journals in Europe such as *Chemisches Zentralblatt* and nineteenth-century compilations such as *Beilsteins Handbuch der organischen Chemie*, *Gmelins Handbuch der anorganischen Chemie*, or the Merck Index. It contained over 12,000 indices in its first year, its one millionth record in 1937. CAS historically relied on thousands of volunteers to create abstracts and index information for each paper – not that far from today's Mechanical Turks at Amazon – and slowly phased them out between the late sixties and the nineties. In addition, CAS employed hundreds of staff members by the 1950s, underscoring both the great value of big data to chemistry and the great cost of getting that same data into neatly formatted into useable form.

The adoption of digital computers for chemical applications in the late 1960s initiated the digitization of chemical big data by facilitating the storage, entry, and very importantly querying of chemical databanks. CAS computer-based Chemical Registry System, like the Beilstein Registry Number before it, assigns unique individual arbitrary numbers to chemicals. It debuted internally in 1964 and was progressively updated and expanded, making the basis for increasingly modern querying and retrieval tools, using command-line and graphical interfaces to retrieve data from local or online records. With around three million records and growing at hundreds of thousands per year in the mid-seventies, the registry grew exponentially to its 30 millionth chemical substances in 2007, 50 millionth in 2009, and 100 millionth in 2015. Competing commercial efforts that also build on older academic work are Elservier's Reaxys (Beilstein and Gmelin) and Thomson-Reuters, now Clarivate.

In 1965, the Kennard group at Cambridge University started collecting published crystallographic data for small molecules. This effort grew into what is known as the Cambridge Structural Database, which now hosts nearly one million curated entries from x-ray and neutron diffraction analyses (Groom et al. 2016). Also in the

late 1960s, joint efforts between Brookhaven National Laboratory and Texas A&M University initiated what would become the Protein Data Bank, a repository for three-dimensional structural data of large biological molecules, such as proteins and nucleic acids, and now holds over 120,000 entries (Berman et al. 2000; Bernstein et al. 1978; Meyer 1997).

Other repositories of experimental crystallographic information (Bruno et al. 2017) are the Crystallography Open Database (COD) (Gražulis et al. 2009, 2012), which stores user-submitted data; the Inorganic Crystal Structure Database, produced cooperatively by FIZ Karlsruhe and NIST that stores crystal structures of inorganic solids (Belsky et al. 2002); and the International Centre for Diffraction Data (ICDD) that stores powder diffraction patterns (Faber et al. 2002).

The rise of the Internet sparked the launch of other big-data repositories and the expansion of online availability of existing ones both in chemistry and materials. The Registry of Research Data Repositories aggregates lists of multiple repositories and datasets along many scientific disciplines including chemistry and materials science (Pampel et al. 2013).

The National Institute of Standards and Technology has hosted the NIST Chemistry WebBook since the 1996 (Linstrom and Mallard 2001), a compendium of mostly spectroscopic and thermodynamic data originally compiled in handbooks and tables. In addition, the nearly 200 Standard Reference Data sets include other data of interest to chemists. NIST 101 (III 1999) in particular contains calculated data quantum chemical data for about 1800 gas-phase atoms and small molecules and tools for comparing experimental and computational ideal-gas thermochemical properties.

Since patents and patent applications are open, they are a big-data, information-rich asset. Patent documents, however, tend to be only text-based or image-based, and their digitization into a format that is useable for data-driven approaches is a standing challenge. The European, United States, Japanese Patent Offices, and the World Intellectual Property Organization can be accessed and queried online, but they are not systematically annotated. The US Patent and Trademark Office, through their Complex Work Unit program, made available digital representation of molecules in patent applications, easing the data-processing pipelines.

In the open-data arena, NextMoveSoftware released close to million chemical reactions, extracted by means of automated text mining of the relevant experimental sections reported in patents, covering the period between 1976 and 2013. SCRIPDB contains curated syntheses, chemicals, and reactions from the patent literature, collected from CWU files coming from granted US patents (Heifets and Jurisica 2012).

SureChem is another molecule database, open-sourced in 2012 to SureChemBL. It used by IBM's Strategic IP Insight Platform and initially released more than two million chemical structures extracted from about 4.7 million patents (1976–2000, only text) and subsequently extended to include patents published up to the end of 2010 and chemical structures were additionally derived from US CWUs and images (2001–2010) (Papadatos et al. 2016). UniChem attempts to unify and cross reference these multiple databases (Chambers et al. 2013).

ChemSpider is a database of chemicals with more than 60 million entries from over 480 data sources. Originally a private enterprise, it was acquired by the Royal Society of Chemistry (RSC) in 2009. It includes a crowd-sourced component, but only limited downloads are available (Pence and Williams 2010).

Because of the large size of the set of possible small organic molecules with biological activity, the large number and diversity of biological targets, the high dimension of many biological assays and measurements and the high value of healthcare applications, cheminformatics, biological chemistry, and drug discovery applications are key target for big data applications in chemistry. Toxicological information of drugs and chemicals are also interesting biological interactions that are recorded in several publicly available databases.

The National Center for Biotechnology Information (NCBI), part of the United States National Library of Medicine (NLM) from the National Institutes of Health (NIH), hosts multiple datasets and informatics tools in biotechnology. Of particular interest in chemistry is PubChem, a database of molecules and their activities against biological assays. Initiated in 2004, it now aggregates over 540 sources, over 90 million compounds, and 233 million bioactivity results for nearly 2.5 million of those. As a federally sponsored service, PubChem has been seen to be in conflict with for-profit repositories such as CAS (Kaiser 2005).

ChemBL is an open database that contains binding, functional, and ADMET (absorption, distribution, metabolism, excretion) measurements for drug-like biologically active compounds, with nearly 15 million bioactivity measurements for more than 1 million compounds and 11,500 protein targets (Gaulton et al. 2012). DrugBank is a web-accessible cheminformatics database and service combining structural and biological target data for drug molecules. The database contains in excess of 9000 small molecule drugs, 3000 FDA-approved drugs, and data for nearly 17,000 drug-target associations (Wishart et al. 2006, 2018). The database for Chemical Entities of Biological Interest follows a similar focus as well (Degtyarenko et al. 2008).

The PDBbind database matches published affinity constants from the literature for the ligand-protein systems whose 3D structures are stored in PDB, undergoing periodic updates (Liu et al. 2015; Wang et al. 2004). BindingDB (Chen et al. 2001; Gilson et al. 2016) and AffinDB (Block et al. 2006) also aim to fulfill a similar task. The comparative Toxicogenomics Database is a volunteer-based genomic resource devoted to toxicologically relevant genes and proteins and their interactions with chemicals and toxins (Davis et al. 2017; Mattingly et al. 2003). MACiE contains enzyme reaction mechanisms focused on the evolution of enzyme catalytic mechanisms and the classification with respect to chemical mechanism (Holliday et al. 2005).

These services are big-data pioneers in chemistry and highlight both the early understanding of how chemistry is a high-dimensional, sparse-data arena where big-data approaches can create great value, as well as the high cost of gathering and curating chemical data. For machine learning applications, these repositories provide extremely valuable labeled data.

# 3    Big Computational Chemistry

The field of computational chemistry quickly followed the deployment of the first digital computers and has grown at a fast pace, matching developments in algorithms and hardware and also contributing its own. Oftentimes, the chemical calculations carried out will push the hardware available to run them: running in parallel over many cores in supercomputers, using large amounts of memory or storage.

In that sense, judging by the volume and velocity of the output data they produce, and by the strain on hardware requirements, computational chemistry calculations have been big-data all along, essentially as big as the available resources allowed and have been drivers of big-data technologies.

In this chapter, we will focus on applications of computational chemistry that combine volume and velocity with also high variety because of a large degree of granularity. These are the cases of (i) distributive computing, where small calculation payloads are distributed to a large grid of small computers, and after computation, the results are consolidated and processed, and (ii) high-throughput virtual screening, where many thousands of candidate molecules or materials are calculated individually in an automated fashion and a data-driven search for the most performant candidate materials is carried out.

## 3.1    Automation and Databases in Computational Chemistry

Many tools have been developed to automate the creation, submission, transferring, processing, parsing, storage, and querying of computational chemistry data. One of the most venerable web-based examples is the Basis Set Exchange, originally assembled at the Environmental Molecular Sciences Laboratory, where a myriad of curated basis sets for most of the periodic table are available for download in multiple formats (Feller 1996; Schuchardt et al. 2007).

Close to half dozen platforms exist with a similar philosophy towards achieving some or all the following: automation of materials science and solid-state electronic structure calculations; data processing and analysis of those calculations; and centralized, web-accessible repositories of the output of these calculations for virtual discovery and machine learning purposes. The multiple solutions offer somewhat overlapping functionality, generally in the materials space, and have been reviewed recently (Lin 2015).

The Electronic Structure Project (Klintenberg et al. 2002; Ortiz et al. 2009) utilized the structural data from the ICSD to screen for novel inorganic materials.

The Computational Materials Repository (Landis et al. 2012) proposes an integrated software solution for computer-driven materials design. It is part of the ecosystem of the Quantum Materials Informatics Project that also includes the Atomic Simulation Environment, a python library for working on atomistic simulations (Hjorth Larsen et al. 2017).

AFLOW is an automatic framework for high-throughput materials discovery (Calderon et al. 2015; Curtarolo et al. 2012a), and the matching repository Aflowlib.org hosts and serves the results of those calculations to the public (Curtarolo et al. 2012b). It now contains 1,748,704 material compounds – with over 173,121,696 calculated properties.

The Python Materials Genomics (pymatgen) is an open-source python library for materials for the analysis of solid-state DFT calculations (Ong et al. 2013) which also has a matching Materials Application Programming Interface (Ong et al. 2015) to interact with the Materials Project, a large-scale database of materials calculations (Jain et al. 2013). Other computational tools in this ecosystem include tools such as Custodian for error handling, Fireworks for workflow management. The Materials Project tools and data have been used in over 100 published papers, and nearly 200 by its creators.

The Open Quantum Materials Database (OQMD) is a fully open project that hosts over 400,000 DFT energy calculations of compounds from the ICSD and also for hypothetical compounds, potentially uncovering valid, but yet to synthesize chemistries (Kirklin et al. 2015).

AiiDA (Pizzi et al. 2016) is a flexible and scalable informatics' infrastructure for simulations, data, and workflows with a heavy focus on plane-wave DFT calculations of materials and much attention to data provenance (Merkys et al. 2017).

The Novel Materials Discovery repository was established to host, organize, and share materials data in a pipeline-agnostic way (Goldsmith 2016) and hosts over 44 million open access user-submitted total-energy calculations from a variety of computer codes.

The ioChem-BD Platform provides a similar solution with an emphasis on molecular data (Álvarez-Moreno et al. 2015). Several toolkits address the simulation and role of defects, such as MAST (Mayeshiba et al. 2017), PyDII (Ding et al. 2015), and others (Goyal et al. 2017). PyChemia is a python library for automatize atomistic simulations, with a focus on materials and interfaces to some DFT codes and data mining functionality.

Multiples datasets of computational chemistry results aimed purely at generating diverse training data exist. QM9 contains B3LYP/6–31 G(2df,p) results for 134k stable small organic molecules made up of CHONF, including harmonic frequencies (Ramakrishnan et al. 2014). PubChemQC is a recent attempt to create training data for machine learning approaches that calculated the ground-state electronic structures of three million molecules based on density functional theory (DFT) at the B3LYP/6-31G* level and 10 lowest excited states of over two million molecules at TD-DFT/B3LYP/6–31 + G* level of theory (Nakata and Shimazaki 2017). ANI-1 contains energies and DFT-level properties for 20 million conformations for over 50,000 small organic molecules distorted along normal modes (Smith et al. 2017). Ab initio molecular dynamics are also available: 5,000 frames at 500 K at the PBE level of theory for 113 structural isomers of $C_7O_2H_{10}$ and hundreds of thousands frames for 8 small organic molecules (Chmiela et al. 2017; Schütt et al. 2017).

A large number of internal tools for data processing have grown into open libraries that are available for data analysis of calculation outputs: the python-based

cclib for parsing and interpreting the results of computational chemistry packages (O'boyle et al. 2008); ESTEST, a free framework for the comparison, validation and sharing of quantum chemical calculation outputs (Yuan and Gygi 2010); ORBKIT, also python-based library for postprocessing of quantum chemical wavefunction outputs from multiple codes; (Hermann et al. 2016); and PyGlobal, spreadsheet-oriented output postprocessing tool for DFT calculations (Nath et al. 2016). Other tools are also available for input generation and pipelining calculations, such as JACOB (Waller et al. 2013) a framework for computational chemistry aimed at enterprise application, PyADF for scripting multiscale quantum chemistry using the ADF package (Jacob et al. 2011).

This ample landscape suggests that increasing both the velocity and volume of quantum chemical calculations is of great interest. These increases, however, come with a tradeoff in the variety of the applications. Because of the added complexity, most of these rarely see adoption outside the groups or consortia that created them (Thygesen and Jacobsen 2016).

## 3.2 High-Throughput Virtual Screening

As computational methods become more accurate and computing hardware more affordable, the possibility of automatically prescreening compounds virtually before synthesis grows more promising. Various teams have used HTVS for discovery of many inorganic materials. These are treated in depth in other chapters of this book. Here, the focus will be on organic molecular materials in the domains of organic optoelectronics for light-energy interconversion (photovoltaics and light emitting diodes) and for electrical energy storage (Pyzer-Knapp et al. 2015).

### 3.2.1 Optoelectronics

Merging concepts from both the volunteer, distributive computing efforts and the HTVS vision, lies the Clear Energy Project (CEP). Since its inception around 2006 and throughout two phases, this project ran on IBM World Community Grid, where volunteers donated computer time to virtually screen *p*-type, and later *n*-type, organic photovoltaic oligomers.

CEP tackled many of the challenges for automated virtual testing of chemical compounds: programmatic generation of candidate molecules, automation of the quantum chemical calculation, data storage, and analysis.

Combining a pool of 20 fragments through covalent linking at active sites and also by forming fused rings adjacent to these labeled reactive atoms, the CEP molecular generation processed went up to tetramers and produced over two million candidates that were screened exhaustively. The quantum chemical calculations carried out included multiple DFT functionals and amount to the largest computational chemistry project to that date. The candidate tetramers were assessed using the Scharber model for photovoltaic efficiency, assuming fullerenes as electron acceptors and both raw and empirically calibrated donor energy levels. The statistical analysis of the large dataset produced afforded correlations for the

most and least promising fragments and fragment combinations (Hachmann et al. 2011, 2014; Olivares-Amaya et al. 2011).

The CEP, because of the large theoretical dataset, and the existence of numerous independent experimental results in the area of OPV has proven a testing ground for novel approaches to materials discovery. A probabilistic kernel-based calibration scheme to improve theoretical gas-phase results and to capture the bulk effects using a collection of experimental results from the literature (Lopez et al. 2016) improved the predictive performance of DFT calculations (Pyzer-Knapp et al. 2016).

A later subproject has focused on the virtual screening of over 50,000 non-fullerene electron acceptors from the combination of over 100 common organic moieties. Time-dependent density functional theory calculations were also carried out for elected lead compounds. Diketopyrrolopyrroles and quinoidal thiophene derivatives showed good promise and were proposed for additional study (Lopez et al. 2017).

At a less gargantuan scale, other works also addressed screening over bulk heterojunction solar cell components, such as combinatorial band-gap design strategy over 780 different copolymer donor materials (Shin et al. 2014).

Some works have addressed virtual discovery of molecules for other classes of solar cells, such as $TiO_2$-based dye-sensitized solar cells, optimizing over common dyes (Martsinovich and Troisi 2011) and also over porphyrins (Ørnsø et al. 2014).

A successful example of blending computational chemistry with deep learning for applied materials discovery has been reported in the area of thermally activated delayed fluorescence (TADF) organic light-emitting diodes (Gómez-Bombarelli et al. 2016). Using custom software that mimics cross-coupling reactions on existing staring materials, a database spanning nearly two million feasible compounds was created from over two hundred starting donor and acceptor fragments. The TADF character of the compounds, as well as their color, was estimated using accurate, empirically calibrated TD-DFT calculations. For accelerated results, the candidates were screened through a neural network, using topological fingerprints as features. The leading compounds with the most promising predicted chemical properties were assessed by a team of experts who synthesized and tested the consensus champion compounds. These were then tested in optoelectronic devices, where they matched the performance of human-generated champion compounds (Fig. 1).

### 3.2.2   Electrolytes and Energy Storage

Energy storage is one of the most active areas of materials science and engineering, given the strong demand in both lightweight, high-energy density applications such as mobile phones or transportation and static, low-cost, grid-scale storage.

Flow batteries are large, static batteries where liquid electrolytes are stored in tanks and circulated across an electrochemical cell when charging or discharging. Although they show somewhat inferior energy densities compared to solid-state batteries such as lithium-ion, flow batteries are potentially a much better solution to grid-scale electrical storage because of the lower cost and use of earth-abundant and cheap electrolyte materials. The independent scaling of power (depending on effects such as the kinetics of the electrochemical reaction and the electrode surface area)
**Fig. 1** Overview of TADF OLED chemical space. Red dots represent overlap with previous experimental reports in the literature, orange triangles correspond to theoretical leads, cyan squares represent experimentally confirmed theoretical leads. The log-density of molecular candidates as a function of singlet-triplet gap and oscillator strength of shown. The dashed lines follow iso-contours of estimated rate of delayed fluorescence

and energy (related to the total size of the tanks, the concentration of the electrolyte in solution, and the degree of ionization of the electrolyte) allows more flexible engineering for flow-battery solutions. Using water as solvent further reduces the installation costs and increases the operational safety. Because they can be sources from oil and from sustainable biomatter, the great design flexibility of organic molecules, and their promising performance, organic electrolytes for flow batteries are heavily considered contestants (Kowalski et al. 2016; Leung et al. 2017; Wei et al. 2017).

High-throughput simulation, particularly when coupled with experimental follow-on, has become a powerful tool in the discovery of electrolyte materials for organic flow batteries. The report of an efficient, metal-free, low-cost flow battery design using acidic aqueous solutions of anthraquinone disulfonate and bromine/hydrobromic acid leveraged thousands of DFT calculations of potential quinone molecules to optimize reduction potential of the negolyte and its aqueous solubility (Huskinson et al. 2014). The careful analysis of the theoretical predictions allowed to identify useful design rules and structure-property relationships over the domain of benzo-, naphto-, and anthraquinones bearing any of 13 functional groups (Er et al. 2015). Other high-volume calculations of bio-inspired thiophenoquinone derivatives also identified potentially useful electrolytes for flow batteries (Pineda Flores et al. 2015).

The Electrolyte Genome project used the Materials Project backbone to perform high-throughput calculations on a set of nearly 5000 molecules derived mostly from quinoxaline and anthraquinone, thiane, thiophene, and bipyridine derivatives (Qu et al. 2015). Special attention was paid to error handling and estimation of redox potentials, ion pair dissociation, and complex salt formation. A detailed analysis of nearly 1400 quinoxalines for nonaqueous flow batteries estimating redox potentials,

solvation energies, and structural changes was also reported (Cheng et al. 2015), as well as over 4000 five- or six-membered rings with one or two functional groups attached (Pelzer et al. 2017).

Somewhat smaller scale virtual searches have also been reported. Starting from experimentally reported molecules available in PubChem, and down-selecting manually to 315 after deploying a neural network, improved experimental performance was observed for a quinoxaline derivative (Park et al. 2015, 2016).

The chemical stability of organic molecules for electrochemical applications, which impact battery shelf-life and long-term cyclability, is one of the standing issues of virtual discovery applications. For this purpose, the first and second reduction and oxidation of organic solvents for lithium-ion batteries have been analyzed using DFT (Borodin et al. 2015). Similarly, bio-inspired alloxazine electrolytes have been shown experimentally to provide excellent stability in alkaline aqueous flow batteries, by including stability criteria in the virtual search, in addition to redox and solubility requirements (Lin et al. 2016).

Smaller approaches with less focus on automation and extreme throughput have been reported, focusing on aspects such as low $Li^+$ binding affinity over 32 organic molecules (Park et al. 2011), 15 counterions for magnesium electrolytes (Qu et al. 2017), redox-switchable polymer-based membranes (Ward et al. 2017), or tuning the reduction potential of organic molecules to optimize the combination of small redox active molecules with conducting polymers (Araujo et al. 2017).

HTVS has also been applied for materials related to other electrochemical applications such as double layer capacitors (Schütter et al. 2016) or other green-chemistry applications such as switchable-hydrophilicity solvents (R. Vanderveen et al. 2015).

## 4 Applied Machine Learning for Accelerated Discovery

As is the case in many other areas, machine learning applications to chemistry are not a novel enterprise (Pierce and Hohne 1986). As is also the case in many other applications, the combination of deep learning algorithms with larger datasets and specialized computing hardware has resulted in many effective applications of machine learning for chemistry.

## 4.1 Quantitative Structure-Property Relationships

Most applications of machine learning to computational chemistry applications are related to building fast statistical proxies to expensive calculations on three-dimensional atomic arrangements or chemical graphs. This is, in a sense, building quantitative structure-property relationships trained either on molecular structures or on 3D geometries, often generated on-the-fly using molecular mechanics.

Other chapters in this same publication give a thorough review of many recent contributions to this area, so only a brief overview will be provided. Readers are encouraged to explore further in this same book.

The idea of using neural network models to interpolate over potential energy surfaces goes back to the 1990s (Blank et al. 1995). Very early contemporary works applying machine learning to computational chemistry are those by Behler where neural networks were used for molecular dynamics simulations and other PES exploration techniques (Behler 2011b, a; Behler et al. 2007; Behler and Parrinello 2007). These and many other applications of neural-networks, mostly to bulk and heterogenous systems, have been reviewed recently (Behler 2017).

Another line of application of machine learning techniques to computational chemistry, with a heavier focus on molecules, rather than bulk materials initially leveraged kernel methods, with emphasis on mapping 3D coordinates (Rupp et al. 2012; Schütt et al. 2017) or electronic densities (Brockherde et al. 2017; Snyder et al. 2012) to properties. These approaches are well covered in other chapters of this publication.

One of the most important issues in predictions based on molecular structures is the choice of features to represent molecules. Chemists tend to think of molecules as undirected graphs, with atoms in the nodes and bonds in the edges, and some additional considerations for stereochemistry. In quantum chemistry, molecules are three-dimensional arrangements of atoms that correspond to a local minimum in the potential energy hypersurface. For multiple decades, cheminformatics applications, mostly in pharma and drug discovery, have created descriptive, rich features for machine learning over both graphs: pharmacophore fingerprints, topological fingerprints, and also 3D conformations.

Recent applications of machine learning to molecules in chemistry have focused on QSPR over quantum-chemical properties and placed their focus on more information-rich features. The Coulomb matrix, for instance, is a permutation-dependent symmetry invariant modified distance matrix. Contemporary highly powerful neural network approaches also leverage 3D information (Gilmer et al. 2017; Lubbers et al. 2017; Schütt et al. 2017). In the case of molecules whose 3D structure is unknown, which is generally the case when carrying out predictions, these features are calculated from guess geometries calculated on the fly at the molecular mechanics level of theory. Molecular mechanics methods, through the underlying force fields, are heavily parametrized, generally on quantum chemical calculations but eventually on the experimental data used to parametrize those too. Therefore, the machine learning methods applied over these features are heavily supervised, with their inputs essentially embedding quantitatively a large amount of prior chemical knowledge and hand-tuning.

Learning on graphs presents a very unique set of challenges, because of graph-isomorphism. Machine learning approaches over graph structures have much interest beyond chemistry, such as in networks of any kind in transportation, databases, telecommunications. Whereas extended connectivity circular fingerprints address graph isomorphism, the process of encoding the graph, hashing, muddles chemical information and can lead to different chemical substructures activating the

same feature. Neural fingerprints, a differentiable deep-learning extension of ECFP, have recently been proposed as a more flexible and learnable alternative (Duvenaud et al. 2015). These continuous counterparts of topological fingerprints and derivative graph convolutions for chemistry (Kearnes et al. 2016) have proven to outperform some traditional cheminformatics descriptors from QSPR, particularly for larger datasets, and open a new avenue for molecular screening.

## 4.2    Searching and Optimizing in Chemical Space

An interesting subset of applications of machine learning to the computational chemistry/cheminformatics community is moving in the discrete, high-dimensional space spanned by all possible molecules, or by a relevant subset, such as the small organic molecules with aromatic rings, or similar subsets of interest.

Chemical space is extremely large, with estimates ranging by many orders or magnitude, from $10^{23}$ to $10^{60}$. Rule-based efforts to enumerate molecules, exhaustively for small compounds and culling nonpractical but formally valid and even potentially stable molecules, have been reported as follows: GDB-11 lists 26.4 million small organic molecules of up to 11 atoms of C, N, O, and F (Fink and Reymond 2007); GDB-13 enumerates 978 billion molecules with up to up to 13 atoms of C, N, O, S, and Cl (Blum and Reymond 2009); and GDB-17 contains 166.4 billion molecules of up to 17 atoms of C, N, O, S, and halogens (Ruddigkeit et al. 2012). Extrapolating from those sets, the size of drug-like chemical space has been extrapolated to $10^{33}$ (Polishchuk et al. 2013).

In addition to the size of the space, molecules are discrete graphs and rules exist regarding the types and degrees of connectivity that are allowed. Even further, molecules that are formally valid may still be chemically unstable at the temperatures, pressures, and timescales of interest. Hence, performing local, or even more challenging global, optimization is of big interest in materials and drug design and also a great challenge. The Chemical Space Project leverages the GDB databases to develop visualization and exploration tools, with a focus on drug candidate molecules (Reymond 2015).

Custom molecular libraries have proven a very effective way of navigating chemical space, as the human-driven design allows to embed rules and chemical requirements that are hard to capture without strong supervision, particularly regarding synthetic accessibility of molecules. This success is reflected in the ease of experimental applicability of the examples in the previous section.

Multiple machine-learning approaches to this area suggest that the large existing datasets of chemical reactions from the patent literature (Lowe 2012) or from commercial databases can be leveraged to automatically construct reactivity prediction tools for organic synthesis reactions and retrosynthetic analysis software. Recent examples include prediction the outcome of chemical reaction from fingerprints of the reactants after training on rule-generated examples (Wei et al. 2016) and selection of the major product by ranking a self-generated list of candidates (Coley et al. 2017a; Jin et al. 2017). Sequence-to-sequence models following approaches

to machine translation (Fooshee et al. 2018; Schwaller et al. 2018) or similarity searches (Coley et al. 2017b) have proven effective at automatically predicting organic synthesis reactions in an automatic, data-driven way. Even more promising results have been obtained from larger, better-curated datasets (Segler et al. 2017; Segler and Waller 2017a, b).

A well-understood approach to chemical optimization are genetic-algorithms, where mutations from a hand-prepared list of chemical transformations and stochastically applied to starting molecules, and the resulting compounds, if the show improvement in a desired property, are kept for further evolution. Because they rely on hand-picked mutations and hyperparameters, and oftentimes also on manually tuned tradeoffs between target properties, these approaches involve a certain degree of chemical intuition. By compounding mutations that may be allowed individually but not in combination, the molecules generated tend to be quite complex. These types of genetic approaches have been used to navigate chemical space (van Deursen and Reymond 2007; Virshup et al. 2013) and to optimize multiple classes of molecules, such as organic light-emitting diodes (Rupakheti et al. 2016; Shu and Levine 2015), organic photovoltaics (Kanal and Hutchison 2017), diamondoids (Teunissen et al. 2017), visible chromophores with high hyperpolarizability (Elward and Rinderspacher 2015), or small molecules with high electrical dipole (Rupakheti et al. 2015).

## 4.3    Generative Models

Generative models are machine learning models that aim to produce natural-seeming data that capture the intrinsic statistical properties of the training populations. They can be trained in an unsupervised way and thus are not inhered by the need for labeled data. Given the large size of chemical space, and the very abundant number of chemicals known (see Sect. 2) numbering around 100 million known compounds, unsupervised deep learning models based on existing molecules have been assessed recently.

One of the most basic examples of generative models in chemistry has been the use of recurrent neural networks (RNN) to predict the next character of the SMILES representation of molecules. By feeding $n$ characters to the network to predict the $n + 1$th, RNNs have proven very powerful at generating valid – if nonsensical – text (Karpathy 2015). A simple and comprehensive string representation of molecules that is human readable and can be stored a single string exists: the simplified molecular-input line-entry system (SMILES) (Weininger 1988). SMILES contain the full molecular connectivity using a series of rules and a canonicalization procedure. The same principles shown for text have proven to work well for generating molecules through their string-based SMILES representation. Additional work has been directed towards generating molecules for generating leads that capture the statistical behavior of the training data (Bjerrum 2017; Ertl et al. 2017; Gupta et al. 2018). A further step involves evolutionary refinement of the molecule pool to bias the set towards a given property (Olivecrona et al. 2017).

Autoencoders are deep learning models that are trained to reproduce a high-dimensional input, subjecting it to a low-dimension information bottleneck. Some of the thorniest issues in molecular design emerge from the discrete nature of molecules and the extremely large size of the search domain. Hence, this low-dimension, real-valued, decodable embedding would potentially allow to apply gradient-based optimization algorithms to molecular optimization. A further improvement is the use of a variational autoencoder, where random noise is added to the encoding step, which results in more continuous coverage in the latent space and fewer *dead areas* that do not correspond to valid decoded points.

As discussed above, there are available strategies for using chemical graphs as inputs for machine learning systems. However, deep learning tools that efficiently write chemical graphs are still an open problem. Neural networks architectures have been shown to efficiently write text and images, and hence, the first report (Gómez-Bombarelli et al. 2018) of variational autoencoders (VAE) for chemical discovery used a string-based chemical representation. This work showed how a VAE can accurately reconstruct molecules from a continuous real-valued array representation. Even further, it explored how transformations in the latent space, particularly molecular optimization with respect to properties of interest, can be carried out. This application was particularly efficient in the case of jointly trained VAE plus predictor systems, where the deep learning system was simultaneously trained as an unsupervised generator and a supervised predictor. In this case, the latent space is topologically shaped by chemical property (Fig. 2).

The original VAE model suffers from several flaws, generally related to its ability to write out molecules, particularly the string output is probabilistic. Because of the string representation used, and its need for internal consistency and even arithmetic (opening and closing rings and branches), the VAE models produce many invalid molecules, in more than one sense. On the one hand, syntax errors result in strings that are invalid as SMILES and do not correspond to an actual chemical graph (cycles that open but do not close, parenthesis that open but do not close, representing unfinished branches, etc.), a similar type of failure is to write complete graphs that are not chemically valid graph (generally related to valences and the octet rule: carbon atoms with valence higher than five, oxygen atoms with valence three, etc.). A different type of writeout failure is molecules that are formally and chemically valid, but when re-encoded, do not correspond to the original point in the latent space: the stochastic text generation strays away from the original point.

A number of works are rapidly expanding this area, addressing these performance issues, and exploring further avenues for deep generative models in chemistry (Blaschke et al. 2018; Xu et al. 2017). These include using a series of grammar rules for SMILES as the output of the decoder (Kusner et al. 2017), active learning over the validity of the output (Janz et al. 2017), performing constrained Bayesian optimization to avoid exploring dead areas of the latent space (Griffiths and Hernández-Lobato 2017), performing local optimization near encoded latent points (Mueller et al. 2017), combining an additional RNN to generate higher-quality outputs through reinforcement learning (Jaques et al. 2016).
**Fig. 2** Diagram of a Variational Autoencoder with joint property prediction: an encoder neural network takes in the string repetition of a molecule and converts it into a real-valued array that can be decoded back into a string through decoded neural network. By training jointly with a property prediction network, the latent space can be navigated for property optimization

Further improvements and applications towards generating DNA (Killoran et al. 2017) and protein sequences (Sinai et al. 2017) have been reported, as well as adversarial approaches with the ability to apply bias towards desired properties (Guimaraes et al. 2017; Sanchez-Lengeling et al. 2017).

## 5    Conclusions

Machine learning and data-driven application have taken computational chemistry by storm. Tasks that have been deemed *holy grails* for decades seem closer than ever thanks to deep learning approaches: affordable computational predictions that match or surpass experimental accuracy, computerized retrosynthesis that can beat humans, etc.

Chemistry in general and computational chemistry, in particular, have long strived with high-volume, high-velocity, and high-variety data. The pain points are dissimilar however. In computational chemistry, the acquisition velocity is less and less of a bottleneck. Experimentally they are many more constraints on the pace and reproducibility, and they come at a much larger cost. Computational chemistry, on the other hand, has shown difficulty addressing variety: as parametrization increases the transferability and the trust in the predictive power decrease.

The more digitized and automated it is, the more experimental chemistry assimilates to computational chemistry, and hence the easiest to leverage these extremely promising data-driven tools. For a broader impact, and if computational chemistry is truly a sandbox and an accelerator for ideas that will ultimately change experimental chemistry, more focus is needed on addressing heterogeneous, unstructured data. Unsupervised machine learning and transfer learning are promising tools for this task.
