*We wish to dedicate this book to the memory of Walter Kohn and Aneesur Rahman, founders of the modern approach to the physics and chemistry of real materials, both theoretical and computational. While their contributions will forever stand as milestones in the progress of science, we wish to commemorate their courage and vision in proposing new methods that would be fully implemented only decades later. We – and everyone who has known them personally – continue to remember them also for their tireless enthusiasm for science, their generous sharing of ideas, their unique kindness, and their charisma. As their articles start to disappear from citation lists in the same way as those of the founders of quantum mechanics, it is both humbling and comforting to know that any present and future development rests on the work of two wonderful people who have truly embodied the values of science.*

*Wanda Andreoni and Sidney Yip*

# Preface to *HMM2*

The *Handbook of Materials Modeling*, published in 2005, was the first reference work of its kind, providing a comprehensive description of an emerging field of research and helping to grow a community at the intersection of *Computational Science* and *Materials Science and Technology* through the development of the theory, modeling, and simulation of materials across the disciplines of physics, chemistry, and engineering. In producing the first edition, the editors were guided by a simple vision – target students, young researchers, and nonspecialists as the primary audience, introduce the concept and practice of linking materials research at different resolution levels (from the atomic to the meso- to the macroscale), and stimulate exploration and applications. The e-book version became available two years later.

The *Handbook of Materials Modeling Second Edition* (*HMM2*) follows its predecessor in serving the broad community of *Computational Science* and *Materials Science and Technology*. Its goal is to update the current state of the art of materials modeling and simulation in two complementary ways:

- *Strengthen* the foundations of materials theory, modeling, and simulation
- *Broaden* the scope to include challenges and opportunities of interdisciplinary interest

In both objectives, *HMM2* strives to promote open discussion of the capabilities and limitations of current methodologies and applications. The Second Edition is composed of two companion sets: *Handbook of Materials Modeling – Methods: Theory and Modeling*, and *Handbook of Materials Modeling – Applications: Current and Emerging Materials*. These will be abbreviated as *MTM* and *ACE*, respectively. Each set is a stand-alone publication with its own Table of Contents and individual chapters that are grouped under a number of parts. Both *MTM* and *ACE* are three-volume sets. There are 11 parts in *MTM* containing, beyond the Introduction, 10 sections with 88 chapters and 16 parts in *ACE* containing, beyond the Introduction, 15 sections with 120 chapters. The chapters which constitute the primary scientific content of the handbook are organized by the section editors in each set, working in coordination with the editors in chief. The section editors also provide an introductory overview of their own section, thus facilitating access to the following chapters.

Logistical issues aside, we think it is important to emphasize the holistic aspects of materials modeling and simulation, as an evolving discipline across science and technology and the complementarity of the two sets. As the community grows in scope and relevance, learning "in depth" with the aim of mastering the relevant theoretical and computational algorithms becomes more and more important. Equally, it becomes important to be able to discern unresolved materials issues for which information from simulations could "make a difference" and to properly apply and critically assess the chosen models and methods. Thus *all readers* should recognize the beneficial overlap of the two sets. In the respective introductions we will elaborate further on this point.

An undertaking of this magnitude can only succeed as a collective effort. The *Handbook of Materials Modeling Second Edition* would not be a reality without the dedicated efforts of former Springer Editor *Maria Bellantone*, to whom we are especially indebted. She brought us together and provided us with essential logistical support. We thank *Lydia Mueller* for her early guidance. Our deepest gratitude goes to *Juby George* and *Sunaina Dadhwal* for their invaluable editorial assistance, efficient communication with authors and editors, and efficient management of the Springer platform *Meteor*. Their assistance made it possible to complete the project on an admittedly ambitious schedule. That 200 plus chapters could be commissioned, manuscripts collected, revisions, etc., be undertaken and published in less than four years is an accomplishment for which the credit properly should go to the section editors and their authors. We would like to think all participants will take pride in what we have achieved together. This is a journey that will continue. We trust the community will be diligent in upholding standards and maintaining respect and collegiality among all stakeholders.

February 2020                                                                          Wanda Andreoni
                                                                                              Sidney Yip
                                                                                                Editors

# About the Editors

**Wanda Andreoni**
Institute of Physics
Swiss Federal Institute
of Technology – Lausanne
Lausanne, Switzerland

**Wanda Andreoni** is Emeritus Professor of Physics at the Swiss Federal Institute of Technology of Lausanne (EPFL). She has been involved in Computational Materials Science since the early days of her research activity, in both academic and industrial institutions, covering also teaching, organizational, and research managing positions. She is a Fellow of the American Physical Society. She was Zernike Professor at the Groningen University (NL) (2011) and CECAM Director (2009–2012). Regarding editorial work, she was Coeditor of *Europhysics Letters* (1990–1993) and Editor of *The Chemical Physics of Fullerenes 10 (and 5) Years Later*, NATO ASI Series E: Applied Sciences, Vol. 316 (Kluwer, 1996), and of *The Physics of Fullerene-Based and Fullerene-Related Materials*, Series on the Physics and Chemistry of Materials with Low-Dimensional Structures, Vol. 23 (Kluwer, 2000).

**Sidney Yip**
Department of Nuclear Science
and Engineering
Department of Materials Science
and Engineering
Massachusetts Institute of Technology
Cambridge, MA, USA

**Sidney Yip** immigrated to the USA from China in 1950 at age 14. After receiving degrees in Mechanical Engineering and Nuclear Engineering from the University of Michigan and spending two postdoctoral years at Cornell University, he joined the Nuclear Engineering Faculty at MIT in 1965. From early research in theoretical studies of particle and fluid transport, he became broadly involved in atomistic modeling and simulation of materials. He edited the first edition of the *Handbook of Materials Modeling* as well as *Spectroscopy in Biology and Chemistry: Neutron, X-Ray, Laser* (1974) and *Materials Interfaces: Atomic-Level Structure and Properties* (1993). Other books include the monographs, *Foundations of Neutron Transport Theory* (1967), *Neutron Molecular Spectroscopy* (1968), and *Molecular Hydrodynamics* (1980), and a text, *Nuclear Radiation Interactions* (2014). He received Guggenheim Fellowship, US Senior Scientist Prize of the Alexander von Humboldt Foundation, Distinguished Alumnus Award of the University of Michigan, and the Robert Cahn Award. A Fellow of the American Physical Society, he became Professor Emeritus in 2009.

# Introduction

# Theory and Methods for Materials Modeling: An Introduction

**1**

Wanda Andreoni and Sidney Yip

## Contents

**Abstract**

The current problems facing mankind concerning energy, health, waste, and pollution have recently begun to have a strong influence on the development of materials science and start to define its main goals. In particular, the urgent need for novel materials and for more efficient processes for their synthesis is currently driving formidable research efforts, in which modeling and computer experiments play a special role. In many scenarios, multiscale materials modeling is called for because of its ability to interrelate the descriptions of a system at various length scales – ranging from the atomic (or molecular) scale (including the description of the electronic structure) to the microscopic scale and to the

e-mail: syip@mit.edu

mesoscopic and the macroscopic scales. This coupling is expected to enable improved predictions of microstructure evolution and thereby to lead to the development of improved materials and to improved design. However, currently, ensuring the reliability of the treatment of the system at each resolution level is still a major task for computational materials science. The *Handbook of Materials Modeling* (*HMM*) had recorded the state of the art up to 2005. The present *Handbook of Materials Modeling – Methods: Theory and Modeling* (*MTM*) presents a variety of more recent algorithms for the simulation at multiple scales and also some recent successful examples of multiscale approaches. Their explanation and critical assessment is the focus of the ten sections for which we provide here a brief survey. Moreover, we emphasize three lines of research: modeling at the mesoscale, whose critical importance has recently been recognized; multiscale simulations of complex physical and chemical processes for the diagnosis of materials behavior and as part of the synthesis protocol; and the emergence of data-driven artificial intelligence strategies.

# 1 The Attributes of Materials Modeling and Simulation

The principles of materials design are rooted in the correlation of molecular structure with physical properties. From these correlations, models are formulated that are capable of predicting microstructural evolutions. Such models allow the researcher to investigate the mechanisms underlying the critical behaviors of materials and to systematically arrive at improved design.

Recognition of this principle was evident throughout the emergence and growth of the materials modeling community as one can follow through a series of reports from the US government agencies and funding organizations, as well as reference work publications (PITAC 2005; SBES 2006; NRC 2008; WTEC 2009; MGIGC 2011; DOE-BES 2012; Konings 2012), and a commentary (Yip and Short 2013). It is worthwhile to note the perceived global societal impact of information technology in these discussions and the particular challenges of the mesoscale in building multiscale materials models. The former issue has given rise to the currently emerging field of artificial intelligence in the materials innovation domain, while the latter has given awareness to the importance of modeling and simulation at the mesoscopic level (DOE-BES 2012). This is an outcome of the "tyranny of scales" manifestation (SBES 2006).

The benefits from materials innovation can be illustrated by the current progress in nanoscience and nanotechnology, a worldwide enterprise that one may compare to computational drug design. Linking methods capable of describing a system at the atomic scale – including the quantum regime – and techniques capable of describing phenomena at the mesoscale is expected to ensure that the different phases of materials innovation and development, from design to synthesis to testing to performance and lifetime evaluations, can all be simulated, analyzed, and optimized.

In the broad arena of societal impact, one can expect materials modeling and simulation to have considerable potential for societal benefits because they sit at the crossroads of computational science and materials science and technology.

To keep the various communities connected, we declare at the outset that the terms "materials modeling and simulation" and "computational materials science" are to be regarded as synonymous unless specifically stated otherwise.

We can briefly recall three attributes of materials modeling and simulation that will endure throughout the developmental and application phases (SBES 2006). Together they constitute the essence of the "intellectual glue" joining *MTM* and *ACE*.

**Exceptional bandwidth** – The conceptual basis of materials modeling and simulation encompasses all disciplines of physical sciences and even beyond. It makes no distinction between what belongs to physics, chemistry, engineering, etc. The universality of the materials modeling enterprise becomes evident when one considers what is actually involved in formulating models for simulation. If we define modeling as the "physicalization" of a concept and simulation as the numerical implementation of this concept, then it is clear that modeling and simulation lie at the basis of all scientific disciplines that involve formulating a hypothesis and testing via simulation (or experiment) and then repeating this process through understanding and subsequent manipulation (design).

**Elimination of empiricism** – A virtue of multiscale modeling and simulation is that the results from both are conceptually and operationally quantifiable. "Quantifiability" here means one can interrogate a particular operation and determine its outcome in a controlled manner, effectively akin to an ability to investigate "cause and effect." A complex phenomenon therefore can be probed one detail at a time. This is significant because of its broad implication that empirical assumptions can be systematically replaced by physically based, quantifiable descriptions.

**Visualization of phenomena** – The numerical output of a simulation generally is in the form of data on the degrees of freedom characterizing the model. The availability of this kind of data lends itself not only to direct animation and visualization but also to data analysis and subsequent visualization of the functional properties of interest. In microscopy, for example, one can obtain structural information but usually without the energetics. Through simulation one can have both. The same is true for studies of mechanisms and reaction pathways where it would be desirable to correlate spatial and energetic information.

## 2   Complementarity of Methods and Applications and *MTM* Sections

The first edition of the *Handbook of Materials Modeling* (*HMM*) consisted of individual contributions (a total of 141 chapters) and of a special section called Plenary Perspectives containing brief commentaries (39).

In contrast, as specified in the Preface, the present edition consists of two standalone sets, namely the *Handbook of Materials Modeling – Methods: Theory*

*and Modeling* (*MTM*) and *the Handbook of Materials Modeling: Current and Emerging Applications (ACE).*

This division is not only meant to make it easier to read but also, and especially, to emphasize the interplay of methodology and "best practice" and to promote a comprehensive knowledge of materials science. It is true that, currently, the availability of several powerful and user-friendly computer codes makes it possible for researchers to undertake applications without concerning themselves with a profound and detailed understanding of the methods on which such codes are based and of the several approximations implemented therein. Such an attitude would, however, obviously be detrimental for any application because its scientific value strongly depends on the capability of the researcher to master "his/her instrument," and in particular to test and clarify the range of validity of the methods he/she is using. On the other hand, an awareness of the problems that modeling and simulation are expected to help solve, namely those that experimentalists and technologists face in diverse areas of materials science, is essential for the development of useful methods.

The theoretical and computational approaches presented in *MTM* represent to a large extent the state of the art for the study of the physics, chemistry, and mechanics of (hard and soft) materials. Note that they do not include the additional procedures that are required in any application, namely, the reduction of a specific complicated real system to a virtual model that can be treated with available computational means, the choice of the theoretical and computational approaches with assessment of the level of accuracy and limitations of the calculations, and the analysis of the results aimed at understanding and providing physical insight and connection to experiment. Why are these procedures so important? Let us not forget that what we simulate is the virtual system and what we learn from our calculations is the physics of that model. Therefore, we have to be cautious when pretending that a model represents the real system. The same is true for the simulation of the dynamics of a certain process because, for example, the duration of the virtual experiment may not allow to detect the relevant mechanisms. See also our discussion in ▶ Chap. 23, "Atomistic Simulations: An Introduction."

As seen in the Table of Contents (*TOC*), *MTM* is composed of ten sections, with each section having a number of chapters, nine on average. To give the readers who are relatively new to the community an appreciation of the scientific themes of *MTM* at an introductory level, Table 1 also shows a listing of the keywords characterizing the particular theme of each of them. These are abstracted from the titles of the sections as given in the *TOC*, intended only for a very qualitative comparison with other similar listings such as that for *ACE*. In each entry of this Table, it is implicit that the overall context is methods, theory, and models for materials modeling and simulation. The keyword abstraction is but one way of characterizing the content organization of the handbook, and clearly one can consider many other ways to categorize it. To make use of Table 1, we can look at the list for *ACE* which has 15 sections, while we need to keep in mind that the overall context for that list is

**Table 1** List of keyword descriptors of topical themes for each of the ten sections in *MTM*. For full section titles and the individual chapters in each section, see the *Table of Contents*

| Plenary topics |

## 3    Brief Section Overviews

Here we briefly introduce the ten *MTM* sections and refer the reader to the overviews by the section editors for a more complete and useful account.

From the list in Table 1, we see that *MTM* begins with a "Plenary Topics" section dedicated to wide perspectives as well as to subjects that can be related to several specific sections of both *MTM* and *ACE*.

The first topical section ("Electronic Structure of Materials by Ab Initio Methods" Editor: Rubio) is dedicated to advanced quantum-mechanical methods

**Table 4** List of the sessions of the *19th Workshop on Computational Physics and Materials Science: Total Energy and Force Methods, Trieste (Italy), Jan 9–11, 2019*

for the calculation of the electronic structure and related properties of extended systems. Applications of the methods discussed therein permeate this handbook, both in *MTM* as components of nonempirical simulation methods (see, e.g., the next section) and in numerous implementations and practical examples included in *ACE*.

The text proceeds with the explanation of advanced algorithms for simulations using atomistic models ("Atomistic Simulations" Editors: Andreoni and Yip). In particular, emphasis is given to simulations of the dynamics of complex physical and chemical processes in condensed phases, for which considerable progress has been made over the last 15 years. Some of the methods in both the sections just mentioned are rooted in well-established approaches that were explained in *HMM*. We refer, in particular, to GW-BSE calculations for the study of electronic excited states (Louie and Rubio 2005) and DFT-based molecular dynamics (Car et al. 2005). We have also endeavored to present very recent and promising methods that are opening new horizons for computational approaches and new opportunities for applications.

The next section ("Computational Methods for Long-Timescale Atomistic Simulations" Editors: Perez and Uberuaga) emphasizes the importance of long-scale atomistic simulations and reports on well-known – widely used – direct acceleration techniques (see also Uberuaga et al. 2005 in *HMM*) and recent extensions.

The study of magnetism requires approaches on a vast range of length and time scales. The section "Modeling Tools for Magnetism, Magnetic Materials and Spintronics" (Editor: Sanvito) is especially instructive in that it comprises theoretical and computational schemes targeted at diverse scales and models, ranging from descriptions at the atomic level to the continuum. Moreover, this section is well connected to the companion section in *ACE* (Editor: Sanvito).

Multiscale methods coupling different length scales are fundamental for the study of a large number of physical systems. Many discussions are presented in *MTM* and also in *ACE* (see, in particular, "Hierarchical Materials Modeling: Mechanical Performance" Editors: Buehler and Martin-Martinez; "Modeling the Structural Development and the Mechanics of Complex Soft Materials" Editors: Del Gado and Pellenq; "Multiscale Modeling of Diseases" Editors: Dao and Karniadakis).

The "grand challenge" pertains to the "mesoscale," and the establishment of methods for a physically sound and mathematically correct connection from the micro- to the macro-scale regimes. A full section is dedicated to the related issues ("Modeling of Microstructure Evolution: Mesoscale Challenges" Editors: Sarrao and Stan). More comments will be given below (see Sect. 4.1).

A coarse-grained representation is often extremely useful especially allowing for the transfer of information from one domain to the next within multiscale methods. Coarse-grained models and the inclusion of stochastic approaches are the focus of the next section ("Stochastic, Coarse-grained Models of Materials Mechanics" Editors: Homers, Chen, Schuh). Both basic concepts and examples of implementations and applications are discussed.

The next two sections discuss systems, properties, and processes for which advanced multiscale algorithms are called for and illustrate state-of-the-art models for simulations at different length scales.

An outstanding area is that of "soft matter" to which one full section is devoted ("Soft Matter/Polymers Simulations" Editor: Kremer). An extensive description from the atomic level to the continuum level appears to be critical in the search for structure-property and ultimately structure-process-property relations.

On the other side, namely crystalline materials, modeling plastic deformation is a key topic that has also long stimulated the development of multiscale approaches (see "Crystal Plasticity: From the Atomic Scale to the Macroscale" Editors: Cai and Ghosh).

The last section ("Materials Informatics" Editor: Marzari) deals with an area of increasing interest in the community. The explicit target here is the discovery of new materials with certain desired properties, and it is based on the data-driven "knowledge" of structure-property relations. Several chapters discuss machine-learning strategies (either established or under development) and different protocols for the creation of the reference data. We remark on an interesting application to the search for novel magnetic materials in the *ACE* part of this handbook (Chap. 17, "Machine Learning and High-Throughput Approaches to Magnetism" by Sanvito et al.). We take care to indicate also other – more recently published – machine-learning algorithms with other important applications, e.g., to predict chemical reactivity of complex organic molecules (Schwaller et al. 2018) and mechanical stability of metal-organic frameworks (Moghadam et al. 2019). This section is complemented by a chapter in the "Plenary Topics" section (as mentioned above). We shall say more below (Sect. 4.3) about artificial intelligence applied to materials science, namely about its significance and the expectations for the near future.

## 4    Highlights

In the next paragraphs, we take care to emphasize three lines of research that are bound to be central to the progress of computational materials science in the next decade and more.

## 4.1    Modeling and Simulation Challenges at the Mesoscale

A question that has been noted repeatedly in assessing the merits of materials modeling and simulation is how one can exploit the understanding of molecular mechanisms to predict the functional behavior of materials at the macroscale. In the spirit of multiscale materials modeling, one can define "mesoscale science" as the process of linking microscale models and simulations to macroscale behavior. The scientific challenges of the mesoscale have received particular interest in the community (DOE-BES 2012). They have been illustrated in attempts to explain longstanding problems in materials phenomena, such as the temperature variation of the viscosity of supercooled liquids, the temporal evolution of the shear modulus in the setting of cement paste, and the effects of loading on crack propagation in stress corrosion cracking of a glass (Yip and Short 2013). In each case, there exists a common challenge in dealing with mesoscopic time scales in molecular simulation. A section has been devoted to exploring the various issues that have been raised (Editors: Sarrao and Stan).

## 4.2    Beyond Material Properties via Simulations

As mentioned above, the search for structure-property relations is at the heart of materials science and has been guiding the development of computational tools for materials design for many years. Today's great challenge is to exploit advanced computational methods for the simulation of the physical and chemical processes that "real" materials undergo: their formation (see growth, nucleation), their transformations, and eventually their degradation. Indeed, in principle, computer experiments can provide unique information about a given material, because they can explore its behavior in conditions or at scales that are not accessible by real experiments. As pointed out by Galli in the "Plenary Topics" section, one of the most ambitious goals is to render first-principles simulations part of synthesis protocols. On the other hand, in his section overview, Kremer underlines the need to establish structure-process-property relations, which is especially critical for soft-matter/polymer systems whose observed configuration depends on their history, e.g., on the preparation method.

As demonstrated, e.g., by the accomplishments of density-functional-theory-based molecular dynamics over the last 30 years, the success will depend on the synergy of ingenious theoretical and computational algorithms aided by efficient procedures of computer science and code development.

## 4.3    Artificial Intelligence: Toward a New Paradigm in Materials Modeling

In the last few years, there has been an upsurge of interest in the materials modeling community to embrace the concepts and tools of artificial intelligence, machine

learning and deep learning. As mentioned above, this handbook contains several contributions in this area and many references. A few more comments are probably necessary to point out the significance of this new way of doing research. We remark that by now, data-based artificial intelligence strategies are considered to form the fourth paradigm of computational materials science. Born simultaneously in many different labs, this new "paradigm" is however still in its infancy and a great effort is ongoing to establish accurate transparent and shareable data. There is no doubt that this formidable endeavor will continue to offer unique opportunities in bridging the communities of computer science and computational materials science to the benefit of both. On the one hand, the development and impact in materials science will continue to be bound to the progress of the traditional approaches, theory, experiment, and computation, and the degree of interaction among them. On the other hand, the application of artificial intelligence tools is bound to create new and also unsuspected challenges, e.g., for the synthesis of the virtual materials (certainly a huge quantity) that will be produced.

Wanda Andreoni and Sidney Yip

## Contents

**Abstract**

The articles of this section cover themes that we expect to usefully complement the broad collection of topics presented in this part of the Handbook (MTM). When matching the contents of other MTM sections, they provide additional information and new perspectives. Also comprehensive reviews are presented of well-established theories, namely time-dependent density-functional theory and the modern theories of polarization and orbital magnetization, especially including recent formulations. Moreover, this Plenary Topic section establishes further connections (and thus reading support) to the chapters in the companion Set on Applications (ACE).

# 1     Introduction

The scope of the section on "Plenary Topics" is twofold: providing topical overviews and perspectives of general interest to the readers of the Handbook and presenting the discussion of themes that were not included in the specific sections.

Some theoretical methods that have been widely applied in the last 15 years (not reported in the first issue of this Handbook) are explained extensively. For example, this is the case for time-dependent density-functional theory on which the majority of calculations of electronic excited states, electron dynamics and electron-nuclear dynamics are currently based, especially in extended systems. One of the chapters reports on general guidelines currently followed in data-based artificial intelligence applications aimed at discovering novel materials. Other chapters elucidate the role that computational approaches currently play in materials science and are expected to play in the future.

The brief survey below is meant to guide the reader through the seven chapters.

# 2     A Brief Chapter Overview

The Section opens (Cohen: ► Chap. 3, "Modeling Solids and Its Impact on Science and Technology") with an excursion over a century going through the development of modeling-based approaches to the physics of solids and its extension to nanostructured materials. We also remark that Cohen's earlier contribution to the first edition of the Handbook (Cohen 2005) remains on the recommended reading list for students and researchers coming into the community. Based on the author's address on the occasion of the 2018 Franklin Medal award, the review presented in this section leads the reader from textbook-level to some issues on which current research is focused. It shows how computational methods have emerged and progressed from empirical to "ab initio" and emphasizes the role of computational materials science as companion to experiment.

The following chapter (Galli: ► Chap. 4, "The Long and Winding Road: Predicting Materials Properties Through Theory and Computation") explains why and how first-principles calculations are presently used to explore the complex systems relevant to contemporary technology and what are the main expectations from further method developments. It is argued that exchange of information to and from experiment continues to be essential and that the envisaged role of non-empirical simulations is that of generating unique knowledge for the design of novel materials and novel synthetic routes. Another issue touched in this article is the need for accuracy, validation, and reproducibility of the results, so as to ensure the unique role of first-principles calculations in the application of data-based artificial intelligence to materials science.

For a discussion of the application of artificial intelligence, machine-learning procedures, and the use of Big Data in the realm of materials science, we refer

the reader to the Section "Materials Informatics" (Editor: Marzari). The additional contribution reported here (Draxl and Scheffler: ▶ Chap. 5, "Big Data-Driven Materials Science and Its FAIR Data Infrastructure" ) gives a detailed account of the general guiding (FAIR) principles for the "management" of the data, machine-learning models currently in use, and several recent results. Moreover, some of the problems still to be solved are clarified and important targets of future developments are mentioned.

The so-called first-principles simulations rely on a chosen description of the electronic structure of the system under investigation. For many years now, several and diverse approximate schemes of density functional theory (DFT) have been commonly used to calculate ground state properties and to drive ab initio (Car-Parrinello and Born-Oppenheimer) molecular dynamics. On the other hand, excited state properties and electron dynamics have long been a thorny problem especially for extended systems. To date, it is fair to say that time-dependent density-functional theory (TDDFT) – within the same approximations for the exchange-correlation functional as those used in ground-state DFT calculations – has become the method of choice. This fact explains why a comprehensive and detailed review is presented in this section (Agostini, Curchod, Vuilleumier, Tavernelli, and Gross: ▶ Chap. 6, "TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter"). In particular, recent extensions of TDDFT to treat non-adiabatic electron-nuclear dynamics beyond Ehrenfest (mean field) dynamics are reviewed. For a further discussion of TDDFT, we wish to direct the reader to ▶ Chap. 40, "Time-Dependent Density Functional Theory for Spin Dynamics" by Elliott et al. in this Handbook (section "Modeling Tools for Magnetism, Magnetic Materials and Spintronics" Editor: Sanvito), where the important extension to include the electron spin degree of freedom (TDSDFT) and its interaction with a magnetic field is presented in detail. Currently, TDSDFT is the only ab initio method available for the investigation of ultrafast spin dynamics and – as shown in the chapter by Elliot et al. – has successfully been applied to complex magnetic systems.

The development of methods going beyond DFT and also TDDFT and perturbative DFT approaches like GW is presently very active. Several examples are reported in the section "Electronic Structure of Materials by Ab Initio Methods" (Editor: Rubio). Here a chapter is included that describes the auxiliary-field quantum Monte Carlo (AFQMC) (Zhang: ▶ Chap. 7, "Ab Initio Electronic Structure Calculations by Auxiliary-Field Quantum Monte Carlo") for correlated many-electron systems. We recall that the core of the method relies on the utilization of the Hubbard-Stratonovich transformation to express the quantum evolution operator – of the correlated system under study – in imaginary time as an "average" (with respect to a classical Gaussian probability distribution) of free evolution-like operators. Especially for the ground state, AFQMC appears to be a clean, efficient, and relatively "simple" algorithm to handle and implement. Extension to treat excited states is also discussed. Illustrative examples refer to lattice models as well as molecules and  solids.

The last two chapters are concerned with fundamental concepts in condensed matter physics and related theories.

Under the denomination "modern theories of polarization and orbital magnetization" go rigorous definitions for a periodic system. Explicit expressions of the measurable changes in terms of a Berry phase are obtained and make direct calculations possible. The theory of polarization was well established already more than 20 years ago, and relevant applications – within DFT – started to appear soon after, leading to advances in the understanding of piezoelectricity and ferroelectricity and calculations of related properties as well as of infrared spectra of liquids and amorphous materials. Examples can be found in the ACE component of this Handbook (Picozzi: "Multiferroic and Ferroelectric Rashba Semiconductors" (Section "Applications of Materials Modeling to Magnetism, Magnetic Materials, and Spintronics" Editor: Sanvito) and Lu and Rondinelli: "Design of New Multiferroic Oxides" (Section "Oxides in Energy and Information Technologies" Editor: Franchini and Yildiz)). Extension to orbital magnetization is more recent and has allowed one to calculate, in particular, the nuclear magnetic resonance shielding tensor and the electron paramagnetic resonance $g$-tensor (from changes of the orbital magnetization) for periodic systems. ▶ Chapter 8, "Electrical Polarization and Orbital Magnetization: The Position Operator Tamed" by Resta provides an exhaustive review especially of the conceptual background and the mathematical formulation of the methods. We also wish to direct the reader to an interesting article showing the importance of the modern theory of orbital magnetization for the study of inhomogenous magnetic systems and especially of spintronics (Hanke et al. 2016).

The physics underlying the formation of a glass continues to be a severe challenge for the theory of condensed matter. The last chapter of this section (Rizzo: ▶ Chap. 9, "Critical Phenomena in Glasses") discusses the state of the art of theoretical approaches. It focuses on the mode-coupling theory, its successes and shortcomings, and incorporates recent developments aimed at improving the present characterization and understanding of the critical behavior of glasses.

## 3 Conclusions

The chapters of the section here introduced are diverse, spanning theoretical and computational methods as well as a few illustrative "best practice" examples. Each chapter provides a clear and critical view of current research and also of future challenges. In spite of the different focus of each chapter, a few important common messages can be extracted: the need for theoretical methods of wider reach, the importance of the interplay of theory, computations and experiment, and the need for more accurate algorithms as well as for their systematic validation. The latter requirements are crucial in view of the growing demand for virtual experiments and the generation of an increasing volume of data as basis for fully machine-driven approaches.

# Modeling Solids and Its Impact on Science and Technology

**3**

Marvin L. Cohen

## Contents

**Abstract**

An attempt will be made here to describe how modeling of solids in condensed matter physics and materials science has influenced science and technology for the past 100 plus years along with several examples.

## 1 Introduction

Since the focus when modeling solids and more generally condensed matter physics (CMP) is on energies, physical sizes, and time scales that are not extremely big or extremely small, but somewhere we loosely call the "middle," it can be argued that this characteristic of CMP allows it to have many links to other branches of physics

e-mail: mlcohen@berkeley.edu

and more generally other areas of science and engineering. In addition, the domain of CMP is very broad. It has both applied and fundamental components. This paper will focus mainly on the latter with emphasis on "modeling solids" which gave rise to many intellectual and conceptual contributions to science and to applications. The description here is centered on the development of concepts and models and on the research involving the electronic structure of materials, semiconductors, superconductors, and nanoscience. It begins by briefly discussing the development of these areas over the past hundred years, followed by examples of some current achievements and discoveries.

## 2     Basic or Applied?

William Gladstone, English Finance Minister (later Prime Minister), said to Michael Faraday, "But what is the practical use of electricity?". Faraday responded, "I don't know, but someday you may tax it." When a student asks, "Should I do basic or applied science," the appropriate answer is the same as it is for the question of whether light is a particle or a wave. The correct answer is "Yes."

We have so many questions of this type in science and mathematics. In the latter case, computer-based proofs, using the products of applied computer science, are more readily accepted in recent years. If we set aside the philosophies connected with motivation or goals in science and look at what really takes place, there are countless examples of how developments in basic science have led to marvelous technical advances and countless examples of how the discovery of new insights into nature was arrived at through the pursuit of applications. Many of the great successes in science and technology resulted from conceptual advances, sometimes on a philosophical level, ab initio developments from fundamental theories, empirical models, modeling, and simulation. There were arguments made by great scientists, like Dirac, suggesting that the beauty and simplicity of an equation are often connected with its correctness. At the other end, there are complex approaches, particularly in the biosciences, that work well but have many widgets and appendices. Even though they don't have the "elegance" of the Dirac equation, they can be profound, highly appropriate for solving the problems at hand and the genesis of new insights. Early America's most famous scientist, Benjamin Franklin, is an excellent example of someone who benefitted from the cross-fertilization between basic and applied studies. Franklin's famous experiments were designed to prove that lightning is electricity, and these experiments led to his invention of the lightning rod. In the course of his studies, he was the first to label different electrical components as positive and negative, and he was the first to discover the principle of conservation of charge. Hence the notion of there being only an "Einstein or Edison" approach to science is not well founded whether one is looking for discoveries of new principles or new technologies.

When describing the modeling of solids and its associated fields like condensed matter physics (CMP) and materials science, it is useful to point out that like Franklin, CMP embodies similar attributes. It rivals chemistry in its useful applications, and its contributions to basic physics are often at the forefront. CMP is the largest branch of physics with one foot in fundamental physics and the other in applied physics where inventions such as the transistor have had a large effect on developed and some underdeveloped societies. More than 28 Nobel Prizes have been awarded in this field, covering achievements in basic and applied areas. In addition, CMP has strong connections to most areas of science and engineering because of its focus on the sizes of energies, distances, and lengths of time that are sort of "in the middle" of those studied in physics. Since these sizes are of interest in many other fields, the result is that CMP is diverse and it is in a "sweet spot" or "Goldilocks area" of science.

## 3    Empirical and Ab Initio

In covering this time span, it is important to realize that around 1900 the existence of atoms was still debated, and research such as that represented by Einstein's thesis on sugar molecules and his work on Brownian motion were important in establishing belief in the existence of atoms. Einstein's interest in problems in CMP was certainly based on an atomic model of solids. A classic example is his paper on the heat capacity of solids. The theory of electrons produced by Paul Drude is similar in spirit, and his simple approach to transport is still widely used today. Hence the concept of a solid being composed of interacting atoms was being established at that time, and the introduction of X-ray crystallography produced the picture of a crystalline solid as a periodic array of interacting atoms. When one adds the chemical identity of the constituent atoms, this view or model of a solid allows some schemes for classifications of solids.

We will return to the conceptional models later; let us first consider the question of how to calculate properties once a conceptional model has been developed. Often the first approach can be characterized as empirical, semiempirical, or heuristic. Even Einstein's Nobel Prize winning theory of the photoelectric effect was characterized as heuristic. The Bohr model of an atom was tremendously useful for explaining experimental data, for understanding many aspects of quantum theory, and it is still considered an excellent teaching aid in atomic and quantum physics and a reliable model for making estimates of physical properties in a large number of cases. Conceptually and practically, the Bohr model has been replaced by the quantum mechanical approach where, for example, wavefunctions can be calculated and used to calculate the probabilities associated with determining the position of an electron in contrast to the purely planetary model of Bohr with electrons viewed as particles. This is a good example of an ab initio approach, such as the use of

the Schrodinger equation replacing the empirical Bohr model. A major point to be made is that the use of the empirical model in explaining and understanding the physics of atoms had a large effect on the development of the ab initio approach. Another point is that at a fairly fundamental level, the Bohr model solved a host of problems and in some sense "skimmed the cream" in the early days of applying quantum ideas to atomic physics. The photoelectric effect is another case where the heuristic theory was followed by more fundamental approaches. However, it is important to emphasize that not only did the empirical theories provide conceptual models to use when developing ab initio theories, but the empirical theories were first and therefore have the characteristics of a "breakthrough."

## 4     Models for Modeling

As was proposed above, modeling a crystalline solid as a periodic array of interacting atoms is a natural approach, and this model has become the most popular. In the end, properties are calculated based on this model, and the results are compared to experiment. Usually the comparison is made using a response function such as the reflectivity which is a representative response function for an electromagnetic probe.

Since the goal of many calculations of the properties of solids is the construction of a desired response function, another way of thinking about describing or modeling solids, often referred to as the elementary excitation model, is based on considering the response function first. Fundamentally, measuring response functions is the central task of experimentalists, and in a sense the principal job for theorists is to explain and/or predict the response functions. The concept of a response function is associated with the basic question about how we learn about the physical world. In most cases, we probe and respond. Our senses are seeing, hearing, touching, smelling, and tasting. The probes for these senses are light, vibrations, changing the temperature, using a stream of liquid or gas. By using these probes and our "built-in" response sensors, we learn about the physical world around us. Similarly, for measuring properties of solids, a few examples of the probes and their associated response functions are light (dielectric function), magnetic field (magnetic susceptibility), and temperature change (heat capacity). In the elementary excitation model, we describe a solid in terms of its excitations which we create when we probe the solid as illustrated in Fig. 1. The focus in this approach is on the responses and hence the response function.

We have described two basic models. The interacting atom model focuses on the building blocks and their interactions, while the elementary excitation model focuses on the responses to probes and the emergent excitations characterizing the solid. Both methods are important, and their applications have had a tremendous influence on technology, and the related concepts have influenced other scientific areas and science philosophy. The usefulness of the two approaches depends on what properties are being studied. Early goals were classifications of solids in terms of properties such as hardness or composition or structure. Although these

**Fig. 1** Illustration of the elementary excitation model. A probe (hammer) creates elementary excitations (phonons) measured by a response sensor (ear)

mechanical, chemical, or structural properties are important for classifying and modeling solids, a more influential property involves the electronic nature of a solid, the electrical resistivity. This is discussed next using the interacting atom model. The questions related to the building blocks in this model would be the atoms. Models of atoms such as the Bohr model or the Thomas-Fermi model can give insight, but using a full quantum mechanical approach with some approximations for potentials is the standard approach. Sometimes the building blocks are not really atoms, and the solid is considered to be just a box of free electrons. The discussion of the resistivity below illustrates the use of the model and some of the approximations.

## 5    Electronic, Optical, and Structural Properties

The range of values of resistivity is enormous. For example, consider copper with a value of $10^{-8}$ ohm-m compared to quartz with $10^{17}$ ohm-m. To emphasize this span, it has been stated that the range is the same as the comparison between the size of our galaxy and the head of a pin. Materials are classified according to their resistivities: metals with values around $10^{-8}$ ohm-m, semimetals $10^{-5}$, semiconductors $10^{-4}$ to $10^{11}$, and insulators $10^{16}$ to $10^{24}$. The resolution of the problem of finding the origin of this wide range of properties and the four classes of materials is based in the concepts related to electronic band theory of crystalline solids. The central concept is an energy gap or forbidden energy region which can arise when atoms interact. In the interacting atom model, the overlap between the atomic wavefunctions spreads or widens the energies of the sharp atomic levels into bands of allowed energy bands with energy regions or gaps where electron states are not available for occupancy. As a result one can have several scenarios. Suppose electron states are filled within each band of energies up to the energy gap. Because of the Pauli principle, the states can have at most two electrons, each in a different spin state, e.g., one with spin up and one with spin down. Because the next unoccupied state is above the gap in energy, if the energy to "jump over" this

gap is not supplied by electromagnetic radiation or heat, the electrons are frozen and won't contribute to electrical conductivity when an electric field is applied. At finite temperatures, some electrons will be free to conduct, and the number will depend on the size of the energy gap. This is a description of a semiconductor or insulator. Roughly speaking, if the gap is 3 eV or less, the material is considered to be a semiconductor. If the gap is larger, it is classified as an insulator. When bands are partially filled, the separation between an occupied and empty state is extremely small for a bulk solid, and the amount of energy required to free an electron so that it can contribute to the transport of current is minute. Hence partially filled bands lead to metallic behavior. Semimetallic behavior is the result of having bands with low densities of electrons arising from the overlapping of the bands.

To calculate the resistivity which is the response function for an electric field, we need the band structure represented by the function $E_n(k)$ where n is the band index and k represents the electron wavevector. In a sense the grouping of electrons into bands arises from the periodicity of the crystal structure. One can argue that since the cells in a crystal repeat, the effect on the electronic states is similar to the effect of confinement in a box which leads to discrete electronic states. Now the discrete electron states group into bands because of their interactions with the ionic cores. Once we have determined $E_n(k)$, we can then compute response functions resulting from electronic excitations.

How do we obtain $E_n(k)$? What models give this important function? A model introduced in the 1930s and still useful today is called the free electron gas (FEG) model where we assume that the outer electrons have been freed from the atoms and the positive cores have been smoothed out into a constant positive background "jelly." This model is sometimes called the jellium model. Because the electrons are now free to move through the solid, the model is appropriate for a metal where any excitation will allow an electron to contribute to the transport of current in the sample. If scattering is introduced empirically to this model, we have the Drude approach used to explain resistivity from a classical point of view. However now we have a quantum model, and this model can explain many quantum effects such as the electronic heat capacity, magnetism, and other properties that were mysterious in the 1930s. Starting with the second row of the periodic table, Na, Mg, and Al are metals, so this FEG model is appropriate for describing their electron properties. However, the next element is Si which is a semiconductor with bonds where valence electrons pile up between the cores as shown in Fig. 2, and a gap in $E_n(k)$ exists which is related to the energy required to liberate an electron from a bond.

As described above, semiconductors have filled bands, valence bands, empty bands, and conduction bands. The valence bands contain the electrons responsible for creating the bonds holding the crystal together. When an electron is excited to states above the gap and makes a transition into the conduction band, it is free to conduct electricity and respond to electric fields much like a metal does. The bonds and gaps arise primarily from the interaction of the valence electrons with the attractive positive cores. In the FEG, the cores were smeared out into a structureless jelly, but now the model describing a semiconductor or insulator is a periodic lattice of positive cores as shown in Fig. 2. If the potential describing the valence

**Fig. 2** Schematic picture of a semiconductor like silicon showing ionic cores (made of the nucleus and core electrons) and valence electrons forming bonds between the cores. The simple cubic structure is used here for illustration. Experimentally, silicon exists in the diamond structure at atmospheric pressures at room temperature
electron-core interaction is weak, the FEG won't be changed much, but the symmetry of the lattice and the nature of the potential can affect the electrons and create the bonds and gaps. At large distances from the core, a valence electron responds to the attractive Coulomb 1/r potential, but near the core, the Pauli principle is effective in keeping the valence electrons from occupying core states and keeps the valence electrons out of the regions near the core and into the bonding sites. This effect can be expressed by a repulsive potential which cancels part of the Coulomb potential and results in a net weak potential called the pseudopotential (Fermi 1934; Phillips and Kleinman 1959) which is illustrated schematically in Fig. 3. If we assume pseudopotentials at each lattice site, or more specifically, at each atomic site associated with a lattice point, then these atomic potentials perturb the FEG and produce bonds such as the covalent bonds in Si shown in Fig. 2.

The above model is the standard model for a solid. Because of the periodicity, it is convenient to express the potential as a Fourier sum in reciprocal or wavevector space. There is a one-to-one relationship between the real space lattice and a lattice in reciprocal space characterized by lattice vectors G. When the real space crystal pseudopotential is expressed as a sum of atomic pseudopotentials in a Fourier sum, the form factors for the potential are V(G). A structure factor is used to put the potentials at the proper atomic sites. Using Si as an example, the V(G) for the three smallest Gs allowed by the symmetry of the lattice, $V(G^2) = V(3), V(8)$, V(11), are large. The values for V(G) decrease for larger G, roughly representing the potential at smaller distances where the potential is weak. So all that is needed is three numbers to represent the potential. Once these are known, the FEG can be perturbed using a standard quantum mechanical approach.

The empirical pseudopotential method (EPM) (Cohen and Bergstresser 1966) is an approach in which the V(G) values are obtained from experiment. For the Si example, optical data alone provides the three needed coefficients. In fact, they are overdetermined. A similar approach is appropriate for diamond, Ge, and gray

**Fig. 3** Schematic plot of an atomic pseudopotential as a function of distance from the nucleus. The core region containing the nucleus and the core electrons is shaded. The large distance behavior of the pseudopotential is Coulombic, but this attractive potential is effectively canceled in the core region because of the Pauli exclusion principle acting on the core-valence electron interactions
Sn since they all have the same crystal structure. Once the V(G) form factors are determined, a calculation of $E_n(k)$ is straightforward along with a calculation of the corresponding wavefunction for each state. From these one can calculate the desired response function. For example, the optical constants such as the reflectivity, transmission, or absorption describing responses to light with energies from the IR to the UV arising from electronic transitions can be obtained from a calculation of the complex frequency-dependent dielectric function using $E_n(k)$ and the wavefunctions. The results of these calculations have been impressive. Starting in the 1960s, dozens of materials were studied, and for the most part, the data were explained and successful predictions were and are common for the EPM. The method was extended to allow the valence electron density to adjust to nonperiodic changes to study surfaces and interfaces. In addition to response functions, it was possible to explore the electron density by squaring the wavefunction (Walter and Cohen 1971). The prediction of the spacially dependent electron density was later verified using X-ray scattering data.

In the above work, the crystal structure of the solid is taken from experiment. To calculate the crystal structure from first principles, an ab initio pseudopotential (ABP) is generated starting with atomic wavefunctions. There are many methods for creating the ABP. Most are based on producing a pseudopotential which reproduces the atomic wavefunctions at distances outside the core region and then allows the pseudowavefunction to go smoothly to zero in the core region. The only input information needed to produce the ABP is the atomic number. Once the ABP is determined, the total energies for the solid can be computed using a density functional approach (Kohn and Sham 1965). The energies of different candidate crystal structures can be compared at varying volumes or pressures, and this can be used to compare the stabilities of the candidate structures with the overall rule that at

**Fig. 4** Total energy calculation for Si as a function of volume (normalized to the atmospheric pressure volume for Si in the diamond structure) for various candidate structural phases. The dashed line illustrates the pressure-induced path for the solid-solid structural phase transition from diamond to β-tin

a given volume or pressure, the candidate structure with the lowest energy is the one expected to be chosen by nature. By adding the atomic mass to the input data, it is possible to compute the vibrational properties and the interaction between electrons and vibrations. This scheme allows the determination of crystal structures (see Fig. 4), solid-solid structural phase transitions, lattice constants, elastic constants, bulk moduli, vibrational spectra, electron-phonon couplings, anharmonic properties, and even superconducting properties (Cohen 1982, 1985; Liu and Cohen 1989). The successful predictions of new high-pressure crystalline phases of Si and Ge and the prediction of superconductivity (Chang et al. 1985) in some high-pressure phases of Si are dramatic proofs of the applicability of this ABP-total energy approach for calculating properties of solids.

## 6   Surfaces, Interfaces, and Nanoscience

The discussion above focused on studies of bulk solids, and it was stated that it is possible to use the similar methods for surfaces and interfaces. An important approach for doing the latter and for dealing with localized and lower dimensional systems is based on the concept of a supercell (Cohen et al. 1975). The fundamental

idea is to deal with the lack of periodicity, for example, when a surface is considered, by imposing a different periodicity. For the surface case, by constructing a unit cell with a slab containing the surface atoms plus a region of vacuum above it and repeating this cell infinitely many times, we have the same situation as in the case of a periodic solid with several atoms at a lattice site. Another aspect of this method which is unlike the EPM is that the charge density of the valence electrons which makes up the electronic part of the potential is allowed to readjust to the surface. This is done via a self-consistent method where the calculation is performed for a trial starting arrangement of charge density, and then the output wavefunctions are used to construct a new charge density which is fed back into the calculation. When input and output converge to the same value, then the results are considered self-consistent.

When nanoscience studies became more popular, questions arose as to whether the above methods for bulk three-dimensional configurations would be appropriate for nanoscale systems. Possible concerns involved the nature of the electronic states when there is confinement and different symmetry conditions because of the reduced dimensional nature of the system. The results for calculations of molecular systems, quantum dots, nanotubes, graphene, and a variety of one- and two-dimensional structures proved very successful using a supercell approach. For example, the theoretical methods successfully predicted new nanotube devices; the existence of new nanotubes (e.g., see Fig. 5) containing B, N, and C; the properties of graphene; BN graphene-like layer materials; and superlattices formed from graphene and BN layers. This is a very active area of research, and there is considerable collaboration between theorists, experimentalists, and engineers. It is a field embraced by physicists, chemists, material scientists, computer scientists, device engineers, biologists, etc. because of the size scale which is of interest in all these areas.

**Fig. 5** Schematic illustration of the structure of the predicted BN nanotube subsequently verified by experiment
## 7    Emergence

Earlier when describing the models of a solid, it was pointed out that in addition to the interacting atom model, a solid could be described in terms of its elementary excitations. The interacting atom model focuses on the building blocks and their interactions, whereas the elementary excitation model focuses on the responses to probes and the emergent excitations characterizing the solid. In the early part of the twentieth century, there was considerable discussion about reality in science since we do express our findings in terms of human responses. In the elementary excitation model, response functions like resistivity can be described by fictitious particles. For example, the concept of a "hole" which can represent the absence of one electron out of $10^{23}$ is very useful, since it is far easier to explore the dynamics of this positron-like particle than all the remaining electrons after one is removed. So the emergent particle here is a positive fermion with electron characteristics. Similarly, in analogy with the particle-wave duality quantum concept for light, we can treat sound waves in a solid in terms of their associated particles called phonons. The phonon is a boson of spin zero, and many physical measurements involving excitations of sound waves can be treated effectively by using the phonon concept. One may ask whether when using this approach we are losing track of reality. Henri Bergson, a French mathematician, physicist, philosopher, and Nobel Laureate in literature, would have argued that all we know is what we sense; therefore, if this approach explains the observed properties, it is an acceptable view. The concept of emergence and emergent properties is widely discussed not only in condensed matter physics but in many other areas. For example, it has even been proposed that space-time is an emergent property.

Magnetism, superconductivity, and topological insulators with metallic surface currents while having semiconducting bulk properties are examples of emergent properties, so is the quantum Hall effect where resistance can be quantized (see Fig. 6). The fractional quantum Hall effect is an excellent example showing how quasiparticles can emerge from an electronic system having fractional charges like 1/3 e. Since the properties of the systems studied can be explained in terms of these fractionally charged particles, then in the "Bergson sense," this is a fully appropriate way of explaining what the response function is measuring.

For superconductors, the emergence of this intriguing property of solids has excited researchers since 1911. The formulation of the BCS theory (Bardeen et al. 1957) 46 years later appeared to answer all the experimental questions related to superconducting materials discovered up to that time. The central ideas were that the electrons formed pairs – Cooper pairs with zero spin – and these pairs behaved in an almost boson manner allowing zero resistance. However, the pairs were not Heitler-London pairs since for a superconductor like Al, the electrons in a pair are far enough apart to have a million other pairs between them. Roughly speaking, to excite or create a superconducting quasiparticle, one breaks a pair with EM radiation or by raising the temperature. In the BCS scheme, this quasiparticle behaves like a combination of an electron and a hole. The energy needed to break the pair is referred to as a superconducting gap energy which is

## Topological Insulator

## Quantum Hall effect

Hall bar in a strong magnetic field at low temperatures

$$\sigma_{xy} = ne^2 / h$$

**Fig. 6** Two examples of emergent states are a so-called topological insulator which is a semiconductor having conducting edge states while the bulk remains a semiconductor and the quantum Hall effect where the Hall conductivity is quantized. For the fractional quantum Hall effect, the quasi-electrons can have fractional charges

proportional to the superconducting transition temperature $T_c$. The superconducting gap differs fundamentally from the semiconducting gap. The latter is caused by electron-lattice interactions, while the former is related to the effective electron-electron interactions. The pairing of the electrons is caused by polarizing the lattice which in effect causes an attraction between electrons represented by the electron-phonon pairing parameter $\lambda$. In the simplest form of the BCS theory, if $\lambda$ is larger than the repulsive Coulomb pairing parameter $\mu$, then the electrons can form pairs. Superconductors which can be described by the BCS theory with the attractive pairing interaction originating from electron-lattice (electron-phonon) interactions are considered to be Class 1 superconductors. The properties of these superconductors are well understood, and it is likely that all experiments on these superconductors can be explained using BCS theory.

In the late 1980s, the so-called high $T_c$ superconductors containing copper and oxygen were discovered with $T_c$ values above the liquid nitrogen boiling point. In fact, under pressure, $T_c$ values in the range of 160 K were achieved. However, in the past 30 years, despite extensive and creative research, there is no consensus on a theoretical mechanism for the superconductivity in these systems. A similar situation exists for the Fe-based high $T_c$ superconductors. If we group these and put them into a separate Class 2 category, the general situation presently is that the Class 1 superconductors are completely understood in principle, but there is no general agreement on a theory for Class 2 materials, except perhaps that electron pairs are a central feature here too.

The quest for room temperature superconductivity has been a longtime goal. Because of the high values for $T_c$ of Class 2 superconductors, it was generally felt that the best path to this goal is to try to enhance $T_c$ in this group. However, since a theoretical basis for predicting new Class 2 isn't available, at this point the quest is

in the hands of the experimentalists. In contrast, using BCS theory and the models discussed above, it is possible to predict new Class 1 superconductors (Chang et al. 1985) and explain the properties of materials such as $MgB_2$ (Nagamatsu et al. 2001; Choi et al. 2002) which has the highest reported and experimentally reproduced $T_c$ for Class 1 superconductors. There is a recent report from one group (Drozdov et al. 2015) of superconductivity near room temperature in a hydrogen-sulfur system under pressure, and currently experiments are underway worldwide to reproduce these findings and extend them.

Since Class 1 superconductors are well understood, theory can be used to explore the question of what path is favorable for higher $T_c$ values for Class 1. It is clear that having a large $\lambda$ is an advantage. Also in BCS theory, $T_c$ scales with the phonon frequency. For very large $\lambda$, $T_c \sim \omega \lambda^{1/2}$, where $\omega$ is some average of the phonon frequencies. So we want large $\omega$ and large $\lambda$. It can be shown that $\lambda$, which is dimensionless, can be expressed as the ratio of electronic and lattice spring constants. Hence it is desirable to have strong bonds and light masses, and this makes doped carbon systems desirable. Boron-doped diamond was found to be superconducting first with $T_c \sim 4$ K (Ekimov et al. 2004), and as the doping levels increased, $T_c \sim 11.4$ K. Studies (Moussa and Cohen 2008) of this system predict possible values for $T_c$ of approximately 55–80 K. However, experimentally achieving higher levels of doping with boron is very difficult.

Since the arguments made above and the predictions are more generally applicable than just to diamond, it is important to examine carbon-based materials that can accommodate higher B concentrations. The recently synthesized Q-carbon (Narayan and Bhaumik 2015) is just such a material, and it was found that with a B doping of approximately 17%, this material became superconducting at 36 K (Bhaumik et al. 2017) which is comparable to $MgB_2$ at 39 K (see Fig. 7). At this point, the detailed structural and electronic properties of boron-doped Q-carbon have not been determined. However, many features have been reproduced theoret-

**Fig. 7** Temperature-dependent (normalized) resistivity measurements of B-doped Q-carbon thin films showing the onset of the superconducting transition temperature at 37.8 K. The inset depicts the enlarged view of the superconducting transition showing the transition width to be 1.5 K. (Bhaumik et al. 2017)
ically (Sakai et al. 2018) using a simulated amorphous carbon system with boron atoms replacing the carbon atoms one by one. It is found that the boron acceptor states can be either shallow or deep, depending on the surrounding geometries. The shallow acceptor states are important for achieving superconductivity because they contribute to the holes at the Fermi energy. Hence this property can be controlled by choosing specific substitutional sites. The electron-phonon coupling is also studied to show that the shallow acceptor states can induce a superconductivity transition as in boron-doped diamond. By calculating the Eliashberg spectral function $\alpha^2 F(\omega)$, $\lambda$ and $T_c$ can be determined. It was found that for a 14% boron doping, $T_c = 37$ K and $\lambda = 1.11$. This result is in agreement with the measurements for B-doped Q-carbon (see Fig. 8). This theoretical approach can be used to calculate other systems and other dopings to maximize $T_c$ for related systems (see Fig. 9). However, it should be noted that at this point, the experimental results of Bhaumik et al. (2017) have not been reproduced by other researchers.

## 8    Conclusions

The discussion in this overview of models for solid systems and their evolution over the past century focused on the fact that often the models and theories explaining and predicting properties of solids and in other areas of science start with empirical approaches and develop into schemes that can be classified as being more fundamental or ab initio. In addition to discussing the models and modeling approaches, a few important examples of their applications to recent studies of semiconductors, nanostructures, and superconductors were given. These fields are extremely active at this time motivated by the hope that understanding will lead to new materials which will allow better and smaller devices and higher temperature superconductors. This theme of the importance of motivation from applied science resulting in advances in basic science and vice versa is emphasized here. For example, the quest for a deeper understanding of semiconductors led to new methods for electronic structure calculations which gave us a deeper understanding of the quantum nature of materials. For superconductors, the motivation to understand superconductivity and possibly predict new useful superconductors stimulated fundamental research which led to the development of the BCS theory which was not only a major achievement in condensed matter physics, but it has had an impact on other areas of physics. There is, of course, the influence of applied physics research which led to the development of new instruments such as the laser and the scanning tunneling microscope. New instruments for probing matter and the synthesis of new materials have been essential for the advancement of this area of science. It has been the synergy of pure and applied approaches to the study of matter and its diversity and connections to other fields that has made this area of science and engineering so important.

# The Long and Winding Road: Predicting Materials Properties Through Theory and Computation

**4**

Giulia Galli

## Contents

**Abstract**

First-principles simulations of materials provide both computational microscopes and predictive tools, which we aspire to turn into design strategies for materials with target properties. One requisite to meet this goal is the enablement of predictions of material properties on a large scale, so as to generate a vast amount of validated computational data that may eventually be used to solve inverse problems. However it is challenging to use big data to address the "why question." First-principles calculations of specific materials and properties can instead be extremely effective at answering the "why question," namely, at unraveling mechanisms and providing fundamental, physical insights, thus paving the way to innovative design strategies. In this chapter, we present first-principles predictions of material properties relevant to energy conversion processes. We also discuss some open challenges related to automated integration of theory and computation with experiments and with validated, interpreted data.

# 1    Introduction

Science and engineering of materials is a vast field ultimately enabling the development of new technologies, with impact in energy, quantum information science, medicine and health, and national security. Almost 10 years ago, in the United States, President Obama launched the Materials Genome Initiative (MGI) (Obama 2011), with a speech at Carnegie Mellon (June 2011). MGI has been a game changer in the way the scientific community thinks of and approaches research in materials. The ambitious goal set by Obama, "To help businesses discover, develop, and deploy new materials twice as fast . . . ," catapulted research on materials at the forefront of science and engineering on the national scene and pointed out clearly and forcefully that business as usual was not an option in materials research. The MGI pushed toward innovation, to developing brand new techniques to make, study, and predict materials, and recognized theory and computation not only as an integral part of the innovative process but as a driver seat player. Projects in developing predictive tools and databases for materials flourished, for example, the Materials Projects (Jain et al. 2013a) initiated at MIT and then established at LBNL and several related initiatives (Curtarolo et al. 2012; Jain et al. 2013a, 2016; Saal et al. 2013; Bhat et al. 2015; Kalidindi and De Graef 2015; Rajan 2015; Blaiszik et al. 2016; Thygesen and Jacobsen 2016; Chard et al. 2018).

In 2015 the US DOE established for the first time computational materials centers (CMS) to develop methods and software to predict materials properties – importantly to develop software open to the community – thus further enhancing the pace of research and innovation. Three centers were established, two at National Laboratories (BNL: https://www.bnl.gov/comscope/ and ANL: http://miccom-center.org/) and one on a university campus (USC: https://magics.usc.edu/). A year later two additional centers were created, at LBNL (http://c2sepem.lbl.gov/) and ORNL (https://cpsfm.ornl.gov/). These centers were born in the ecosystems of the energy hubs conceived by Steven Chu (JCESR (www.jcesr.org) and JCAP (https://solarfuelshub.org/)); the hubs have a clear mission toward a societal grand challenge, climate change (global warming), and within that ecosystems, many of the projects of DOE centers and other agencies, notably NSF (www.nsf.gov/pubs/2019/nsf19516/nsf19516.htm), focused their research on functional materials for energy.

A question that arises in many instances when discussing the impact of MGI and the US CMS, as well similar centers established in in Europe and Asia, is simply what's new relative to the deployment of software in the semiconductor and pharmaceutical industry: in these industries codes for materials and molecular systems have been used for decades. However such codes have traditionally been used as mostly end of the line engineering tools, e.g., to test molecules that would not be synthetized first in the laboratory or to help design chips that had already been planned, based on specific material choices. The theories, codes, and software developed and pushed by MGI-like ideas are meant to become (and in some cases are already becoming) beginning of the line multi-scale tools to produce innovative

ideas on materials that have not yet been made, have not yet been planned, and do not even come from conventional synthetic and fabrication sources.

These theories and codes are envisioned to be general enough to meet two upcoming scientific revolutions: artificial intelligence (AI) and big data (De Mauro et al. 2015) and quantum information science and technology (Bennett and DiVincenzo 2000). It is important to emphasize that *general* applicability is a key, distinctive feature relative to the codes used in the semiconductor industry, for example, which have traditionally been developed for specific tasks, targeting one specific class of materials and processes. General codes may be used to produce the data needed for AI technologies for vast classes of materials. Computer generated data may then be part of design strategies that include innovative feedback loops with experiments, as well as strategies to make data reproducible and available to the scientific community worldwide (see, e.g., Govoni et al. 2019).

Contemporary computational methods and database mining techniques have already made tremendous strides in the prediction of equilibrium properties of materials that exhibit simple morphologies. However, the functionality of modern materials depends critically on the integration of dissimilar components and on the interfaces that arise between them. Hence the atomic- and molecular-scale manipulation of these components and the heterogeneous structures that emerge from them are key to materials design. In particular, the controlled and driven assembly of building blocks into hierarchical systems, as well as the control of defects and complex morphologies, offers the opportunity to create artificial materials that do not exist in nature and that exhibit superior physical properties for, e.g., emerging energy and quantum information technologies.

The simulations of heterogeneous materials and of the assembly process of artificial materials are much less advanced than the study of equilibrium properties. In order to accelerate the discovery of innovative functional materials, it will be key to acquire the ability not only to compute the properties of the end product but also to simulate and validate the assembly processes that take place during synthesis and fabrication. In addition, in order to design materials relevant to many technologies, it is essential to predict functionalities of systems with complex defective structures and ultimately complex morphologies and to simulate and eventually engineer the basic mass, charge, and energy transport phenomena, as pictorially illustrated in Fig. 1. We emphasize that most transport phenomena, e.g., electron transport, and phenomena involved in the spectroscopic characterization of materials, which involve interaction with light, are inherently quantum mechanical and thus require a first-principles, quantum mechanical treatment of interatomic interactions, at the atomistic scale.

In the following, we focus on two examples (interfaces for energy conversion processes, in Sect. 2 and materials composed of complex building blocks, in Sect. 3), and we describe recent progress in describing heterogeneous, defective materials with complicated morphologies using first-principles methods (Martin 2004, Martin et al. 2016). We aim at showing the importance of unraveling mechanisms and providing fundamental, physical insights, in order to pave the way to material design

**Fig. 1** Integrated predictions of multiple properties are key to define effective design strategies for materials with target characteristics. These properties encompass the atomistic structure of the material, possibly derived from the assembly of complex building blocks, the response to electromagnetic fields (light) used to probe and characterize the material and transport properties, including mass, charge, and heat transport

strategies. We close (Sect. 4) by describing open challenges in understanding and predicting synthetic pathways to obtain materials with target properties.

## 2  Energy Conversion at Interfaces from First Principles

In Figs. 2 and 3, we show some of the key processes and properties that one aims at understanding to establish a structure-function relationship and eventually predict optimal materials for solar-to-fuel and solar energy conversion, respectively. The figures illustrate the complexity of the predictive endeavor and the multitude of properties one should be able to compute, validate, and ultimately integrate with experiments. We concentrate here on materials for photo-electrochemical cells (PECs; Fig. 2).

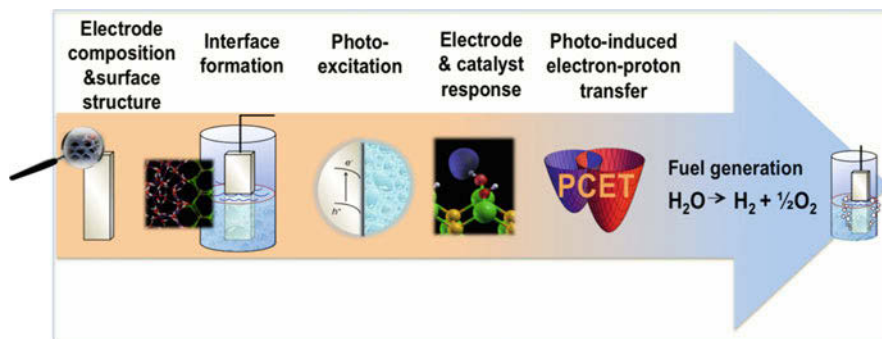
The generation of hydrogen from water and sunlight through PECs is one of the promising approaches investigated by the scientific community in the last decades for producing sustainable carbon-free energy (Walter et al. 2010; McKone et al. 2013; Pham et al. 2017). A key aspect to building an efficient PEC is the availability of Earth-abundant semiconducting photoelectrode materials that can absorb sunlight and eventually drive water-splitting reactions when interfaced with the liquid. Despite steady efforts, no single material has yet been found that simultaneously satisfies the efficiency and stability required for the widespread commercialization of hydrogen technology, and efforts have been concentrated on architectures composed of different materials, notably absorber solids interfaced with catalysts. Hence, understanding the properties of the interfaces between the various components is key to predict novel systems and eventually to optimize the device performance.


**Fig. 2** Pictorial representation of key processes and systems involved in water-splitting reactions occurring on a catalytic surface, which starts with harvesting light to form charge carriers and involves proton-coupled electron transfer (PCET) processes

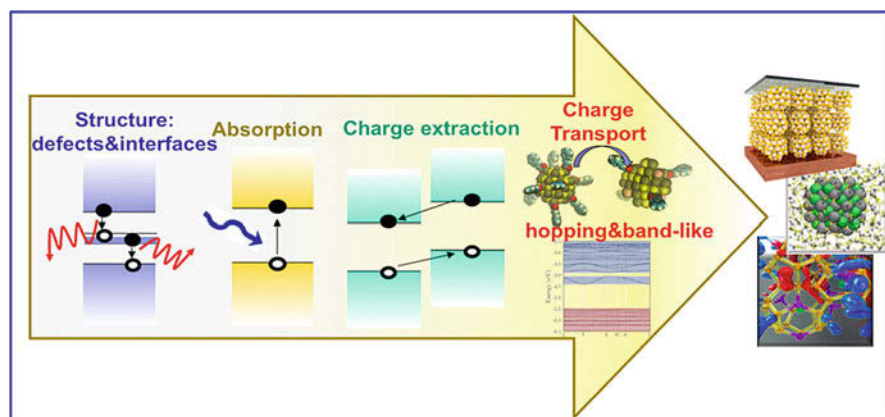

**Fig. 3** Pictorial representation of the key physical processes involved in the prediction and design of nanostructured semiconducting materials for solar energy conversion, including ensembles of nanoparticles (NPs), embedded NPs, and inorganic clathrates (icons on right hand side). Electronic (absorption, photoemission, and band offsets) and transport properties may be obtained from calculations based on density functional and many-body perturbation theory

In this regard, electronic and structural properties of absorbers/catalysts/water interfaces play a critical role, as rapid charge transfer between the photoelectrode, the catalysts, protective layers, and electrolytes is required for efficient fuel production. Interfacial structural and electronic properties of PECs are of course intertwined. For example, band edge positions of photoelectrode absorbers depend on the surface termination, the reconstruction, and the concentration of impurities and defects. In addition, the stability of the absorbers against oxidation (reduction) is determined by the relative energy between their valence band maximum (conduction band minimum) and intrinsic oxidation (reduction) potential. Such a complex interplay results in a multi-property optimization problem which, given recent

advances in high-performance computing and sophisticated electronic structure theories and codes (Kresse and Hafner 1993; Soler et al. 2002; Gygi 2008; Blum et al. 2009; Giannozzi et al. 2009; Hutter et al. 2014; VASP, Kresse and Furthmüller (1996a, b) Kresse and Hafner (1994) www.vasp.at; SIESTA, www.icmab.es/siesta; Qbox, www.qbox-code.org; FHI-AIMS, http://aims.fhi-berlin.mpg.de/; Quantum Espresso, www.quantum-espresso.org; CP2K, www.cp2k.org; CPMD, www.cpmd.org;), is now conceivable to tackle using first-principles simulations.

In recent years, it has been successfully demonstrated that first-principles calculations can be employed to scan thousands of combinations of elements across the entire periodic table to suggest new photoelectrode candidates (Greeley et al. 2006; Jain et al. 2013b; Castelli et al. 2015). However, computational screening schemes available thus far in the literature have mostly focused on bulk properties of candidate materials, and only recently the structural and chemical properties of surfaces and interfaces with the electrolyte have attracted the attention that they deserve to build successful design strategies. To paraphrase what Herbert Kroemer so elegantly pointed out is his Nobel lecture (Kroemer 2000) on semiconductor heterojunctions, the interface is *still* the device! As shown by us and others, the effective predictions of band offsets for water photocatalysis require the simulations of the electronic structure of solvated surfaces at finite temperature and in the case of oxide surface, importantly of *defective* solvated surfaces (Gerosa et al. 2018).

For example, in a case we have recently studied, $WO_3$ (Gerosa et al. 2018 and reference therein), we have shown that the average potential energy difference at the interface of pristine and defective $WO_3$ varies by $\sim$1 eV and that solvation is absolutely critical (see Fig. 4). In addition, we have shown the key importance of using a high level of theory, beyond the widely used density functional theory (DFT)

**Fig. 4** Energy levels (valence band maximum, blue; conduction band minimum, red; defect state due to oxygen vacancies; yellow) of a $WO_3$ surface in vacuo, at $T = 0$ and at room temperature, in the presence of water (solvated). The energy levels have been obtained using first-principles molecular dynamics simulations and calculations at the many-body perturbation theory level (GW), starting from electronic states computed with hybrid density functionals (From Gerosa et al. 2018). Note the striking difference of the positions of the levels on the right and left hand side, relative to the redox levels of liquid water

(Hohnberg and Kohn 1964; Kohn and Sham 1965; Martin 2004) and hybrid DFT (Perdew et al. 1996 ; Heyd et al. 2003, 2006) to carry out predictive calculations. The latter have allowed us to understand that the excess charge present at defective $WO_3$ surfaces due to oxygen vacancies forms a large 2D polarons ($\sim$10 A radius) on the plane of the surface; the predicted charge localization properties hint at possible formation of stable ($OH^-$) groups at the surface in contact with water and at the fact that holes transferred to water would then form a highly reactive $(OH)^*$, a possible precursor of water-splitting reactions. Altogether our calculations have identified three major factors determining the chemical reactivity of oxide absorbers interfaced with water: the presence of surface defects, the dynamics of excess charge at the surface, and finite temperature fluctuations of the surface electronic orbitals. These general descriptors are essential for the understanding and prediction of optimal oxides for water oxidation.

This was presented as an example of the importance of gaining fundamental physical insight into descriptors in order to define material design strategies and in particular into non-intrinsic properties of materials such as interfaces between complex components and defects present at finite temperature. We now turn to a second example of materials made of complex, nanostructured building blocks, where again interfaces – specifically buried interfaces – dominate the scene.

## 3   Building Blocks for Electronic Materials and Materials for Energy Conversion

In this section we consider materials made of nanostructured building blocks, in particular semiconducting colloidal nanocrystals (NCs) (Scalise et al. 2018; Greenwood et al. 2018; Talapin et al. 2010). Systems built from the assembly of these "artificial atoms" are emerging as tunable, earth-abundant, and potentially nontoxic materials for solar energy conversion, light emission, and electronic applications (Talapin 2012; Kovalenko 2013; Wippermann et al. 2013, 2014, 2016). The electronic and transport properties of NC-based solids depend on many factors that encompass the intrinsic characteristics of the individual NCs, for example, their shape, size, and composition, as well as their surface chemistry and mutual interactions. Organic ligands traditionally used in NC synthesis play a central role in controlling shape and size, as well as in driving self-assembly into superlattices. However, these ligands are often composed of long hydrocarbon chains, which create an insulating barrier that leads to low charge carrier mobilities. Significantly higher mobilities could be achieved by using inorganic ligands, and their use has enabled significant performance improvements of NC-based solar cells, transistors, and lasers.

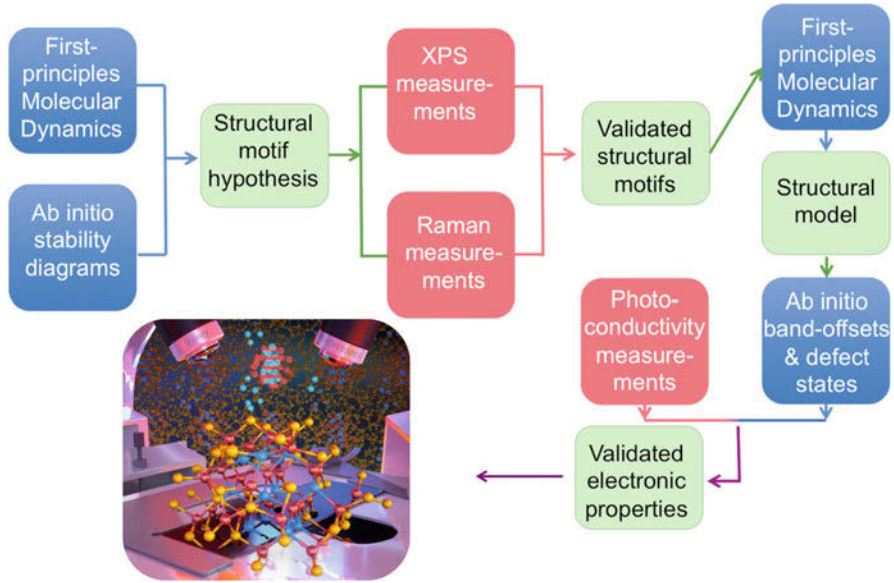
For example, InAs and CdSe NCs capped with molecular metal chalcogenide complexes (MCC) were shown to exhibit high electron mobilities (Lee et al. 2011; Liu et al. 2013), with III–V-based nanomaterials preferable for commercial applications due to their lower toxicity. However, the atomistic structure of these materials is difficult to characterize, in particular that of the NC surfaces and


**Fig. 5** Schematic representation of the integrated experimental and computational strategy adopted to obtain validated structural models and electronic properties of all inorganic semiconductor materials composed of colloidal nanocrystals, represented in the inset on the bottom right (see text)

interfaces, whose control is required to engineer systems with the desired properties. Recently we proposed (Scalise et al. 2018) a strategy to model a broad class of nanocrystal-in-glass systems that extends significantly beyond semiconductor quantum dots and MCC ligands.

Our strategy is summarized in Fig. 5. By combining first-principles molecular dynamics (MD) and ab initio stability diagram calculations (ab initio electronic structure calculations of surface energies and stability), main structural motifs were identified; in particular the structure of buried interfaces was determined. Before proceeding to derive a complete structural model, the motifs obtained computationally were experimentally validated, by carrying out XPS and Raman measurements, which both confirmed the results of the calculations. Using these validated structural motifs as a starting point of additional first-principles MD simulations, a structural model consistent with experiment was finally derived and used to analyze the electronic structure of the composite material. The predicted electronic states were used to interpret and understand the reasons for the measured negative photoconductivity, thus identifying specific reasons giving rise to properties that had remained unexplained and controversial for some time.

Overall, by combining electronic structure calculations and first-principles molecular dynamics (MD) simulations with experiments, we showed that the ligands are not absorbed as intact units but rather they decompose on contact with

the NC surface to form an amorphous matrix that encapsulates the nanoparticles (NPs). The intrinsic electronic properties of the isolated NCs are greatly modified in the matrix, whose atomistic structure plays a key role in enabling an efficient electronic transport. The structural model derived in this way permitted an explanation of the origin of the measured negative photoconductivity of the nanocomposite. This was presented as an example of novel material properties emerging when assembling building blocks at the nanoscale and as an example of the importance of tightly integrating theory, computation, and experiments. The future challenge will be to achieve such integration automatically and to define general validation strategies appropriate for broad classes of systems.

## 4   The Synthetic Challenge

One of the open challenges in computational materials science is the understanding and prediction of how to synthesize materials with target properties (De Yoreo et al. 2016). Using experimental data and simulations, the challenge is to establish correlations between synthesis protocols (SP) and material structure (M) and between synthesis protocols and material properties (P). This endeavor requires the solution of both direct and so-called inverse problems (Kaipio and Somersalo 2005). The former include answering first the question: Given a synthesis protocol (SP), what material (M) does one obtain? This forward problem is a grand challenge for predictive, computational methods. We still lack well-defined physics models that can describe synthesis; in addition "realistic" materials encompass complex descriptors including crystal structure, morphology, defects, and surface coverings. An even more complex forward problem concerns materials properties and the following questions: Given a synthesis protocol, which properties (P) does one get? This forward problem is clearly not unrelated to the first one (SP $\rightarrow$ M); however, it poses additional experimental and theoretical challenges. In particular, on the theory side, the prediction of certain complex properties is still in the making, e.g., obtaining optoelectronic and vibrational spectroscopic data and transport data, which require the use of sophisticated, cannot yet be used efficiently to acquire large amount of data for broad classes of systems.

The ultimate goal of the science of synthesis research is to solve the inverse problems associated with the forward problems mentioned above: Given a desired material, what synthesis protocol should be used to obtain it? Given a set of desired materials properties, what synthesis protocol should be used to obtain them? Solutions to inverse problems are found by solving many forward problems in a regression loop, which requires forward problems to be rapidly computable and the use of data analytic approaches, designed to mine experimental and theoretical data.

Ultimately, by seeking correlations between data and synthesis conditions, one will enable the discovery of materials and synthesis ontologies, i.e., a set of descriptors linking materials and synthetic pathways (e.g., crystal phase and synthesis temperature). Accurate ontologies are not yet known for synthesis, and their definition may come from the use of machine learning (ML) to search for the

most relevant descriptors for a given outcome and to relate different descriptors used by different researchers. We expect that with the increasing population of experimental and computational databases in the materials science community, ML workflows (Jain et al. 2015; Pizzi et al. 2016; Meng and Thain 2017; Adorf et al. 2018; Freire and Chirigati 2018) may be used to train models of materials synthesizability and properties and hence to predict novel materials.

In closing, we would like to comment on data and data availability. A key guiding principle for materials research is to make data findable, accessible, interoperable, and reusable. The reproducibility of experiments and computations and of the corresponding results is an important and critical part of the overall research process of all scientific disciplines and in particular of materials predictions heavily relying on large amount of data. Yet the data presented in most published scientific papers are not made available to the community, and the procedures followed to obtain or generate the data are often not articulated step by step or in any detail. Hence making all data available to the public (Govoni et al. 2019), on a paper-by-paper basis, so as to increase experimental and computational rigor in reporting results, together with transparency, should become integral part of the research process. This endeavor will also greatly contribute to devising improved validation procedures for computational data as well as establishing experimental and computational automatic feedback loops.

# Big Data-Driven Materials Science and Its FAIR Data Infrastructure

**5**

Claudia Draxl and Matthias Scheffler

## Contents

**Abstract**

This chapter addresses the fourth paradigm of materials research – big data-driven materials science. Its concepts and state of the art are described, and its challenges and chances are discussed. For furthering the field, open data and an all-embracing sharing, an efficient data infrastructure, and the rich ecosystem of computer codes used in the community are of critical importance. For shaping this fourth paradigm and contributing to the development or discovery of improved and novel materials, data must be what is now called FAIR – *Findable*, *Accessible*, *Interoperable*, and *Repurposable/Reusable*. This sets the stage for advances of methods from artificial intelligence that operate on large data sets to find trends and patterns that cannot be obtained from individual calculations and not even directly from high-throughput studies. Recent progress is reviewed and

demonstrated, and the chapter is concluded by a forward-looking perspective, addressing important not yet solved challenges.

## 1 Introduction

Materials science is entering an era where the growth of data from experiments and computations is expanding beyond a level that can be handled by established methods. The so-called 4 V challenge – concerning *Volume* (the amount of data), *Variety* (the heterogeneity of form and meaning of data), *Velocity* (the rate at which data may change or new data arrive), and *Veracity* (the uncertainty of data quality) – is clearly becoming eminent. Most importantly, however, is that big data of materials science offer novel, extraordinary, and expansive opportunities for achieving scientific knowledge and insight. These opportunities require new research concepts and lines of thought. While this chapter focuses on computational materials science, we emphasize that what is described here applies to experimental data as well.

Today's common approach in computational materials science is to publish results as focused research studies, reporting only those few data that are directly relevant for the respective topic. Thus, even from very extensive computations (expending thousands or millions of CPU core hours), very few results are shared with the community. Most data, in particular when they were not deemed of immediate relevance, are kept private or even thrown away. Since a few years, the community of computational materials science and engineering is undergoing "a change in scientific culture" and has started the extensive sharing of data of this field. Sharing of *all* data, i.e., the full input and output files of computations, implies that calculations don't need to be repeated again and again, and the field will have access to big data which can be used in a totally new research manner, i.e., by artificial intelligence methods (Draxl and Scheffler 2019 and references therein). As will be elaborated in the next sections, one can find structure and patterns in big data, gaining new insight that cannot be obtained by studying small data sets, and in this way even allegedly inaccurate data can get value. A popular example from daily life of the impact of big data analytics is the tracking of the movement of mobile phones which provides instantaneous information on traffic flow and jam. Another example is the local information of google searches for *flu symptoms and medicine* which reflect the spreading of a flue wave. The latter example also illustrates the danger of data analytics, as the "google flue trend" worked well for the first few years, but then, in 2012, some aspects became unreliable. Reasons may be, among others, anxiety-stimulated searches caused by reports in public and social media and changes in google search technology, e.g., recommending searches based on what others have searched (Lazer et al. 2014). This example also illustrates that big data should not be viewed as substitute but as complement to traditional analysis. Specifically, we note that even if the amount of data may be big, the independent information may be small when data are correlated, or data may be even irrelevant

or misleading for the purpose of interest. If such aspects are not considered properly, a statistical analysis will be flawed.

Overcoming the "silo mentality" of computational materials science and the development and implementation of concepts for an extensive data sharing was achieved by the NOMAD Center of Excellence (NOMAD; Draxl and Scheffler 2019), considering all aspects of what is now called the FAIR data principles (NOMAD 2014, Wilkinson et al. 2016): Data are *Findable* for anyone interested; they are stored in a way that make them easily *Accessible*; their representation follows accepted standards (Ghiringhelli et al. 2016, 2017a); and all specifications are open – hence data are *Interoperable*. All of this enables the data to be used for research questions that could be different from their original purpose; hence data are *Repurposable*. We note that the NOMAD CoE uses the term repurposable, while in the FAIR concept it was termed reusable. The former makes explicit that data can not only be reused but even used for a different purpose. Obviously, FAIR data also become usable for artificial-intelligence tools.

The chapter is structured as follows. In Sect. 2, we briefly summarize the history of the four research paradigms of materials science, with particular focus on the fourth one, "big data-driven materials science." Section 3 then stresses the importance of an extensive data sharing for the advancements of science and engineering. Section 4 addresses artificial-intelligence concepts for materials science data with some specific examples. Finally, in Sect. 5, we give an extensive outlook on the developments and open questions of big data-driven materials science.

## 2 The Four Research Paradigms of Material Sciences

The historical evolution of methods and concepts of materials science are sketched in Fig. 1. We recall that experimental research dates back to the Stone Age, and the basic techniques of metallurgy were developed in the Copper and Bronze Ages which started in the late sixth millennium BCE. The control of fire prompted a major experimental breakthrough. Toward the end of the sixteenth century, scientists began to describe physical relationships through equations. Well-known names from the early days are Tycho Brahe (1546–1601), Tomas Harriot (ca. 1560–1621), Galileo Galilei (1564–1642), Johannes Kepler (1571–1630), Isaac Newton (1643–1727), and Gottfried Wilhelm Leibniz (1646–1716). The latter two also developed the concept of the mathematical differential and derivatives. Thus, analytical equations became the central instrument of theoretical physics. Second from the left in Fig. 1, this new way of thinking – the 2. paradigm – is symbolized by the Schrödinger equation. Needless to say, the first paradigm, the empirical and experimental sciences, did not become obsolete, but theoretical physics represents an important complementary methodology.

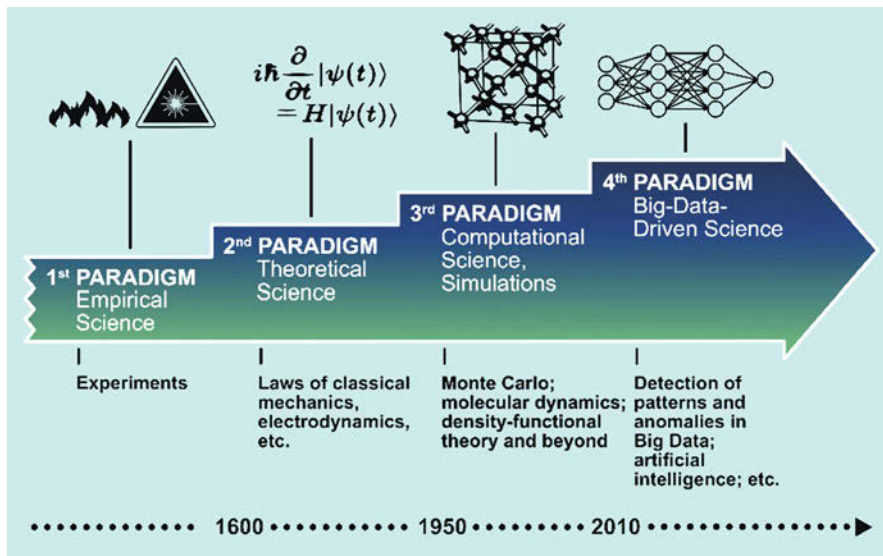
Since the 1950s electronic structure theory was advanced for materials by J. C. Slater (e.g., Slater 1937, 1953, 1965, 1967; Slater and Johnson 1972), the Monte


**Fig. 1** Development of research paradigms of materials science and engineering

Carlo method was introduced by Metropolis et al. (1953) and Alder and Wainwright (1958, 1962, 1970), and Rahman (1964) introduced molecular dynamics. Hohenberg and Kohn (1964) and Kohn and Sham (1965) laid the foundation of density-functional theory (DFT) (see ▶ Chap. 11, "Recent Developments in Density Functional Approximations" by Li and Burke) in the mid-1960s. All these developments enabled computer-based studies and analysis of thermodynamics and statistical mechanics on the one hand and of quantum mechanical properties of solids and liquids on the other hand. They define the beginning of computational materials science, what is nowadays considered the third paradigm. Herewith "computer experiments" were introduced, i.e., simulations, whose results are often treated and analyzed analogously to those of experimental studies. Initially developed independently, the fields of electronic-structure theory and statistical mechanics and thermodynamics are now growing together (Reuter et al. 2005 and references therein). Likewise, in parallel to DFT, many-body techniques based on Green functions were developed (Hedin 1965), which are now synergistically interleaved with DFT to form the forefront of electronic-structure theory, including excitations.

Today, big data and artificial intelligence revolutionize many areas of our life, and materials science is no exception (Gray 2007; Agrawal and Choudhary 2016). Jim Gray had probably first discussed this fourth paradigm arguing explicitly that big data reveal correlations and dependencies that cannot be seen when studying small data sets. Let us generalize the "big data" concept by noting the complexity of materials science (and others sciences as well): The number of potential but initially unknown descriptive parameters that characterize or identify the properties and functions of interest may be very big. Thus, the diversity and complexity of

mechanisms represents a big data issue in materials science as well. A further important difference to the second paradigm is that we accept that many materials properties, i.e., patterns and correlations in big data, cannot be described in terms of a closed mathematical formulation, as they are governed by several, intermingled theoretical concepts and multilevel, intricate processes. As a consequence, such patterns represent and advance knowledge, but they do not necessarily reflect understanding.

What is our vision for exploiting the fourth research paradigm of our field? Figure 2 provides a schematic view on it: The space of different chemical and structural materials is practically infinite. However, when asking, e.g., for high-performance thermal-barrier coatings, there are just a few suitable materials. Thus, in terms of functional materials, the materials space is sparsely populated as most of the already existing or in the future synthesized materials are irrelevant. Hence, the relevant data are a *statistically exceptional minority,* and if this situation is ignored, a statistical analysis that assigns the same importance to all data may well be problematic. Finding regions or patterns that correspond to materials with superior functional performance requires the identification of appropriate descriptors, noted as $d_1$ and $d_2$ in Fig. 2. Obviously, in general, the dimensionality will likely be higher than just two. At this point, Fig. 2 is just a sketch, and as for most properties, the appropriate descriptors are unknown, and the patterns remain hidden. The scientific challenge is to find appropriate descriptors. Let us emphasize, as the actually relevant data is not big enough (in most cases of interest in materials science), it is important if not crucial to use as much domain knowledge as possible. Compressed sensing, subgroup discovery, and other methods of artificial intelligence are able to identify these descriptors and patterns, and we will address these methods in Sect. 3 below.

We close this section by noting the radically decreasing time scales of new developments and paradigms: sixth millennium BCE, 1600, 1950, and 2010. Thus, a next research paradigm may be just ahead of us.

**Fig. 2** Big data contain correlations and structure that are not visible in small data sets. Finding descriptors that determine a specific property or function of a material is a crucial challenge. Once this is in place, we will be able to machine learn the data and eventually draw maps of materials. In difference to the sketch, these maps will be typically of higher dimension than just two

## 3 Extensive Data Sharing: Why and How?

Data are a crucial raw material of this century. Our community is producing materials data by CPU-intensive calculations since many years. Typically, the results are stored on PCs, workstations, or local computers, and most of these data are not used and often even thrown away, though the information content could well be significant. The field is now slowly changing its scientific culture toward *Open Science* and *Open Data*, and there are many reasons for doing so. Open access and FAIRness of data implies that data can be used by anyone, not just by the experts who develop or run advanced computer codes. If data were openly available (and well described), many more people would work with the data, e.g., computer scientists, applied mathematicians, analytic condensed matter scientists, and more. We will be surprised what people will do with data when they are made available, probably using tools that the present computational materials science community does not even know.

Let us mention one example, a "crowd sourcing" data analytics competition at the Internet platform Kaggle (Kaggle/NOMAD2018 2018). This competition addressed the search for novel transparent and semiconducting materials using a data set of $(Al_xGa_yIn_z)_2O_3$ compounds (with $x + y + z = 1$). The aim of this challenge was to identify the best machine-learning model for the prediction of two key physical properties that are relevant for optoelectronic applications: the electronic bandgap energy and the crystal formation energy. These target properties were provided for 2400 systems covering 7 different crystal space groups and unit cells ranging from 10 to 80 atoms. Six hundred additional systems made the test set for the competition.

The competition was launched in December 2017, and when it finished, 2 months later, an impressive number of 883 solutions had been submitted by researchers or research teams from around the world, employing different methods. Interestingly, the three top approaches, summarized in a recent publication (Sutton et al. 2019), adopted completely different descriptors and regression models. For example, the winning solution employed a crystal-graph representation to convert the crystal structure into features by counting the contiguous sequences of unique atomic sites of various lengths (called *n*-grams) and combined this with kernel ridge regression (KRR). This *n*-grams approach was new for materials science.

To enable the envisioned success of big data-driven materials science, the field obviously needs a suitable data infrastructure that facilitates efficient collection, data description in terms of metadata, and sharing of data. For the field of computational materials science, this was developed by the NOMAD Center of Excellence (NOMAD) which also instigated comprehensive data sharing. The synergetic relationship with other major key data bases, in particular AFLOW (see also ▶ Chap. 82, "The AFLOW Fleet for Materials Discovery" by Toher et al. in this handbook, and Curtarolo et al. (2012), Calderon et al. (2015)), Materials Project (see also Jain et al. (2013) and ▶ Chap. 81, "The Materials Project: Accelerating Materials Design Through Theory-Driven Data and Tools," by Jain et al. in this handbook), and OQMD (see also Saal et al. (2013)), made it the biggest repository in the field. Uploaded data files are tagged by a persistent identifier (PID), and users

can request a DOI (digital object identifier) to make data citable. Downloading does not require any registrations and refers to the Creative Commons License.

So what is behind FAIR? What does it mean for computational materials science?

The *F* stands for *Findable*. Making research data open and keeping them for at least 10 years are now requested by many research organizations. Seen from a practical point of view, it is also useful to avoid doubling of work and thus save human and computational resources and energy. Since individual researchers create their data on various platforms – from workstations to compute clusters to high-performance computing (HPC) centers – it is often impossible to find a student's or postdoc's data, some time after she/he has left the research group. Besides matters of organization, issues may be related to automatic erasure of data in HPC centers, missing permissions on local machines, data protection, and alike. Clearly, making data findable requires a proper data infrastructure, including documentation, metadata, search engines, and hardware. This is one of the reasons why the NOMAD Repository and its metadata were established (see Meta info at NOMAD, NOMAD 2014).

The *A* stands for *Accessible*. Accessibility in materials science has different facets. First, we should not forget about the proper hardware that allows for swift access to data. Second, we need to provide application programming interfaces (APIs). To make data fully accessible requires an important additional step, namely, the formal description of the data, i.e., its metadata that also consider the metadata interrelations. This connects to the *I* in FAIR.

The *I* stands for *Interoperable*. Here we need to consider in a first place the extreme heterogeneity of computational materials data. The wider community is using about 40 different, major computer codes (considering electronic-structure, molecular-dynamics, and quantum-chemistry packages for materials) that differ in various aspects of methodology and implementation. Consequently, the necessity arises to make their results comparable, which is a major challenge not only in the sense that they need to be brought to a common format and common units; we also recall that one quantity may be named differently in different (sub-)communities or one and the same expression may have a different meaning in one or the other area. Thus, "dictionaries" are needed to translate between them. Obviously, if one would restrict everything to just one computer program package, translations or conversion are not necessary. However, then a significant part of the available data and, even more importantly, of the community would be missed. In this sense, the NOMAD concept is general and in fact orthogonal to essentially all other data repositories that typically focus on just one computer code (see Draxl and Scheffler 2019).

Still, we need to ask if one can operate upon all available data in a meaningful way. Apart from formats and units, there are more severe restrictions that may hamper such important undertaking. These concern the computational parameters – and consequently the numerical precision – that are used in different calculations. We recall here that for extensive sharing, all open data can be considered valid in the sense that, when the code and code version are provided, output files correspond to the provided input files in a reproducible way. Nevertheless, data have been created for different purposes which may require different levels of convergence in terms
**Fig. 3** Convergence of total energies of 71 elemental solids with increasing basis-set quality for 4 different electronic-structure codes. Red symbols indicate the materials with maximal error, and black symbols display averages over all 71 materials. All values refer to the respective fully converged results. $RK_{max}$ is the LAPW-specific parameter defining the basis set size, $E_{cut}$ is the GPAW cutoff energy, and PREC is the VASP-specific parameter for basis set quality. The black vertical lines for FHI-aims indicate light (left) and tight (right) settings, and the gray lines indicate Tier1, Tier2, and Tier3 basis sets (from left to right). Note that the errors are displayed at a logarithmic scale

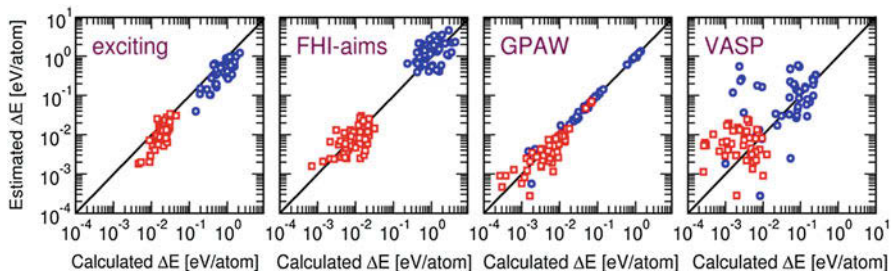

**Fig. 4** Predicted versus actual errors in total energy for 63 binary alloys, obtained from the errors in elemental solids for four different electronic structure codes. Blue data are from calculations performed at low-precision settings, and red data are from "standard quality" settings. Note that they are close to the straight black line. For details see Carbogno et al. (2020)

of basis set size and alike (e.g., the determination of the atomic geometry may need less stringent parameters than details in the electronic band structure. (see also the discussion of Figs. 3 and 4)). More than that, we may even ask whether different codes aiming at the solution of one and the same problem with "safe" settings give the same results. For the latter, we point to the community effort led by Stefaan Cottenier (Lejaeghere et al. 2016), where the equations of state for 71 elemental solids were calculated with many different *ab initio* electronic structure packages. Over a time span of a few years, it turned out that upon improvements of codes, basis sets, and in particular pseudopotentials, all codes lead to basically the same answer. In fact, in the list at https://molmod.ugent.be/deltacodesdft, one has to choose a reference where obviously an all-electron code is the natural choice, and the precision of the all-electron packages WIEN2k, exciting, and FHI-

aims are practically identical. Such investigations are extremely helpful and have set the stage toward a culture of benchmarking, which had been established in quantum chemistry for molecules already decades ago. The study by Lejaeghere et al. (2016) is, however, only the beginning. Clearly, other properties, like energy barriers, bandgaps, spectra, etc., and systems, like point defects, surfaces, interfaces, and inorganic/organic hybrid materials, etc., will be much less forgiving than total energies of simple bulk solids and will make discrepancies more obvious. Therefore, more investigations along these lines are on the way.

While the above comparison (Lejaeghere et al. 2016) could only be made with parameter sets that represent full convergence, calculations performed in daily life are often far from this optimal case and are, in fact, often sufficient. This situation obviously leads to the question how to compare and operate on calculations that have been performed with different settings, e.g., in terms of basis sets, meshes for Brillouin zone integrations, and alike. Below, it is shown that this is, in fact, possible.

Let us demonstrate that fully converged results of *complex* materials can be estimated by learning from errors of calculations of *simple* materials (Carbogno et al. 2020). Four different codes have been employed for this study: two very different all-electron codes and two projector augmented wave/plane-wave codes. These are exciting (Gulans et al. 2014) and FHI-aims (Blum et al. 2009) and GPAW (Enkovaara et al. 2010) and VASP (Kresse and Furthmüller 1996). Sources for discrepancies of different calculations in publications and/or the various data repositories are incomplete basis sets, approximate treatment of the **k**-space integration, the use of pseudopotentials, and more. Since incomplete basis sets are, indeed, the most severe issue, Fig. 3 shows how the total energies for fixed geometries change as a function of basis set quality for the 71 elemental solids adopted from Lejaeghere et al. (2016). The red symbols in Fig. 3 mark the materials exhibiting the largest error, and the black symbols refer to the average taken over all materials. The error, $\Delta E$, is defined for each material with respect to the fully converged value obtained with settings as or even more precise than the ones used in Lejaeghere et al. (2016). In all cases, the error decreases systematically from the order of 1 eV for small basis sets down to meV precision for the high-quality basis set. The fact that not all computer codes show a monotonous behavior for small basis set sizes reflects the specific characteristics of different methods and implementations (see Carbogno et al. 2020 for a detailed discussion). Based on these errors of the elemental solids, the authors estimated the errors arising from the basis set incompleteness in multicomponent systems, utilizing a simple analytic model, i.e., by linearly combining the respective errors of the constituents (elemental solids) obtained with the same settings:

$$\overline{\Delta E_{\text{tot}}} = \frac{1}{N} \sum_N N_i \Delta E_{\text{tot}}^i. \tag{1}$$

Here $N_i$ is the number of atoms of species $i$ present in the compound, and $\Delta E_{\text{tot}}^i$ is the error of this species in the respective elemental solid. This model was applied to 63 binary solids that were chosen such to cover the chemical space (1 for each element with atomic number up to 71, without noble gases). The approach is validated by comparing the estimated errors to those of corresponding DFT calculations for these binaries, as depicted in Fig. 4. The authors of this work find a clear correlation between predicted and actual errors for all four codes (with the details depending on peculiarities of the specific codes). For more in-depth analysis, also including relative energies and ternary alloys and an extensive discussion about the role of the employed method/basis set, we refer the reader to Carbogno et al. (2020). In essence, the conclusion can be drawn that even when total energies are calculated for a not converged basis set, the energetics for the fully converged case can be extrapolated. This study sets the stage for data coming from different sources fulfilling an important condition for the *I*.

The *R* stands for *Reusable*. In fact, we prefer the term *repurposable* that gives a better impression about what is meant in the materials science context. It means that we can use data that has been created for some specific scientific question, in a different connection. Indeed, one and the same material can be considered for various applications. So why should a researcher working on one aspect not allow another researcher to use the same data for focusing on a different topic? Let us illustrate this with the example of $TiO_2$ which is an important support material for heterogeneous catalysis. The detailed results are not only useful for researchers working in this area but also in a different context. For example, for photovoltaics $TiO_2$ is a component of dye-sensitized solar cells. And, as another example we note that $TiO_2$ is used as pigment in paints and in cosmetic products.

It is generally agreed that research results obtained in academia should be published. In view of what was discussed above, it should be a duty to publish all the results, i.e., making also the complete data underlying a publication available. This has been said by many people, funding agencies, politicians, and research journals. Indeed, a few research journals have started to request that all details are uploaded at a certified repository. Obviously, as mentioned above, data must be connected to established metadata and workflows.[1] However, to fully apply such concepts, the necessary data infrastructure hardly exists so far. Let us cite from a recent Nature Editorial "Empty rhetoric over data sharing slows science" (Nature editorial 2017): "Everyone agrees that there are good reasons for having open data. It speeds research, allowing others to build promptly on results. It improves replicability. It enables scientists to test whether claims in a paper truly reflect the whole data set. It helps them to find incorrect data. And it improves the attribution of credit

---

[1] In technical terms "workflow" refers to the sequence and full description of operations for creating the input file and performing the actual calculations. Important workflow frameworks that allow to automatically steer, analyze, and/or manage electronic structure theory calculation are ASE (atomic simulation environment) (Larsen et al. 2017), Fireworks (Jain et al. 2015), AFLOW (Calderon et al. 2015), and AiiDa (Pizzi et al. 2016).

to the data's originators. But who will pay? And who will host?" – and further "Governments, funders and scientific communities must move beyond lip-service and commit to data-sharing practices and platforms." For computational materials science though, NOMAD had already implemented an appropriate program (Draxl et al. 2017, Draxl and Scheffler 2018, 2019).

## 4    Artificial-Intelligence Concepts for Materials Science Data

We are using "artificial intelligence (AI)" as umbrella term for computational methods that "learn from experience". As already mentioned, for materials science, the complexity of the actuating mechanisms is big, but the number of relevant data is typically on the lower side. Zhang and Ling (2018) recently addressed this issue in terms of the degree of freedom of the model and the prediction precision. In a similar sense, we argue that a proper analysis of data needs to consider at least some aspects of the causality that drives the correlations of interest, i.e., one needs to include domain knowledge in the learning process in order to achieve a trustworthy description, interpretability, and possibly even deeper understanding of the cause behind the structure or patterns in the data. Specifically, we recall that from the practically infinite number of possible materials, only 10 or 100 may be relevant for a certain purpose. Standard machine learning tools address a description of the crowd or the majority and optimize the overall root-mean-square error or alike and also introduce a regularization to avoid overfitting and/or to achieve a smooth description. As a result, it is likely that statistically exceptional data are concealed. But only these may carry the information we are interested in. The lower the employed domain knowledge is, the larger is the amount of data that is needed for the learning process, and it may happen that data are fitted but predictions and even interpolations are not reliable. AI is a wide and interdisciplinary field, and machine learning (learning from data) and compressed sensing (originating from signal compression; primarily aiming at the identification of a low-dimensional descriptor) are important subdomains.

As noted above (see the discussion of Fig. 2), big data may reveal correlations (structure and patters) if and only if the data are arranged in a proper way, e.g., represented by appropriate descriptors. These correlations can be found by AI, but the identification of such correlations does not necessarily go along with deeper insight or understanding. To some extent we like to argue that the wish for insight and understanding is often overrated. This is well documented by the Periodic Table of the Elements that may arguably be considered as one of the most impacting achievements for chemistry, condensed matter physics, engineering, and biophysics. When Mendeleev published his table in 1871, based on knowledge of 63 atoms (their weights and chemical behavior), there was no understanding of the deeper cause behind the structure of the table (Scerri 2008; Pyykkö 2012). Still, the table predicted the existence of at that time unknown atoms. The underlying causality, i.e., that the different rows reflect the different number of nodes of the radial wave functions of the outer valence electrons and that the different columns refer to the

number of valence electrons, was unknown when the table was created. It only was understood about 50 years later, when the shell structure of electrons in atoms was described by quantum mechanics.

Thus, identifying correlations, structures, and patterns in (big) data is an important step by its own. When the relationship between a property of interest, $P$, and a set of useful descriptive parameters (the descriptors $d_1$, $d_2$, ... – also called representation) is known, graphs as in Fig. 2, or approximate equations, can be obtained for the relationship $P(d_1, d_2, ...)$. For the example of the Periodic Table, the descriptors are the row and column numbers. Obviously, as the number of possible materials is practically infinite, building a map as in Fig. 2 is a highly demanding task, of much higher complexity than building the Periodic Table of the Elements.

How to find the descriptors for materials properties? The general and complete descriptor for a quantum mechanical materials problem is given by the position of all atoms, the nuclear numbers, and the total number of electrons: $\{\boldsymbol{R}_I, Z_I\}$, $N^e$. These descriptive parameters fully identify the many-body Hamiltonian, but "learning" the properties that result from a given Hamiltonian is a very demanding goal. Thus, the amount of data needed for training (fitting) a materials property or function directly in terms of $\{\boldsymbol{R}_I, Z_I\}$, $N^e$ is typically unrealistically high. Instead, for choosing proper descriptors, that relate to the actuating mechanism of the property of interest, we distinguish three concepts: (a) the descriptor may be selected out of a huge, systematically created pool of candidates; (b) the descriptor may be built in the machine learning step in an abstract manner; and (c) one may just hand pick a known descriptor assuming that with many data the actual choice may be not so important. Concept (a) will be discussed below when we describe compressed sensing and subgroup discovery. Concept (b) is realized in neural network approaches which, in the learning step, minimizes an objective function that quantifies the difference between the predicted and the correct (known) data. Through this minimization, the weights (i.e., parameters) of the neural network are optimized (Hinton 2006; Hinton et al. 2006), and in this way, the network learns the descriptors. Doren and coworkers and Lorenz et al. (Blank et al. 1995; Lorenz et al. 2004, 2006) have shown early examples of representing potential-energy surfaces of materials by neural networks. Hellström and Behler describe recent advances in ▶ Chap. 31, "Neural Network Potentials in Materials Modeling." Concept (c) is probably the most widely used approach. Example descriptors that encode the chemical and geometrical information are Coulomb matrices (Rupp et al. 2012; Hansen et al. 2013), scattering transforms (Hirn et al. 2015), diffraction patterns (Ziletti et al. 2018), bags of bonds (Hansen et al. 2015), many-body tensor representation (Huo and Rupp (2017), smooth overlap of atomic positions (SOAP) (Bartók et al. 2010, 2013), and several symmetry-invariant transformations of atomic coordinates (Seko et al. 2017; Schütt et al. 2014; Faber et al. 2015). This concept is nicely described in ▶ Chap. 87, "Machine Learning of Atomic-Scale Properties Based on Physical Principles" by Ceriotti et al. The recent work by Xie and Grossmann (2018) may be viewed as a combination of concepts b) and c) where the input to their neural network is provided in terms of crystal graphs, an encoding of the above noted $\{\boldsymbol{R}_I, Z_I\}$ geometry and chemistry information.

A systematic understanding of the suitability of various machine learning (ML) models and thorough benchmarking studies are still lacking in materials science. A first step was only recently addressed in terms of a public data analytics competition that was hosted on the Internet platform Kaggle using a data set of 3000 $(Al_xGa_yIn_z)_2O_3$ compounds ($x + y + z = 1$), already mentioned in Sect. 3 above (see Sutton et al. 2019).

Some caution may be appropriate. In general, an observed correlation will have a causal reason – provided that it is supported by a sufficiently large data set (Pearl 2009). Thus, a correlation that is described by the function $P(d_1, d_2, \dots)$ may reflect that $(d_1, d_2, \dots) = \boldsymbol{d}$ are the actuators: $\boldsymbol{d} \to P$. However, it could well be that the reverse is true: $P \to \boldsymbol{d}$. Thirdly, it is possible that there is an "external master," $M$, who controls both $\boldsymbol{d}$ and $P$, with no direct relationship between $\boldsymbol{d}$ and $P$. And fourthly, the data may be selected with a significant bias of the researcher or research community. We fear that the latter may be happening much more frequently than realized. But then the observed correlation may just reflect this bias. All this needs to be kept in mind when tools of artificial intelligence are applied to big (or not so big) data and when we ask for interpretability or even causality.

Let us add another warning about big data of materials science. The number of possible materials is practically infinite, and we like to identify new materials that have better performance or functionality than the materials that are used today. Clearly, the amount of available data in materials science is getting big though from the few (about 250,000) inorganic materials that have been synthesized up to now, we often just know the atomic structure and hardly their electronic, elastic, or other properties. Getting more and more data, however, does not imply that all the data are relevant for all properties of interest. Materials science shows a high diversity, i.e., it is ruled by a significant number of different properties and mechanisms, and experience seems to show that at the end, the number of materials that are good for a certain group of functions is very small. For example, if we ask for a highly transparent materials with excellent heat conductivity and scratch resistance, there is probably nothing better than and nothing even close to diamond. Another example is the recent study by Singh et al. (2019) who studied 68,860 candidate materials for the photocatalytic reduction of $CO_2$. Only 52 of them turned out to be possibly relevant. In general, it is likely that in the few "high-performance materials", a mechanism is active (or inactive) that is not relevant (or dominant) in the majority of materials. Thus, the amount of available data may be big but the number of *relevant* data, i.e., data that contain the needed information, is small. In simple words, in materials science and engineering, we are often looking for "needles in a hay stack," i.e., for very few systems that are statistically exceptional, in some ways. Fitting all data (i.e., the hay) with a single, global model may average away the specialties of the minority (i.e., the needles). Thus, we need methods that identify the relevant, possibly small, statistically exceptional subgroups in the large amount of data right away.

Let us sketch this challenge for kernel methods of machine learning approaches which presently play a significant role in the field. The property of interest is written as a sum over a large, appropriate subset of all known data $j$

$$P(\boldsymbol{d}) = \sum_{j=1}^{N} c_j K(\boldsymbol{d}, \boldsymbol{d_j}).\tag{2}$$

There are many options for the kernel $K$. A most popular and very successful choice is the Gaussian kernel

$$K(\boldsymbol{d}, \boldsymbol{d_j}) = \exp\left(-\left(\boldsymbol{d} - \boldsymbol{d_j}\right)^2 / 2\sigma_j^2\right).\tag{3}$$

Fitting a set of say $N = 100,000$ known data is achieved by determining 100,000 coefficients by minimizing

$$\text{Min}\left\{\sum_{i=1}^{N}\left(\hat{P}_i - P(\boldsymbol{d_i})\right)^2 - \lambda\,||m||\right\}.\tag{4}$$

Here $\left\{\hat{P}_i\right\}$ are the actually known data that should be fitted, and we also introduced a regularization term which prevents overfitting and creates a result that does not go exactly trough the known data points but is smooth. This regularization is noted as "norm of the applied model, $m$." Figure 5 gives an example of such fitting/machine learning approach. Let us, at first, ignore that these are two types of data (noted as squares and circles): Obviously, fitting $N$ data points with a function that contains $N$ free parameters must work, but the regularization creates some uncertainty (a smooths curve), and the interpretability of the very many determined coefficients is typically lacking. Figure 5 also shows a subgroup (statistically exceptional data), together with its selector. These data are not described well by the employed kernel approach. Unfortunately, typically we don't know which data

**Fig. 5** Sketch for a machine learning method, i.e., fit of 1,000 data points (full line) and the confidence interval, which contains 69% of all the data using Gaussian process regression. Also noted is a subgroup (encircled by a blue dashed line) that is statistically exceptional but not treated correctly in the global machine-learned description. The selector equation is noted in blue (Boley 2017). For details see the subsection on subgroup discovery
are relevant for the scientific question of interest and which are not. Otherwise, a weighted sampling could be imposed (Chawla et al. 2002 and references therein). The example of Fig. 5 reveals that the general statement "more data provide a better description" does typically not apply to ML for materials science as it may just mean, add more irrelevant information (more hay) to the information pool (the hay stack). Obviously, this will not help to find the needles. Alternatively, could we turn this around? Can we attempt to fit the hay and then consider the few materials that are distinguished by a high fitting error as an interesting subgroup that contains the needles? The difficulty here is that materials are very heterogeneous, and this heterogeneity is not just restricted to the direct hay-needle comparison. Also the "hay" is heterogeneous, and a high fitting error could also result from over- or underfitting and is not necessarily correlated with the target properties of interest.

Nevertheless, whenever we attempt a global description, machine learning is a great tool. ▶ Chapter 86, "Quantum Machine Learning in Chemistry and Materials" by Huang et al. gives an excellent description, and the abovementioned work on metal oxides (Sutton et al. 2019) is a good example.

Two interpretability-driven approaches have recently been adopted by materials science. These are *subgroup discovery* on the one hand and *compressed sensing* on the other. Let us introduce them briefly.

## 4.1    Subgroup Discovery

As noted above, a global model addressing the quantitative description of the entire data set may be difficult to interpret. For many requirements in materials research, local models that identify and describe subgroups would be advantageous. For illustration (see Fig. 6), a globally optimal regression model could predict a negative relationship between the data (Fig. 6 left). However, a subgroup discovery analysis may reveal that there are two statistically exceptional data groups (indicated by blue and red color in the right part of the figure). Thus the relationship in the data set does not have a negative slope (the global model) but positive slopes (the two subgroups). As a physical example, the transition metals of the Periodic Table are a subgroup, and the actinides, lanthanides, and halogens are other subgroups. Thus,

**Fig. 6** Left, data points and a global regression machine learning model predicting a negative relationship between material properties $y_1$ and $y_2$. Right, subgroup discovery identifies statistically exceptional regions marked as red and blue, and machine learning of these two regions exhibits positive slopes.
identification of subgroups is useful to gain an understanding of similarities of and differences between families of materials.

The concepts of subgroup discovery (SGD) was introduced in the early 1990s, when the advent of large databases motivated the development of explorative and descriptive analytics tools as an interpretable complement to global modeling (Duivesteijn et al. 2016; Klösgen 1996; Atzmueller 2015; Herrera et al. 2011; Siebes 1995; Wrobel 1997; Friedman and Fisher 1999). Simply speaking, the identification of subgroups is built on three components:

(i) The use of a description language for identifying subpopulations within a given pool of data. These are Boolean expressions, e.g., "the ionization potential of atom A minus the ionization potential of atom B is smaller than $X$" where $X$ is a number that may be chosen iteratively. These expressions are called selectors.

(ii) The definition of utility functions that formalize the interestingness (quality) of a subpopulation. This may include requests as "the bandgap of the material is between 1.1 and 1.5 eV" and "the cohesive energy is larger than 3 eV."

(iii) The design of search algorithms to find selectors that describe the subpopulations of interest (e.g., Goldsmith et al. 2017).

Figure 7 illustrates the approach for a recent study of heterogeneous catalysis: finding potential catalysts that can transform the greenhouse gas $CO_2$ into useful chemicals or fuels (Mazheika et al. 2019). This study concentrated on metal oxides and realized that a global model (fitting all the data at once) failed to provide an accurate description. However, searching for subgroups by considering several potential indicators for a good catalytic activity and many potential selectors reveals several subgroups that are statistically exceptional.

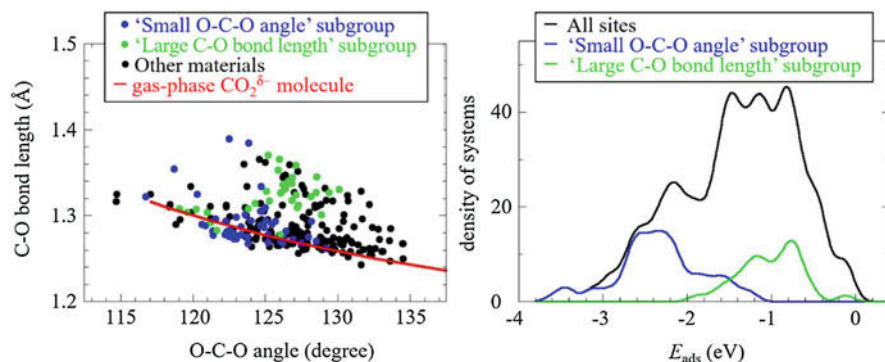

**Fig. 7** Two subgroups of pristine oxide materials in a data set that describes the $CO_2$ adsorption. The blue subgroup is characterized by "small" angles of the O-C-O molecule (the neutral free molecule is linear (180°)). And the green subgroup is characterized by at least one large C-O bond length (the bond lengths of the neutral free molecules are 1.17 Å). Both subgroups reflect a weakening of the bond, but only the green one correlates with a good catalytic activity. Right: density of systems of the full data set and of the two subgroups as function of adsorption energy

Only one of them (marked in green in Fig. 7) contains the known catalytically active materials. Details can be found in Mazheika et al. (2019). The study identified a new indicator for the catalytic $CO_2$ activation, and it provided several suggestions for new potentially good catalysts.

## 4.2    Compressed Sensing and the SISSO Approach

As noted in the discussion of Fig. 2, finding a descriptor (two-dimensional in Fig. 2), i.e., the set of parameters that capture the underlying mechanism of a given materials property or function, is the key, intelligent step toward identification of structure or patterns in (big) data. This central role of the descriptor was only recently addressed explicitly and systematically in the works of Ghiringhelli and coworkers (Ghiringhelli et al. 2015, 2017b; Ouyang et al. 2018). These authors recast the descriptor identification challenge into a systematic formulation using compressed sensing (CS).

The CS approach had been originally introduced for efficiently reproducing a high-quality signal from a very small set of observations (Candès and Wakin 2008; Nelson et al. 2013; Candès et al. 2006; Candro et al. 2006; Donoho 2006). Mathematically, this can be sketched as follows. Given a set of data $P_1, P_2, \ldots P_N$, where $i = 1-N$ labels different materials (or different conditions), CS finds the sparse solution $\boldsymbol{c}$ of an underdetermined system of linear equations

$$P(\boldsymbol{d}_i) = \sum_{k=1}^{M} \hat{c}_k \, d_{ki} \; . \tag{5}$$

$\{d_{ki}\} = \boldsymbol{D}$ is called the sensing matrix with the number of rows $k = 1-M$ significantly bigger than the number of columns, $i = 1-N$. Thus, the sensing matrix is built from $N$ vectors (the columns), each of length $M$. Material $i$ is characterized by vector $i$, i.e., by $k = 1-M$ values (descriptive parameters), $d_{ki}$. Equation (5) corresponds to Eq. (2) when the linear kernel is used. If most elements of the vector $\hat{\boldsymbol{c}}$ were zero, specifically when the number of nonzero elements of $\hat{\boldsymbol{c}}$ is smaller than $N$, the dimensionality of the problem is reduced (Candès et al. 2006; Donoho 2006; Candès and Wakin 2008). In order to achieve this reduction, the coefficients $\hat{c}_k$ are determined by solving Eq. (4) with the norm $||m||$ taken as the $l_0$ norm of $\hat{\boldsymbol{c}}$. The norm zero of a vector is defined as the number of nonzero elements. Thus, the regularization $\lambda||\hat{\boldsymbol{c}}||_0$ is a constraint that favors solutions for $\hat{\boldsymbol{c}}$ where most elements of $\hat{\boldsymbol{c}}$ are zero. However, using the norm zero poses a combinatorically extensive problem, and it has been shown that this is (asymptotically) NP hard. As a consequence it has been suggested to approximate the norm zero by the norm $l_1$, and a popular approach to it is LASSO (least absolute shrinkage and selection operator) (Tibshirani 1996). For materials science this has been introduced by Ghiringhelli and coworkers (Ghiringhelli et al. 2015, 2017b).

Thus, the idea behind the compressed sensing approach is to offer many descriptor candidates and then let the optimization approach (Eq. (4)) find out which of these candidates are relevant. Since Eq. (5) is linear, it is necessary that the offered descriptor candidates contain the potential nonlinearities. Consequently, different descriptor candidates, i.e., different columns of the sensing matrix, may become correlated. Furthermore, the dimension of the sensing matrix increases rapidly with the number of data points, and as LASSO requires that the matrix is stored, the approach is getting intractable. These problems have been recently tackled by Ouyang and coworkers (Ouyang et al. 2018) by solving the $l_0$ challenge in an iterative approach called SISSO (sure independence screening and sparsifying operator). Interestingly, the mentioned correlations are not causing problems, and the number of candidate descriptors can be increased in SISSO to many billions and even trillions. Initially, from the previously mentioned "basic descriptors" $\{\boldsymbol{R}_I, Z_I\}$, $N^e$, only $Z_I$-derived quantities were used explicitly, e.g., the ionization potentials of the atoms, the electron affinities, and information about the extension of the atomic wave functions. Then, a combination of algebraic/functional operations is recursively performed for extending the space of descriptor candidates. Details are described in Ouyang et al. (2018). Clearly, when different structures are considered or different charge states $\{\boldsymbol{R}_I\}$, $N^e$-related features are needed as well.

## 5 Outlook

Computational materials science took off with impressive early work by Moruzzi et al. (1978) on various properties of metals and by Cohen and coworkers (Yin and Cohen 1982) on the cohesion and phase transition of silicon and germanium (see ▶ Chap. 3, "Modeling Solids and Its Impact on Science and Technology" by M. Cohen in this handbook, in particular Fig. 4). A number of computer codes for solving the Kohn-Sham equations have been developed since then, initially involving approximations like pseudopotentials (removing the core electrons, creating smooth potentials) or introducing touching or slightly overlapping atom-centered spheres in which the potential was sphericalized. During the 1980s significant advancements in the original pseudopotential approach have been made (see the work of Vanderbilt and coworkers: Garrity et al. 2014 and references therein), and all-electron codes have been developed that don't require a shape approximation for the potentials (e.g., Wimmer et al. 1981; Blaha et al. 1990; Gulans et al. 2014; Blum et al. 2009). The work by Lejaeghere et al. (2016) provides a nice overview of the precision of modern electronic-structure codes for elemental bulk solids, also demonstrating how to involve the community. Clearly, this kind of work is important and needs to be extended to more complicated structures and compositions, defects, surfaces, and interfaces. Work in this direction is underway, as are studies for advanced electronic structure methods, like the *GW* approach (van Setten et al. 2015). Furthermore, the field urgently needs benchmarks for the various numerical approximations and for exchange-correlation potentials in order to address also accuracy, not only numerical precision. The MSE (materials science and engineering) project (Zhang et al. 2019)

is a promising step in this direction. Without all this, data-driven science will be limited in its capabilities.

Computational materials science is presently dominated by the third research paradigm (cf. Fig. 1), but advancements in AI methods has been significant in recent years, and the fourth paradigm is playing an increasing role. Still, at present there is more hype than realism in what AI can do. Much of this relates to the fact that the amount of relevant or independent data is often not really big. Machine learning techniques can help a lot when general trends are of interest and when one needs to fit and predict "the behavior of a big crowd" (see, e.g., the methods used in the Kaggle competition for predicting properties of transparent conductors Sutton et al. 2019). Often, the sensible needs of materials science and engineering are, however, different: We are typically not looking for a crowd behavior, but we are searching for materials with extraordinary performance on certain functions or properties, often even a combination of several properties. There are typically just a few, statistically exceptional, suitable materials among the enormous number of possible materials (already existing ones and those that will be synthesized in the future). However, in many cases we don't know how to identify this "class" of potentially interesting functional materials. How can we distinguish which data/materials are relevant and which are not? Learning about less than 0.01% relevant materials from thousands or millions of irrelevant data is obviously problematic, and standard methods, which optimize the regularized root-mean-square error, even emphasize the importance of the irrelevant data, while surpassing the special cases. If the data could be grouped in "a majority classes" and a "minority class," methods have been developed to deal with the problem (Chawla et al. 2002 and references therein). However, often these classes are unknown, and advancements of the subgroup discovery concept for the materials science domain are urgently needed.

What is missing at present? Let us list some issues:

- Close coupling of materials property prediction with stability analysis and prediction of routes reproducible synthesis.
- High-throughput studies of *metastable* materials and of the lifetimes of these metastable states.
- Materials under real conditions ($T$, $p$, and reactive environment): stability and properties. This very much concerns multiscale modeling with robust, error-controlled links with knowledge of uncertainty between the various simulation methodologies. This has been often stated in the past but is still not fully realized.
- Error estimates of calculations in terms of numerical approximations (basis sets, pseudopotentials, etc.) for specific properties (structure, elastic and electronic properties, etc.).
- Computations beyond standard DFT as, for example, coupled-cluster methods for calculations for solids (possibly also getting prepared for quantum computers).
- Complete description of scientific results accounting for the heterogeneity of data, i.e., to improve and complement present metadata definitions. While significant progress has been made for computational data from the many computer

codes and the development of corresponding metadata (Ghringhelli et al. 2016, 2017a; Meta Info at NOMAD), it is now urgent that the same is being achieved also for experimental data. The latter challenge is even bigger than the first. The sample material used in the experimental study corresponds to the input file of a calculation; the experimental condition ($T$, $p$, environment) and the experimental equipment to the computer code. A not fully solved challenge is the complete characterization of the sample material. In fact, this will often be impossible. Obviously, closely coupled to the definition of metadata is the description of workflows in the sample preparation and running of the experiment.

The field is just developing the methods for the fourth paradigm. The learning curve connecting paradigms 1, 2, 3, and 4 is apparently getting steep. Thus the next paradigm may be close, even though the fourth has not been developed well, so far. What could be the next paradigm? Considering that "the future is already here – it's just not very evenly distributed" (Gibson 1999), it may be hintingly visible already today. We guess that it may be virtual reality with direct and instantaneous connection to new calculations or a merger of theory (predictions and analysis) and experiment. There are exciting times ahead of us.

**Abstract**

Time-dependent density functional theory (TDDFT) is currently the most efficient approach allowing to describe electronic dynamics in complex systems, from isolated molecules to the condensed phase. TDDFT has been employed to investigate an extremely wide range of time-dependent phenomena, as spin dynamics in solids, charge and energy transport in nanoscale devices, and photoinduced exciton transfer in molecular aggregates. It is therefore nearly impossible to give a general account of all developments and applications of TDDFT in material science, as well as in physics and chemistry. A large variety of aspects are covered throughout these volumes. In the present chapter, we will limit our presentation to the description of TDDFT developments and applications in the field of quantum molecular dynamics simulations in combination with trajectory-based approaches for the study of nonadiabatic excited-state phenomena. We will present different quantum-classical strategies used to describe the coupled dynamics of electrons and nuclei underlying nonadiabatic processes. In addition, we will give an account of the most recent applications with the aim of illustrating the nature of the problems that can be addressed with the help of these approaches. The potential, as well as the limitations, of the presented methods is discussed, along with possible avenues for future developments in TDDFT and nonadiabatic dynamics.

## 1    Introduction

Photoinduced isomerization processes, photosynthetic and photovoltaic energy conversion phenomena, and charge and energy transport through molecular junctions are all typical examples of, so-called, nonadiabatic processes. Nonadiabatic processes are characterized by a strong coupling between electronic and nuclear motion; in fact, nuclear motion is responsible for inducing electronic (nonadiabatic) transitions, and in turn, the time evolution of the electronic states also affects the nuclear dynamics at very short timescales (down to a few tens of fs). In this nonadiabatic regime, thus when the Born-Oppenheimer approximation breaks down, performing (quantum) molecular dynamics simulations is tremendously challenging. Accurate electronic structure properties are required to describe electronic dynamics and to correctly *drive* the nuclear evolution. Identifying regions of nuclear configuration space where the electronic states are coupled, as avoided crossings and conical intersections, is essential to predict quantum yields. Efficient evolution techniques have to be employed to describe nuclear motion in order, for instance, to determine final molecular structures or to account for possible quantum effects. Therefore, theoretical and numerical developments need to address the problem from the perspective of both electronic structure theory and nuclear quantum dynamics.

Perhaps the most celebrated method to investigate excited electronic states is time-dependent density functional theory (TDDFT). TDDFT offers an in principle exact formalism for propagating the time-dependent electronic density and, within

linear-response theory, for calculating excitation energies as well as critical excited-state properties. It is therefore without any surprise that TDDFT became the electronic structure method of choice to be coupled with nonadiabatic dynamics. Particularly successful has been the combination of TDDFT, employed to solve the electronic problem, with the description of nuclear motion in terms of trajectories that evolve or hop between coupled (electronic) potential energy surfaces. The most well-known method is Tully's "fewest switches" trajectory surface hopping (Tully 1990), which has evolved into a widely used and successful technique. The mean-field Ehrenfest dynamics is often employed to investigate explicitly the electronic dynamics, combined, for example, with real-time TDDFT (Tavernelli et al. 2005; Tavernelli 2006). Full multiple spawning (Martínez et al. 1996; Martínez and Levine 1997; Ben-Nun and Martínez 1998, 2002; Ben-Nun et al. 2000; Hack et al. 2001; Virshup et al. 2008) propagates coupled Gaussian functions along classical trajectories, whereas the coupled-trajectory mixed quantum-classical (CT-MQC) scheme (Min et al. 2015) derived from the exact factorization (Abedi et al. 2010) is based on the propagation of trajectories along a time-dependent potential energy surface (Abedi et al. 2013a). Other techniques like the quantum-classical Liouville equation (Kapral and Ciccotti 1999; Nielsen et al. 2000; Kapral 2006), Bohmian dynamics (Wyatt et al. 2001; Lopreore and Wyatt 2002; Rassolov and Garashchuk 2005; Curchod and Tavernelli 2013), variational multiconfiguration Gaussians (Worth et al. 2004, 2008; Lasorne et al. 2006, 2007; Mendive-Tapia et al. 2012; Richings et al. 2015), multiconfigurational Ehrenfest (Shalashilin 2010; Saita and Shalashilin 2012; Makhov et al. 2017), or linearization approaches to compute time-correlation functions (Bonella and Coker 2005; Huo and Coker 2012; Dunkel et al. 2008) have been also proposed for nonadiabatic dynamics. Despite their differences, all the methods mentioned above are rooted in the Born-Huang representation of the total molecular wavefunction, i.e., an expansion in an infinite sum over the correlated Born-Oppenheimer electronic states. In contrast, the recently introduced exact factorization of the time-dependent molecular wavefunction offers a paradigm shift in our perception of nonadiabatic dynamics, away from the Born-Huang picture, and blazes a trail for the development of nonadiabatic techniques away from Born-Oppenheimer concepts. It is important to mention here that ensembles of trajectories, when properly constructed via the method of characteristics (Agostini et al. 2018), can represent, in principle arbitrarily closely, the solution of the underlying partial differential equation. Practical implementations, however, involve further-going approximations where, for instance, interference and tunneling effects are neglected or only approximately taken into account. The advantage of trajectory-based method is that they circumvent the enormous numerical effort associated with quantum wave packets propagation techniques, such as multiconfiguration time-dependent Hartree approach (MCTDH) (Meyer et al. 1990; Burghardt et al. 1999; Wang and Thoss 2003; Meyer and Worth 2003). By its very nature, this approach requires the computation of the relevant potential energy surfaces (PESs) and corresponding couplings before the actual propagation of nuclear wave packets. This clearly implies an important computational effort that limits the applicability of this method to a small number of degrees of freedom (up to ∼10). In addition,

the determination of the relevant degrees of freedom to include in the dynamics can also become a challenging problem, which requires some a priori knowledge of the "active" vibrational modes involved in the dynamics. Such wavefunction-based nonadiabatic approaches are beyond the scope of this chapter and will not be discussed further.

The goal of this chapter is to present in a self-contained manner the key theoretical concepts and equations of the most important methods cited above, starting from the electronic structure problem and (LR-)TDDFT up to nuclear dynamics methods like surface hopping, Ehrenfest dynamics, and ab initio multiple spawning. To contrast with these Born-Huang-based methods, we also present the formalism of the exact factorization and introduce the reader to the first mixed quantum-classical algorithm derived from this formalism, coined coupled-trajectory mixed quantum-classical (CT-MQC) dynamics.

## 2  Coupled Electron-Nuclear Dynamics in Molecules

In molecules and condensed phase systems, the time evolution of interacting electrons and nuclei is described by the time-dependent Schrödinger equation:

$$\hat{H}\Psi(\mathbf{r}, \mathbf{R}, t) = i\hbar\partial_t\Psi(\mathbf{r}, \mathbf{R}, t), \tag{1}$$

where the electron-nuclear wavefunction $\Psi(\mathbf{r}, \mathbf{R}, t)$ describes the state of the system over time and $\hat{H}$ is the molecular Hamiltonian, i.e.:

$$\hat{H}(\mathbf{r}, \mathbf{R}) = \sum_{v=1}^{N_n} \frac{-\hbar^2}{2M_v}\nabla_v^2 + \hat{T}_e(\mathbf{r}) + V_{ee}(\mathbf{r}) + V_{nn}(\mathbf{R}) + V_{en}(\mathbf{r}, \mathbf{R})$$

$$= \sum_{v=1}^{N_n} \frac{-\hbar^2}{2M_v}\nabla_v^2 + \hat{H}_{BO}(\mathbf{r}, \mathbf{R}). \tag{2}$$

Here, $\mathbf{r} = (\mathbf{r}_1, \ldots, \mathbf{r}_{N_{el}})$, $\mathbf{R} = (\mathbf{R}_1, \ldots, \mathbf{R}_{N_n})$, $N_{el}$ is the number of electrons and $N_n$ the number of nuclei. The first term on the right-hand side of Eq. (2) is the nuclear kinetic energy, with $\nabla_v$ indicating the spatial derivative with respect to the position of the nucleus $v$ and $M_v$ its mass, whereas $\hat{H}_{BO}$ is the so-called Born-Oppenheimer (BO), or electronic, Hamiltonian. $\hat{H}_{BO}$ is defined as the sum of the electronic kinetic energy, $\hat{T}_e$; the electron-electron, $\hat{V}_{ee}$; the nucleus-nucleus $V_{nn}$; and the electron-nucleus, $V_{en}$, interactions.

Usually, the problem is reformulated adopting the Born-Huang expansion of the molecular wavefunction in the adiabatic basis. The adiabatic, or BO, states, $\varphi_{\mathbf{R}}^{(k)}(\mathbf{r})$, are defined as the eigenfunctions of the BO Hamiltonian:

$$\hat{H}_{BO}(\mathbf{r}, \mathbf{R})\varphi_{\mathbf{R}}^{(k)}(\mathbf{r}) = \varepsilon_{BO}^{(k)}(\mathbf{R})\varphi_{\mathbf{R}}^{(k)}(\mathbf{r}), \tag{3}$$

with eigenvalues $\varepsilon_{BO}^{(k)}(\mathbf{R})$. The electronic time-independent problem is diagonalized at each nuclear position $\mathbf{R}$; thus the eigenfunctions and eigenvalues depend on $\mathbf{R}$. Nuclear positions are interpreted here as parameters, which label both the electronic states and the electronic energies. If Eq. (3) is solved for all nuclear configurations, $\varepsilon_{BO}^{(k)}(\mathbf{R})$ identify the so-called BO potential energy surfaces (PESs). In the Born-Huang expansion of the electron-nuclear wavefunction,

$$\Psi(\mathbf{r}, \mathbf{R}, t) = \sum_k \chi_k(\mathbf{R}, t) \varphi_{\mathbf{R}}^{(k)}(\mathbf{r}), \qquad (4)$$

the coefficients $\chi_k(\mathbf{R}, t)$ clearly depend on nuclear positions and on time. These coefficients can be interpreted as the nuclear contributions corresponding to the electronic states included in the sum and can be also referred to as nuclear wave packets. In fact, it can be easily proven that the nuclear density, defined as the integral of $|\Psi(\mathbf{r}, \mathbf{R}, t)|^2$ over electronic coordinates,

$$\int d\mathbf{r} \, |\Psi(\mathbf{r}, \mathbf{R}, t)|^2 = \sum_k |\chi_k(\mathbf{R}, t)|^2, \qquad (5)$$

can be written as the sum of adiabatic contributions, $|\chi_k(\mathbf{R}, t)|^2$. Here, the orthogonality of the BO states

$$\int d\mathbf{r} \varphi_{\mathbf{R}}^{(l)*}(\mathbf{r}) \varphi_{\mathbf{R}}^{(k)}(\mathbf{r}) = \left\langle \varphi_{\mathbf{R}}^{(l)} \middle| \varphi_{\mathbf{R}}^{(k)} \right\rangle_{\mathbf{r}} = \delta_{lk} \qquad (6)$$

has been used.

The Born-Huang expansion (4) is inserted in Eq. (1), which is then projected on $\varphi_{\mathbf{R}}^{(k)*}(\mathbf{r})$ and integrated over $\mathbf{r}$. A set of partial differential equations are derived for the expansion coefficients:

$$\left[ \sum_v^{N_n} \frac{-\hbar^2}{2M_v} \nabla_v^2 + \varepsilon_{BO}^{(k)}(\mathbf{R}) \right] \chi_k(\mathbf{R}, t) + \sum_l \mathscr{F}_{kl}(\mathbf{R}) \chi_l(\mathbf{R}, t) = i\hbar \partial_t \chi_k(\mathbf{R}, t). \qquad (7)$$

The last term on the right-hand side is responsible for coupling the evolution of the $k$-th coefficient to all other coefficients, via the nonadiabatic couplings

$$\mathscr{F}_{kl}(\mathbf{R}) = \int d\mathbf{r} \, \varphi_{\mathbf{R}}^{(k)*}(\mathbf{r}) \left[ \sum_v^{N_n} \frac{-\hbar^2}{2M_v} \nabla_v^2 \right] \varphi_{\mathbf{R}}^{(l)}(\mathbf{r})$$

$$+ \sum_v^{N_n} \frac{1}{M_v} \left\{ \int d\mathbf{r} \, \varphi_{\mathbf{R}}^{(k)*}(\mathbf{r}) \left[ -i\hbar \nabla_v \varphi_{\mathbf{R}}^{(l)}(\mathbf{r}) \right] \right\} \cdot [-i\hbar \nabla_v], \qquad (8)$$

arising from the effect of the nuclear kinetic energy operator on the parametric dependence of the BO states on $\mathbf{R}$. In the most general case, the non-diagonal

elements of $\mathscr{F}_{kl}(\mathbf{R})$ are non-zero and induce a coupling between different electronic states due to the motion of the nuclei. The nonadiabatic coupling term is responsible for exchanging "nuclear contributions" between the electronic adiabatic states $k$ and $l$. The BO framework presented so far is widely adopted by a large community of physicists and chemists to interpret the coupled electron-nuclear problem under nonadiabatic conditions. However, such framework is not the only one, as we will discuss below.

An alternative perspective on the coupled electron-nuclear problem has been recently proposed, the exact factorization of the electron-nuclear wavefunction (Abedi et al. 2010, 2012). In this framework, we make an Ansatz different from the Born-Huang representation of the molecular wavefunction, namely:

$$\Psi(\mathbf{r}, \mathbf{R}, t) = \Phi_{\mathbf{R}}(\mathbf{r}, t)\chi(\mathbf{R}, t). \tag{9}$$

Here $\chi(\mathbf{R}, t)$ is the nuclear wavefunction and $\Phi_{\mathbf{R}}(\mathbf{r}, t)$ is the electronic wavefunction which parametrically depends on the nuclear positions and satisfies the partial normalization condition (PNC):

$$\int d\mathbf{r}\, |\Phi_{\mathbf{R}}(\mathbf{r}, t)|^2 = 1 \quad \forall\, \mathbf{R}, t. \tag{10}$$

The theorems introduced in Abedi et al. (2010, 2012) prove the existence and uniqueness of Eq. (9), up to within a $(\mathbf{R}, t)$-dependent gauge transformation. The PNC guarantees the interpretation of $|\chi(\mathbf{R}, t)|^2$ as the probability of finding the nuclear configuration $\mathbf{R}$ at time $t$ and of $|\Phi_{\mathbf{R}}(\mathbf{r}, t)|^2$ itself as the conditional probability of finding the electronic configuration $\mathbf{r}$ at time $t$ given the nuclear configuration $\mathbf{R}$.

The stationary variations (Frenkel 1934) of the quantum-mechanical action with respect to $\Phi_{\mathbf{R}}(\mathbf{r}, t)$ and $\chi(\mathbf{R}, t)$ lead to the derivation of the following equations of motion:

$$\left(\hat{H}_{BO}(\mathbf{r}, \mathbf{R}) + \hat{U}_{en}^{coup}[\Phi_{\mathbf{R}}, \chi] - \varepsilon(\mathbf{R}, t)\right)\Phi_{\mathbf{R}}(\mathbf{r}, t) = i\hbar\partial_t \Phi_{\mathbf{R}}(\mathbf{r}, t) \tag{11}$$

$$\left[\sum_{v=1}^{N_n} \frac{[-i\hbar\nabla_v + \mathbf{A}_v(\mathbf{R}, t)]^2}{2M_v} + \varepsilon(\mathbf{R}, t)\right]\chi(\mathbf{R}, t) = i\hbar\partial_t \chi(\mathbf{R}, t), \tag{12}$$

where the PNC is enforced by means of Lagrange multipliers (Alonso et al. 2013; Abedi et al. 2013b). The electron-nuclear coupling operator (Agostini et al. 2015b),

$$\hat{U}_{en}^{coup}[\Phi_{\mathbf{R}}, \chi] = \sum_{v=1}^{N_n} \frac{1}{M_v}\left[\frac{[-i\hbar\nabla_v - \mathbf{A}_v(\mathbf{R}, t)]^2}{2}\right.$$
$$\left. + \left(\frac{-i\hbar\nabla_v\chi}{\chi} + \mathbf{A}_v(\mathbf{R}, t)\right)\left(-i\hbar\nabla_v - \mathbf{A}_v(\mathbf{R}, t)\right)\right], \tag{13}$$

the time-dependent potential energy surface (TDPES) (Abedi et al. 2013a; Agostini et al. 2013; Suzuki et al. 2015; Agostini et al. 2015a; Curchod et al. 2016a; Suzuki and Watanabe 2016),

$$\varepsilon(\mathbf{R}, t) = \langle \Phi_{\mathbf{R}}(t) | \hat{H}_{BO} + \hat{U}_{en}^{coup} - i\hbar \partial_t | \Phi_{\mathbf{R}}(t) \rangle_{\mathbf{r}} , \tag{14}$$

and the time-dependent vector potential (Curchod and Agostini 2017),

$$\mathbf{A}_v(\mathbf{R}, t) = \langle \Phi_{\mathbf{R}}(t) | - i\hbar \nabla_v \; \Phi_{\mathbf{R}}(t) \rangle_{\mathbf{r}} \tag{15}$$

are responsible for the coupling between electrons and nuclei in a formally exact way. It is worth noting that the electron-nuclear coupling operator, $\hat{U}_{en}^{coup}[\Phi_{\mathbf{R}}, \chi]$, in the electronic equation (11), depends on the nuclear wavefunction and acts on the parametric dependence of $\Phi_{\mathbf{R}}(\mathbf{r}, t)$ as a differential operator. This "pseudo-operator" includes the coupling to the nuclear subsystem beyond the parametric dependence in the BO Hamiltonian $\hat{H}_{BO}(\mathbf{r}, \mathbf{R})$. The symbol $\langle \cdot \rangle_{\mathbf{r}}$ indicates an integration over electronic coordinates only. The nuclear equation (12) has the particularly appealing form of a Schrödinger equation that contains a time-dependent vector potential (15) and a time-dependent scalar potential (14) that govern the nuclear dynamics and yield the nuclear wavefunction. $\chi(\mathbf{R}, t)$ is interpreted as the nuclear wavefunction since it leads to an $N$-body nuclear density, and an $N$-body current-density, which reproduce the true nuclear $N$-body density and current-density (Abedi et al. 2012) obtained from the full wavefunction $\Psi(\mathbf{r}, \mathbf{R}, t)$.

In order to connect the Born-Huang representation to the exact factorization, the electronic wavefunction $\Phi_{\mathbf{R}}(\mathbf{R}, t)$ is expanded in terms of the BO states, similarly to what is done for the molecular wavefunction of Eq. (4), namely:

$$\Phi_{\mathbf{R}}(\mathbf{r}, t) = \sum_k C_k(\mathbf{R}, t) \varphi_{\mathbf{R}}^{(k)}(\mathbf{r}). \tag{16}$$

The expansion coefficients in Eqs. (4) and (16) are related,

$$\chi_k(\mathbf{R}, t) = C_k(\mathbf{R}, t) \chi(\mathbf{R}, t), \tag{17}$$

by virtue of the factorization (9). Additionally, the PNC can be rewritten as

$$\sum_k |C_k(\mathbf{R}, t)|^2 = 1 \quad \forall \; \mathbf{R}, t. \tag{18}$$

We point out that even in the case where the nuclear wave packet splits into more than one BO PESs, the full wavefunction is still a single product: the nuclear wave function has contributions (projections) on different BO PESs, while the electronic wavefunction is a linear combination of the adiabatic states, but still we may write:

$$\Psi(\mathbf{r}, \mathbf{R}, t) = \left( e^{\frac{i}{\hbar} S(\mathbf{R},t)} \sqrt{\sum_l |\chi_l(\mathbf{R}, t)|^2} \right) \left( \sum_k C_k(\mathbf{R}, t) \varphi_{\mathbf{R}}^{(k)}(\mathbf{r}) \right) \qquad (19)$$

where the first term in parenthesis is $\chi(\mathbf{R}, t)$, with a phase $S(\mathbf{R}, t)$ determined by fixing the gauge freedom, and the second term in parenthesis is $\Phi_{\mathbf{R}}(\mathbf{r}, t)$, using Eq. (16).

In the absence of nonadiabatic couplings in Eq. (7), the evolution equations for the coefficients $\chi_k(\mathbf{R}, t)$ decouple, and each nuclear contribution now evolves *adiabatically* according to the TDSE

$$\left[ \sum_v^{N_n} \frac{-\hbar^2}{2M_v} \nabla_v^2 + \varepsilon_{BO}^{(k)}(\mathbf{R}) \right] \chi_k(\mathbf{R}, t) = i\hbar \partial_t \chi_k(\mathbf{R}, t), \qquad (20)$$

under the effect of a potential produced only by the electrons in the adiabatic state $k$. This is the essence of the BO approximation. Analogously, in the limit of infinite nuclear masses, Eqs. (11) and (12) (Scherrer et al. 2015, 2017; Schild et al. 2016; Eich and Agostini 2016) reduce to the fundamental equations of the BO approximation, namely, the static electronic equation (3) and a nuclear evolution equation identical to Eq. (20) with $\chi_k(\mathbf{R}, t)$ replaced by the nuclear wavefunction $\chi(\mathbf{R}, t)$ of the exact factorization.

If the nonadiabatic couplings cannot be neglected, the fully coupled electron-nuclear problem, summarized in Eq. (7) or Eqs. (11) and (12), has to be solved.

Electronic dynamics is simulated at a quantum-mechanical level employing quantum chemistry approaches, either based on the electronic wavefunction or on the electronic density. If either the adiabatic or the diabatic basis is used to characterize the electronic subsystem, electronic dynamics is implied in the time evolution of the expansion coefficients (see, e.g., Eqs. (4) or (16)), since the basis functions are time-independent. On the other hand, (real-time) TDDFT yields an explicit evolution of the electronic subsystem, as the electrons are represented via their time-dependent one-body density. As we will show below, real-time TDDFT can be combined with a mean-field solution of the coupled electron-nuclear dynamics. The linear response formulation of TDDFT, instead, is able to provide information about the time-independent electronic properties, such as adiabatic forces and nonadiabatic couplings, needed for approaches based on the Born-Huang expansion. Possible extensions of TDDFT to solve the electronic equation of the exact factorization are currently under investigation (Requist and Gross 2016). Section 3 is devoted to a thorough review of the basis of TDDFT and of LR-TDDFT

Nuclear dynamics can be treated exactly or approximated at different levels, depending on the complexity of the system of interest. Simulation methods that retain the quantum character of nuclear dynamics are indeed very expensive, as the numerical cost for solving the quantum-mechanical problem scales exponentially with the number of degrees of freedom. Therefore, different strategies have been proposed over the years to make the problem numerically tractable. Quantum wave

packet propagation techniques aim at solving Eq. (7) either on grids (Lauvergnat and Nauts 2010, 2014; Sadri et al. 2012) or by expanding the nuclear wave packets $\chi_k(\mathbf{R}, t)$ on a basis where calculations are computationally cheaper (Meyer et al. 1990; Burghardt et al. 1999; Wang and Thoss 2003; Meyer and Worth 2003; Sadri et al. 2014). The major bottleneck of these approaches is the "pre-calculation" of the electronic properties, i.e., BO PESs and of the nonadiabatic couplings, needed to solve the nuclear equations. Attempts at solving exactly the coupled equations at the basis of the exact factorization are currently under investigations. On-the-fly calculations of electronic properties are instead possible, if only local nuclear information is necessary to solve (in an approximate way) Eq. (7). Full and ab initio multiple spawning methods (Martínez et al. 1996; Martínez and Levine 1997; Ben-Nun and Martínez 1998, 2002; Ben-Nun et al. 2000; Hack et al. 2001; Virshup et al. 2008), similarly to direct dynamics techniques (Worth et al. 2004, 2008; Lasorne et al. 2006, 2007; Mendive-Tapia et al. 2012; Richings et al. 2015), employ a representation of the nuclear wave packets in terms of moving Gaussian functions, which evolve along trajectories determined either variationally or classically. Trajectory-based quantum-classical schemes adopt a representation of nuclear dynamics in terms of purely classical trajectories, as in the Ehrenfest and surface-hopping methods. They are indeed numerically cheaper than the methods above, but the price to pay is sometimes the neglect of important quantum-mechanical features both in the nuclear dynamics and in the coupling between electronic and nuclear motion. Similarly to direct dynamics and full multiple spawning, evolving the nuclei along trajectories enables us to exploit the locality of classical dynamics for on-the-fly simulations, where electronic information is needed, and thus computed, only for the visited nuclear configurations. Trajectory-based solutions of Eqs. (11) and (12) have been proposed (Agostini et al. 2014; Abedi et al. 2014), and the most recent developments (Min et al. 2017) will be reviewed in Sect. 4, along with Ehrenfest dynamics (Tully 1998), trajectory surface hopping (Tully 1990; Doltsinis and Marx 2002; Böckmann et al. 2010; Jasper et al. 2004, 2006; Subotnik et al. 2013; Curchod and Tavernelli 2013; Jaeger et al. 2012; Fang and Hammes-Schiffer 1999; Tapavicza et al. 2007; Craig et al. 2005; Akimov and Prezhdo 2014), and full/ab initio multiple spawning (Martínez et al. 1996; Martínez and Levine 1997; Ben-Nun and Martínez 1998, 2002; Ben-Nun et al. 2000; Hack et al. 2001; Virshup et al. 2008).

## 3 Electronic Dynamics: Time-Dependent Density Functional Theory

### 3.1 Time-Dependent Density Functional Theory

The Hohenberg-Kohn (HK) theorem (Hohenberg and Kohn 1964) of ground-state DFT states that knowledge of the ground-state density uniquely determines the external potential of the system (up to within a trivial constant) and thus the entire electronic Hamiltonian and the associated total ground-state energy. It is important to realize that ground-state DFT in nearly all applications is intimately tied to the

BO approximation: the electronic density one calculates is the one produced by *clamped* nuclei. Then, by varying the positions of the clamped nuclei, ground-state DFT provides an efficient approach to map out the lowest BO PES and to calculate physical observables associated with the lowest BO PES, such as vibrational spectra, cohesive energies, barrier heights, etc. Higher BO PESs and the time evolution of systems strongly driven by external fields are not accessible with ground-state DFT.

In their seminal paper, Runge and Gross (1984) proved a theorem that established a 1-1 correspondence between the time-dependent density and the time-dependent external potential for systems evolving from a given initial many-electron state, $\Phi_0$. The time evolution of the many-electron wavefunction is governed by the time-dependent Schrödinger equation:

$$\hat{H}_{el}(t)\Phi(\mathbf{r}, t) = i\hbar \frac{\partial}{\partial t}\Phi(\mathbf{r}, t) \tag{21}$$

$$\Phi(\mathbf{r}, t_0) = \Phi_0(\mathbf{r})$$

with Hamiltonian

$$\hat{H}_{el}(t) = \hat{T}_e(\mathbf{r}) + V_{ee}(\mathbf{r}) + v_{ext}(\mathbf{r}, t). \tag{22}$$

The general time-dependent external potential appearing in (22) covers different scenarios: one important case is the (short-time) electron dynamics with clamped nuclei, driven by an applied laser field:

$$v_{ext}(\mathbf{r}, t) = V_{nn}(\mathbf{R}) + V_{en}(\mathbf{r}, \mathbf{R}) + \delta v_{app}(\mathbf{r}, t). \tag{23}$$

Another case is the time-dependent electric potential produced by classically propagated point-like nuclei:

$$v_{ext}(\mathbf{r}, t) = V_{nn}(\mathbf{R}(t)) + V_{en}(\mathbf{r}, \mathbf{R}(t)). \tag{24}$$

In complete detail, the Runge-Gross theorem ensures that the densities $\rho(\mathbf{r}, t)$ and $\rho'(\mathbf{r}, t)$ evolving from a common initial many-body state $\Phi_0 = \Phi(t_0)$ under the influence of two potentials $V_{ext}(\mathbf{r}, t)$ and $V'_{ext}(\mathbf{r}, t)$ will become different infinitesimally later than $t_0$ if the potentials are Taylor expandable around the initial time $t_0$ and differ by more than a purely time-dependent constant $V_{ext}(\mathbf{r}, t) \neq V'_{ext}(\mathbf{r}, t) + C(t)$. This implies that the potentials-to-densities map can be inverted:

$$\rho(\mathbf{r}, t) \rightarrow v_{ext}[\rho](\mathbf{r}, t). \tag{25}$$

The Runge-Gross proof does not depend on the particular form of the particle-particle interaction. The proof is valid for essentially any interaction, in particular also for no interaction. This establishes the map for noninteracting particles:

$$\rho(\mathbf{r}, t) \rightarrow v_s[\rho](\mathbf{r}, t), \tag{26}$$

implying that the potential $v_s(\mathbf{r}, t)$, which reproduces the interacting density, $\rho(\mathbf{r}, t)$, in a noninteracting system is uniquely defined. From now on, this unique potential $v_s[\rho](\mathbf{r}, t)$ will be called the *time-dependent Kohn-Sham potential*. The corresponding system of single-particle time-dependent Schrödinger equations

$$i\hbar \frac{\partial}{\partial t} \phi_k(\mathbf{r}, t) = \left(-\frac{1}{2}\nabla^2 + v_s(\mathbf{r}, t)\right) \phi_k(\mathbf{r}, t), \quad k = 1, \ldots, N, \tag{27}$$

whose orbitals reproduce the interacting density via

$$\rho(\mathbf{r}, t) = \sum_{i=1}^{N} |\phi_k(\mathbf{r}, t)|^2 \tag{28}$$

is called *time-dependent Kohn-Sham (TDKS) equations*.

The Runge-Gross theorem guarantees uniqueness of the potentials $v_{\text{ext}}[\rho, \Phi_0](\mathbf{r}, t)$ and $v_s[\rho, \{\phi_k^{(0)}(\mathbf{r})\}]$ for given initial many-body state $\Phi_0$ and given initial orbitals $\{\phi_k^{(0)}(\mathbf{r})\}$, respectively (Gross and Kohn 1990). Apart from uniqueness, whether or not, for a given function $\rho(\mathbf{r}, t)$, the potentials $v_{\text{ext}}(\mathbf{r}, t)$ and $v_s(\mathbf{r}, t)$ actually exist, is a separate question, known as (interacting and noninteracting) v-representability problem. This problem has been solved – once and for all – by van Leeuwen (1999), who demonstrated under mild conditions to be satisfied by the densities $\rho(\mathbf{r}, t)$ that the potentials $v_{\text{ext}}(\mathbf{r}, t)$ and $v_s(\mathbf{r}, t)$ can be constructed explicitly as solutions of the Sturm-Liouville problem. Since this is a constructive proof, the solution of the TDDFT v-representability problem is much more satisfactory than the status of the v-representability problem in ground-state DFT where a complete characterization of the domains of the $v_{\text{ext}}^{gs}(\mathbf{r}, t)$ and $v_s^{gs}(\mathbf{r}, t)$ is still lacking.

The TDKS potential in Eq. (27) is usually written in the following form:

$$v_s(\mathbf{r}, t) = v_0(\mathbf{r}, t) + v_H[\rho](\mathbf{r}, t) + v_{xc}[\rho](\mathbf{r}, t) \tag{29}$$

where $v_0(\mathbf{r}, t)$ is the given external potential of the system at hand, $v_H[\rho](\mathbf{r}, t)$ is the time-dependent Hartree potential,

$$v_H[\rho](\mathbf{r}, t) = \int d\mathbf{r}' \frac{\rho(\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|} \tag{30}$$

and $v_{xc}[\rho](\mathbf{r}, t)$ is the universal exchange-correlation ($xc$) functional of TDDFT

$$v_{xc}[\rho](\mathbf{r}, t) := v_s[\rho](\mathbf{r}, t) - v_{\text{ext}}[\rho](\mathbf{r}, t) - v_H[\rho](\mathbf{r}, t). \tag{31}$$

The $xc$ functional is well-defined through the right-hand side of Eq. (31): uniqueness of $v_s[\rho]$ and $v_{ext}[\rho]$ is guaranteed by the Runge-Gross theorem, and the existence over a well-characterized domain is covered by the van Leeuwen theorem. Formally, in addition to dependence on the density $\rho(\mathbf{r}, t)$, the $xc$ potential also depends on the initial many-body state $\Phi_0$ and on the initial orbitals $\{\phi_k^{(0)}(\mathbf{r})\}$. If the initial state is a ground state, both $\Phi_0$ and $\{\phi_k^{(0)}(\mathbf{r})\}$ are functionals of the initial ground-state density $\rho_0^{gs}(\mathbf{r}, t)$ via the HK theorem, and then the time-dependent $xc$ potential becomes a functional of the time-dependent density alone. The density dependence of the exact time-dependent $xc$ functional $v_{xc}[\rho(\mathbf{r}', t')](\mathbf{r}, t)$ is nonlocal both in space and in time, i.e., the potential $v_{xc}(\mathbf{r}, t)$ at point $\mathbf{r}$ and time $t$ depends on the density values at all points $\mathbf{r}'$ and at all previous times $t' \leq t$.

An important aspect of the ground-state DFT is the HK variational principle which ensures that the total energy as functional of the density is minimized by the true ground-state density of the system at hand, and the value of the functional at the minimum is the true ground-state energy. The HK variational principle is important in two respects: first of all, the total energy is a quantity of prime interest and the variational principle guarantees that the lowest possible value is achieved. Of equal importance is the fact that the variational principle usually implies numerical stability of the iterative algorithms, such as the Kohn-Sham (KS) self-consistency cycle, because they ultimately go "downhill" in the total energy functional.

In the time-dependent case, variational principles play a less important role. First of all, the usual Frenkel variational principle of quantum mechanics

$$\delta \int_{t_0}^{t_1} dt \ \langle \Phi(t) | i\hbar \frac{\partial}{\partial t} - \hat{H} | \Phi(t) \rangle = 0 \tag{32}$$

normally does not have a minimum at the solution of the time-dependent Schrödinger equation. There is only a stationary point, and consequently there is no guarantee of the stability of the associated time propagation algorithms. Moreover, unlike the ground-state energy, the value of functional (32) in the stationary point is zero and of no physical significance. Nevertheless, a TDDFT variational principle might still be desirable for some purposes, e.g., for the optimization of constrained densities.

Straightforward combination of the Runge-Gross map with the Frenkel variational principle (32) leads to a variational formulation of TDDFT (Runge and Gross 1984) which was later found to give rise to serious inconsistencies (Gross et al. 1994). In particular, a noncausal $xc$ kernel is found. This so-called causality paradox arises from the fact that arbitrary density variations lead to variations of the wavefunction at the upper boundary $t_1$ of the Frenkel integral (32). If the variations of the wavefunction are explicitly included, the causality paradox disappears (Vignale 2008). Another way of getting rid of the upper boundary $t_1$ of the Frenkel integral (32) is to formulate the TDDFT variational principle on the Keldysh contour which maps the final time back to the initial time. This formulation of the TDDFT variational principle was achieved by van Leeuwen (1998).

## 3.2   Linear-Response TDDFT

Many applications of TDDFT deal with weak probes of the ground state of a static potential $v_0(\mathbf{r})$, mediated by a small time-dependent perturbation $\delta v_{\text{app}}(\mathbf{r}, t)$. The goal of linear-response TDDFT is to calculate the induced first-order change $\delta\rho(\mathbf{r}, t)$ in the density (Gross et al. 1996). To this end, we look at the density $\rho[v_{ext}](\mathbf{r}, t)$ as functional of the external potential and perform a functional Taylor expansion at the unperturbed ground-state potential $v_0(\mathbf{r}, t)$:

$$\rho[v_{ext}](\mathbf{r}, t) = \rho \left[ v_0 + \delta v_{app} \right] (\mathbf{r}, t) \tag{33}$$

$$= \rho[v_0](\mathbf{r}) + \int d\mathbf{r}' \int dt' \left. \frac{\delta\rho(\mathbf{r}, t)}{\delta v_{ext}(\mathbf{r}', t')} \right|_{v_0} \delta v_{app}(\mathbf{r}', t') + \dots . \tag{34}$$

The functional derivative on the right-hand side of Eq. (34), which connects the change in the density with the perturbation is of enormous physical significance. It is known as *density-density response function* and will henceforth be denoted by $\chi(\mathbf{r}, t, \mathbf{r}', t')$:

$$\chi(\mathbf{r}, t, \mathbf{r}', t') = \left. \frac{\delta\rho(\mathbf{r}, t)}{\delta v_{ext}(\mathbf{r}', t')} \right|_{v_0} . \tag{35}$$

The associated change in the density is known as *linear density response*:

$$\delta\rho(\mathbf{r}, t) = \int d\mathbf{r}' \int dt' \, \chi(\mathbf{r}, t, \mathbf{r}', t') \delta v_{app}(\mathbf{r}', t'). \tag{36}$$

Since $\chi(\mathbf{r}, t, \mathbf{r}', t')$ only depends on $t - t'$, Eq. (36) is usually Fourier-transformed to the frequency domain:

$$\delta\rho(\mathbf{r}, \omega) = \int d\mathbf{r}' \, \chi(\mathbf{r}, \mathbf{r}', \omega) \delta v_{app}(\mathbf{r}', \omega) \tag{37}$$

where, for simplicity, we use the same symbol for a function and for its Fourier transform. The poles of $\chi(\mathbf{r}, \mathbf{r}', \omega)$ provide the charge-neutral excitation energies of the unperturbed many-body system.

One may also look at the density $\rho_s[v_s](\mathbf{r}, t)$ of noninteracting particles and their density-density response function:

$$\chi_s(\mathbf{r}, t, \mathbf{r}', t') = \left. \frac{\delta\rho_s(\mathbf{r}, t)}{\delta v_s(\mathbf{r}', t')} \right|_{v_{s,0}} . \tag{38}$$

While the full interacting density-density response function (35) is very hard to evaluate (in many-body language, it is the reducible polarization propagator of the

interacting system), the noninteracting counterpart is relatively easy to calculate: Its Fourier transform reads

$$\chi_s(\mathbf{r}, \mathbf{r}', \omega) = \sum_{ij\sigma,kl\tau} \phi_{i\sigma}(\mathbf{r})\phi_{j\sigma}^*(\mathbf{r})\phi_{k\tau}(\mathbf{r}')\phi_{l\tau}^*(\mathbf{r}')\chi_{ij\sigma,kl\tau}^{s}(\omega). \tag{39}$$

with

$$\chi_{ij\sigma,kl\tau}^{s}(\omega) = \delta_{\sigma,\tau}\delta_{i,k}\delta_{j,l}\frac{f_{j\sigma} - f_{i\sigma}}{\omega - (\varepsilon_{i\sigma} - \varepsilon_{j\sigma})}, \tag{40}$$

where $\varepsilon_{i\sigma}$ are the ground-state KS orbital energies and $f_{i\sigma}$ their occupations in the ground state. Multiplying this equation – in the operator sense – from the left with $\chi_s$ and from the right with $\chi$, and performing a Fourier transform to frequency space, one obtains the following Dyson-like equation for the response function (Petersilka et al. 1996):

$$\chi(\omega) = \chi^s(\omega) + \chi^s(\omega) * f_{Hxc}(\omega) * \chi(\omega). \tag{41}$$

This equation constitutes the cornerstone of linear-response TDDFT.

Acting with the operator in Eq. (41) on an arbitrary perturbation $\delta v_{\mathrm{app}}(\mathbf{r}, \omega)$ and using the definition (37) of the linear density response, one ends up with an integral equation for the desired density response:

$$\delta\rho(\omega) = \chi_s(\omega) * \big(\delta v_{\mathrm{app}}(\omega) + f_{Hxc}(\omega) * \delta\rho(\omega)\big). \tag{42}$$

An iterative numerical solution of this equation yields the full linear density response as function of $\omega$ and was first achieved by Zangwill and Soven (1980) for atoms in the frequency regime above the continuum threshold. If one is interested in the discrete spectrum of the system, i.e., the discrete poles of the linear density response, a considerable simplification can be achieved (Gross and Kohn 1985; Grabo et al. 2000; Casida 1995; Petersilka et al. 1996; Jamorski et al. 1996), leading to a generalized eigenvalue equation:

$$\begin{bmatrix} \mathbb{A} & \mathbb{B} \\ \mathbb{B}^* & \mathbb{A}^* \end{bmatrix} \begin{bmatrix} \mathbf{X}_n \\ \mathbf{Y}_n \end{bmatrix} = \omega_n \begin{bmatrix} \mathbb{I} & 0 \\ 0 & -\mathbb{I} \end{bmatrix} \begin{bmatrix} \mathbf{X}_n \\ \mathbf{Y}_n \end{bmatrix}. \tag{43}$$

where the matrices $\mathbb{A}(\omega)$ and $\mathbb{B}(\omega)$ are given by

$$A_{ia\sigma,jb\tau}(\omega) = \delta_{\sigma,\tau}\delta_{i,j}\delta_{a,b}(\varepsilon_{a\sigma} - \varepsilon_{i\sigma}) + K_{ia\sigma,jb\tau}(\omega) \tag{44}$$

$$B_{ia\sigma,jb\tau}(\omega) = K_{ia\sigma,bj\tau}(\omega). \tag{45}$$

The matrices $\mathbb{A}$ and $\mathbb{B}$ are frequency-independent within the *adiabatic approximation*, which approximates that the exchange-correlation kernel $f_{xc}$ has a frequency-

independent term (Casida 2009). (Note that memory-dependent functionals were proposed (Dobson et al. 1997; Ullrich and Tokatly 2006; Wijewardane and Ullrich 2008; Kurzweil and Baer 2004), even if not commonly used.) Solving the Casida equation Eq. (43) provides excitation energies and oscillator strengths for a molecular system.

A common approximation, the Tamm-Dancoff approximation (TDA), consists in neglecting the hole-particle terms, $\mathbf{Y}_n \equiv 0$, leading to the simpler eigenvalue equation (Hirata and Head-Gordon 1999):

$$\mathbb{A}\mathbf{X}_n = \omega_n \mathbf{X}_n. \tag{46}$$

While the TDA allows for the design of better-converging algorithms (Hirata and Head-Gordon 1999; Hutter 2003), it also sometimes leads to better results than the full Casida equation (Casida et al. 2000; Tapavicza et al. 2008; Casida and Huix-Rotllant 2012). This observation might find its source from the form of the Casida equation for pure density functional theory. The Casida equation involves the linear response of the one-body density matrix and therefore accommodates the response treatment of hybrid functions in a natural way. However, when functionals with no Hartree-Fock contribution are considered, the matrix $(\mathbb{A} - \mathbb{B})$ becomes diagonal (with no Hartree-Fock exchange contribution in the functional, $(\mathbb{A} - \mathbb{B})$ becomes (Casida 2009): $(\mathbb{A} - \mathbb{B})_{ia\sigma, jb\tau} = \delta_{i,j}\delta_{a,b}\delta_{\sigma,\tau}(\varepsilon_{a\tau} - \varepsilon_{i\tau})$). Then, the exact secular equation takes a similar form as within the TDA, with $\mathbb{A}$ corrected by a contribution from $\mathbb{B}$ (Casida 2009) and relates to the exact equation derived from pure density functional response theory (Grabo et al. 2000). It is, however, important to note that within TDA the Thomas-Reiche-Kuhn sum rule is not fulfilled (Furche 2001; Hutter 2003).

### 3.2.1 Pitfalls of the Approximation of Practical LR-TDDFT

LR-TDDFT has been successfully applied to compute excitation energies and properties for a large number of molecular systems (Stratmann et al. 1998; Hirata and Head-Gordon 1999; Maitra et al. 2003; Dreuw and Head-Gordon 2005; Ullrich 2012; Casida 2009; Elliott et al. 2009; Casida and Huix-Rotllant 2012; Adamo and Jacquemin 2013; Laurent and Jacquemin 2013) However, while the LR-TDDFT formalism is *in principle* exact, its practical application to compute excitation energies for molecules requires the use of a series of approximations of the *xc*-functional and its functional derivatives (like the adiabatic approximation), which can lead to dramatic failures (Ullrich 2012; Marques et al. 2012; Casida 2009; Casida and Huix-Rotllant 2012). As a result of the adiabatic approximation, LR-TDDFT is, for example, not able to properly describe electronic states with a dominant (>50%, see Tozer and Handy 2000; Ullrich 2012) double excitation character (Hsu et al. 2001; Maitra et al. 2004; Cave et al. 2004; Levine et al. 2006; Elliott et al. 2011). Also, the combination of an inaccurate description of derivative discontinuities, the problem of self-interaction error, the incorrect long-range properties of currently used *xc*-potentials, and the adiabatic approximation are all at the heart of the most critical issue of LR-TDDFT: the charge transfer

failure (Dreuw et al. 2003; Tozer 2003; Gritsenko and Baerends 2004; Dreuw and Head-Gordon 2004; Maitra 2005; Wiggins et al. 2009; Hellgren and Gross 2012). LR-TDDFT, within the adiabatic approximation and using standard functionals, suffers to describe charge transfer excitations, i.e., excitations between a donor and an acceptor that are spatially separated. Long-range corrected functionals (Leininger et al. 1997; Iikura et al. 2001; Yanai et al. 2004) can, however, strongly improve the situation. The adiabatic approximation also leads to difficulties in describing conical intersections between the ground and first electronic state (Levine et al. 2006), even if, at least in some cases, the use of the TDA improves the description of these critical points (Tapavicza et al. 2008; Marques et al. 2012).

## 3.3    Nonadiabatic Coupling Vectors and Nuclear Forces Within LR-TDDFT

The Casida equation introduced above gives a direct access to excitation energies and oscillator strength. Nonadiabatic dynamics will require additional quantities like nonadiabatic coupling vectors (last electronic term in Eq. (8)) or excited-state nuclear forces. In the following, we will describe a strategy to compute matrix elements of one-body operator within a LR-TDDFT framework, using the concept of *auxiliary many-electron wavefunctions* that will give us access to nonadiabatic coupling vectors as well as other quantities.

### 3.3.1    Matrix Elements in LR-TDDFT

Our goal is to find a general strategy for evaluating matrix elements of the form

$$\langle \varphi_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(n)} \rangle \tag{47}$$

within LR-TDDFT, where the states $|\varphi_{\mathbf{R}}^{(0)}\rangle$ and $|\varphi_{\mathbf{R}}^{(n)}\rangle$ describe the ground-state and $n$th electronic excited-state wavefunctions, respectively. To achieve this goal, we will proceed by a direct comparison with the same quantity derived using many-body perturbation theory (MBPT). Therefore, we start with a short outline of the main linear-response equations in MBPT.

From the definition of the retarded density-density response function

$$\chi(\mathbf{r}, t, \mathbf{r}', t') = \Pi^R(\mathbf{r}, t, \mathbf{r}', t') = -i\theta(t - t') \frac{\langle \varphi_{\mathbf{R}}^{(0)} | [\hat{\rho}(\mathbf{r}, t), \hat{\rho}(\mathbf{r}', t')] | \varphi_{\mathbf{R}}^{(0)} \rangle}{\langle \varphi_{\mathbf{R}}^{(0)} | \varphi_{\mathbf{R}}^{(0)} \rangle}, \tag{48}$$

the change of an observable $\mathscr{O}$, under the influence of a perturbation $v_{\text{ext}}(\mathbf{r}', t')$ in the linear-response regime, is given by

$$\delta \mathscr{O}(t) = \int_0^\infty dt' \int d\mathbf{r} \int d\mathbf{r}' \, o(\mathbf{r}) v_{\text{ext}}(\mathbf{r}', t') \chi(\mathbf{r}, t, \mathbf{r}', t') \tag{49}$$

(here we consider an interaction of the form $\delta v^{ext}(\mathbf{r}', t') = v'(\mathbf{r}')E(t')$). If $\chi$ depends only on the difference $(t - t')$, the Fourier transform in time gives

$$\delta \mathscr{O}(\omega) = \int d\mathbf{r} \int d\mathbf{r}' \, o(\mathbf{r})v'(\mathbf{r}')E(\omega)\chi(\mathbf{r}, \mathbf{r}', \omega) . \tag{50}$$

This expression can be rewritten, after a bit of algebra (Curchod et al. 2013), as a sum-over-states (SOS) formula:

$$\delta \mathscr{O}(\omega) = -2 \sum_n \frac{\omega_n \langle \varphi_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(n)} \rangle \langle \varphi_{\mathbf{R}}^{(n)} | \hat{v}' E(\omega) | \varphi_{\mathbf{R}}^{(0)} \rangle}{\omega_n^2 - \omega^2} , \tag{51}$$

where $|\varphi_{\mathbf{R}}^{(n)}\rangle$ and $\omega_n$ are the true excitation energies and wavefunctions.

Meanwhile, if we use the KS representation of LR-TDDFT as above, the change of observable is in matrix representation:

$$\delta \mathscr{O}(\omega) = \sum_{ij\sigma, kl\tau} o_{ij\sigma} \chi_{ij\sigma, kl\tau}(\omega) v'_{kl\tau} E(\omega) , \tag{52}$$

where $o_{ij\sigma} = \langle \phi_{i\sigma} | \hat{\mathscr{O}} | \phi_{j\sigma} \rangle$ and $v'_{kl\tau} = \langle \phi_{l\tau} | v'(\mathbf{r}) | \phi_{k\tau} \rangle$. Similarly, a SOS formula can also be derived for LR-TDDFT (see Curchod et al. 2013 for a derivation) and reads

$$\delta \mathscr{O}(\omega) = -2 \sum_n \mathbf{o}^\dagger \frac{(\mathbb{A} - \mathbb{B})^{1/2} \mathbf{Z}_n \mathbf{Z}_n^\dagger (\mathbb{A} - \mathbb{B})^{1/2}}{\omega_n^2 - \omega^2} \mathbf{v}' E(\omega) . \tag{53}$$

with $\mathbf{Z}_n$ is related to the eigenvectors of Eq. (43) according to Casida (2009) $\mathbf{Z}_n = (\mathbb{A} - \mathbb{B})^{-1/2}(\mathbf{X}_n + \mathbf{Y}_n)$.

Comparing the residues of LR-TDDFT response function Eq. (53) with the residues of the MBPT response function Eq. (51) at equal energy $\omega_n$, we obtain the following identity:

$$\langle \varphi_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(n)} \rangle = \sum_{ij\sigma}^{(f_{i\sigma} - f_{j\sigma}) > 0} \frac{1}{\sqrt{\omega_n}} o_{ij\sigma} \left( (\mathbb{A} - \mathbb{B})^{1/2} \mathbf{Z}_n \right)_{ij\sigma} . \tag{54}$$

(As stated before, with no Hartree-Fock exchange contribution in the functional, $(\mathbb{A} - \mathbb{B})$ is diagonal and becomes (Casida 2009): $(\mathbb{A} - \mathbb{B})_{ia\sigma, jb\tau} = \delta_{i,j} \delta_{a,b} \delta_{\sigma,\tau} (\varepsilon_{a\tau} - \varepsilon_{i\tau})$.)

This equation was derived by Casida (1995) and then applied by Tavernelli et al. and Hu et al. for the calculation of the nonadiabatic coupling vectors between the ground state and an excited state. A similar equation was also given in Chernyak and Mukamel (1996).

### 3.3.2 The Concept of Auxiliary Many-Electron Wavefunction

It may be useful at this point to investigate the possibility to further simplify the definition and the calculation of matrix elements within LR-TDDFT by means of the definition of a set of "auxiliary" multideterminantal many-electron wavefunctions based on KS orbitals. This route was first explored by Casida (1995) to solve the assignment problem of the LR-TDDFT excited-state transitions and then further developed by Tapavicza et al. (2007) in relation to the calculation of matrix elements in the linear and second-order response regimes (Tavernelli et al. 2009a, b, 2010).

In Tavernelli et al. (2009a), it was showed that defining the ground-state many-electron wavefunction $\langle \mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots, \mathbf{r}_{N_{el}} | \tilde{\varphi}_{\mathbf{R}}^{(0)} \rangle$ as a Slater determinant of all occupied KS orbitals $\{\phi_i\}_{i=1}^{N_{el}}$ and the excited-state wavefunction corresponding to the excitation energy $\omega_n$ as

$$\langle \mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots, \mathbf{r}_{N_{el}} | \tilde{\varphi}_{\mathbf{R}}^{(n)} \rangle = \sum_{ia\sigma} \sqrt{\frac{\varepsilon_a - \varepsilon_i}{\omega_n}} (\mathbf{Z}_n)_{ia\sigma} \hat{a}_{a\sigma}^\dagger \hat{a}_{i\sigma} \langle \mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots, \mathbf{r}_{N_{el}} | \tilde{\varphi}_{\mathbf{R}}^{(0)} \rangle$$

$$= \sum_{ia\sigma} \mathscr{C}_{ia\sigma}^n \langle \mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots, \mathbf{r}_{N_{el}} | \tilde{\varphi}_{\mathbf{R},i\sigma}^{a\sigma} \rangle, \tag{55}$$

we obtain for any one-body operator of the form $\hat{\mathscr{O}} = \sum_{pq\sigma} o_{pq\sigma} \hat{a}_{p\sigma}^\dagger \hat{a}_{q\sigma}$ (where $p, q$ are general indices) the correct linear-response expression for the matrix element $\langle \varphi_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(n)} \rangle$. Eq. (55) is derived from Eq. (54) where now the index $i$ runs over all occupied and $a$ over the unoccupied (virtual) KS orbitals and $|\tilde{\varphi}_{\mathbf{R},i\sigma}^{a\sigma}\rangle$ denotes a singly excited Slater determinant defined by the transition $i\sigma \rightarrow a\sigma$. This theory was then successfully extended to the case of the calculation of matrix elements between two excited-state wavefunctions, $\langle \varphi_{\mathbf{R}}^{(n)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(m)} \rangle$ as will be briefly discussed in the next section on the calculation of nonadiabatic coupling vectors.

It is important to further stress the fact that both auxiliary functions introduced above have a physical meaning only when used within LR-TDDFT for the calculation of matrix elements of the type $\langle \tilde{\varphi}_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \tilde{\varphi}_{\mathbf{R}}^{(n)} \rangle$ and eventually $\langle \tilde{\varphi}_{\mathbf{R}}^{(n)} | \hat{\mathscr{O}} | \tilde{\varphi}_{\mathbf{R}}^{(m)} \rangle$. The use of this representations of the ground-state and excited-state KS many-electron wavefunctions in other contexts is not justified.

### 3.3.3 Nonadiabatic Coupling Vectors Within LR-TDDFT

Using the concept of the auxiliary many-electron wavefunction approach described above, we can now propose an approach for the calculation of nonadiabatic vectors within LR-TDDFT.

#### Couplings Between Ground and Excited States

One can use an alternative definition of the nonadiabatic coupling vectors (Epstein 1954) (see also Ch. 5 of Baer 2006 for a complete discussion) between the ground (0) state and the $n^{th}$ excited state for a molecular system characterized by nuclear coordinates $\mathbf{R}$ in the configuration space ($\mathbb{R}^{3N_n}$):

$$\mathbf{d}_{0n}^{\gamma} = \frac{\langle \varphi_{\mathbf{R}}^{(0)} | \partial_{\gamma} \hat{H}_{BO} | \varphi_{\mathbf{R}}^{(n)} \rangle}{\varepsilon_{BO}^{(n)}(\mathbf{R}) - \varepsilon_{BO}^{(0)}(\mathbf{R})} \tag{56}$$

where $\gamma$ is an atomic label, $\hat{H}_{BO}$ is the electronic Hamiltonian, and $\partial_{\gamma} \hat{H}_{BO} = \partial \hat{H}_{BO} / \partial \mathbf{R}_{\gamma}$.

Applying the results of the above sections on the evaluation of matrix elements of the form $\langle \varphi_{\mathbf{R}}^{(0)} | \hat{\mathscr{O}} | \varphi_{\mathbf{R}}^{(n)} \rangle$ in LR-TDDFT to the nonadiabatic coupling vectors gives directly the expression:

$$\mathbf{d}_{0n}^{\gamma} = \sum_{ij\sigma}^{(f_{i\sigma} - f_{j\sigma})>0} \frac{1}{(\omega_n)^{3/2}} h_{ij\sigma}^{\gamma} \left( (\mathbb{A} - \mathbb{B})^{1/2} \mathbf{Z}_n \right)_{ij\sigma} \tag{57}$$

where $h_{ij\sigma}^{\gamma} = \int d\mathbf{r} \, \partial_{\gamma} \hat{H}_{BO} \, \phi_{i\sigma}^{*}(\mathbf{r}) \phi_{j\sigma}(\mathbf{r})$.

This formula for the nonadiabatic coupling vectors within LR-TDDFT was derived several times in the literature using slightly different formalisms. The first derivation was given by Chernyak and Mukamel (2000) using a classical Liouville dynamics for the single-electron density matrix, followed by Baer (2002). Later, Tapavicza et al. (2007), Tavernelli et al. (2009b), and Hu et al. (2007, 2008) arrived to the same result (Eq. (57)) using the formulation based on Casida's LR-TDDFT equations (Casida 1995).

Concerning the numerical implementation of Eq. (56), several approaches have also been proposed that differ mainly in the choice of the basis set and in the way the implicit dependence of the pseudopotentials on the nuclear positions is treated. Due to the technical nature of this subject, we will not go through the numerical details but better refer to the literature, which is very rich on this subject (Tavernelli et al. 2009b; Hu et al. 2007, 2010, 2012; Send and Furche 2010).

### Couplings Between Excited States

LR-TDDFT only gives access strictly speaking to the couplings between ground and excited state. However, the concept of LR-TDDFT auxiliary many-electron wavefunctions can also be used as a good approximation, exact within the Tamm-Dancoff approximation, to compute couplings between excited states (Tavernelli et al. 2010), $\mathbf{d}_{kn}$. An exact derivation of these coupling terms *beyond* the linear-response formalism of TDDFT was also proposed in the literature (Li and Liu 2014; Li et al. 2014; Ou et al. 2015). However, this formalism implies the calculation of an exchange-correlation hyperkernel and leads to the critical appearance of divergences in the couplings as a result of the adiabatic approximations (Parker et al. 2016).

## 3.4    Nuclear Forces Within LR-TDDFT

Excited-state dynamics using LR-TDDFT will also require the calculation of nuclear forces. Among the different approaches developed for the calculation of analytic derivatives, the Lagrangian method (Helgaker and Jørgensen 1989) is of particular interest because of its numerical efficiency. However, the derivation of LR-TDDFT forces is technically involved and goes beyond the scope of this chapter. We refer the interested reader to the abundant literature on the subject (Pulay 1987; Hutter 2003; Deglmann et al. 2002; Rappoport and Furche 2005; Marx and Hutter 2009).

## 4    Nuclear Dynamics: Trajectory-Based Quantum-Classical Dynamics

In this section, different approaches to nonadiabatic electron-nuclear dynamics will be presented, namely, the Ehrenfest scheme (Tully 1998), surface hopping (Tully 1990), the coupled-trajectory mixed quantum-classical (CT-MQC) method derived from the exact factorization (Min et al. 2015), and full multiple spawning (Martínez et al. 1996). Their common feature is the use of trajectories to explore the nuclear configuration space, which are subject to the time-dependent effect of the electrons in the ground state as well as in the excited states. The electronic properties needed in the calculations can be determined on-the-fly based on ab initio electronic structure methods. For the purpose of this work, TDDFT and its LR formulation will be employed. Other approaches based on Bohmian trajectories are also possible (Curchod et al. 2011; Curchod and Tavernelli 2013; Tavernelli 2013), but they will not be discussed in this book chapter.

Ehrenfest, surface hopping, and CT-MQC are based on a purely classical description of nuclear motion, which is coupled to the quantum-mechanical evolution of the electrons. In the three approaches, a hypothesis is made to decompose the full TDSE into two coupled equations, one describing the evolution of the electronic subsystem and the other describing the evolution of the nuclear subsystem. The main difference among them lies in the procedure followed for such decomposition. In particular, only the exact factorization starts from an Ansatz for the molecular wavefunction, which translates into exact coupled electronic and nuclear equations. Only in a second step, the nuclear evolution is modeled using classical trajectories. The full multiple spawning scheme, on the other hand, introduces an expansion in terms of Gaussian wave packets to represent each nuclear coefficients $\chi_k(\mathbf{R}, t)$ of the Born-Huang expansion (4). The parameters of the Gaussians are evolved classically, under the assumption that classical dynamics samples correctly the nuclear configuration space. Indeed, in the limit of an infinite number of Gaussians, full multiple spawning converges to an exact description of the electron-nuclear problem.

## 4.1 Ehrenfest Dynamics

To derive Ehrenfest decomposition, one makes the assumption that the full wave-function can be written as a single product of a purely electronic $\Phi(\mathbf{r}, t)$ and a purely nuclear $\chi(\mathbf{R}, t)$ wavefunction:

$$\Psi(\mathbf{r}, \mathbf{R}, t) = e^{\frac{i}{\hbar} \int_0^t dt' E_{BO}(t')} \Phi(\mathbf{r}, t) \chi(\mathbf{R}, t) . \tag{58}$$

Here, the time-dependent phase on the right-hand side is inserted to simplify the following equations derived from such an Ansatz; thus the energy $E_{BO}(t)$ is chosen as

$$E_{BO}(t) = \int d\mathbf{r} \, \Phi^*(\mathbf{r}, t) i\hbar \partial_t \Phi(\mathbf{r}, t) . \tag{59}$$

The product form of the molecular wavefunction in Eq. (58) is clearly uncorrelated, and in this initial Ansatz lies the fundamental approximation of the Ehrenfest scheme. When Eq. (58) is inserted into the molecular TDSE (1), the coupled equations

$$\left[ \hat{T}_e(\mathbf{r}) + \hat{V}_{ee}(\mathbf{r}) + \int d\mathbf{R} \, \chi^*(\mathbf{R}, t) \left[ \hat{V}_{nn}(\mathbf{R}) + \hat{V}_{en}(\mathbf{r}, \mathbf{R}) \right] \chi(\mathbf{R}, t) \right] \Phi(\mathbf{r}, t)$$
$$= i\hbar \partial_t \Phi(\mathbf{r}, t) \tag{60}$$

$$\left[ \sum_v \frac{-\hbar^2}{2M_v} \nabla_v^2 + \int d\mathbf{r} \, \Phi^*(\mathbf{r}, t) \hat{H}_{BO}(\mathbf{r}, \mathbf{R}) \Phi(\mathbf{r}, t) \right] \chi(\mathbf{R}, t)$$
$$= i\hbar \partial_t \chi(\mathbf{R}, t) \tag{61}$$

are derived, by averaging over the instantaneous nuclear, in Eq. (60), and electronic, in Eq. (61), state. In both equations, the wavefunctions $\Phi(\mathbf{r}, t)$ and $\chi(\mathbf{R}, t)$ are supposed to be normalized. Therefore, Eq. (60) describes the evolution of the electrons in the mean field created by the nuclei, whereas the nuclei move according to Eq. (61) in the mean field of the electrons.

A quantum-classical algorithm can be derived from Eqs. (60) and (61) by approximating classically the nuclear equation, that is, by determining the force to propagate the nuclei as trajectories. A standard procedure can be followed, by introducing a complex-phase representation of $\chi(\mathbf{R}, t)$ and by only considering terms $\mathcal{O}(\hbar^0)$ in the asymptotic expansion of the complex phase in powers of $\hbar$ (Van Vleck 1928). The equation for the zeroth order term $S(\mathbf{R}, t)$ of this expansion is thus obtained, namely:

$$\partial_t S(\mathbf{R}, t) = - \left[ \sum_v \frac{[\nabla_v S(\mathbf{R}, t)]^2}{2M_v} + \int d\mathbf{r} \, \Phi^*(\mathbf{r}, t) \hat{H}_{BO}(\mathbf{r}, \mathbf{R}) \Phi(\mathbf{r}, t) \right] . \tag{62}$$

This Hamilton-Jacobi-like equation can be solved via characteristics, thus yielding the expression of the classical (Ehrenfest) force as

$$\mathbf{F}_v(t) = -\nabla_v \int d\mathbf{r}\, \Phi^*(\mathbf{r}, t)\hat{H}_{BO}(\mathbf{r}, \mathbf{R})\Phi(\mathbf{r}, t)\,. \tag{63}$$

The classical approximation is also introduced in the electronic evolution equation (60). Here, the nuclear density $|\chi(\mathbf{R}, t)|^2$ is approximated as a product of $\delta$-functions centered at each time at the position of the classical nuclei, that is, at the position of the classical trajectory $\mathbf{R}^{(I)}(t)$. Therefore, the TDSE describing the evolution of $\Phi(\mathbf{r}, t)$ becomes

$$\hat{H}_{BO}\left(\mathbf{r}, \mathbf{R}^{(I)}(t)\right)\Phi\left(\mathbf{r}, \mathbf{R}^{(I)}(t), t\right) = i\hbar\partial_t\Phi\left(\mathbf{r}, \mathbf{R}^{(I)}(t), t\right). \tag{64}$$

The electronic wavefunction acquires an implicit dependence on the nuclear positions, expressed as the classical trajectory, via the dependence of the BO Hamiltonian on $\mathbf{R}^{(I)}(t)$. The trajectory $I$ of the nucleus $v$ is determined by solving Newton's equation with force:

$$\mathbf{F}_v^{(I)}(t) = \int d\mathbf{r}\, \Phi^*(\mathbf{r}, \mathbf{R}^{(I)}(t), t)\left[-\nabla_v\hat{H}_{BO}(\mathbf{r}, \mathbf{R}^{(I)}(t))\right]\Phi(\mathbf{r}, \mathbf{R}^{(I)}(t), t)\,, \tag{65}$$

where now a label $(I)$ has been introduced to show that along a trajectory, Eqs. (64) and (65) have to be evolved consistently. Multiple trajectories can also be employed, to "wash out" some of the details of the coherent evolution along a single trajectory. Nuclear and electronic observables can thus be determined as averages over this ensemble of trajectories.

As it provides the true time-dependent electronic density, TDDFT can be used within an Ehrenfest dynamics scheme to perform nonadiabatic molecular dynamics. The mapping of the nuclear equation (Eq. (65)) into the DFT formalism is straightforward and only requires the description of the forces $\langle -\nabla_v\hat{H}_{BO}(\mathbf{r}, \mathbf{R}^{(I)}(t))\rangle$ as a functional of the time-dependent density $\rho(\mathbf{r}, t)$. If we replace the expectation value of the electronic Hamiltonian with the DFT energy evaluated with the exchange-correlation potential $v_{xc}[\rho]|_{\rho(\mathbf{r})\leftarrow\rho(\mathbf{r},t)}$, the gradient with respect to the nuclear coordinates can be performed analytically as in the case of the adiabatic BO dynamics and the Car-Parrinello (Car and Parrinello 1985) molecular dynamics schemes (Marx and Hutter 2009).

### 4.1.1 Application of Ehrenfest Dynamics Combined with TDDFT

As Ehrenfest dynamics gives a direct access to electronic dynamics, it is a method of choice to investigate the dynamics of the electronic density and subsequent nuclear dynamics after a strong perturbation. Such perturbation can be induced by the action of an external light pulse or through the collision with a highly charged particle, generating either an electronic excitation or, in the some other cases, electron abstraction (Tavernelli et al. 2005; Tavernelli 2006, 2015; Castro

et al. 2004; Li et al. 2005; Yagi and Takatsuka 2005; Andrade et al. 2009; Moss et al. 2009; Liang et al. 2010; Gaigeot et al. 2010; Lopez-Tarifa et al. 2011; Elliott and Maitra 2012). The latter takes place when an XUV attosecond pulse interacts with a molecule and leads to a core ionization. In a Born-Huang picture, such an ultrafast ionization leads to the generation of an electronic wave packet, i.e., the generation of a coherent superposition of different nuclear contributions on a large number of electronic states (the number of electronic states being considered depends on the bandwidth of the ionizing pulse). Ehrenfest dynamics combined with TDDFT offers an alternative to the Born-Huang picture by only requiring the generation of an initial electronic density to represent the initial ionized state. Martín et al. employed this strategy to study the role of nuclear motion in the electronic dynamics upon XUV ultrafast ionization of a small amino acid, glycine (Lara-Astiaso et al. 2017). The one-electron ionization generated by the sub-300-as XUV pulse generates an electronic wave packet that can be described by a coherent superposition of more than ten one-hole states, in an energy domain ranging from 17 to 35 eV (the pulse bandwidth). The electronic density corresponding to this electronic wave packet, $\rho(\mathbf{r}, t_0)$, is used as initial condition for two simulations: (*i*) real-time TDDFT with frozen nuclei and (*ii*) real-time TDDFT combined with Ehrenfest dynamics. As a result of the nature of the electronic wave packet, the time evolution of the unpaired electron (with respect to the initial density) shows that the electron migrates over the entire molecular scaffold with a dynamics that is characterized by only few, system dependent, frequencies (Fig. 1). This is the behavior that one would expect in the case the ionized electron is removed from one given localized orbital. Comparing the two panels of Fig. 1, one can observe that nuclear motion starts altering the electronic dynamics already after the first 10 fs of dynamics, emphasizing the importance of including nuclear dynamics in such simulations. However, it is important to note that the mean-field character of Ehrenfest dynamics might hamper a more detailed study of the electronic wave packet dynamics, in particular due to the underestimation of decoherence and dephasing effects at longer timescales (Vacher et al. 2017). The ease of the Ehrenfest formalism combined with

**Fig. 1** Spin density differences at different times after interaction of a XUV attosecond pulse with the glycine molecule. The initial conditions correspond to a geometry obtained after thermalization at 100 K. (Adapted from Lara-Astiaso et al. 2017, Copyright (2017), with permission from Elsevier)

the efficiency of TDDFT offers nevertheless a valid tool for the study of the short-time electronic wave packet dynamics in molecular systems.

## 4.2 Surface Hopping

Surface-hopping decomposition is derived under the preliminary assumption that the nuclei evolve along classical trajectories. Therefore, the BO Hamiltonian acquires an implicit time dependence via its dependence on the nuclear coordinates. A TDSE is proposed in this way, namely:

$$\hat{H}_{BO}(\mathbf{R}^{(I)}(t))\Phi_{\mathbf{R}^{(I)}(t)}(\mathbf{r}, t) = i\hbar\partial_t\Phi_{\mathbf{R}^{(I)}(t)}(\mathbf{r}, t), \tag{66}$$

for the electronic wavefunction, which is, itself, dependent on the classical trajectories. As done above, a classical trajectory is labeled by the index $(I)$. An expansion in the adiabatic basis is introduced for $\Phi_{\mathbf{R}^{(I)}(t)}(\mathbf{r}, t)$:

$$\Phi_{\mathbf{R}^{(I)}(t)}(\mathbf{r}, t) = \sum_k C_k(t)\varphi^{(k)}_{\mathbf{R}^{(I)}(t)}(\mathbf{r}), \tag{67}$$

and Eq. (66) yields

$$\dot{C}^{(I)}_k(t) = \frac{-i}{\hbar}\varepsilon^{(k)}_{BO}\left(\mathbf{R}^{(I)}(t)\right)C^{(I)}_l(t) - \sum_l C^{(I)}_l(t)\sum_{v=1}^{N_n}\frac{\mathbf{P}^{(I)}_v(t)}{M_v}\cdot\mathbf{d}_{v,kl}\left(\mathbf{R}^{(I)}(t)\right). \tag{68}$$

Here, the BO PES $\varepsilon^{(k)}_{BO}(\mathbf{R})$ and the nonadiabatic coupling vectors, i.e.,

$$\mathbf{d}_{v,kl}(\mathbf{R}) = \int d\mathbf{r}\,\varphi^{(k)*}_{\mathbf{R}}(\mathbf{r})\nabla_v\varphi^{(l)}_{\mathbf{R}}(\mathbf{r}) = \left\langle\varphi^{(k)}_{\mathbf{R}}\middle|\nabla_v\varphi^{(l)}_{\mathbf{R}}\right\rangle_{\mathbf{r}}, \tag{69}$$

which are functions of the nuclear coordinates, are evaluated at the instantaneous positions along the trajectories; they thus become functions of the trajectory itself. Henceforth, a superscript $(I)$ will be introduced to indicate this dependence on the trajectory.

The surface-hopping scheme takes its name from the idea suggested for the evolution of the classical nuclear trajectories, namely, that a trajectory evolves according to one adiabatic BO force, determined as (minus) the gradient of the BO potential energy surface (PES), until a stochastic hop occurs onto another BO PES. The classical (surface-hopping) force can then be written as

$$\mathbf{F}^{(I)}_v(t) = -\nabla_v\varepsilon^*_{BO}, \tag{70}$$

with the symbol * indicating that the force state is selected stochastically at each time step. The discontinuity in the force, and thus in the potential energy, for a given trajectory, is compensated by a discontinuity in the velocity, and thus in the kinetic energy, that guarantees energy conservation. The hopping scheme fewest switches (Tully 1990) prescribes that the trajectory $I$ hops from surface $k$ to surface $l$ according to the probability:

$$\mathscr{P}_{k \rightarrow l} = \max \left[ 0, \frac{-2\,dt}{\left| C_k^{(I)}(t) \right|^2} \; \text{Re} \left[ C_k^{(I)^*}(t) C_l^{(I)}(t) \right] \sum_v \frac{\mathbf{P}_v^{(I)}(t)}{M_v} \cdot \mathbf{d}_{lk,v}^{(I)} \right], \quad (71)$$

with $dt$ the integration time step.

The major drawback of the surface-hopping scheme is the (over)coherent evolution of the electronic coefficients coupled to the classical (independent) trajectories. The issue has been well-documented in the literature (Subotnik et al. 2013; Bittner and Rossky 1995; Curchod and Tavernelli 2013; Gao and Thiel 2017), and several schemes have been proposed (Shenvi et al. 2011a, b; Shenvi and Yang 2012; Subotnik and Shenvi 2011a, b; Jaeger et al. 2012; Jasper and Truhlar 2007; Granucci and Persico 2007) to cure or alleviate this shortcoming.

### 4.2.1   Application of Surface Hopping Combined with LR-TDDFT

Surface hopping has been used to study a large number of excited-state mechanisms, and we refer the interested reader to specialized reviews (Barbatti 2011; Curchod et al. 2013; Persico and Granucci 2014) for a list of applications. The application presented here highlights the combination of surface hopping with LR-TDDFT (using the concepts developed in Sect. 3.2), including implicitly and explicitly the role of spin-orbit coupling as well as explicit solvent effects. Ruthenium (II) trisbipyridine, $[\text{Ru(bpy)}_3]^{2+}$, is an inorganic molecule recognized for its extremely efficient intersystem crossing process, i.e., when the molecule changes, in this particular case, from a singlet electronic state to a triplet electronic state (Cannizzo et al. 2006; Gawelda et al. 2006). $[\text{Ru(bpy)}_3]^{2+}$ is initially photoexcited in a singlet metal-to-ligand-charge-transfer ($^1$MLCT) state before it rapidly relaxes among other $^1$MLCT or $^3$MLCT, as a result of the high density of states; the overall dynamics to the triplet states has been observed experimentally in water within a ∼50 fs timescale (Fig. 2).

In the first theoretical study (Tavernelli et al. 2011), the excited-state dynamics of the $[\text{Ru(bpy)}_3]^{2+}$ in water was studied by employing surface hopping with LR-TDDFT, in a QM/MM formalism where water molecules were treated classically. Intersystem-crossing events were analyzed a posteriori, monitoring the crossings between singlet and triplet states and evaluating spin-orbit coupling from qualitative rules. Owing to the cost of the overall dynamics, this study was limited to only two trajectories. Nevertheless, both trajectories indicated an ultrafast decay of the molecule toward triplet states in less than 50 fs, in good correlation with experimental evidences. The MLCT character of the different excited states implies
**Fig. 2** Two surface-hopping trajectories for $[Ru(bpy)_3]^{2+}$ in water. The driving state is highlighted with blue circles, while the seven singlet excited states considered in the surface hopping dynamics are represented by gray dashed lines and the seven triplet states by red continuous lines. Filled circles indicate the analyzed crossings between singlet and triplet states, using the following color coding: white = weak, gray = medium, and black = optimal SOC strength. The inset provides a ball-and-stick representation of the $[Ru(bpy)_3]^{2+}$ molecule with part of its first water solvation shell of water molecules for two selected frames (black arrows), highlighting the fast rotation of a classical water molecule (in yellow) occurring during the dynamics. (Adapted from Tavernelli et al. 2011, Copyright (2011), with permission from Elsevier)

that an electron moves from the central metal to one (or two, depending on the state) solvent-exposed bipyridine ligands. Hence, the simulation showed that water molecules in the first solvation shell can rapidly rearrange in a non-diffusive rotation around the hydrogen bond axis to stabilize an extra charge located on a close ligand. An explicit treatment of solvent molecules is central to capture such effects as well as a proper ordering of the different electronic states.

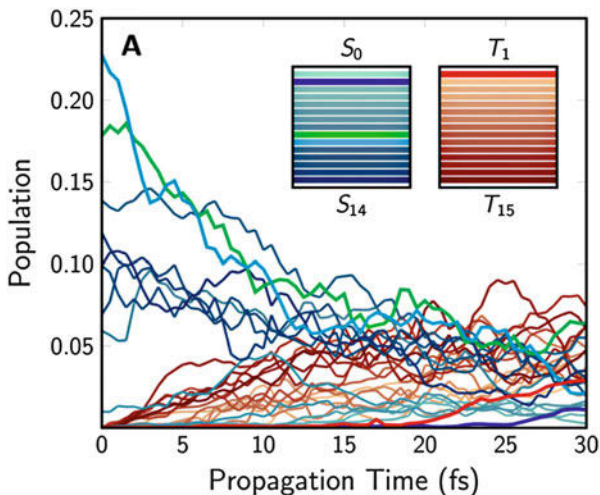
In a more recent study (Atkins and González 2017), surface hopping combined within LR-TDDFT was used to simulate the excited-state dynamics of $[Ru(bpy)_3]^{2+}$ in gas phase but with the explicit treatment of spin-orbit coupling in a perturbative ZORA formalism (Wang and Ziegler 2005) and a larger number (101) of trajectories. This study confirmed the ultrafast decay of the original $^1$MLCT population toward triplet states, already at the early time of the dynamics. Horizontal intersystem crossing processes were observed, followed by ultrafast nonadiabatic dynamics among the triplet states (Fig. 3). Thanks to normal mode and principal component analysis, the authors could identify that the motion of both the ruthenium and the coordinated nitrogens is activated, even within such short timescale, leading potentially to the intersystem crossing events.


**Fig. 3** Population trace of singlet (bluish) and triplet (brownish) states over 30 fs of surface hopping (population of the three sublevels of each triplet are summed together). (Adapted with permission from Atkins and González 2017, Copyright (2017) American Chemical Society)

### 4.3    Coupled-Trajectory Mixed Quantum-Classical Scheme

Within the exact factorization formalism, a trajectory-based solution of the electronic (11) and nuclear (12) equations is constructed by (i) determining the classical limit of the nuclear equation, thus deriving the corresponding Newton's equation with forces computed from the time-dependent vector $\mathbf{A}_v(\mathbf{R}, t)$ and scalar $\varepsilon(\mathbf{R}, t)$ potentials, (ii) introducing the Born-Huang-like expansion of Eq. (16) of the electronic wavefunction, (iii) approximating the explicit dependence on the nuclear wavefunction, i.e., the term $-i\hbar\nabla_v\chi(\mathbf{R}, t)/\chi(\mathbf{R}, t)$ in the definition of the coupling operator $\hat{U}_{en}^{\text{coup}}[\Phi_{\mathbf{R}}, \chi]$ (13) employing information obtained from the trajectories. A thorough account of the steps adopted for the derivation of the algorithm is given in Agostini et al. (2016). Following this procedure, the electronic and nuclear equations of the exact factorization can be rewritten as

$$\dot{C}_l^{(I)}(t) = \dot{C}_{\text{Eh}.l}^{(I)}(t) + \dot{C}_{\text{qm}\,l}^{(I)}(t) \tag{72}$$

$$\mathbf{F}_v^{(I)}(t) = \mathbf{F}_{\text{Eh}.\,v}^{(I)}(t) + \mathbf{F}_{\text{qm}\,v}^{(I)}(t) \,. \tag{73}$$

The electronic equation yields a set of ordinary differential equations $\dot{C}_l^{(I)}(t)$ for the expansion coefficients in the Born-Huang expansion, each labeled by a superscript $(I)$ indicating that they are calculated along the $I$−th classical trajectory. The nuclear equation allows one to identify the classical force $\mathbf{F}_v^{(I)}(t)$ acting on the $v$−th nucleus that evolves along the $I$−th trajectory. Both equations can be decomposed

as the sum of two terms: the first, indicated by Eh., comprises Ehrenfest-like terms, while the second, qm, originates from the exact factorization. These last terms depend on the so-called quantum momentum, whose expression is given below. The Ehrenfest-like terms are

$$\dot{C}^{(I)}_{\text{Eh.},l}(t) = \frac{-i}{\hbar}\varepsilon^{(l)(I)}_{BO}C^{(I)}_l(t) - \sum_k C^{(I)}_k(t)\sum_{v=1}^{N_n}\frac{\mathbf{P}^{(I)}_v(t)}{M_v}\cdot\mathbf{d}^{(I)}_{v,lk} \tag{74}$$

$$\mathbf{F}^{(I)}_{\text{Eh.},v}(t) = -\sum_k\left|C^{(I)}_l(t)\right|^2\nabla_v\varepsilon^{(k),(I)}_{BO} - \sum_{k,l}C^{(I)*}_l(t)C^{(I)}_k(t)\left(\varepsilon^{(k),(I)}_{BO} - \varepsilon^{(l),(I)}_{BO}\right)\mathbf{d}^{(I)}_{v,lk}, \tag{75}$$

where we introduced the symbols $\varepsilon^{(l)(I)}_{BO}$ for the electronic adiabatic potential energy surface corresponding to state $l$ and evaluated at the position of the $I-$th trajectory, $\mathbf{d}^{(I)}_{v,lk}$ for the nonadiabatic coupling vectors defined as $\langle\varphi^{(l)(I)}|\nabla_v\varphi^{(k)(I)}\rangle_{\mathbf{r}}$, as well evaluated at the position of the trajectory $I$, and $\mathbf{P}^{(I)}_v(t)$ for the classical momentum of the $v-$th nucleus evolving along the $I-$th trajectory. The additional terms in Eqs. (72) and (73), namely:

$$\dot{C}^{(I)}_{\text{qm}\,l}(t) = -\sum_{v=1}^{N_n}\frac{\mathcal{Q}^{(I)}_v(t)}{\hbar M_v}\cdot\left[\sum_k\left|C^{(I)}_k(t)\right|^2\mathbf{f}^{(I)}_{k,v}(t) - \mathbf{f}^{(I)}_{l,v}(t)\right]C^{(I)}_l(t), \tag{76}$$

$$\mathbf{F}^{(I)}_{\text{qm}\,v}(t) = -\sum_l\left|C^{(I)}_l(t)\right|^2\left(\sum_{v'=1}^{N_n}\frac{2}{\hbar M_{v'}}\mathcal{Q}^{(I)}_{v'}(t)\cdot\mathbf{f}^{(I)}_{l,v'}(t)\right)$$
$$\left[\sum_k\left|C^{(I)}_k(t)\right|^2\mathbf{f}^{(I)}_{k,v}(t) - \mathbf{f}^{(I)}_{l,v}(t)\right], \tag{77}$$

can be derived *only* in the context of the exact factorization, as they both depend on the quantum momentum (Garashchuk and Rassolov 2003) $\mathcal{Q}^{(I)}_v(t) = -\hbar(\nabla_v|\chi^{(I)}(t)|^2)/(2|\chi^{(I)}(t)|^2)$. Here, $|\chi^{(I)}(t)|^2$ stands for the value of the nuclear density evaluated at the position of the $I-$th trajectory. The quantum momentum appears in the expression of $\hat{U}^{coup}_{en}[\Phi_{\mathbf{R}},\chi]$ as a purely imaginary correction to the (real-valued) classical momentum. As exhaustively described in Agostini et al. (2016), the evaluation of the quantum momentum along the $I-$th trajectory at a given time requires knowledge of the positions of all other trajectories at the same time. This peculiar feature couples the trajectories in a nontrivial manner, thus allowing for the correct description of quantum decoherence effects. The additional new quantities appearing in Eqs. (76) and (77) are the adiabatic forces accumulated over time $\mathbf{f}^{(I)}_{l,v}(t) = -\int^t dt'\nabla_v\varepsilon^{(l),(I)}_{BO}$.

The electronic structure inputs required in the propagation of the CT-MQC equations of motion are the Born-Oppenheimer energies and the nonadiabatic

coupling vectors. Any electronic structure methods providing these quantities can therefore be used in combination with CT-MQC. In the following, we make the choice of employing LR-TDDFT.

### 4.3.1 Applications

As an application of the CT-MQC approach, we report the analysis presented in Min et al. (2017) and Curchod et al. (2018) where the photoinduced ring-opening process in oxirane (Cordova et al. 2007; Tapavicza et al. 2008) triggered by the excitation from $S_0$ to $S_2$. The following discussion is based on Curchod et al. (2018). Electronic structure calculations are performed with the CPMD code using the GGA functional PBE (Perdew et al. 1996) for ground state and excited states. Linear-response TDDFT calculations are based on the Tamm-Dancoff approximation (Tamm 1945; Dancoff 1950). The Kleinman-Bylander (Kleinman and Bylander 1982) pseudo-potential has been used for all atom species together with a plane-wave cutoff of 70 Ry. Initial conditions, i.e., positions and momenta, have been sampled from an ab initio ground-state 2 ps trajectory at 300 K. $N_{tr} = 100$ trajectories are propagated with a time step of 0.12 fs (5 a.u.).

Figure 4 shows the electronic populations (upper panel) and an indicator of decoherence (lower panel), both quantities averaged over the 100 coupled trajectories. As indicated in Eq. (72), the coefficients in the expansion of the electronic wavefunction are labeled by the trajectory index ($I$); therefore the average population can be determined as

$$\rho_k(t) = \frac{1}{N_{tr}} \sum_{I=1}^{N_{tr}} \left| C_k^{(I)}(t) \right|^2 \quad \text{for } k = 1, 2 \,. \tag{78}$$

Between 7 and 15 fs, the trajectories cross the coupling region $S_1/S_2$; thus population is transferred from the initially occupied electronic state $S_2$ to $S_1$. After about 20 fs, the nonadiabatic event is almost complete, and some trajectories evolving in $S_1$ will encounter a second coupling region $S_0/S_1$, as it is clearly shown by the increase of population of $S_0$ (and consequent decrease of population of $S_1$) at about 25 fs.

Similarly to Eq. (78), the indicator of decoherence introduced in Agostini et al. (2016), and Min et al. (2015, 2017) is computed between the states $S_1$ and $S_2$ as an average over the trajectories:

$$\eta_{12}(t) = \frac{1}{N_{tr}} \sum_{I=1}^{N_{tr}} \left| C_1^{(I)^*}(t) C_2^{(I)}(t) \right|^2 \,. \tag{79}$$

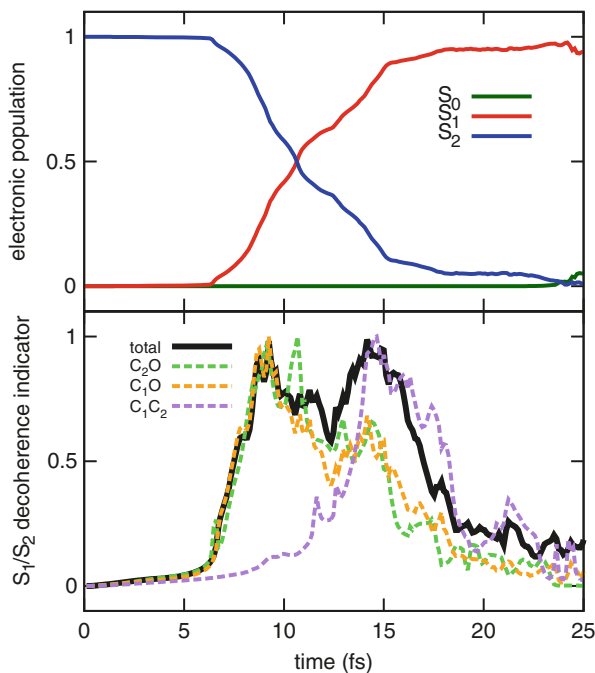
The quantity $C_1^{(I)^*}(t) C_2^{(I)}(t)$ stands for the off-diagonal element of the electronic density matrix in the adiabatic representation between the first two excited states and depends on nuclear positions through the dependence on the trajectory index ($I$). The decoherence indicator depends on the choice of the representation used to


**Fig. 4** Upper panel: electronic populations of $S_0$ (dark-green line), $S_1$ (red line), and $S_2$ (blue line) as functions of time. Lower panel: (normalized) indicator of decoherence for the element $S_1/S_2$ (black line) and its decomposition contributions arising from three sets of trajectories. The sets of trajectories labeled by $C_1O$ (dashed orange line) and $C_2O$ (dashed green line) lead to a final configuration where the oxirane ring opens via the breaking of one of the two equivalent CO bonds; the set of trajectories labeled $C_1C_2$ (dashed purple line) yields final configurations where the ring opens via elongation of the CC bond

describe the electronic states. Our particular choice has fallen on the adiabatic representation, which is a natural choice since the dynamics is simulated in the adiabatic basis. Furthermore, this indicator of decoherence contains information simultaneously about electronic coherences and nuclear dynamics, via the parametric dependence of the adiabatic basis on the nuclear coordinates. Decoherence can thus be related to the spatial separation in configuration space of different bundles of trajectories (and thus of different wave packets), which "loose memory" of each other while evolving along diverging paths after funneling through the conical intersection. As abundantly discussed in the literature (Jasper et al. 2006; Granucci and Persico 2007; Jaeger et al. 2012; Subotnik et al. 2013; Gao and Thiel 2017; Schwartz et al. 1996; Fang and Hammes-Schiffer 1999; Granucci and Persico 2007; Shenvi et al. 2011a, b; Shenvi and Yang 2012; Subotnik and Shenvi 2011a, b; Agostini et al. 2016; Min et al. 2015, 2017), Ehrenfest dynamics and surface hopping (in their standard formulations) are not able to capture the decay of such quantity, observed here between 15 and 25 fs.

Additional information on the dynamics can be extracted from the analysis of the indicator of decoherence of Fig. 4. In fact, the pronounced double-peak structure suggests that two groups of trajectories funnel through the $S_1/S_2$ conical intersection at subsequent times. In order to interpret this observation, the indicator of decoherence has been decomposed in different contributions (represented by the colored curves in the lower panel of Fig. 4) arising from the different paths followed by the trajectories after crossing the conical intersection $S_1/S_2$. The structures identified at the end of the simulated trajectories are (i) a right-open ring structure (observed with probability 36%), (ii) a left-open ring structure (observed with probability 47%), (iii) a CC-extended bond structure (observed with probability 10%), and (iv) a closed-ring structure (observed with probability 7%). Structures (i) and (ii) are indeed equivalent; thus the difference in the probabilities can be probably cured by improving the statistics. These structures yield the ring-opening of oxirane via breaking of one of the two CO bonds. In structure (iii), the oxirane ring opens via the elongation of the CC bond. A few trajectories, identified as structure (iv), are not reactive, since the molecule more or less stays in its original configuration. If the indicator of decoherence is decomposed in contributions arising from trajectories ending in structures (i), (ii), or (ii), we observe that the first peak between 6 and 12 fs is produced by a first bundle of trajectories that leads to the breakage of the equivalent CO bonds. However, the $\eta_{12}(t)$ curves do not decay monotonically. Instead, the curves corresponding to the $C_1O$ and $C_2O$ groups both contribute to the second peak (between 12 fs and 17.5 fs). This feature indicates that the first group of trajectories is reached by a second group while funneling through the conical intersection. The main contribution to the second peak between 12 and 16 fs is given by trajectories yielding a final CC-extended bond structure. These trajectories clearly encounter the nonadiabatic region with some delay if compared to the sets of trajectories analyzed before. Here, the indicator of decoherence is clearly single peaked, suggesting that the corresponding trajectory bundle undergoes a transition through the $S_1/S_2$ conical intersection in a single step.

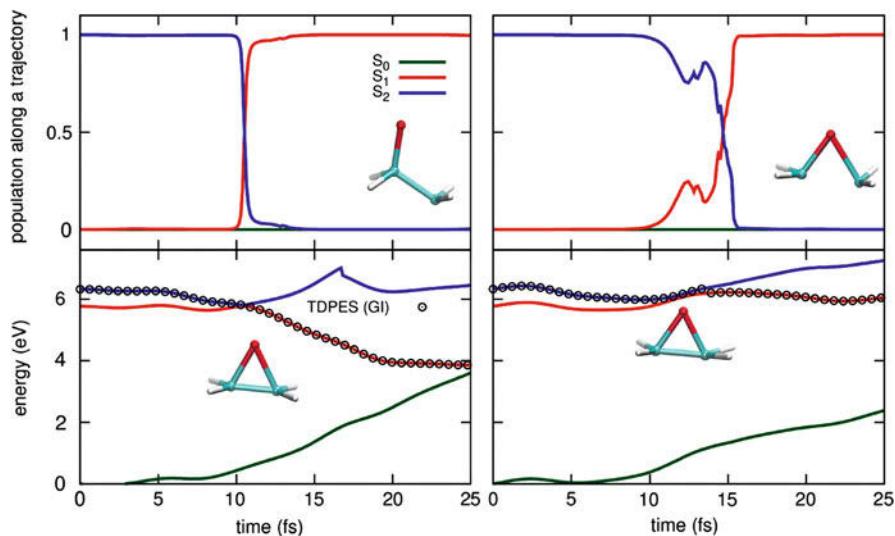
Observation of different final structures is related to the different paths undergone by the trajectories after crossing the $S_1/S_2$ region of nonadiabatic coupling. Two representative trajectories have been selected among the 100, one yielding a right-open ring structure (i) and one yielding a CC-extended bond configuration (iii). Clearly, the analysis presented for the right-open ring structure can be applied also to the equivalent left-open ring structure (ii). In Fig. 5 (upper panels), we show the electronic populations $|C_k^{(I)}(t)|^2$ as functions of time and for the selected trajectories, along with the energy profiles (lower panels) of the three adiabatic states considered here and the gauge-invariant (GI) part of the TDPES (the first two terms on the right-hand side of Eq. (14)). The TDPES provides information about the "active" electronic state: if one wants to connect the interpretation of the dynamics based on the exact factorization to the standard perspective in terms of wave packets evolving "on" different adiabatic surfaces, it is instructive to compare the TDPES with the BO PES, as done in Fig. 5 (lower panels).


**Fig. 5** Upper panels: populations of the electronic states $S_0$, $S_1$, and $S_2$ as functions of time for two selected trajectories of type (i) (left) and of type (iii) (right). The color code is the same used in Fig. 4. Lower panels: energy profiles (in eV) along the selected trajectories, as in the upper panels. The zero is set to be the value of the energy of $S_0$ at time $t = 0$ fs. In the upper panels, a ball-stick representation of oxirane at the final time is shown, whereas in the lower panels, the configurations at the time of electronic population exchange are shown

The upper panels of Fig. 5 confirm that the coupling region is encountered by trajectories of type (iii) (right panels) at later times if compared to trajectories of type (i) or (ii) (left panels). Additionally, the $S_2/S_1$ population exchange is very sharp for type (i) and smooth for (iii). Observing the TDPES, we can argue that after about 5 fs, trajectories (i) encounter a steep $S_2$ potential, which directs them toward the conical intersection. Trajectories (iii) are trapped in a region of flat potential, which prevents them from a fast de-excitation to $S_1$. Subsequently, very different paths are undertaken, and thus different regions of the $S_1$ PES are explored. Toward the end of the simulated dynamics, only trajectories of type (i) are expected to relax to the ground state $S_0$, as confirmed by the closing of the energy gap between $S_0$ and $S_1$ at 25 fs (lower left panel of Fig. 5). At this time, the trajectory of type (iii) is evolving on a portion of the BO PES $S_1$ that is located at about 4 eV from the ground state.

## 4.4    Full and Ab Initio Multiple Spawning

### 4.4.1    Full Multiple Spawning

Full multiple spawning (FMS) (Martínez et al. 1996; Martínez and Levine 1997; Ben-Nun and Martínez 1998, 2002; Ben-Nun et al. 2000; Hack et al. 2001; Virshup

et al. 2008) proposes to expand the nuclear amplitudes in the Born-Huang expansion in a linear combination of frozen multidimensional Gaussian functions (Heller 1981). But these Gaussians functions do not form a static grid; on the contrary, they are evolving over time in both position and momentum space to better adapt to the evolution of the nuclear wavefunctions, forming a set of trajectory basis functions (TBFs):

$$
\Psi(\mathbf{r}, \mathbf{R}, t) = \sum_k \sum_I^{N_{TBFs,k}} C_I^{(k)}(t) \tilde{\chi}_I^{(k)} \left( \mathbf{R}; \overline{\mathbf{R}}_I^{(k)}(t), \overline{\mathbf{P}}_I^{(k)}(t), \overline{\gamma}_I^{(k)}(t), \boldsymbol{\alpha} \right) \varphi_{\mathbf{R}}^{(k)}(\mathbf{r}),
$$

(80)

where $C_I^{(k)}(t)$ is the complex coefficient for the TBF $I$ evolving on electronic state $(k)$ (used here as a label) and $\tilde{\chi}_I^{(k)} \left( \mathbf{R}; \overline{\mathbf{R}}_I^{(k)}(t), \overline{\mathbf{P}}_I^{(k)}(t), \overline{\gamma}_I^{(k)}(t), \boldsymbol{\alpha} \right)$ is the traveling multidimensional Gaussian $I$ on state $(k)$ with mean position $\overline{\mathbf{R}}_I^{(k)}(t)$, momenta $\overline{\mathbf{P}}_I^{(k)}(t)$, phase $\overline{\gamma}_I^{(k)}(t)$, and frozen width $\boldsymbol{\alpha}$. In FMS, the TBFs follow classical trajectories, i.e., $\overline{\mathbf{R}}(t)$ and $\overline{\mathbf{P}}(t)$ are propagated according to Hamilton's equation of motion (and the phase is integrated semi-classically). We note that this classical propagation of the TBFs does not imply that the method is semiclassical in itself, as the TBFs are only a support for the propagation of the nuclear wavefunctions. Indeed, in the limit of a large number of TBFs ($N_{TBFs}$), the FMS expansion would be exact. In fact, in the limit of an infinite number of Gaussian functions, their dynamics is redundant, and we have a (infinitely fine) grid. We note that other methods were proposed where the TBFs follow Ehrenfest trajectories (Shalashilin 2009, 2010; Saita and Shalashilin 2012; Makhov et al. 2017) (multiconfiguration Ehrenfest, MCE) or quantum trajectories (Worth et al. 2004, 2008; Lasorne et al. 2006, 2007; Mendive-Tapia et al. 2012; Richings et al. 2015) (variational Multiconfiguration Gaussian, vMCG), as well as mixed strategies (Makhov et al. 2014; Meek and Levine 2016; Izmaylov and Joubert-Doriol 2017; Joubert-Doriol et al. 2017).

One can express the time-dependent Schrödinger equation (1) in the basis of TBFs by inserting Eq. (80) in the former, left multiplying by

$$
\left[ \tilde{\chi}_J^{(l)} \left( \mathbf{R}; \overline{\mathbf{R}}_J^{(l)}(t), \overline{\mathbf{P}}_J^{(l)}(t), \overline{\gamma}_J^{(l)}(t), \boldsymbol{\alpha} \right) \varphi_{\mathbf{R}}^{(l)}(\mathbf{r}) \right]^*
$$

and integrating over both nuclear and electronic coordinates, leading, in atomic units, to (Ben-Nun and Martínez 2002):

$$
\frac{d}{dt} \mathbf{C}^l(t) = -i(\mathbf{S}_{ll}^{-1}) \left[ \left[ \mathbf{H}_{ll} - i\dot{\mathbf{S}}_{ll} \right] \mathbf{C}^l + \sum_{k \neq l} \mathbf{H}_{lk} \mathbf{C}^k \right].
$$

(81)

for each electronic state $l$ considered. The nonorthonormality of the Gaussian basis results in overlap matrices $\mathbf{S}_{ll}$ and $\dot{\mathbf{S}}_{ll}$, with elements $(\mathbf{S}_{ll})_{JI} = \langle \tilde{\chi}_J^{(l)} | \tilde{\chi}_I^{(l)} \rangle_{\mathbf{R}}$ and $(\dot{\mathbf{S}}_{ll})_{JI} = \langle \tilde{\chi}_J^{(l)} | \frac{\partial}{\partial t} \tilde{\chi}_I^{(l)} \rangle_{\mathbf{R}}$. We note that in Eq. (81) $\mathbf{S}_{lk} = \dot{\mathbf{S}}_{lk} = 0, \forall l \neq k$, due to the orthonormality of the electronic basis.

As mentioned earlier, the trajectories in FSSH are uncoupled. This is *not* the case in FMS, and TBFs are coupled thanks to the Hamiltonian matrix $\mathbf{H}$ in Eq. (81). Let us consider the Hamiltonian matrix element between two TBFs $J$ and $I$ evolving in adiabatic electronic states:

$$
\begin{aligned}
H_{kl}^{IJ} =& \langle \tilde{\chi}_I^{(k)} | \hat{T}_{\text{nuc}} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \delta_{kl} + \langle \tilde{\chi}_I^{(k)} | \varepsilon_{BO}^{(k)} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \delta_{kl} \\
& - \langle \tilde{\chi}_I^{(k)} | \sum_{\rho=1}^{3N} \frac{1}{M_\rho} \langle \varphi_{\mathbf{R}}^{(k)} | \frac{\partial}{\partial R_\rho} | \varphi_{\mathbf{R}}^{(l)} \rangle_{\mathbf{r}} \frac{\partial}{\partial R_\rho} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \\
& - \langle \tilde{\chi}_I^{(k)} | \sum_{\rho=1}^{3N} \frac{1}{2M_\rho} \langle \varphi_{\mathbf{R}}^{(k)} | \frac{\partial^2}{\partial R_\rho^2} | \varphi_{\mathbf{R}}^{(l)} \rangle_{\mathbf{r}} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}}
\end{aligned}
\tag{82}
$$

If the two TBFs are in the same electronic state $k$, they will be coupled *via* the first two terms on the r.h.s of Eq. (82): the nuclear kinetic energy operator and the (adiabatic) electronic energy. If the two TBFs belong to different electronic states $k$ and $l$, then a term containing the nonadiabatic coupling vectors (third term on the r.h.s) and the second-order nonadiabatic couplings (fourth term on the r.h.s of Eq. (82)) will ensure their coupling. We note that the diagonal second-order nonadiabatic couplings (also known as "diagonal Born-Oppenheimer correction") will contribute an additional intrastate coupling. FMS can easily incorporate additional source of couplings between TBFs like spin-orbit coupling (Curchod et al. 2016b), tunneling effects (Ben-Nun and Martínez 2000), or an external electromagnetic field (Mignolet et al. 2016), for example.

### 4.4.2 Spawning Algorithm

Up to this point, we have discussed the formal equations of FMS when a large number of TBFs is considered. However, FMS, as its name indicates, proposes to replace the large number of trajectory basis functions by an algorithm, coined the *spawning algorithm*, that will adapt the size of the basis set dynamically during the simulation. In other words, the spawning algorithm proposes the following alteration: $N_{TBFs} \rightarrow N_{TBFs}(t)$. In short, a TBF is evolving on a given PES, and as soon as a sizable coupling with a different electronic state is recorded, a spawning mode is triggered and will determine if, where, and when a new TBF should be created ("spawned") on the coupled state to maximize the coupling with the existing TBF and, therefore, the description of nonadiabatic transitions. Different versions of the spawning algorithm have been proposed, and the interested reader is encouraged to read Ben-Nun and Martínez (2002) and Yang et al. (2009) for more information. It is perhaps important to note at this stage that the time dependence of the number

of TBFs, $N_{TBFs}(t)$, implies that the size of matrices and vectors in Eq. (81) will vary during the dynamics.

### 4.4.3 Ab Initio Multiple Spawning

FMS is in principle exact. However, the coupling between TBFs given in Eq. (82) implies integration, and therefore knowledge, of electronic structure properties like PESs or nonadiabatic couplings over the full nuclear configuration space. Approximations are, therefore, needed to treat molecular systems in their full dimensionality. Let us start by performing a Taylor expansion of the electronic quantity of interest (e.g., here the electronic energy) around the centroid position of two TBFs $J$ and $I$ evolving in electronic state $k$: $\overline{\mathbf{R}}_{JI}^{(kk)} = \frac{\overline{\mathbf{R}}_J^{(k)} + \overline{\mathbf{R}}_I^{(k)}}{2}$:

$$\varepsilon_{BO}^{(k)}(\mathbf{R}) = \varepsilon_{BO}^{(k)}\left(\overline{\mathbf{R}}_{JI}^{(kk)}\right) + \sum_{\rho}^{3N} \left(R_\rho - \overline{R}_{\rho,JI}^{(kk)}\right) \frac{\partial \varepsilon_{BO}^{(k)}(\mathbf{R})}{\partial R_\rho}\Big|_{R_\rho = \overline{R}_{\rho,JI}^{(kk)}}$$

$$+ \frac{1}{2} \sum_{\rho\rho'}^{3N} \left(R_\rho - \overline{R}_{\rho,JI}^{(kk)}\right) \frac{\partial^2 \varepsilon_{BO}^{(k)}(\mathbf{R})}{\partial R_\rho \partial R_{\rho'}}\Big|_{R_\rho = \overline{R}_{\rho,JI}^{(kk)}, R_{\rho'} = \overline{R}_{\rho',JI}^{(kk)}} \left(R_{\rho'} - \overline{R}_{\rho',JI}^{(kk)}\right) + \dots$$

Owing to the locality of Gaussian functions, one will consider that, to a good approximation, only the term of order zero can be retained; in other words $\varepsilon_{BO}^{(k)}(\mathbf{R}) \approx \varepsilon_{BO}^{(k)}\left(\overline{\mathbf{R}}_{JI}^{(kk)}\right)$ (Ben-Nun and Martínez 2002). This approximation, called the saddle-point approximation of order zero (SPA0), strongly simplifies the coupling between TBFs as the Hamiltonian matrix elements become

$$H_{kl}^{IJ} = \langle \tilde{\chi}_I^{(k)} | \hat{T}_{nuc} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \delta_{kl} + \varepsilon_{BO}^{(k)}\left(\overline{\mathbf{R}}_{IJ}^{(kk)}\right) \langle \tilde{\chi}_I^{(k)} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \delta_{kl}$$

$$- \sum_{\rho=1}^{3N} \frac{1}{M_\rho} \langle \varphi_{\mathbf{R}}^{(k)} | \frac{\partial}{\partial R_\rho} | \varphi_{\mathbf{R}}^{(l)} \rangle_{\mathbf{r}}\Big|_{R_\rho = \overline{R}_{\rho,IJ}^{(kl)}} \langle \tilde{\chi}_I^{(k)} | \frac{\partial}{\partial R_\rho} | \tilde{\chi}_J^{(l)} \rangle_{\mathbf{R}} \quad (83)$$

(note that we also dropped the terms depending on second-order couplings). Hence, calculating the coupling between TBF $J$ and $I$ only requires the extra calculation of electronic structure quantities at their mutual centroid position, which can easily be achieved in an on-the-fly dynamics scheme. The SPA0 allows to port the *in principle* exact framework of FMS to the nonadiabatic dynamics of molecules. The resulting nonadiabatic method within the SPA0 is often called ab initio multiple spawning (AIMS). (We note that an additional approximation is commonly employed within AIMS – the independent first generation approximation – that approximates the initial nuclear wave packet at time $t = 0$ by a set of independent parent TBFs, i.e., coupling between parent TBFs is neglected. Couplings between all the TBFs spawned by each parent TBF are preserved (Ben-Nun and Martínez 2002)). AIMS has been coupled with different level of electronic structure

like SA-CASSCF (Levine et al. 2008), MS-CASPT2 (Tao et al. 2009), FOMO-CASCI (Pijeau et al. 2017), or LR-TDDFT (Curchod et al. 2017).

### 4.4.4    Applications

AIMS has recently (Curchod et al. 2017) been interfaced with an implementation of LR-TDDFT accelerated by graphical processing units (GPUs) (Isborn et al. 2011), offering an important speedup for the calculation of electronic energies, analytical gradients, and nonadiabatic coupling terms. The combination of AIMS and GPU-accelerated LR-TDDFT was employed to shed light on the excited-state dynamics of 4-N,N'-dimethylaminobenzonitrile (DMABN). DMABN is a molecule known to exhibit dual fluorescence depending on its environment, and it was proposed that the nature of the two emitting states is correlated with a twist of the dimethylamino (DMA) group (Grabowski et al. 2003) (see molecular structure in the inset of Fig. 6). However, DMABN is photoexcited into its second excited state, $S_2$, and relaxes to the first excited state $S_1$ where emission will occur at a later time. One question is then: does the $S_2/S_1$ nonadiabatic dynamics imply a twist of the DMA group, which could potentially have an influence on the fate of the molecule at later time in the $S_1$ state? Early static calculations have predicted that the $S_2/S_1$ transfer should be fast and that a twist of the DMA was not required for the nonadiabatic transition to occur (Gómez et al. 2005). AIMS combined with GPU-accelerated LR-TDDFT confirmed that the $S_2$ population decays to $S_1$ in less than $< 50$ fs (blue line, left panel of Fig. 6). Also, the transfer of the nuclear wave packet to $S_1$ is not correlated

**Fig. 6** Left panel: Population traces (with standard errors) of the different electronic states considered in the AIMS/LR-TDDFT dynamics. The gray dashed line indicates the number of TBFs during the dynamics. Right panel: Twist angle of the DMA group for the entire swarm of TBFs. The line width is proportional to the TBF population. Inset: representation of the DMABN molecule, with the DMA group highlighted in red. (Adapted with permission from Curchod et al. 2016c. Copyright (2016) American Chemical Society)

with the torsion of the DMA group, as showed by the projection of the TBFs on the twist coordinate (right panel of Fig. 6). The DMA group in fact starts its rotation only after the molecule reached $S_1$ ($t > 50$ fs, see right panel of Fig. 6), and such a transfer implies a change in the electronic character of the wave packet from *charge transfer* in $S_2$ around the Franck-Condon region to *locally excited* after the nonadiabatic transfer to $S_1$. On a more technical note, the gray dashed line on the left panel of Fig. 6 indicates the number of TBFs during the AIMS dynamics. Starting from 21 parent TBFs, the spawning algorithm rapidly creates a large amount of child TBFs to ensure a good basis for the propagation in the different nonadiabatic regions encountered.

## 5    Conclusions

The aim of this chapter has been to provide a broad overview of quantum molecular dynamics methods to simulate nonadiabatic phenomena in isolated and condensed phase systems, adopting a quantum-classical perspective. The combination of classical and quantum-mechanical approaches is, in fact, capable to describe, accurately and efficiently, dynamical processes involving electronic excited states. The assumption that a good description of the nuclear dynamics can be achieved based on classical mechanics is based on the fact that at the molecular scale, atoms (usually heavier than a proton) are associated to a relatively short de Broglie wavelength, e.g., shorter than the typical scale of variation of the potential. Electrons, on the other hand, require a purely quantum-mechanical description, which in this work has been achieved using the framework of time-dependent density functional theory. The challenges faced in the development of theoretical and numerical approaches for nonadiabatic dynamics are copious, justifying the rise over the years of a multitude of strategies to tackle these types of problems, some of which have been described in this review chapter.

TDDFT has emerged as a very powerful method to describe electronic excited-state dynamics, both for molecular systems and in condensed phase. TDDFT describes the evolution of the electronic density in a time-dependent external potential, and within the linear-response regime, LR-TDDFT allows the calculation of excited-state properties, e.g., energies, forces, and nonadiabatic couplings at a modest computational cost. The straightforward combination of the fundamental TDDFT theorem (leading to the time-dependent Kohn-Sham equations) with the classical motion of the nuclei gives rise to the conceptually simple Ehrenfest dynamics scheme. We described some of its applications to molecular processes involving explicit time-dependent electronic wave packet dynamics, pointing out its limitations related to the mean-field character of the underlying approximations.

The strong interplay of electronic and nuclear motion is, however, highly nontrivial, and effects beyond the mean-field approximations are difficult to capture with trajectory-based approaches. In particular, the accurate description of the electronic "nonadiabatic effects" on the nuclear dynamics requires the derivation of a suitable theoretical framework that enables the separation of electronic and nuclear motions.

Building on the TDDFT or LR-TDDFT description of the electronic dynamics within either the Born-Huang or the exact factorization framework, we have then reviewed three quantum-classical nonadiabatic simulation techniques that extend beyond the mean-field Ehrenfest approach, namely, surface hopping, coupled-trajectory mixed quantum-classical dynamics, and multiple spawning, along with some of their recent applications. The common denominator of all these techniques is that they combine "on-the-fly" trajectory-based dynamics with the computational advantages of TDDFT.

In the past years, large progresses have thus been accomplished in mixed quantum-classical nonadiabatic dynamics, and we hope that this chapter will help newcomers to engage in this exciting field of research. We believe that TDDFT-based nonadiabatic dynamics can become the method of choice for treating photochemical and photophysical processes of complex molecular systems in the gas and condensed phases. While it is hard to predict the outcome of current and future developments, the improvement of the exchange-correlation functionals, for instance, going beyond the adiabatic approximation, is one of the key issues that should be addressed, aiming to get more reliable excited-state energies, nonadiabatic couplings, nuclear forces, and electronic dissipation effects.Finally, the development of coupling schemes to describe the interaction with electromagnetic fields described quantum mechanically is underway (Flick et al. 2017a, b; Dimitrov et al. 2017) and will open new research areas in the field of cavity quantum electrodynamics.

# Ab Initio Electronic Structure Calculations by Auxiliary-Field Quantum Monte Carlo

**7**

Shiwei Zhang

## Contents

## Abstract

The auxiliary-field quantum Monte Carlo (AFQMC) method provides a computational framework for solving the time-independent Schrödinger equation in atoms, molecules, solids, and a variety of model systems by stochastic sampling. We introduce the theory and formalism behind this framework, briefly discuss the key technical steps that turn it into an effective and practical computational method, present several illustrative results, and conclude with comments on the prospects of ab initio computation by this framework.

# 1    Introduction

Predicting materials properties requires robust and reliable calculations at the most fundamental level. Often the effects being studied or designed originate from electron correlations, and small errors in their treatment can result in crucial and qualitative differences in the properties. The accurate treatment of interacting quantum systems is one of the grand challenges in modern science. In condensed phase materials, the challenge is increased by the need to account for the interplay between the electrons and the chemical and structural environment. Progress in addressing this challenge will be fundamental to achieving the materials genome initiative.

Explicit solution of the many-body Schrödinger equation leads to rapidly growing computational cost as a function of system size (see, e.g., Szabo and Ostlund 1989). To circumvent the problem, most computational quantum mechanical studies of large, realistic systems rely on simpler independent-particle approaches based on density-functional theory (DFT) (see, e.g., Kohn 1999; Martin 2004), using an approximate energy functional to include many-body effects. These replace the electron-electron interaction by an effective potential, thereby reducing the problem to a set of one-electron equations. Methods based on DFT and through its Car-Parrinello molecular dynamics implementation (Car and Parrinello 1985) have been extremely effective in complex molecules and solids (Kohn 1999). Such approaches are the standard in electronic structure, widely applied in condensed matter, quantum chemistry, and materials science.

Despite the tremendous successes of DFT, the treatment of electronic correlation is approximate. For strongly correlated systems (e.g., high-temperature superconductors, heavy-fermion metals, magnetic materials, optical lattices), where correlation effects from particle interaction crucially modify materials properties, the approximation can lead to qualitatively incorrect results. Even in moderately correlated systems when the method is qualitatively correct, the results are sometimes not sufficiently accurate. For example, in ferroelectric materials the usually acceptable 1% errors in DFT predictions of the equilibrium lattice constant can lead to almost full suppression of the ferroelectric order.

The development of alternatives to independent-particle theories is therefore of paramount fundamental and practical significance. To accurately capture the quantum many-body effects, the size of the Hilbert space involved often grows exponentially. Simulation methods utilizing Monte Carlo (MC) sampling (Kalos et al. 1974; Foulkes et al. 2001; Ceperley 1995; Blankenbecler et al. 1981; Sugiyama and Koonin 1986; Zhang and Krakauer 2003) are, in principle, both non-perturbative and well-equipped to handle details and complexities in the external environment. They are a unique combination of accuracy, general applicability, favorable scaling (low-power) for computational cost with physical system size, and scalability on parallel computing platforms (Esler et al. 2008).

For fermion systems, however, a so-called "sign" problem (Schmidt and Kalos 1984; Loh et al. 1990; Zhang 1999a) arises in varying forms in these MC simulation methods. The Pauli exclusion principle requires that the states be antisymmetric

under interchange of two particles. As a consequence, negative signs appear, which cause cancelations among contributions of the MC samples of the wave function or density matrix. In some formalism, as discussed below, a phase appears which leads to a continuous degeneracy and more severe cancelations. As the temperature is lowered or the system size is increased, such cancelation becomes more and more complete. The net signal thus decays *exponentially* versus noise. The algebraic scaling is then lost, and the method breaks down. Clearly the impact of this problem on the study of correlated electron systems is extremely severe.

In this chapter, we discuss the auxiliary-field quantum Monte Carlo (AFQMC) method for many-body computations in real materials. We cast the MC random walks in a space of over-complete Slater determinants, which significantly reduce the severity of the sign problem. In this space we formulate constraints on the random walk paths which lead to better approximations that are less sensitive to the details of the constraint. We then develop internal checks and constraint release methods to systematically improve the approach. These methods have come under the name of constrained path Monte Carlo (CPMC) (Zhang et al. 1997) for systems where there is a sign problem (e.g., Hubbard-like models where the auxiliary fields are real due to the short-ranged interactions). For electronic systems where there is a phase problem (as the Coulomb interaction leads to complex fields), the methods have been referred to as phaseless AFQMC (Zhang and Krakauer 2003; Al-Saidi et al. 2006; Motta and Zhang 2018). Here we will refer to the method as AFQMC; when necessary to emphasize the constrained-path (CP) approximation to distinguish the method from unconstrained free-projection, we will refer to it as CP-AFQMC.

## 2 Formalism

The Hamiltonian for any many-fermion system with two-body interactions (e.g., the electronic Hamiltonian under the Born-Oppenheimer approximation) can be written as

$$\hat{H} = \hat{H}_1 + \hat{H}_2 = -\frac{\hbar^2}{2m}\sum_{m=1}^{M}\nabla_m^2 + \sum_{m=1}^{M}V_{\text{ext}}(\mathbf{r}_m) + \sum_{m<n}^{M}V_{\text{int}}(\mathbf{r}_m - \mathbf{r}_n), \qquad (1)$$

where $\mathbf{r}_m$ is the real-space coordinate of the $m$-th fermion. The one-body part of the Hamiltonian, $\hat{H}_1$, consists of the kinetic energy of the electrons and the effect of the ionic (and any other external) potentials. (We have represented the external potential as local, although this does not have to be the case. For example, in plane-wave calculations, we will use a norm-conserving pseudopotential, which will lead to a nonlocal function $V_{\text{ext}}$.) The two-body part of the Hamiltonian, $\hat{H}_2$, contains the electron-electron interaction terms. The total number of fermions, $M$, will be fixed in the calculations we discuss. For simplicity, we have suppressed spin-index, but the spin will be made explicit when necessary. In that case, $M_\sigma$ is the number

of electrons with spin $\sigma$ ($\sigma = \uparrow$ or $\downarrow$). We assume that the interaction is spin-independent, so the total $S_z$, defined by $(M_\uparrow - M_\downarrow)$, is fixed in the calculation, although it will be straightforward to generalize our discussions to treat other cases, for example, when there is spin-orbit coupling (SOC) (Rosenberg et al. 2017).

With any chosen one-particle basis, the Hamiltonian can be written in second quantization in the general form

$$\hat{H} = \hat{H}_1 + \hat{H}_2 = \sum_{i,j}^{N} T_{ij} c_i^\dagger c_j + \frac{1}{2} \sum_{i,j,k,l}^{N} V_{ijkl} c_i^\dagger c_j^\dagger c_k c_l , \tag{2}$$

where the one-particle basis, $\{|\chi_i\rangle\}$ with $i = 1, 2, \cdots, N$, can be lattice sites (Hubbard model), plane waves (as in solid state calculations) (Suewattana et al. 2007), Gaussians (as in quantum chemistry) (Al-Saidi et al. 2006; Purwanto et al. 2011), etc. The operators $c_i^\dagger$ and $c_i$ are creation and annihilation operators on $|\chi_i\rangle$, satisfying standard fermion commutation relations. The one-body matrix elements, $T_{ij}$, contain the effect of both the kinetic energy and external potential, while the two-body matrix elements, $V_{ijkl}$, are from the interaction. The matrix elements are expressed in terms of the basis functions, for example,

$$V_{ijkl} = \int d\mathbf{r}_1 d\mathbf{r}_2 \chi_i^*(\mathbf{r}_1) \chi_j^*(\mathbf{r}_2) V_{int}(\mathbf{r}_1 - \mathbf{r}_2) \chi_k(\mathbf{r}_2) \chi_l(\mathbf{r}_1) . \tag{3}$$

In quantum chemistry calculations, these are readily evaluated with standard Gaussian basis sets. In solid state calculations with plane waves, the kinetic and electron-electron interaction terms have simple analytic expressions, while the electron-ion potential leads to terms which are provided by the pseudopotential generation. We will assume that all matrix elements in Eq. (2) have been evaluated and are known as we begin our many-body calculations.

## 2.1   Non-orthogonal Slater Determinant Space

The AFQMC method seeks to obtain the ground state of the Hamiltonian in Eq. (2), representing it stochastically in the form

$$|\Psi_0\rangle = \sum_\phi \alpha_\phi |\phi\rangle , \tag{4}$$

where $|\phi\rangle$ is a Slater determinant:

$$|\phi\rangle \equiv \hat{\varphi}_1^\dagger \hat{\varphi}_2^\dagger \cdots \hat{\varphi}_M^\dagger |0\rangle . \tag{5}$$

In Eq. (5), the operator $\hat{\varphi}_m^\dagger \equiv \sum_i c_i^\dagger \varphi_{i,m}$, with $m$ taking an integer value among $1, 2, \cdots, M$, creates an electron in a single-particle orbital $\varphi_m$: $\hat{\varphi}_m^\dagger |0\rangle = \sum_i \varphi_{i,m} |\chi_i\rangle$. The content of the orbital can thus be conveniently expressed as an

$N$-dimensional vector $\{\varphi_{1,m}, \varphi_{2,m}, \cdots, \varphi_{N,m}\}$. The Slater determinant $|\phi\rangle$ in Eq. (5) can then be expressed as an $N \times M$ matrix:

$$\Phi \equiv \begin{pmatrix} \varphi_{1,1} & \varphi_{1,2} & \cdots & \varphi_{1,M} \\ \varphi_{2,1} & \varphi_{2,2} & \cdots & \varphi_{2,M} \\ \vdots & \vdots & & \vdots \\ \varphi_{N,1} & \varphi_{N,2} & \cdots & \varphi_{N,M} \end{pmatrix}.$$

Each column of this matrix represents a single-particle orbital that is completely specified by its $N$-dimensional vector. For convenience, we will think of the different columns as all properly orthonormalized, which is straightforward to achieve by, for example, modified Gram-Schmidt (see e.g., Zhang 2003, 2013; Motta and Zhang 2018).

The mean-field Hartree-Fock (HF) solution is of course an example of a Slater determinant: $|\phi_{HF}\rangle = \prod_\sigma |\phi_{HF}^\sigma\rangle$, where $|\phi_{HF}^\sigma\rangle$ is defined by a matrix $\Phi_{HF}^\sigma$ whose columns are the $M_\sigma$ lowest HF eigenstates. Similarly, the occupied manifold in a DFT calculation forms a "wave function" which is a Slater determinant.

In standard quantum chemistry (QC) methods, the many-body ground-state wave function is also represented by a sum of Slater determinants. However, there is a key difference between it and the AFQMC representation. In QC methods, the different Slater determinants are orthogonal. As illustrated in the left panel in Fig. 1, each of the determinants is formed by excitations from the HF determinant. In other words, each $|\phi\rangle$ on the right-hand side of Eq. (4) is given by a set of $M$ molecular orbitals (MOs), and the corresponding matrix is formed by orthonormal *unit vectors*. In contrast, in AFQMC the different Slater determinants on the right-hand side of Eq. (4) are not orthogonal: $\langle\phi'|\phi\rangle \neq 0$. They are obtained by rotations of the occupied orbitals using one-body Hamiltonians involving random auxiliary fields (see further details below), as illustrated in the right panel in Fig. 1.

Several properties of non-orthogonal Slater determinants are worth mentioning. The overlap between two of them is given by

$$\langle\phi|\phi'\rangle = \det\left(\Phi^\dagger \Phi'\right). \tag{6}$$

We can define the expectation of an operator $\hat{O}$ with respect to a pair of non-orthogonal Slater determinants:

$$\langle\hat{O}\rangle_{\phi\phi'} \equiv \frac{\langle\phi|\hat{O}|\phi'\rangle}{\langle\phi|\phi'\rangle}, \tag{7}$$

for instance, single-particle Green's function $G_{ij} \equiv \langle c_i c_j^\dagger\rangle_{\phi\phi'}$:

$$G_{ij} \equiv \frac{\langle\phi|c_i c_j^\dagger|\phi'\rangle}{\langle\phi|\phi'\rangle} = \delta_{ij} - [\Phi'(\Phi^\dagger \Phi')^{-1}\Phi^\dagger]_{ij}. \tag{8}$$
**Fig. 1** Schematic illustration of the connection and difference between quantum chemistry (QC) approaches and AFQMC. A fictitious system, with $M_\uparrow = 2$, $M_\downarrow \leq M_\uparrow$ and $N$ basis functions, is shown. Vertical scale indicates single-particle energy. In QC-based methods (left), Slater determinants are constructed using the molecular orbitals from a (restricted-orbital) HF calculation. ("O" denotes occupied, "V" denotes virtual, and the thick line indicates the Fermi level.) All resulting Slater determinants are orthogonal to each other and to the reference HF state. In AFQMC, each Slater determinant in Eq. (4) is sampled by random walk. Each walker $|\phi\rangle$ has only "occupied" orbitals (denoted by the red and green lines) which are rotated during the random walk, under the influence of stochastic auxiliary fields (illustrated by the *wiggly* lines, which move up and down as the walker evolves from one step to the next). The Slater determinants generated in AFQMC are non-orthogonal to each other

Given the Green's function matrix $G$, the general expectation defined in Eq. (7) can be computed for most operators of interest. For example, we can calculate the expectation of a general two-body operator, $\hat{O} = \sum_{ijkl} O_{ijkl} c_i^\dagger c_j^\dagger c_k c_l$, under the definition of Eq. (7):

$$\langle \hat{O} \rangle_{\phi\phi'} = \sum_{ijkl} O_{ijkl}(G'_{jk}G'_{il} - G'_{ik}G'_{jl}), \tag{9}$$

where the matrix $G'$ is defined as $G' \equiv I - G$.

A key property of Slater determinants we will invoke is the *Thouless Theorem*: any one-particle operator $\hat{B}$ of the form

$$\hat{B} = \exp\left( \sum_{ij} c_i^\dagger U_{ij} c_j \right), \tag{10}$$

when acted on a Slater determinant, simply leads to another Slater determinant (Hamann and Fahy 1990), i.e.,

$$\hat{B}|\phi\rangle = \hat{\phi}_1'^\dagger \hat{\phi}_2'^\dagger \cdots \hat{\phi}_M'^\dagger |0\rangle \equiv |\phi'\rangle \tag{11}$$

with $\hat{\phi}_m'^\dagger = \sum_j c_j^\dagger \Phi'_{jm}$ and $\Phi' \equiv e^U \Phi$, where $U$ is a square matrix whose elements are given by $U_{ij}$ and $B \equiv \exp(U)$ is therefore an $N \times N$ square matrix as well. In other words, the operation of $\hat{B}$ on $|\phi\rangle$ simply involves multiplying an $N \times N$ matrix to the $N \times M$ matrix representing the Slater determinant.

There are several generalizations of the formalism we have discussed which extends the capability and/or accuracy of the AFQMC framework. These can be thought of as generalizing one or both of the Slater determinants in Eqs. (6), (7), and (8). From the viewpoint of AFQMC, as we shall discuss below, the"bra" in these equations represents the trial wave function, and the "ket" represents the random walker:

- The first generalization is to replace $\langle\phi|$ by a projected Bardeen-Cooper-Schrieffer (BCS) wave function, that is, to use a projected BCS as a trial wave function, which can be advantageous for systems with pairing order. The corresponding overlap, Green functions, and two-body mixed expectations have been worked out (Carlson et al. 2011).
- The second is to have both $\langle\phi|$ and $|\phi'\rangle$ in generalized HF (GHF) form, which is necessary to treat systems with spin-orbit coupling (SOC). The required modification to the formalism outlined above is given by Rosenberg et al. (2017).
- The third generalization is to have both sides in Hartree-Fock-Bogoliubov (HFB) form, for example, to treat Hamiltonians with pairing fields. This will also be useful when using AFQMC as an impurity solver in which the embedding induces pairing order. The corresponding AFQMC formalism has been described (Shi and Zhang 2017).

## 2.2    Ground-State Projection

Most ground-state quantum MC (QMC) methods are based on iterative projection:

$$|\Psi_0\rangle \propto \lim_{\tau\to\infty} e^{-\tau\hat{H}}|\Psi_T\rangle; \tag{12}$$

that is, the ground state $|\Psi_0\rangle$ of a many-body Hamiltonian $\hat{H}$ can be projected from any known trial state $|\Psi_T\rangle$ that satisfies $\langle\Psi_T|\Psi_0\rangle \neq 0$. In a numerical method, the limit can be obtained iteratively by

$$|\Psi^{(n+1)}\rangle = e^{-\Delta\tau\hat{H}}|\Psi^{(n)}\rangle, \tag{13}$$

where $|\Psi^{(0)}\rangle = |\Psi_T\rangle$. Ground-state expectation $\langle\hat{O}\rangle$ of a physical observable $\hat{O}$ is given by

$$\langle\hat{O}\rangle = \lim_{n\to\infty} \frac{\langle\Psi^{(n)}|\hat{O}|\Psi^{(n)}\rangle}{\langle\Psi^{(n)}|\Psi^{(n)}\rangle}. \tag{14}$$

For example, the ground-state energy can be obtained by letting $\hat{O} = \hat{H}$. A so-called mixed estimator exists, however, which is exact for the energy (or any other $\hat{O}$ that commutes with $\hat{H}$) and can lead to considerable simplifications in practice:

$$E_0 = \lim_{n \to \infty} \frac{\langle \Psi_T | \hat{H} | \Psi^{(n)} \rangle}{\langle \Psi_T | \Psi^{(n)} \rangle}. \tag{15}$$

QMC methods carry out the iteration in Eq. (13) by Monte Carlo (MC) sampling. The difference between different classes of methods amounts primarily to the space that is used to represent the wave function or density matrix and to carry out the integration. The AFQMC methods work in second quantized representation and in an auxiliary-field space, while Green's function Monte Carlo (GFMC) or diffusion Monte Carlo (DMC) works in first-quantized representation and in electron coordinate space (Kalos et al. 1974; Foulkes et al. 2001). The full-configuration interaction QMC (FCIQMC) (Booth et al. 2009) works in orthogonal Slater determinant space as in QC methods.

Let us assume that $|\Psi_T\rangle$ is of the form of a single Slater determinant or a linear combination of Slater determinants, as in Eq. (4). The operation of $e^{-\tau \hat{H}_1}$ on a Slater determinant simply yields another determinant, per Thouless theorem. The ground-state projection would therefore turn into the propagation of a single Slater determinant if it were somehow possible to write the two-body propagator $e^{-\tau \hat{H}_2}$ as the exponential of a one-body operator.

The above is realized in independent-electron theories. In the HF approximation, $\hat{H}_2$ is replaced by one-body operators times expectations with respect to the current Slater determinant wave function, schematically:

$$c_i^\dagger c_j^\dagger c_k c_l \to c_i^\dagger c_l \langle c_j^\dagger c_k \rangle - c_i^\dagger c_k \langle c_j^\dagger c_l \rangle. \tag{16}$$

(A decomposition that includes pairing is also possible, leading to a Hartree-Fock-Bogoliubov calculation.) In the local density approximation (LDA) in DFT, $\hat{H}_2$ is replaced by $\hat{H}_{\text{LDA}} = \hat{H}_1 + \hat{V}_{xc}$, where $\hat{V}_{xc}$ contains the density operator in real-space, with matrix elements given by the exchange-correlation functional which is computed with the local density from the current Slater determinant in the self-consistent process. In both these cases, an iterative procedure can be used, following Eq. (13), to project out the solution to the approximate Hamiltonians, as an imaginary-time evolution of a single Slater determinant (Zhang and Ceperley 2008). This is illustrated by the blue line in Fig. 2. Note that this procedure is formally very similar to time-dependent HF or time-dependent DFT (TDDFT), except for the distinction of imaginary versus real time.

## 2.3    Hubbard-Stratonovich Transformation

Suppose that $\hat{H}_2$, the two-body part in the Hamiltonian in Eq. (2), can be written as a sum of squares of one-body operators:
**Fig. 2** Illustration of the iterative imaginary-time projection to the ground state. The overlap of the Slater determinants with a test wave function (e.g., the exact ground-state $|\Psi_0\rangle$) is plotted vs. imaginary time $n\Delta\tau$. The thick blue line indicates a projection using $e^{-\Delta\tau \hat{H}_{\text{LDA}}(\phi^{(n)})}$ which converges to the LDA ground state (or a local minimum). The wiggly magenta lines indicate an AFQMC projection which captures the many-body effect beyond LDA as a stochastic linear superposition. The propagator is obtained by expanding the two-body part of the $\hat{H}$, namely, $\hat{H}_2 - \hat{V}_{xc}$, by a Hubbard-Stratonovich transformation as discussed in the next sections. The dotted redline indicates a path which can lead to a sign problem (Sect. 3.2)

$$\hat{H}_2 = \frac{1}{2} \sum_{\gamma=1}^{N_\gamma} \lambda_\gamma \hat{v}_\gamma^2, \tag{17}$$

where $\lambda_\gamma$ is a constant, $\hat{v}_\gamma$ is a one-body operator similar to $\hat{H}_1$, and $N_\gamma$ is an integer. We can then apply the Hubbard-Stratonovich (HS) transformation to each term

$$e^{-\frac{\Delta\tau}{2} \lambda \hat{v}^2} = \int_{-\infty}^{\infty} dx \frac{e^{-\frac{1}{2}x^2}}{\sqrt{2\pi}} e^{x\sqrt{-\Delta\tau\lambda}\,\hat{v}}, \tag{18}$$

where $x$ is an auxiliary-field variable. The constant in front of $\hat{v}$ in the exponent on the right-hand side can be real or imaginary, depending on the sign of $\lambda$. The key is that the quadratic form (in $\hat{v}$) on the left is replaced by a linear one on the right. There are various ways to achieve the decomposition in Eq. (17) for a general two-body term (Negele and Orland 1998). Below we outline the two most commonly applied cases in electronic structure: (**a**) *with plane-wave basis* and (**b**) for a more dense matrix $V_{ijkl}$ resulting from a *general basis set* such as Gaussians in QC.

In a *plane-wave basis*, the two-body part is the Fourier transform of $1/|\mathbf{r}_m - \mathbf{r}_n|$ (Suewattana et al. 2007):

$$\hat{H}_2 \rightarrow \frac{1}{2\Omega} \sum_{i,j,k,l} \frac{4\pi}{|\mathbf{G_i} - \mathbf{G_k}|^2} c_i^\dagger c_j^\dagger c_l c_k \delta_{\mathbf{G_i}-\mathbf{G_k},\mathbf{G_l}-\mathbf{G_j}} \delta_{\sigma_i,\sigma_k} \delta_{\sigma_j,\sigma_l}, \tag{19}$$

where $\{\mathbf{G_i}\}$ are plane-wave wave-vectors, $\Omega$ is the volume of the supercell, and $\sigma$ denotes spin. Let us use $\mathbf{Q} \equiv \mathbf{G_i} - \mathbf{G_k}$ and define a density operator in momentum space:

$$\hat{\rho}(\mathbf{Q}) \equiv \sum_{\mathbf{G},\sigma} c^{\dagger}_{\mathbf{G}+\mathbf{Q},\sigma} c_{\mathbf{G},\sigma}, \tag{20}$$

where the sum is over all $\mathbf{G}$ vectors which allow both $\mathbf{G}$ and $\mathbf{G}+\mathbf{Q}$ to fall within the predefined kinetic energy cutoff in the plane-wave basis. The two-body term in Eq. (19) can then be manipulated into the form

$$\hat{H}_2 \to \sum_{\mathbf{Q}\neq\mathbf{0}} \frac{\pi}{\Omega Q^2} \left[ \hat{\rho}^{\dagger}(\mathbf{Q})\,\hat{\rho}(\mathbf{Q}) + \hat{\rho}(\mathbf{Q})\,\hat{\rho}^{\dagger}(\mathbf{Q}) \right], \tag{21}$$

where the sum is over all $\mathbf{Q}$'s except $\mathbf{Q} = 0$, since in Eq. (19) the $\mathbf{G_i} = \mathbf{G_k}$ term is excluded due to charge neutrality, and we have invoked $\rho^{\dagger}(\mathbf{Q}) = \rho(-\mathbf{Q})$. By making linear combinations of $\left[(\rho^{\dagger}(\mathbf{Q}) + \rho(\mathbf{Q})\right]$ and $\left[(\rho^{\dagger}(\mathbf{Q}) - \rho(\mathbf{Q})\right]$ terms, we can then readily write the right-hand side in Eq. (21) in the desired square form of Eq. (17) (Suewattana et al. 2007).

With a *general basis* such as Gaussians yielding matrix elements given in Eq. (3), the most straightforward way to decompose $\hat{H}_2$ is through a direct diagonalization (Al-Saidi et al. 2006, 2007; Zhang 2013). However, this is computationally costly. A modified Cholesky decomposition leads to $\mathcal{O}(N)$ fields (Purwanto et al. 2011; Motta and Zhang 2018). This approach, which has been commonly used in AFQMC for molecular systems with Gaussian basis sets and for downfolded Hamiltonians (Ma et al. 2015), proceeds as follows. Let us cast $V_{ijkl}$ in the form of a two-index matrix by introducing the compound indices $\mu = (i, l)$ and $\nu = (j, k)$: $V_{\mu\nu} = V_{(i,l),(j,k)} = V_{ijkl}$. The symmetric positive semidefinite matrix $V_{\mu\nu}$ is decomposed using a recursive modified Cholesky algorithm (Koch et al. 2003; Aquilante et al. 2010), to yield

$$V_{\mu\nu} = \sum_{\gamma=1}^{N_\gamma} L_\mu^\gamma L_\nu^\gamma + \Delta_{\mu\nu}^{(N_\gamma)}, \tag{22}$$

where $\Delta_{\mu\nu}^{(N_\gamma)}$ is the residual error at the $N_\gamma$-th iteration. The iterative procedure is repeated until all matrix elements of the residual matrix are less than some predefined tolerance $\delta$:

$$\left| V_{\mu\nu} - V_{\mu\nu}^{(N_{\mathrm{CD}})} \right| = \left| \Delta_{\mu\nu}^{(N_{\mathrm{CD}})} \right| \leq \delta. \tag{23}$$

For molecular calculations, typical values of $\delta$ range between $10^{-4}$ and $10^{-6}$ in atomic units (Motta and Zhang 2018). Using the $N_{\mathrm{CD}}$ Cholesky vectors, we can rewrite the two-body part of the Hamiltonian

$$\hat{H}_2 \rightarrow \frac{1}{2} \sum_{\gamma=1}^{N_{\text{CD}}} \left( \sum_{il} L_{\mu(i,l)}^{\gamma} c_i^{\dagger} c_l \right) \left( \sum_{jk} L_{\nu(j,k)}^{\gamma} c_j^{\dagger} c_k \right) + \mathcal{O}(\delta). \tag{24}$$

Hence the form in Eq. (17) is realized, with $\hat{v}_{\gamma} = \sum_{il} L_{\mu(i,l)}^{\gamma} c_i^{\dagger} c_l$.

Different forms of the HS transformation can affect the performance of the AFQMC method. For example, it is useful to subtract a mean-field "background" from the two-body term prior to the decomposition (Baer et al. 1998; Purwanto and Zhang 2005; Al-Saidi et al. 2006). The idea is that using the HS to decompose any constant shifts in the two-body interaction will necessarily result in more statistical noise. In fact, it has been shown (Shi and Zhang 2013; Motta and Zhang 2018) that the mean-field background subtraction can not only impact the statistical accuracy but also lead to different quality of approximations under the constrained path methods that we discuss in the next section.

If we denote the collection of auxiliary fields by **x** and combine one-body terms from $\hat{H}_1$ and $\hat{H}_2$, we obtain the following compact representation of the outcome of the HS transformation:

$$e^{-\Delta\tau\hat{H}} = \int d\mathbf{x}\, p(\mathbf{x}) \hat{B}(\mathbf{x}), \tag{25}$$

where $p(\mathbf{x})$ is a probability density function (PDF), for example, a multidimensional Gaussian. The propagator $\hat{B}(\mathbf{x})$ in Eq. (25) has a *special form*, namely, it is a product of operators of the type in Eq. (10), with $U_{ij}$ depending on the auxiliary field. The matrix representation of $\hat{B}(\mathbf{x})$ will be denoted by $B(\mathbf{x})$.

Note that the matrix elements of $B(\mathbf{x})$ can become complex, for example, when $\lambda$ in Eq. (18) is positive, which occurs in both of the forms discussed above. Sometimes we will refer to this situation as having complex auxiliary fields, but it should be understood that terms in the PDF of the HS transformation and $\hat{B}(\mathbf{x})$ can be rearranged, and the relevant point is whether the Slater determinant has matrix elements which are real or complex, as further discussed in the next section.

In essence, the HS transformation replaces the two-body interaction by one-body interactions with a set of random external auxiliary fields. In other words, it converts an interacting system into many *noninteracting* systems living in fluctuating external auxiliary fields. The sum over all configurations of auxiliary fields recovers the interaction.

## 3  Ground-State AFQMC Methods

### 3.1  Free-Projection AFQMC

We first briefly describe the ground-state AFQMC method without any constraints. Our goal is to illustrate the essential ideas, in a way which will facilitate our ensuing discussions and help introduce the constrained path approximation and the

framework for the general AFQMC methods that control the sign/phase problem. We will not go into details, which are described in the literature.

We write the usual path-integral and Metropolis form explicitly here to show its connection to the open-ended random walk approach. Ground-state expectation $\langle \hat{O} \rangle$ can be computed with Eqs. (13) and (25). The denominator is

$$
\langle \psi^{(0)} | e^{-n\Delta\tau\hat{H}} e^{-n\Delta\tau\hat{H}} | \psi^{(0)} \rangle
$$

$$
= \int \langle \psi^{(0)} | \left[ \prod_{l=1}^{2n} d\mathbf{x}^{(l)} p(\mathbf{x}^{(l)}) \hat{B}(\mathbf{x}^{(l)}) \right] | \psi^{(0)} \rangle
$$

$$
= \int \left[ \prod_l d\mathbf{x}^{(l)} p(\mathbf{x}^{(l)}) \right] \det\left( [\Psi^{(0)}]^\dagger \prod_l B(\mathbf{x}^{(l)}) \Psi^{(0)} \right). \tag{26}
$$

In the standard ground-state AFQMC method (Sugiyama and Koonin 1986; Sorella et al. 1989; Blankenbecler et al. 1981), a value of $n$ is first chosen and is kept fixed throughout the calculation. If we use $X$ to denote the collection of the auxiliary fields $X = \{\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \ldots, \mathbf{x}^{(2n)}\}$ and $D(X)$ to represent the integrand in Eq. (26), we can write the expectation value of Eq. (14) as

$$
\langle \hat{O} \rangle = \frac{\int \langle \hat{O} \rangle_{LR} D(X) \, dX}{\int D(X) \, dX} = \frac{\int \langle \hat{O} \rangle_{LR} |D(X)| \Theta(X) \, dX}{\int |D(X)| \Theta(X) \, dX}, \tag{27}
$$

where

$$
\Theta(X) \equiv D(X)/|D(X)| \tag{28}
$$

measures the phase of $D(X)$, which reduces to a sign when the overlap, $D(X)$, is real along all paths $\{X\}$. The expectation for a given $X$, as defined in Eq. (7), is:

$$
\langle \hat{O} \rangle_{LR} \equiv \frac{\langle \phi_L | \hat{O} | \phi_R \rangle}{\langle \phi_L | \phi_R \rangle} \tag{29}
$$

with

$$
\langle \phi_L | = \langle \psi^{(0)} | \hat{B}(\mathbf{x}^{(2n)}) \hat{B}(\mathbf{x}^{(2n-1)}) \cdots \hat{B}(\mathbf{x}^{(n+1)})
$$

$$
| \phi_R \rangle = \hat{B}(\mathbf{x}^{(n)}) \hat{B}(\mathbf{x}^{(n-1)}) \cdots \hat{B}(\mathbf{x}^{(1)}) | \psi^{(0)} \rangle,
$$

which are both Slater determinants.

$D(X)$ and $\langle \phi_L |$ and $| \phi_R \rangle$ are completely specified by the path $X$ in auxiliary-field space, given $|\Psi^{(0)}\rangle$. The expectation in Eq. (27) is thus a many-dimensional

integration which can be evaluated by standard MC techniques. Often the Metropolis algorithm (Kalos and Whitlock 1986) is used to sample auxiliary fields $X$ from $|D(X)|$. We will refer to this as free-projection (in contrast with a constrained path calculations). There are special Hamiltonians (e.g., repulsive Hubbard model at half-filling) where special symmetry makes the sign problem absent. In those situations, the Metropolis approach described above is very effective and is the standard approach. It should be mentioned that in those cases, an infinite variance problem arises which must be controlled (Shi and Zhang 2016).

We carry out free-projection calculations with an open-ended random walk (Zhang et al. 1997; Baer et al. 1998) instead of using Metropolis sampling outlined above. For free-projection calculations, the open-ended approach has no real advantage. However, when a sign or phase problem is present, it is difficult to implement a constraint to control the problem in the Metropolis framework, because of ergodicity issues (Fahy and Hamann 1990; Zhang et al. 1997). The open-ended random walk framework avoids the difficulty and is straightforward to project to longer imaginary time in order to approach the ground state. Moreover, when we carry out constraint release (Shi and Zhang 2013), the formalism will rely on the open-ended random walk. These points will become clear after we illustrate the phase problem in electronic structure calculations below and discuss how the constraint can be formulated. The structure of the open-ended random walk is illustrated in Fig. 3.

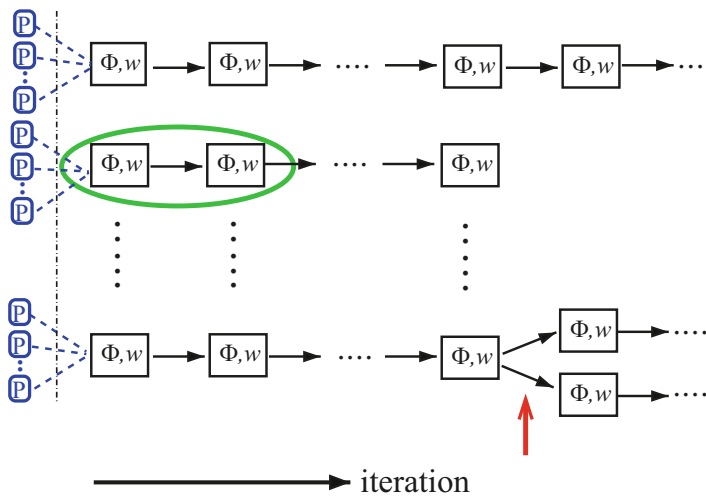

**Fig. 3** Schematic illustration of the AFQMC method. Each box is a random walker, with $|\phi\rangle$ the stochastic Slater determinant and $w$ its weight. A step (green oval) is similar to one SCF (self-consistent-field) step in LDA. The red arrow indicates a population control, where birth/death can occur. This structure allows for exceptional capacity for scaling on parallel computers. Multiple walkers can reside on one processor (blue "P" box), or each walk can be split over processors for large problems

## 3.2    Constrained Path AFQMC

As mentioned, a sign/phase problem occurs in the free-projection AFQMC, except for special cases where the single-particle propagator $\hat{B}(\mathbf{x})$ satisfies particular symmetries (see, e.g., Wei et al. 2016). In these cases, $\Theta(X)$ (defined in Eq. (28)) vanishes, and $D(x)$ is real and nonnegative. Absent such special circumstances, a sign problem arises if $\hat{B}(\mathbf{x})$ is real, and a phase problem arises if $\hat{B}(\mathbf{x})$ is complex. As mentioned, the Coulomb interaction in $V_{\text{int}}$ leads to a phase problem in molecules and solids. In this section we discuss the constrained-path (CP) AFQMC, which for electronic systems has often been referred to as the phaseless or phase-free approximation (Zhang and Krakauer 2003; Purwanto and Zhang 2004).

For real $\hat{B}(\mathbf{x})$ (e.g., Hubbard-type of short-range repulsive interactions decoupled with spin form of HS transformation), the sign problem occurs because of the fundamental symmetry between the fermion ground-state $|\Psi_0\rangle$ and its negative $-|\Psi_0\rangle$ (Zhang 1999a; Zhang and Kalos 1991). For any ensemble of Slater determinants $\{|\phi\rangle\}$ which gives a MC representation of the ground-state wave function, as in Eq. (4), this symmetry implies that there exists another ensemble $\{-|\phi\rangle\}$ which is also a correct representation. In other words, the Slater determinant space can be divided into two degenerate halves ($+$ and $-$) whose bounding surface $\mathscr{N}$ is defined by $\langle\Psi_0|\phi\rangle = 0$. This dividing surface is unknown. (In the cases with special symmetry mentioned above, the two sides separated by the surface are both positive. This has to do with the over-complete nature of the non-orthogonal Slater determinant space in AFQMC. A particular form of $\hat{B}(\mathbf{x})$ can pick out only a part of the space which can be nonnegative.)

The idea of the $\pm$-symmetry can be seen from Fig. 2, where the dotted red line indicates a walker reaching the surface $\mathscr{N}$, which will have a finite probability of occurring in a random walk, unless completely excluded by the dynamics. Once it does, it can, in general, freely sample the two families of solutions which are symmetric about the horizontal axis (above and below). A more detailed illustration and discussion of the sign problem can be found in Zhang (1999b, 2013). The idea of the phase problem is illustrated in Fig. 4. The complex plane now replaces the vertical axis in Fig. 2, denoting the overlap of a random walker $|\phi\rangle$ with the (hypothetically) known exact wave function or the trial wave function $\langle\Psi_T|$.

Cancelation schemes can partially alleviate the problem, as demonstrated in coordinate space (Zhang and Kalos 1991; Diedrich and Anderson 1992) and in Fock space (Booth et al. 2009). To fully stabilize the calculation and restore polynomial scaling, however, an approximation has been necessary. To date, the most effective and accurate method to achieve this has been the constrained path approach.

The method begins with a generalized similarity transformation in the spirit of the importance-sampling transformation. To make the derivation more concrete, we will use an explicit form of the HS transformation and write the two-body propagator that results from Eq. (21) or (24) as $\int e^{-\frac{\mathbf{x}^2}{2}} e^{\mathbf{x}\cdot\hat{\mathbf{v}}} d\mathbf{x}$, where $\mathbf{x}$ is an $N_\gamma$-dimensional vector as given by Eq. (25) (with $\gamma$ labeling the auxiliary fields) and
**Fig. 4** Schematic illustration of the phase problem and constraints to control it. The **left panel** shows, as a function of projection time $\beta \equiv n\Delta\tau$, trajectories of five walkers (shown as five different colors) characterized by the real (Re) and imaginary (Im) parts of their overlap with the ground-state wave function. The **right panel** shows the walker distribution integrated over imaginary time, i.e., the different frames in the left panel stacked together along $\beta$. The phase problem occurs because the initial phase "coherence" of the random walkers rapidly deteriorates with $\beta$, as they become uniformly distributed in the Re-Im-plane. The idea of the phase constraint (Zhang and Krakauer 2003) is to apply a gauge transformation such that confining the random walk in the single magenta plane (left) is a good approximation

$\hat{\mathbf{v}} = \{\hat{v}_\gamma\}$ denotes the collection of one-body operators. We introduce a shift to obtain an alternative propagator:

$$\int e^{-\frac{\mathbf{x}^2}{2}} e^{\mathbf{x}\cdot\bar{\mathbf{x}} - \frac{\bar{\mathbf{x}}^2}{2}} e^{(\mathbf{x}-\bar{\mathbf{x}})\cdot\hat{\mathbf{v}}} d\mathbf{x} \,, \tag{30}$$

which is exact for any choice of the shift $\bar{\mathbf{x}}$, including complex shifts.

We recall that the random walk is supposed to lead to a MC sampling of the coefficient $\alpha_\phi$ in Eq. (4):

$$|\Psi_0\rangle \doteq \sum_{\{\phi\}} w_\phi |\phi\rangle \,. \tag{31}$$

The sum in Eq. (31), which is over the population of walkers after an "equilibration" portion of the open-ended random walk has been discarded, is in a Monte Carlo sense, and is typically much smaller than the sum in Eq. (4). The weight of each walker $|\phi\rangle$, $w_\phi$, can be thought of as 1 (all walkers with equal weight); it is allowed to fluctuate only for practical (efficiency) consideration.

Using the idea of importance sampling, we seek to replace Eq. (31) by the following to sample Eq. (4):

$$|\Psi_0\rangle = \sum_\phi w_\phi \frac{|\phi\rangle}{\langle\Psi_T|\phi\rangle} \,, \tag{32}$$

where any overall phase of the walker $|\phi\rangle$ is canceled in the numerator and denominator on the right-hand side (Zhang and Krakauer 2003). This implies a modification to the propagator in Eq. (30):

$$\int \langle \Psi_T | \phi'(\mathbf{x}) \rangle e^{-\frac{\mathbf{x}^2}{2}} e^{\mathbf{x}\bar{\mathbf{x}} - \bar{\mathbf{x}}^2/2} e^{(\mathbf{x}-\bar{\mathbf{x}})\cdot \hat{\mathbf{v}}} \frac{1}{\langle \Psi_T | \phi \rangle} d\mathbf{x}, \tag{33}$$

where $|\phi'(\mathbf{x})\rangle = e^{(\mathbf{x}-\bar{\mathbf{x}})\cdot \hat{\mathbf{v}}}|\phi\rangle$ and the trial wave function $|\Psi_T\rangle$ represents the best guess to $|\Psi_0\rangle$. Let us define the following shorthand:

$$\bar{\mathbf{v}} \equiv -\frac{\langle \Psi_T | \hat{\mathbf{v}} | \phi \rangle}{\langle \Psi_T | \phi \rangle} \sim \mathcal{O}(\sqrt{\Delta\tau}); \quad \bar{\mathbf{v}^2} \equiv \frac{\langle \Psi_T | \hat{\mathbf{v}}^2 | \phi \rangle}{\langle \Psi_T | \phi \rangle} \sim \mathcal{O}(\Delta\tau). \tag{34}$$

We can then evaluate the ratio $\langle \Psi_T | \phi'(\mathbf{x}) \rangle / \langle \Psi_T | \phi \rangle$ in Eq. (33) by expanding the propagator (Moskowitz et al. 1982; Zhang and Krakauer 2003; Purwanto and Zhang 2004) to $\mathcal{O}(\tau)$, to obtain:

$$\frac{\langle \Psi_T | \phi'(\mathbf{x}) \rangle}{\langle \Psi_T | \phi \rangle} e^{\mathbf{x}\cdot\bar{\mathbf{x}} - \bar{\mathbf{x}}^2/2} \doteq \exp\left[ -(\mathbf{x}-\bar{\mathbf{x}})\cdot\bar{\mathbf{v}} + \frac{1}{2}(\mathbf{x}-\bar{\mathbf{x}})^2\bar{\mathbf{v}^2} - \frac{1}{2}(\mathbf{x}-\bar{\mathbf{x}})^2\bar{\mathbf{v}}^2 + \mathbf{x}\cdot\bar{\mathbf{x}} - \bar{\mathbf{x}}^2/2 \right]. \tag{35}$$

The optimal choice of the shift $\bar{\mathbf{x}}$, which we shall refer to as a force bias, minimizes the fluctuation of Eq. (35) with respect to $\mathbf{x}$, and it is straightforward to show that it is $\bar{\mathbf{x}} = \bar{\mathbf{v}}$. With this choice, Eq. (33) can be written approximately as (Zhang 2013)

$$\int e^{-\frac{\mathbf{x}^2}{2}} e^{(\mathbf{x}-\bar{\mathbf{v}})\cdot\hat{\mathbf{v}}} e^{\frac{\bar{\mathbf{v}}^2}{2}} d\mathbf{x}. \tag{36}$$

Restoring $\hat{H}_1$, we obtain the complete propagator:

$$\int e^{-\frac{\mathbf{x}^2}{2}} \exp\left[ -\frac{\Delta\tau \hat{H}_1}{2} \right] \exp\left[ (\mathbf{x}-\bar{\mathbf{v}})\cdot\hat{\mathbf{v}} \right] \exp\left[ -\frac{\Delta\tau \hat{H}_1}{2} \right] \exp[-\Delta\tau E_L(\phi)] \, d\mathbf{x}, \tag{37}$$

where $E_L$ is the local energy, the mixed estimate of the Hamiltonian:

$$E_L(\phi) \equiv \frac{\langle \Psi_T | \hat{H} | \phi \rangle}{\langle \Psi_T | \phi \rangle}. \tag{38}$$

In the limit of an exact $|\Psi_T\rangle$, $E_L$ is a *real* constant, and the weight of each walker remains real. The mixed estimate for the energy from Eq. (15) is phaseless:

$$E_0^c = \frac{\sum_\phi w_\phi E_L(\phi)}{\sum_\phi w_\phi}. \tag{39}$$

With a general $|\Psi_T\rangle$ which is not exact, a natural approximation is to replace $E_L$ in Eq. (37) by its real part, Re$E_L$. The same replacement is then necessary in Eq. (39).

When $\hat{B}(\mathbf{x})$ (i.e., $\hat{\mathbf{v}}$) is real, this formalism reduces to the so-called constrained-path approximation (Zhang et al. 1997). Regardless of whether $\hat{\mathbf{v}}$ is real, the shift $\bar{\mathbf{x}}$ diverges as the random walk in the complex plane (see the right panel of Fig. 4) approaches the origin, i.e., as $\langle\Psi_T|\phi'\rangle \to 0$. The effect of the divergence is to move the walker away from the origin. With a *real* $\hat{\mathbf{v}}$, the random walkers move only on the real axis. If they are initialized to have positive overlaps with $|\Psi_T\rangle$, $\bar{\mathbf{x}}$ will ensure that the overlaps remain positive throughout the random walk.

For a general case with a complex $\hat{\mathbf{v}}$, however, the formalism above by itself is not sufficient to remove the phase problem. To see this we consider the phase of $\langle\Psi_T|\phi'(\mathbf{x}-\bar{\mathbf{x}})\rangle/\langle\Psi_T|\phi\rangle$, which we denote by $\Delta\theta$. In general, $\Delta\theta \sim \mathcal{O}(-\mathbf{x}\text{Im}(\bar{\mathbf{x}}))$ is non-zero. This means that the walkers will undergo a random walk in the complex plane. At large $\beta$ they will therefore populate the complex plane symmetrically, independent of their initial positions. This is illustrated in the right panel of Fig. 4, which shows $\langle\Psi_T|\phi\rangle$ for a three-dimensional jellium model with two electrons at $r_s = 10$ for a total projection time of $\beta = 250$ (taken from Zhang 2013). The random walk is "rotationally invariant" in the complex plane, resulting in a vanishing signal-to-noise ratio asymptotically, even though the walkers are all real initially with $\langle\Psi_T|\phi^{(0)}\rangle = 1$. An alternative but related way to state the problem is that, despite the divergence of $\bar{\mathbf{x}}$, the buildup of a finite density at the origin of the complex plane cannot be prevented, unlike in the one-dimensional situation (real $\langle\Psi_0|\phi\rangle$, sign problem). Near the origin the local energy $E_L$ diverges, which causes diverging fluctuations in the weights of walkers when the density does not vanish.

Thus the second ingredient of the constraint for the phase problem is to project the random walk back to "one-dimension." This is done by reducing the weight of the walker in each step by the angular deviation of the overlap in the complex plane:

$$w_{\phi'} \to w_{\phi'} \max\{0, \cos(\Delta\theta)\}. \qquad (40)$$

A prerequisite for this approximation to work well is the importance-sampling transformation, which has eliminated the leading order in the overall phase of $|\phi\rangle$ in the propagator in Eq. (35). Given the transformation, several alternative forms to the projection in Eq. (40) were found to give similar accuracy (Zhang and Krakauer 2003; Zhang et al. 2005; Purwanto and Zhang 2005; Zhang 2013).

We can now summarize each step in the constrained path AFQMC formalism as follows. For each random walker $|\phi\rangle$ in the current population $\{|\phi\rangle, w_\phi\}$,

**(a)** Sample $\mathbf{x}$ and propagate the walker to $|\phi'\rangle$

$$|\phi\rangle \to |\phi'\rangle = \exp\left[-\frac{\Delta\tau\hat{H}_1}{2}\right] \exp\left[(\mathbf{x}-\bar{\mathbf{v}})\cdot\hat{\mathbf{v}}\right] \exp\left[-\frac{\Delta\tau\hat{H}_1}{2}\right]|\phi\rangle, \qquad (41)$$

**(b)** Update the weight of the walker

$$w_\phi \to w_{\phi'} = w_\phi \exp\left[-\Delta\tau \cdot \text{Re}\left(E_L(\phi') + E_L(\phi)\right)/2\right] \cdot \max\{0, \cos(\Delta\theta)\}.$$
$$(42)$$

Walkers so generated represent the ground-state wave function with importance sampling, in the sense of Eq. (32).

For additional technical details, we refer the reader to Zhang (2013) and Motta and Zhang (2018), and references therein, for example, re-orthogonalization procedures (White et al. 1989; Zhang 2003) to stabilize the walkers against numerical roundoff errors during the propagation, population control (Umrigar et al. 1993; Zhang et al. 1997) to regularize the branching process, a hybrid alternative (Purwanto et al. 2009a) to the local energy formalism in Eq. (36) to reduce computational cost in evaluating $E_l$, correlated sampling (Shee et al. 2017), constraint release (Shi and Zhang 2013), etc.

## 3.3   Back-Propagation for Observables and Correlation Functions

To calculate a correlation function or the expectation value of an observable which does not commute with the Hamiltonian, the mixed estimate in Eq.(15) is biased, and the full estimator in Eq. (14) needs to be computed. In the path-integral form in Eq. (27), this is straightforward. With the open-ended random walks, however, it is slightly more involved. A back-propagation (BP) technique (Zhang et al. 1997; Purwanto and Zhang 2004; Motta and Zhang 2017) is employed.

The idea of the BP is to create two coupled populations to represent the bra and ket in Eq. (14), respectively. Because the population in the random walk is importance-sampled, two independent populations which are uncoupled would lead to large fluctuations in the estimator after the importance functions have been "undone" (Purwanto and Zhang 2004). In BP, we choose an iteration $n$ and store the entire population $\{|\phi_k^{(n)}\rangle, w_k^{(n)}\}$, where $k$ labels the walker in the population. As the random walk proceeds from $n$, we keep track of the following two items for each new walker: (1) the sampled auxiliary-field values that led to the new walker from its parent walker and (2) an integer label that identifies the parent. After an additional $m$ iterations, we carry out the back-propagation: For each walker $l$ in the $(n + m)$-th (current) population, we initiate a determinant $\langle\psi_T|$ and act on it with the corresponding propagators but taken in reverse order. The $m$ successive propagators are constructed from the items stored between steps $n + m$ and $n$, with $\exp(-\Delta\tau\hat{H}_1/2)$ inserted where necessary. The resulting determinants $\langle\bar{\phi}_l^{(m)}|$ are combined with its parent from iteration $n$, $|\phi_k^{(n)}\rangle$, to compute $\langle\mathcal{O}\rangle_{\text{BP}}$, where $k$ is the index of the walker at step $n$ from which walker $l$ at step $(n + m)$ descended.

In molecular systems, an improvement over the standard procedure has been proposed (Motta and Zhang 2017). The approach, called back-propagation with path restoration (BP-PRes), allows one to "undo" some of the effect of the constraint in

the forward direction (the cos projection and the omission of the phase in $E_l$ in the weight). This reduced the effect of the constraint, which is applied in the forward direction and does not preserve reversal symmetry in imaginary time. With these advances, accurate observables and atomic forces have been obtained in molecules, paving the way for geometry optimization and ab initio molecular dynamics with AFQMC.

Another recent development in methodology is the computation of imaginary-time correlation functions and excitations. The techniques (Vitali et al. 2016), which have been applied in model systems and ultracold atoms so far, are directly applicable to real materials.

## 4    Illustrative Results

The AFQMC method has been applied to lattice models, realistic solids (using plane-wave basis and pseudo potentials), molecular systems (using Gaussian basis sets), and downfolded model Hamiltonians of real materials (using DFT orbitals as basis sets). The method is just coming into form, and rapid advances in algorithmic development and in applications are ongoing. We briefly mention a few examples here to provide a flavor of how it has been applied to date to tackle problems of electron correlations in materials.

For lattice models, most of the applications involve "only" a sign problem, because of the short-range nature of the interaction. Here the constraint has no $\theta$ projection and reduces to a sign constraint. A large body of results exist, including recent benchmark results (LeBlanc et al. 2015). Systems of $\mathcal{O}(1000)$ electrons have been treated quite routinely. The AFQMC method has demonstrated excellent capabilities and accuracy, illustrating its potential as a general many-body computational paradigm. A key recent development (Qin et al. 2016) is to use the density or density matrix computed from AFQMC as a feedback into a mean-field calculation. The trial wave function $|\Psi_T\rangle$ obtained from the mean-field is then fed back into the AFQMC as a constraint, and a self-consistent constraining condition is achieved. This has led to further improvement in the accuracy and robustness of the calculation (Qin et al. 2016; Zheng et al. 2017).

For molecular systems, a recent review article is available (Motta and Zhang 2018) which describes in more detail the application of AFQMC in quantum chemistry. The formulation of AFQMC with Gaussian basis sets has been extremely valuable. Direct comparisons can be made with high-level QC results, which have provided valuable benchmark information and have been crucial in gauging the AFQMC method as a general approach. Figure 5 illustrates the results on molecules using both plane-wave plus pseudopotentials and Gaussian basis sets. In these calculations we have operated largely in an automated mode, inputting only the DFT or HF solutions as $|\Psi_T\rangle$. This illustrates a potential mode of operation for AFQMC as a "post-processing" approach for molecules and solids where additional accuracy is desired beyond standard DFT.
**Fig. 5** Calculated binding energies of molecules compared with experimental values. (Taken from Zhang (2013); Esler et al. 2008). The discrepancy between theory and experiment is plotted. Included are $sp$-bonded molecules, first- and second-row post-$d$ elements, and transition metal oxides. Several different forms of the AFQMC calculations were tested, including all-electron Gaussian basis sets, Gaussian basis with effective-core potentials, and plane wave with pseudopotential. The AFQMC is fed a trial wave function to start, which is taken directly from DFT [with either LDA or the generalized-gradient approximation (GGA) functionals] or HF. The corresponding DFT or HF results are also shown. As can be readily observed, the AFQMC results are in excellent agreement with experiment and significantly improve upon the values from DFT and HF

A benchmark study (Motta et al. 2017) was recently carried out involving a large set of modern many-body methods. AFQMC was among the methods included; consistent with previous findings, the accuracy of AFQMC is found to be comparable to CCSD(T), the gold standard in chemistry (Bartlett and Musiał 2007; Crawford and Schaefer 2000), near equilibrium geometry. For bond breaking, AFQMC was able to maintain systematic accuracy. Large basis sets and system sizes were reached and an accurate equation of state was obtained.

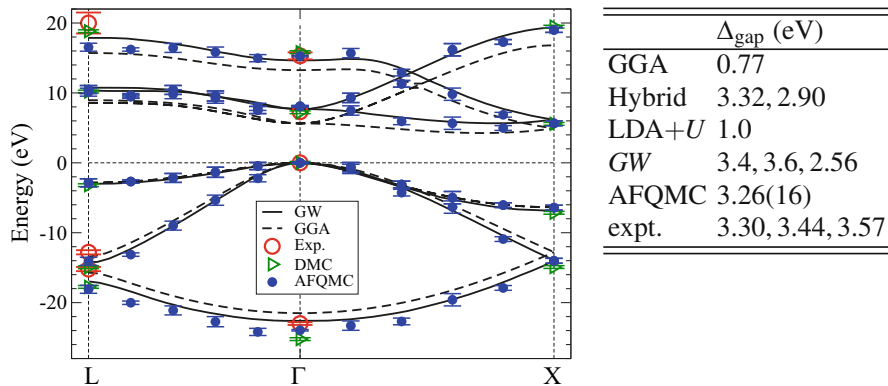
The AFQMC method can be used to study excited states. Excited states distinguished by different symmetry from the ground state can be computed in a manner similar to the ground state. For other excited states, prevention of collapse into the ground state and control of the fermion sign/phase problem are accomplished by a constraint using an excited state trial wave function (Purwanto et al. 2009b). An additional orthogonalization constraint is formulated to use virtual orbitals in solids for band structure calculations (Ma et al. 2013). These constraints are not as "clean" or rigorous as that for the ground state. Use of improved trial wave functions (e.g., multi-determinant $|\Psi_T\rangle$ in molecules) and the imposition of symmetry properties (Shi and Zhang 2013) often lead to improved results. Tests in the challenging case of the $C_2$ molecule yielded spectroscopic constants in excellent agreement with experiment (Purwanto et al. 2009b). In Fig. 6 results from an application in solids are shown for the diamond band structure and for the fundamental band gap in wurtzite ZnO (Ma et al. 2013).


**Fig. 6** Computation of excitations and many-body quasiparticle band structures. (Taken from Ma et al. 2013). The figure presents results on the band gap in diamond. Blue is AFQMC results; $GW$ and DFT band structures are plotted by solid and dashed lines, respectively. Diffusion Monte Carlo (DMC) results at high symmetry points $\Gamma$, $X$, and $L$ are indicated by green triangles. Experimental values are shown as red circles. The table shows the calculated fundamental band gap of wurtzite ZnO, compared with experiment (and three DFT-based methods and $GW$)

Plane-wave calculations in AFQMC can be built on standard plane-wave technologies in DFT calculations, as we have outlined. Norm-conserving pseudopotentials, including multiple-projector pseudopotentials, can be implemented straightforwardly (Ma et al. 2017). In order to reduce the cost of full plane-wave AFQMC calculations, a downfolding approach (Ma et al. 2015) has been developed. The idea is to use Kohn-Sham orbitals (occupied and virtual) as basis sets. The approach is illustrated in Fig. 7. The size of the basis set in the largest calculation on the right, after downfolding, is more than an order of magnitude smaller than the total number of plane waves, leading to large savings in the AFQMC computation.

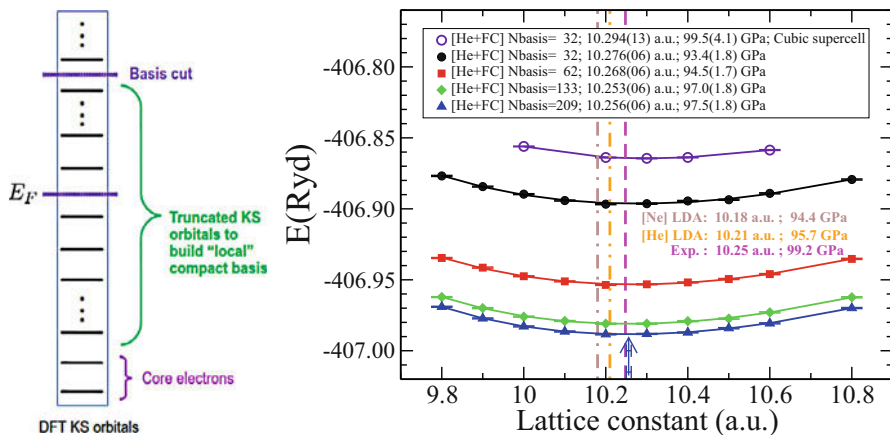
Figure 8 illustrates an application of AFQMC to the adsorption of Co atoms on graphene. The goal of the study was to determine the stability and magnetic state of the Co adatom as a function of its distance from the graphene sheet. The sensitivity and complexity of the energetics requires a correlated treatment. In addition to serving as a useful benchmark, the computed results provided an explanation for experimental results with Co on free-standing graphene (Virgus et al. 2014). The AFQMC calculation was performed by embedding it in a DFT calculation to extend length scales, as illustrated on the right. After the DFT is performed, a many-body Hamiltonian is generated, using a procedure similar to that of producing a frozen-core Hamiltonian (Purwanto et al. 2013), except the "core" here is actually the "outer" region indicated on the right. (Orbital localization procedures are applied as needed.) The resulting Hamiltonian, which describes the region inside the shaded circle embedded in the environment of the outer region whose orbitals are frozen, is then treated by AFQMC. From a QC perspective, this approach can also be viewed as casting AFQMC as a general "solver' for a (very large) active space (Motta and Zhang 2018).


**Fig. 7** Pseudopotential-free calculations in solids, and a simple "down-folding" approach to generate realistic model Hamiltonians. The **left panel** illustrates a scheme to use Kohn-Sham (KS) orbitals obtained from a DFT calculation as basis set for AFQMC. The DFT is performed with a plane-wave basis using a helium-core. Keeping all the KS orbitals, including virtual orbitals, below a certain cutoff ("Basis cut"), we compute the matrix elements with these orbitals as basis, to obtain a many-body Hamiltonian, which is then fed into the AFQMC. In the AFQMC, the KS orbitals corresponding to the neon-core are frozen (Purwanto et al. 2013). In the **right panel**, the calculated equation of state (Ma et al. 2015) is shown for a sequence of "Basis cut" values. The calculated equilibrium lattice constant and bulk modulus are in excellent agreement with experiment

**Fig. 8** Co-adsorption on graphene and embedding AFQMC within DFT. The figure (Taken from Virgus et al. 2014) shows computed binding energy of Co on graphene, as a function of the distance $h$ between the Co atom and the graphene plane. Squares, diamonds, circles, and triangles correspond to hollow (H, as illustrated on the right), bridge (B), and top (T) sites and the van der Waals region, respectively. The dashed line indicates the low-spin H site (open squares). Shaded areas are one-$\sigma$ estimates of uncertainties, including the statistical errors in AFQMC. The right illustrates the embedding scheme for these calculations. The "inner" region with Co and the C atoms inside the circle are treated by AFQMC, with the "outer" region providing a frozen environment

# 5 Summary and Outlook

In this chapter, we have described a general computational framework for many-body calculations which combines a field-theoretic description with stochastic sampling. The approach, referred to as auxiliary-field quantum Monte Carlo (AFQMC), is based on a stochastic superposition of DFT-like calculations. We have shown how the framework can be applied to carry out ab initio electronic structure calculations. As mentioned, some additional references for further details include a set of lecture notes (Zhang 2013) (on which some of the sections in this chapter are based), a pedagogical code for lattice models written in Matlab (Nguyen et al. 2014) and a review on molecular systems (Motta and Zhang 2018).

The AFQMC approach has been applied in both condensed matter physics and quantum chemistry. It has been implemented with both plane waves/pseudopotentials and with Gaussian basis sets. We have discussed both types of calculations, as well as a combination which uses Kohn-Sham orbitals generated from plane-wave DFT as a basis to downfold the Hamiltonian for a solid. In all of these, as well as in many applications to lattice models for strong electron correlation and for ultracold atom systems, AFQMC has shown strong promise with its scalability (with system size and with parallel computing platforms), capability (total energy computation and beyond), and accuracy.

The AFQMC method has low-polynomial (cubic) scaling with system size, by using Monte Carlo sampling to treat the exponential growth of the Hilbert space. It samples the many-body ground state by a linear combination of non-orthogonal Slater determinants. The connection with independent-electron calculations, as we have highlighted, makes it straightforward to build AFQMC as a framework on top of traditional DFT or HF calculations and take advantage of the many existing technical machineries developed over the past few decades in materials modeling.

Recent developments in the computation of atomic forces and geometry optimization, and the treatment of spin-orbit coupling and general magnetic order, are manifestations of this connection. They significantly enhance the capability of stochastic methods for electronic structure. Similarly, the formulation for superconducting Hamiltonians and for embedding AFQMC in independent-electron calculations to extend length scales will broaden the reach in materials computation.

The AFQMC is approximate, because of the constraint to control the sign/phase problem. A major focus during the development of the framework has been to systematically test (and improve) the accuracy of AFQMC. A large database has now been accumulated, thanks in part to the major many-electron benchmark initiatives recently. The accuracy that can be achieved by AFQMC with its present stage of development is such that many applications are now within reach in materials modeling. A variety of new developments are possible and currently being pursued.

The structure of the open-ended random walk, as illustrated in Fig. 3, makes AFQMC ideally suited for modern high-performance computing platforms, with

exceptional capacity for parallel scaling. The rapid growth of high-performance computing resources will thus provide a strong boost to the application of AFQMC in the study of molecules and solids.

The development of AFQMC is entering an exciting new phase. A large number of possible directions can be pursued, including many opportunities for algorithmic improvements and speedups. These will be spurred forward and stimulated by growth in applications, which we hope will in turn allow more rapid realization of a general many-body computational framework for materials.

**Abstract**

Macroscopic polarization **P** and magnetization **M** are the most fundamental
concepts in textbook treatments of condensed media. They are intensive vector
quantities that intuitively carry the meaning of dipole per unit volume. But for
many years, both **P** and the orbital term in **M** evaded even a precise microscopic
definition and severely challenged quantum mechanical calculations. Contrary
to a widespread incorrect belief, **P** *has nothing to do* with the periodic charge
distribution in the bulk of a polarized crystal; analogously, the orbital term
in **M** has nothing to do with the bulk current distribution. When a bounded
sample is addressed, **P** and **M** can indeed be expressed in terms of charge
and current distributions, but the boundary contributions are essential. The
field has undergone a genuine revolution since the early 1990s. The modern
theory of polarization, based on a Berry phase, is a mature topic since the
late 1990s; it is now implemented in most first-principle electronic structure
codes. Many calculations have addressed various phenomena (ferroelectricity,
piezoelectricity, lattice dynamics, infrared spectra of liquid, and amorphous
systems) in several materials and are in spectacular agreement with experiments;
they have provided thorough understanding of the behavior of ferroelectric and
piezoelectric materials. The modern theory of orbital magnetization started in
2005, but some fundamental issues are still in development at the time of writing
(2017). Only a few first-principle calculations have appeared so far.

# 1    Introduction

The elementary definitions of macroscopic polarization **P** and orbital magnetization
**M** address a bounded sample in the large-sample limit:

$$\mathbf{P} = \frac{\mathbf{d}}{V} = \frac{1}{V} \int d\mathbf{r}\ \mathbf{r} \rho^{(\text{micro})}(\mathbf{r}) \tag{1}$$

$$\mathbf{M} = \frac{\mathbf{m}}{V} = \frac{1}{2cV} \int d\mathbf{r}\ \mathbf{r} \times \mathbf{j}^{(\text{micro})}(\mathbf{r}). \tag{2}$$

Here and in the following, we indicate with **M** the orbital term only; $\rho^{(\text{micro})}(\mathbf{r})$ and
$\mathbf{j}^{(\text{micro})}(\mathbf{r})$ are the microscopic charge and current densities, and $V$ is the sample
volume. The previous expressions are clearly dominated by surface contributions,
while instead phenomenologically **P** and **M** are bulk properties.

In general, electronic structure theory addresses bulk material properties by
adopting periodic Born-von Kármán boundary conditions (PBCs), whose main
virtue is that the system has no surface by construction. But the textbook definitions
of **P** and **M**, Eqs. (1) and (2), cannot be implemented within PBCs for a common
reason, i.e., the unboundedness of the position operator **r**. Indeed, the multiplicative
operator **r** is a "forbidden" operator within PBCs (Resta 1998).

The drawback was overcome – and the nasty position operator was effectively tamed – in the early 1990s for **P** and since 2005 onward for **M**. It was realized that for an unbounded periodic system **P** cannot be determined – even in principle – from a knowledge of the microscopic charge density $\rho^{(\mathrm{micro})}(\mathbf{r})$; analogously, **M** cannot be determined from a knowledge of the microscopic current density $\mathbf{j}^{(\mathrm{micro})}(\mathbf{r})$. The expressions for **P** and **M** in use in modern electronic structure theory (Resta 1994; Vanderbilt and King-Smith 1993; Resta and Vanderbilt 2007; Resta 2010; Thonhauser 2011; Spaldin 2012) look somewhat exotic and do not bear any resemblance whatsoever to Eqs. (1) and (2); these expressions are instead deeply rooted in the geometry of the electronic ground state.

The modern theory of polarization is a mature topic since the late 1990s and is implemented in the most popular electronic structure codes, within both density-functional and Hartree-Fock frameworks. The physical properties addressed, for real materials, are spontaneous polarization, Born (alias infrared) effective charges, infrared spectra, and piezoelectric coefficients.

The total magnetization of a sample is the sum of a spin and an orbital contribution: the latter is typically a few percent of the total. The spin term does not present a challenge for electronic structure calculations, while instead before the advent of the modern theory (2005–2006), no formula was available for evaluating orbital magnetization in bulk materials. The theory has been implemented at the first-principle level, e.g., to evaluate **M** in the ferromagnetic metals Ni, Co, and Fe (Ceresoli et al. 2010a; Lopez et al. 2012); it has also been used to address the NMR (nuclear magnetic resonance) shielding tensors in some paradigmatic cases (Thonhauser et al. 2009; Ceresoli et al. 2010b).

At variance with polarization theory, the modern theory of magnetization is partly a work in progress at the time of writing (2017); outstanding contributions appeared very recently (Bianco and Resta 2013; Marrazzo and Resta 2016; Resta 2018). These recent papers emphasize some very important features – detailed below in this chapter – which make **P** to behave very differently from **M**. This is remarkable, given the very similar textbooks definitions (Eqs. (1) and (2)) and given the common drawback therein. It is also remarkable given that the modern expressions for **P** and **M**, as integrals in reciprocal space in terms of Bloch orbitals, look apparently – and only apparently – very similar.

At the phenomenological level, there is another remarkable difference between **P** and **M** which is worth stressing at this point. **P** is well defined only for insulators, which strictly speaking exist only at zero temperature; **M** instead is well defined for both insulators and metals, even at finite temperature. Here we provide only the zero-temperature theory for **M**, as implemented in electronic structure codes (so far density-functional theory only).

The modern theories provide the values of **P** and **M** in vanishing macroscopic fields (electric and magnetic): this concept is illustrated in Sect. 2. Following it, Sect. 3 provides an overview of polarization theory, and Sect. 4 provides the theory in one dimension, where the formulation can be made particularly clear. Section 5 presents the full polarization theory, including the formulas actually implemented in first-principle calculations. Section 6 is an overview of the modern theory of

orbital magnetization, and Sect. 7 is the detailed presentation of it. Both theories are presented here in an original way, which differs from the previous published reviews (Resta 1994; Vanderbilt and Resta 2006; Resta and Vanderbilt 2007; Resta 2010; Thonhauser 2011; Spaldin 2012), and does not follow the historical developments.

## 2    Electric and Magnetic Fields

### 2.1    The Fields E and B

The modern theories – illustrated throughout the present chapter – yield the **P** and **M** values in *absence* of macroscopic fields **E** and **B**. In this section we explain with some detail what this means in the framework of modern electronic structure theory, where one addresses bulk quantities without dealing with real bounded samples.

The microscopic fields $\mathbf{E}^{(\mathrm{micro})}(\mathbf{r})$ and $\mathbf{B}^{(\mathrm{micro})}(\mathbf{r})$ are ideally measurable inside the material, with no reference to what happens outside a bounded sample. Their macroscopic averages **E** and **B**, i.e., the internal (or screened) macroscopic fields, are therefore the variables of choice for a first-principle description. It must be realized that, insofar as we address an infinite system with no boundaries, the macroscopic field (either **E** or **B**) is just an arbitrary boundary condition. To realize this, it is enough to focus on the electrical case for a crystalline material. The microscopic charge density is neutral in average and lattice periodical; the value of **E** is just an arbitrary boundary condition for the integration of Poisson's equation. The usual choice (performed within all electronic structure codes) is to impose a lattice-periodical Coulomb potential, i.e., $\mathbf{E} = 0$. Imposing a given nonzero value of **E** is equally legitimate (in insulators), although technically more difficult (Souza et al. 2002; Umari and Pasquarello 2002).

More generally, even for a noncrystalline and/or correlated large and macroscopically homogeneous sample, the adoption of PBCs amounts to assuming that both the Coulomb potential and the vector potential obey PBCs, ergo $\mathbf{E}^{(\mathrm{micro})}(\mathbf{r})$ and $\mathbf{B}^{(\mathrm{micro})}(\mathbf{r})$ average to zero over the sample.

### 2.2    The Fields D and H

Macroscopic descriptions of homogeneous media customarily adopt the electro-magnetic free-energy density $\mathscr{F}(\mathbf{E}, \mathbf{H})$, where the independent variables are the fields **E** and **H** (not **B**). The conjugate variables are

$$\mathbf{D} = \mathbf{E} + 4\pi\mathbf{P} = -4\pi\frac{\partial\mathscr{F}}{\partial\mathbf{E}}$$

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M} = -4\pi\frac{\partial\mathscr{F}}{\partial\mathbf{H}}. \tag{3}$$

The most general expansion of $\mathscr{F}(\mathbf{E}, \mathbf{H})$ up to second order around $\mathbf{E} = 0$ and $\mathbf{H} = 0$ reads

$$\mathscr{F}(\mathbf{E}, \mathbf{H}) = \mathscr{F}_0 - \mathbf{P}_0 \cdot \mathbf{E} - \mathbf{M}_0 \cdot \mathbf{H} - \frac{1}{8\pi} \mathbf{E} \overset{\leftrightarrow}{\varepsilon} \mathbf{E} - \frac{1}{8\pi} \mathbf{H} \overset{\leftrightarrow}{\mu} \mathbf{H} - \frac{1}{4\pi} \mathbf{E} \overset{\leftrightarrow}{\alpha} \mathbf{H}, \quad (4)$$

where textbooks ignore the last term.

It was discovered by Dzyaloshinskii (1960) that the tensor $\overset{\leftrightarrow}{\alpha}$ is in general nonzero in crystals where both inversion symmetry and time-reversal symmetry are absent. In fact $\mathbf{E}$ is odd under inversion and even under time-reversal, while the opposite happens for $\mathbf{H}$: therefore their combination in the last term of Eq. (4) is odd under each of the two transformation. The tensor $\overset{\leftrightarrow}{\alpha}$ is responsible for the linear magnetoelectric effect, which follows from Eq. (3): an $\mathbf{H}$ field induces polarization (at $\mathbf{E} = 0$), and conversely an $\mathbf{E}$ field induces magnetization (at $\mathbf{H} = 0$). We are not discussing magnetoelectric materials in this chapter, and we therefore set $\overset{\leftrightarrow}{\alpha} = 0$ in the following.

As for the remaining second order terms, $\overset{\leftrightarrow}{\varepsilon}$ is the macroscopic dielectric tensor, and $\overset{\leftrightarrow}{\mu}$ is the magnetic permeability tensor. We draw attention to the *minus* signs, explained, e.g., in the Landau textbook (Landau and Lifshitz 1984).

The first order terms yield the spontaneous polarization $\mathbf{P}_0 = -\partial \mathscr{F}/\partial \mathbf{E}$ and magnetization $\mathbf{M}_0 = -\partial \mathscr{F}/\partial \mathbf{H}$, where the derivatives are evaluated at $\mathbf{E} = 0$ and $\mathbf{H} = 0$.

## 2.3   B vs. H

As said above, $\mathbf{E}$ and $\mathbf{H}$ are customarily chosen as the independent variables. As for the electric field, this is clearly the natural choice. We have stressed that $\mathbf{E}$ (not $\mathbf{D}$) is the *internal* field, which is measurable in principle inside the material. The macroscopic field $\mathbf{E}$ is also a control parameter in first-principle calculations. Matters are different in the magnetic case: the *internal* field, measurable in principle inside the material, is $\mathbf{B}$, not $\mathbf{H}$. In fact the modern theory of magnetization, as discussed in the present chapter, addresses magnetization in zero $\mathbf{B}$ field.

So, why instead one adopts $\mathbf{H}$, and not $\mathbf{B}$, as the independent variable in the free-energy density? There are several reasons. Phenomenologically, the experimenter directly controls $\mathbf{E}$ (e.g., via capacitors) and $\mathbf{H}$ (via, e.g., solenoids or generally currents); the fields $\mathbf{E}$ and $\mathbf{H}$ are directly read on the instruments. Several textbooks even call $\mathbf{H}$ the "magnetic field," which I find strongly misleading. I adopt the nomenclature of the good textbooks, such as Feynman et al. (1964) and Griffiths (1999) popular textbooks, where $\mathbf{B}$ is called "magnetic field" and $\mathbf{H}$ is just "$\mathbf{H}$." All formulas have a pretty symmetric expression in terms of $\mathbf{E}$ and $\mathbf{H}$; Feynman warns however that "although the equations are analogous, the physics is not analogous." The equations would look asymmetrical and ugly using the genuine magnetic field $\mathbf{B}$ instead.

As said above, custom dictates that spontaneous magnetization is defined as $\mathbf{M}_0 = -\partial \mathscr{F}/\partial \mathbf{H}$: this is not what is addressed throughout this chapter. However $\mathbf{B}$ and $\mathbf{H}$ are related by the magnetic permeability tensor as $\mathbf{B} = \overleftrightarrow{\mu} \, \mathbf{H}$, and in normal materials the permeability difference from one (in Gaussian units) is of the order of $(1/137)^2$. There is then little difference between $\mathbf{M}_0$ as addressed in this chapter and $\mathbf{M}_0$ as customarily addressed. Whenever needed, the conversion of the response tensors from their $(\mathbf{E}, \mathbf{H})$ definition to the $(\mathbf{E}, \mathbf{B})$ counterpart requires only straightforward algebra.

## 2.4    Shape Issues

As explained so far, there is no need of addressing bounded samples and external vs. internal fields from a theoretician's viewpoint. Nonetheless a brief digression is in order, given that experiments *are* performed over bounded samples, often in external fields. Suppose a bounded macroscopic sample is inserted in a constant external field $\mathbf{E}^{(\text{ext})}$: the microscopic field $\mathbf{E}^{(\text{micro})}(\mathbf{r})$ coincides with $\mathbf{E}^{(\text{ext})}$ far away from the sample, while it is different inside because of screening effects. If we choose an homogeneous sample of *ellipsoidal shape*, then the macroscopic average of $\mathbf{E}^{(\text{micro})}(\mathbf{r})$, i.e., the macroscopic screened field $\mathbf{E}$, is constant in the bulk of the sample. The shape effects are embedded in the depolarization coefficients (Landau and Lifshitz 1984): the simplest case is the extremely oblate ellipsoid, i.e., a slab of a macroscopically homogeneous dielectric; more details are given in Resta (2010). For the slab geometry in a vanishing external field $\mathbf{E}^{(\text{ext})}$, the internal field $\mathbf{E}$ vanishes when $\mathbf{P}$ is parallel to the slab (transverse polarization), while $\mathbf{E} = -4\pi\mathbf{P}$ is the depolarization field when $\mathbf{P}$ is normal to the slab (longitudinal polarization): see Fig. 1.

The magnetic case can be discussed along similar lines. Suppose a bounded macroscopic sample is inserted in a constant external field $\mathbf{B}^{(\text{ext})}$: the microscopic field $\mathbf{B}^{(\text{micro})}(\mathbf{r})$ coincides with $\mathbf{B}^{(\text{ext})}$ far away from the sample, while it is different inside because of screening effects. If we choose an homogeneous sample of

**Fig. 1** Macroscopic polarization $\mathbf{P}$ in a slab normal to $z$, for a vanishing external field $\mathbf{E}^{(\text{ext})}$. Left: when $\mathbf{P}$ is normal to the slab, a depolarizing field $\mathbf{E} = -4\pi\mathbf{P}$ is present inside the slab, and charges are present at its surface, with areal density $\sigma_{\text{surface}} = \mathbf{P} \cdot \mathbf{n}$ Right: when $\mathbf{P}$ is parallel to the slab, no depolarizing field and no surface charge is present
**Fig. 2** Macroscopic magnetization **M** in a slab normal to $z$, for a vanishing external field $\mathbf{B}^{(\text{ext})}$. Left: when **M** is normal to the slab, no demagnetizing field and no surface current is present. Right: when **M** is parallel to the slab, a demagnetizing field $\mathbf{B} = 4\pi\mathbf{M}$ is present inside the slab, and dissipationless currents $\mathbf{K}_{\text{surface}} = c\,\mathbf{M} \times \mathbf{n}$ flow at the surfaces

*ellipsoidal shape*, then the macroscopic average of $\mathbf{B}^{(\text{micro})}(\mathbf{r})$, i.e., the macroscopic screened field **B**, is constant in the bulk of the sample. The shape effects are embedded in the demagnetization coefficients (Landau and Lifshitz 1984). For the slab geometry in a vanishing external field $\mathbf{B}^{(\text{ext})}$, the internal field **B** vanishes when **M** is normal to the slab (longitudinal polarization), while $\mathbf{B} = -4\pi\mathbf{M}$ is the demagnetization field when **M** is parallel to the slab (transverse polarization): see Fig. 2. Notice that this is *the opposite* of what happens in the electrical case (Fig. 1).

## 3    Overview of Polarization Theory

Novel ideas about macroscopic polarization emerged in the early 1990s (Posternak et al. 1990; Resta 1992); these led to the modern theory, based on a Berry phase, which was founded by King-Smith and Vanderbilt soon afterward (King and Vanderbilt 1993). At its foundation, the modern theory was limited to a crystalline system in an independent-electron framework (either Kohn-Sham or Hartree-Fock). Later, the theory was extended to correlated and/or disordered systems (Ortiz and Martin 1994; Resta 1998).

Addressing polarization *differences* instead of polarization "itself" was instrumental to the first developments of the theory. Soon after the main breakthrough, a key paper by Vanderbilt and King-Smith (1993) reformulated the theory in a way where even polarization itself is a well-defined bulk property, although an apparently exotic one, detailed below. For the time being, let us anticipate that bulk polarization **P** is *not* a single-valued vector, at variance with its treatment in elementary textbooks.

The first calculation ever of spontaneous polarization was published by Posternak et al. (1990). The case study was BeO: it has the simplest structure where a bulk vector property is symmetry-allowed (i.e., wurtzite), and furthermore its constituents are first-row atoms. The idea was to address the macroscopic polarization of a slab of finite thickness, with faces normal to the $c$ axis, embedding it in an ad
hoc medium which (i) has no bulk polarization for symmetry reasons (caveat: this was common wisdom at the time, no longer nowadays!) and (ii) does not produce any geometrical or chemical perturbation at the interface. The optimal choice is a fictitious BeO in the zincblende structure. Because of obvious computational reasons, the system is periodically replicated in a supercell geometry (Fig. 3, top panel). The self-consistent calculation shows well-localized interface charges, of opposite sign, and equal magnitude at the two nonequivalent interfaces (Fig. 3, bottom panel). The interface charge is related to the difference in polarization between the two materials: $\sigma_{\text{interface}} = \Delta\mathbf{P} \cdot \mathbf{n}$. The computer experiment provides the value of $\sigma_{\text{interface}}$, and since $\mathbf{P}$ vanishes by symmetry in the zincblende slab, one thus obtains the bulk value of $\mathbf{P}$ in the wurtzite material.

Notice that here $\mathbf{P}$ is a *longitudinal* polarization, in a depolarizing field, as in Fig. 1. Longitudinal $\mathbf{P}$ is related to the zero-field $\mathbf{P}_0$, as defined in Eq. (4), by $\mathbf{P} = \mathbf{P}_0/\varepsilon$, where $\varepsilon$ is the dielectric constant of the material.

It must be emphasized that the quantity really "measured" in this computer experiment is $\Delta\mathbf{P}$, *not* the polarization $\mathbf{P}$ itself. After the paper was published, a study of the experimental literature showed that – contrary to an incorrect widespread belief – no experimental value of $\mathbf{P}$ in any wurtzite material exists: only estimates are available. This paper marks, as said above, a change of paradigm: its main message was that polarization must be *defined* by means of *differences*, and the concept of polarization "itself" should be abandoned. With hindsight, it is nowadays pretty clear that the problem exists already at the classical level: the dipole per cell of an array of classical charges is ill defined: it depends on the (arbitrary) choice of the unit cell. Most textbooks are missing this very basic fact.

The modern theory, in its original formulation, avoided addressing the "absolute" polarization of a given equilibrium state, quite in agreement with the experiments,

which invariably measure polarization *differences*. Instead, the theory addresses differences in polarization between two states of the material that can be connected by an adiabatic switching process. The time-dependent Hamiltonian is assumed to remain insulating at all times, and the polarization difference was then *defined* (Resta 1992) as the time-integrated transient macroscopic current that flows through the insulating sample during the switching process:

$$\Delta \mathbf{P} = \mathbf{P}(\Delta t) - \mathbf{P}(0) = \int_0^{\Delta t} dt \; \mathbf{j}(t). \tag{5}$$

In the adiabatic limit, $\Delta t \rightarrow \infty$ and $\mathbf{j}(t) \rightarrow 0$, while $\Delta \mathbf{P}$ stays finite. Addressing currents (instead of charges) explains the occurrence of *phases* of the wave functions (instead of square moduli) in the modern theory. Eventually the time integration in Eq. (5) will be eliminated, leading to a two-point formula involving only the initial and final states.

The two-point formula provides two values which can be interpreted as the "absolute" polarizations $\mathbf{P}(0)$ and $\mathbf{P}(\Delta t)$ of the initial and final state, respectively. One arrives therefore at defining polarization "itself," at the price – as explained in detail below – of adopting a new paradigm: polarization is *not* a single-value vector, as instead in elementary theories.

The modern theory of polarization directly addresses polarization in zero $\mathbf{E}$ field: therefore we simplify notations by identifying $\mathbf{P}_0$ with $\mathbf{P}$ in the following. The presentation of the modern theory given here does not follow the historical developments.

## 4    Polarization Theory in One Dimension

For pedagogical reasons we start illustrating the modern theory by addressing in much detail a one-dimensional (1d) system; the 1d formalism applies as well to quasi-1d systems (e.g., polymers), with just a change of notations. The three-dimensional theory will be addressed in the following section, including the details of a first-principle implementation.

### 4.1    Polarization "Itself"

We assume a system of $N$ electrons in a segment of length $L$; the thermodynamic limit ($N \rightarrow \infty$, $L \rightarrow \infty$, $N/L = $ constant) is implicit. Neglecting irrelevant spin variables, the ground-state wave function is

$$\Psi_0 = \Psi_0(x_1, x_2, \ldots x_j, \ldots x_N). \tag{6}$$

This very general form includes disordered and/or correlated systems.

According, e.g., to the popular (Kittel 2005) textbook, **P** is nonzero when ".....the *center* of positive charge does not coincide with the *center* of negative charge" (my italics). Supposing we have 1d nuclei of charge $eZ_\ell$ at sites $X_\ell$, Kittel's definition leads to

$$P_x = e\left(\frac{1}{L}\sum_\ell Z_\ell X_\ell - \frac{2}{L}\langle\Psi_0|\sum_{j=1}^{N} x_j\ |\Psi_0\rangle\right),\tag{7}$$

where the factor of two is included to ensure charge neutrality. The two terms in parenthesis are indeed the centers of positive and negative charge, respectively.

Equation (7) makes sense and is correct for a bounded system, where (i) the sum over $\ell$ is finite and (ii) $\Psi_0$ is square-integrable; it is instead complete nonsense when PBCs are adopted. In the latter case, the sum over $\ell$ is infinite; as for the wave function, PBCs mean that for any $j$

$$\Psi_0 = \Psi_0(x_1, x_2, \ldots x_j, \ldots x_N) = \Psi_0(x_1, x_2, \ldots x_j+L, \ldots x_N).\tag{8}$$

If we restrict both the sum and the integration to a segment of length $L$, the result depends on the choice of the coordinate origin.

The key observation is that within PBCs the $x_j$ coordinates are equivalent to the angles $\vartheta_j = 2\pi x_j/L$, and the centers of positive and negative charges must be obtained from phase angles. The solution is therefore to replace Eq. (7) with

$$P_x = \frac{e}{2\pi}\text{Im ln }\ e^{i\frac{2\pi}{L}\sum_\ell Z_\ell X_\ell} - \frac{e}{\pi}\text{Im ln }\ \langle\Psi_0|e^{i\frac{2\pi}{L}\sum_j x_j}|\Psi_0\rangle;\tag{9}$$

the electronic term therein is the ground-state expectation value of a unitary and periodic operator. We may equivalently write

$$P_x = \frac{e}{2\pi}\text{Im ln }\ \langle\Psi_0|e^{i\frac{2\pi}{L}\left(\sum_\ell Z_\ell X_\ell - 2\sum_j x_j\right)}|\Psi_0\rangle = \frac{e\gamma}{2\pi} = \frac{e}{2\pi}(\gamma^{(\text{nucl})} - 2\gamma^{(\text{el})}),\tag{10}$$

where the phase angle $\gamma^{(\text{el})}$ is a Berry phase of the electronic ground state in disguise; nowadays in electronic structure jargon, this phase is dubbed "single-point Berry phase." Notice that the total phase $\gamma$ in Eq. (10) is invariant by translation of the coordinate origin, as a virtue of charge-neutrality; the nuclear and electronic phases $\gamma^{(\text{nucl})}$ and $\gamma^{(\text{el})}$ are *not* separately invariant.

## 4.2    The Polarization "Quantum"

Given that any phase angle is defined modulo $2\pi$, Eq. (10) shows that polarization itself in 1d is arbitrary modulo $e$: as anticipated above bulk polarization is a 1d lattice, not a single-valued quantity: this is the outstanding message of Vanderbilt

and King-Smith (1993). The quantum arbitrariness is a real-world feature, *not* an artefact of the theory.

When PBCs are adopted, the system has no boundary by construction, and only the bulk electronic distribution is accessible. For any bounded realization of the given linear system, the "modulo" value is determined only after the termination is specified. Among the $P_x$ values allowed by the bulk, nature will choose the minimum-energy one.

We are accustomed to assume that $P_x = 0$ in centrosymmetric linear systems: this is incorrect. The phase angles $\gamma$ compatible with centrosymmetry are either zero or $\pi$: this amounts to a $\mathbb{Z}_2$ topological classification of 1d centrosymmetric insulators, which implies either $P_x = 0 \mod e$ ($\mathbb{Z}_2$-even) or $P_x = e/2 \mod e$ ($\mathbb{Z}_2$-odd). The classification is topological, in the sense that it is impossible to continuously deform the Hamiltonian (and the ground state) of a $\mathbb{Z}_2$-even 1d system into a $\mathbb{Z}_2$-odd one while keeping the system centrosymmetric and insulating.

The proof that the end charge in centrosymmetric linear polymers is topological can be equivalently arrived at by Wannier-function counting– in the special case of independent electrons – using Eq. (39) below (Kudin et al. 2007). Similar arguments also prove the topological nature of the soliton charge in polyacetylene, first discovered by Su et al. (1979). If we insist that we want a singlet wave function – as everywhere here – then the soliton charge can only be $\pm e$. But we may relax this condition, adopting single occupancy (instead of double) for one of the Wannier functions in the soliton region: the soliton is then neutral but carries spin $\pm 1/2$.

A perspicuous illustration of the quantum feature was provided by Kudin et al. (2007), who addressed bounded quasi-1d systems of length $L$. A test case is trans-polyacetylene, whose bulk is centrosymmetric and whose bulk $P_x$ value is 0 mod $e$ ($\mathbb{Z}_2$-even). We chose two different terminations, as illustrated in Fig. 4, and we computed the dipole divided by $L$ as a function of $L$ for large $L$ values. In both cases the whole molecule is polar: therefore at finite $L$ the two dipoles are nonzero and nonquantized. The quantization is exact in the $L \rightarrow \infty$ limit: the simulations reported by Kudin et al. (2007) perspicuously show that the asymptotic value of the dipole per unit length is either zero or $e$ for the two different terminations of the same "bulk" chain.

**Fig. 4** A centrosymmetric insulating quasi-1d "crystal" with two different termination: alternant trans-polyacetylene. In this picture the "bulk" is five-monomer long. (After Kudin et al. 2007)
### 4.3    Polarization vs. Current

We have arrived at our main 1d result, Eq. (10), by a sort of plausibility argument. In order to prove that the $P_x$ expression given above actually is the macroscopic polarization, we have to resort to Eq. (5) and show that when $P_x$ is evaluated using the adiabatic instantaneous eigenstate $|\Psi_0\rangle$ at time $t$, its time derivative coincides with the current density. The current carried by the classical nuclei is trivial; we focus therefore on the electronic one, neglecting once more the factor of two (spinless electrons).

$$
\begin{aligned}
j_x^{(\mathrm{el})}(t) &= -\frac{e}{2\pi}\frac{d}{dt}\gamma^{(\mathrm{el})}(t) = -\frac{e}{2\pi}\frac{d}{dt}\mathrm{Im}\ln\ \langle\Psi_0(t)|e^{i\frac{2\pi}{L}\hat{x}}|\Psi_0(t)\rangle \\
&= -\frac{e}{2\pi}\mathrm{Im}\left(\frac{\langle\dot{\Psi}_0|e^{i\frac{2\pi}{L}\hat{x}}|\Psi_0\rangle}{\langle\Psi_0|e^{i\frac{2\pi}{L}\hat{x}}|\Psi_0\rangle} + \frac{\langle\Psi_0|e^{i\frac{2\pi}{L}\hat{x}}|\dot{\Psi}_0\rangle}{\langle\Psi_0|e^{i\frac{2\pi}{L}\hat{x}}|\Psi_0\rangle}\right),
\end{aligned} \tag{11}
$$

where $|\dot{\Psi}_0\rangle$ is the adiabatic time derivative of the ground eigenstate, $\hat{x} = \sum_j x_j$, and the thermodynamic limit is understood.

   We generalize the many-electron Hamiltonian as

$$
\hat{H}(\kappa) = \frac{1}{2m}\sum_{j=1}^{N}(p_j + \hbar\kappa)^2 + \hat{V}, \tag{12}
$$

where the potential $\hat{V}$ includes one- and two-body terms and is periodic of period $L$, while $\kappa$, called "flux" or "twist," is a gauge transformation. This Hamiltonian was first proposed by W. Kohn (1964), who observed that PBCs violate gauge-invariance in the conventional sense: the ground-state energy actually depends on $\kappa$. The ground eigenstate $|\Psi_0(\kappa)\rangle$, which obtains by adiabatically varying $\kappa$, has a nontrivial $\kappa$-dependence. To lowest order in $\kappa$, we get

$$
|\Psi_0(\kappa)\rangle \simeq |\Psi_0\rangle + \frac{\hbar\kappa}{m}\sum_{n\neq 0}|\Psi_n\rangle\frac{\langle\Psi_n|\ \sum_{j=1}^{N}p_j\ |\Psi_0\rangle}{E_0 - E_n}, \tag{13}
$$

where we set $|\Psi_n(0)\rangle = |\Psi_n\rangle$. We consider next the state $e^{i2\pi\hat{x}/L}|\Psi_0\rangle$: this state obeys Schrödinger equation for $\kappa = -2\pi/L$ and obeys PBCs as well. It is therefore an eigenstate of $\hat{H}(-2\pi/L)$ with energy $E_0$. If the system is an insulator, this state coincides with the ground state $|\Psi_0(-2\pi/L)\rangle$, obtained instead by adiabatically varying $\kappa$ in Eq. (12), hence:

$$
e^{i2\pi\hat{x}/L}|\Psi_0\rangle \simeq |\Psi_0\rangle - \frac{h}{mL}\sum_{n\neq 0}|\Psi_n\rangle\frac{\langle\Psi_n|\ \sum_{j=1}^{N}p_j\ |\Psi_0\rangle}{E_0 - E_n}. \tag{14}
$$

Inserting this into Eq. (11), one gets

$$j_x^{(el)} \simeq \frac{ie\hbar}{mL} \sum_{n \neq 0} \langle \dot{\Psi}_0 | \Psi_n \rangle \frac{\langle \Psi_n | \sum_{j=1}^{N} p_j | \Psi_0 \rangle}{E_0 - E_n} + \text{c.c.}, \tag{15}$$

where c.c. stays for complex conjugate. The $n = 0$ term is omitted from the sum since $\langle \dot{\Psi}_0 | \Psi_0 \rangle + \langle \Psi_0 | \dot{\Psi}_0 \rangle = 0$. This concludes our proof: in fact the right-hand member of Eq. (15) is the electronic current flowing through the system when the potential $\hat{V}$ is adiabatically varied, a well-known expression previously used by Niu and Thouless (1984) in demonstrating the quantization of particle transport.

An important subtlety is worth stressing. The relative phase between eigenvectors $|\Psi_0(\kappa)\rangle$ at two different $\kappa$-values is arbitrary. The choice performed in the conventional formulas of perturbation theory, as in Eqs. (13) and (14), correspond to the so-called parallel-transport gauge; other choices are equally legitimate. Given that the current is gauge-invariant, neglect of this phase factor (as we did here) is harmless.

## 4.4  The King-Smith and Vanderbilt Formula

The modern theory of polarization was originally formulated by King-Smith and Vanderbilt for a crystalline system of noninteracting electrons (in a mean-field sense). Here we proceed in reverse historical order: we are going to derive their formula as a special case of the previous more general one, i.e.

$$P_x = \frac{e}{2\pi}(\gamma^{(nucl)} - 2\gamma^{(el)}), \qquad \gamma^{(el)} = \text{Im ln } \langle \Psi_0 | e^{i\frac{2\pi}{L}\sum_j x_j} | \Psi_0 \rangle. \tag{16}$$

Suppose we have a crystalline system of lattice constant $a$, where we impose PBCs over $M$ linear cells: there are then $M$ equally spaced Bloch vectors in the reciprocal cell $[0, 2\pi/a]$:

$$k_s = \frac{2\pi}{Ma}s, \quad s = 0, 1, \ldots, M-1. \tag{17}$$

The size of the periodically repeated system is $L = Ma$. The one-body orbitals can be chosen to have the Bloch form:

$$\psi_{mk_s}(x + \tau) = e^{ik_s\tau}\psi_{mk_s}(x), \tag{18}$$

where $\tau = la$ is a lattice translation and $m$ is a band index. Throughout this chapter the Bloch orbitals are normalized to one over the unit cell.

There are $N/M$ occupied bands in the Slater determinant wave function, which we write (for spinless electrons) as

$$|\Psi_0\rangle = \frac{1}{\sqrt{M^N}} \mathsf{A} \prod_{m=1}^{N/M} \prod_{s=0}^{M-1} \psi_{mk_s}, \tag{19}$$

where $\mathsf{A}$ is the antisymmetrizer: the $1/\sqrt{M^N}$ factor in Eq. (19) owes to the different normalizations: $|\Psi_0\rangle$ is normalized over $L = Ma$, while the Bloch orbitals $|\psi_{m\mathbf{k}}\rangle$ are normalized over a crystal cell of length $a$. It is now expedient to define a new set of Bloch orbitals:

$$\tilde{\psi}_{mk_s}(x) = \mathrm{e}^{-i\frac{2\pi}{L}x} \psi_{mk_s}(x). \tag{20}$$

We then recast the electronic Berry phase $\gamma^{(\mathrm{el})}$, Eq. (16), as:

$$\gamma^{(\mathrm{el})} = -\mathrm{Im} \ln \langle \Psi_0 | \tilde{\Psi}_0 \rangle, \tag{21}$$

where $|\tilde{\Psi}_0\rangle$ is the Slater determinant of the $\tilde{\psi}$'s. According to a well-known theorem, the overlap among two determinants is equal to the determinant of the overlap matrix among the orbitals:

$$\gamma^{(\mathrm{el})} = -\mathrm{Im} \ln \frac{1}{M^N} \det \mathscr{S}, \tag{22}$$

where

$$\mathscr{S}_{sm,s'm'} = \int_0^L dx\, \psi_{mk_s}^*(x) \mathrm{e}^{-i\frac{2\pi}{L}x} \psi_{m'k_{s'}}(x) = M \int_0^a dx\, \psi_{mk_s}^*(x) \mathrm{e}^{-i\frac{2\pi}{L}x} \psi_{m'k_{s'}}(x), \tag{23}$$

and $\psi_{mk_M}(x) \equiv \psi_{mk_0}(x)$ is implicitly understood (so-called periodic gauge).

Owing to the orthogonality properties of the Bloch functions, the overlap matrix elements vanish except when $k_{s'} = k_s + 2\pi/L$, that is, $s' = s+1$. The $N \times N$ determinant can then be factorized into $M$ small determinants:

$$\frac{1}{M^N} \det \mathscr{S} = \prod_{s=0}^{M-1} \det S(k_s, k_{s+1}), \tag{24}$$

where for the small overlap matrix we use the notation

$$S_{m,m'}(k_s, k_{s+1}) = \int_0^a dx\, \psi_{mk_s}^*(x) \mathrm{e}^{-i\frac{2\pi}{L}x} \psi_{m'k_{s+1}}(x) = \langle u_{mk_s} | u_{m'k_{s+1}} \rangle, \tag{25}$$

where $|u_{mk}\rangle = \mathrm{e}^{-ikx} |\psi_{mk}\rangle$ is the periodic factor in the Bloch orbital. We finally get

$$\gamma^{(\mathrm{el})} \simeq -\mathrm{Im} \ln \prod_{s=0}^{M-1} \det S(k_s, k_{s+1}) : \tag{26}$$

this is the well-known expression of the modern theory of polarization, as implemented in many electronic structure codes. The formula was originally obtained by King-Smith and Vanderbilt by defining a (continuum) Berry phase as a line integral and then discretizing it.

For the sake of simplicity, we assume there is only one occupied band; Eqs. (25) and (26) become then

$$S(k_s, k_{s+1}) = \int_0^a dx \ \psi_{k_s}^*(x) e^{-i\frac{2\pi}{L}x} \psi_{k_{s+1}}(x) = \langle u_{k_s}|u_{k_{s+1}}\rangle \tag{27}$$

$$\gamma^{(\text{el})} \simeq -\text{Im} \ln \prod_{s=0}^{M-1} \langle u_{k_s}|u_{k_{s+1}}\rangle = -\sum_{s=0}^{M-1} \text{Im} \ln \langle u_{k_s}|u_{k_{s+1}}\rangle. \tag{28}$$

If we adopt a gauge such that $|u_k\rangle$ is a differentiable function of $k$, then

$$-\text{Im} \ln\langle u_k|u_{k+\Delta k}\rangle \simeq i\langle u_k|du_k/dk\rangle \, \Delta k. \tag{29}$$

In the large-$M$ limit, the sum converges to the integral

$$\gamma^{(\text{el})} = \int_0^{2\pi/a} i\langle u_k|du_k/dk\rangle \, dk. \tag{30}$$

This integral is a Berry phase (Zak 1989), and the integrand goes under the name of Berry connection. Since $|u_k\rangle$ is gauge-dependent (i.e., arbitrary by a $k$-dependent phase factor), the Berry connection is gauge-dependent as well; the Berry phase, instead, is gauge-invariant modulo $2\pi$. As shown in Sect. 4.3, the electronic current which flows through the one-dimensional sample during the switching process is

$$j_x^{(\text{el})}(t) = -\frac{ie}{2\pi}\frac{d}{dt}\int_0^{2\pi/a} \langle u_k|du_k/dk\rangle \, dk, \tag{31}$$

where the integrand is evaluated with the adiabatic instantaneous eigenstates. We remind that the simplified Eq. (31) holds for one simply occupied band in one dimension; we also remind that the system must be insulating at all times

As observed above, the continuum formulation of Eq. (30) requires $|u_k\rangle$ to be a differentiable function of $k$, while the discrete formulation of Eqs. (26) and (28) is more general. This is of foremost importance in numerical work: in fact, when the orbitals are obtained by numerical diagonalization, the choice of the gauge is erratic; further ambiguity arises from band ordering in the many-band case. We stress that this ambiguity is harmless in both Eqs. (26) and (28), which are *numerically* gauge-invariant in form. To this aim, it is essential that the Hamiltonian is diagonalized $M$ times, not $M + 1$, in order to enforce the periodic gauge, i.e.

$$\langle u_{mk_0}|u_{m'k_M}\rangle \equiv \langle u_{mk_0}|e^{-i2\pi x/a}|u_{m'k_0}\rangle. \tag{32}$$

# 5  Polarization Theory in Three Dimensions

Considerations based on the adiabatic current – similar to those leading to the simplified Eq. (31) – hold for a many-band system in three dimensions: we provide in this section the corresponding formalism in detail. The formulas given below are those implemented in most first-principle codes for electronic structure calculations, both density functional and Hartree-Fock. Since the Berry phase is included in the public distribution of such codes, it is impossible to keep track of the plethora of calculations which have appeared in the literature, for the most diverse materials. As of today (2018), the original 1993 paper by Vanderbilt and King-Smith scores 1,700 ISI citations; most of them are from papers which provided first-principle Berry-phase calculations for real materials.

In the early years (1993 onward), the modern theory has mostly addressed the ferroelectric perovskites, in order to compute (and predict) the spontaneous polarization of the various phases, the Born (a.k.a infrared) effective charges for lattice dynamics and the piezoelectric coefficients. The accuracy of the results clearly depends on the form of the functional adopted and on its reliability in describing the given material; in simple cases the overall accuracy can be evaluated at about 5%. A tabulation of several state-of-the-art results, for many perovskite oxides, has been published by Rabe and Ghosez (2007). In more recent years, the theory has been applied – as said above – to the most diverse materials, with an overall accuracy roughly of the same order, for large-gap materials at least. Small-gap materials may be more critical and may show a stronger dependence on the functional.

Another very successful application concerns the infrared spectra of amorphous and liquid materials, where the modern theory is implemented in the framework of ab initio (Car-Parrinello) molecular dynamics. The formalism is reviewed here in Sect. 5.4; the very first implementations were for amorphous silicon by Debernardi et al. (1997) and for liquid water by Silvestrelli et al. (1997). Water is arguably the most difficult liquid of all: it is hard to model the hydrogen bond with classical forces, and the light mass of hydrogen is the source of additional complications. For this reason the infrared spectrum of water has been computed again several times, with technically different first-principle ingredients. As an example, we quote here a thorough study of water and ice by Chen et al. (2008).

## 5.1  The King-Smith and Vanderbilt Formula

If $n_b$ is the number of occupied bands, then the King-Smith and Vanderbilt formula reads (per spin channel)

$$\mathbf{P}^{(el)} = -\frac{ie}{(2\pi)^3} \sum_{m=1}^{n_b} \int_{BZ} d\mathbf{k} \, \langle u_{m\mathbf{k}} | \nabla_{\mathbf{k}} u_{m\mathbf{k}} \rangle, \qquad (33)$$

where BZ is the Brillouin zone. The adiabatic time derivative of Eq. (33) yields the macroscopic current density due to the (spinless) electrons; the classical nuclear term must be added. The real vector field $i\langle u_{m\mathbf{k}}|\nabla_{\mathbf{k}}u_{m\mathbf{k}}\rangle$ is the Berry connection of band $m$: it is gauge-dependent, while $\mathbf{P}^{(\text{el})}$ is instead gauge-invariant, modulo a "quantum" detailed below.

The integral in Eq. (33) can be equivalently performed over a unit reciprocal cell, defined by the reciprocal vectors $\mathbf{G}_i$, $i = 1, 2, 3$; let the corresponding unit vectors of the direct lattice be $\mathbf{R}_i$, and the cell volume be $V_{\text{cell}} = |\mathbf{R}_1 \cdot \mathbf{R}_2 \times \mathbf{R}_3|$. We introduce the dimensionless variables $\xi_i$, defined as

$$\mathbf{k} = \sum_i \xi_i \mathbf{G}_i, \qquad \xi_i = \frac{1}{2\pi}\mathbf{k} \cdot \mathbf{R}_i. \tag{34}$$

It is expedient to evaluate $\mathbf{G}_i \cdot \mathbf{P}$ for each $i$, which in turn uniquely determine the three components of $\mathbf{P}^{(\text{el})}$. Performing the change of variables in Eq. (33), we get

$$\mathbf{G}_i \cdot \mathbf{P}^{(\text{el})} = -\frac{ie}{V_{\text{cell}}} \sum_{m=1}^{n_{\text{b}}} \int_0^1 d\xi_1 \int_0^1 d\xi_2 \int_0^1 d\xi_3 \ \langle u_m|\frac{\partial}{\partial\xi_i}u_m\rangle, \tag{35}$$

where $|u_m\rangle$ is now a function of the $\xi_i$. We focus now on a given $i$, say $i = 3$, and we write

$$\mathbf{G}_3 \cdot \mathbf{P}^{(\text{el})} = -\frac{e}{V_{\text{cell}}} \sum_{m=1}^{n_{\text{b}}} \int_0^1 d\xi_1 \int_0^1 d\xi_2 \ \gamma(\xi_1, \xi_2) \tag{36}$$

$$\gamma(\xi_1, \xi_2) = i \sum_{m=1}^{n_{\text{b}}} \int_0^1 d\xi_3 \ \langle u_m|\frac{\partial}{\partial\xi_3}u_m\rangle, \tag{37}$$

where $\gamma(\xi_1, \xi_2)$ is clearly a one-dimensional Berry phase in the variable $\xi_3$.

First-principle calculations of $\mathbf{P}$ for real materials are based on the discretization of Eqs. (36) and (37). The integral in $(\xi_1, \xi_2)$, Eq. (36), is discretized in the trivial way. Instead the many-band Berry phase, Eq. (37), is discretized in terms of overlap matrices according to Eq. (26). Numerical diagonalizations at different $(\xi_1, \xi_2, \xi_3)$ points provide eigenvectors which are affected by erratic phase factors; further ambiguity is due to band ordering. This arbitrariness does not affect the result, which is *numerically* gauge-invariant. Two features are essential, though: (i) the periodic gauge must be enforced, according to Eq. (32), and (ii) the computed $\gamma(\xi_1, \xi_2)$ at the mesh points must be equivalent to the discretization of a continuous function. As for the latter point, we observe that the phases at each mesh point are (independently) arbitrary by $2\pi$; one must choose instead the phases at adjacent mesh point by ensuring that their difference is much smaller than $2\pi$.

Notice that the Berry-phase formula, as in the previous equations, yields the electronic term for spinless electrons (i.e., for spin channel). When implemented

for real materials, this $\mathbf{P}^{(\text{el})}$ value has to be multiplied by two, and the classical nuclear term must be added. The Berry-phase formula is usually implemented – within a first-principle framework – in order to evaluate differences in polarization $\Delta\mathbf{P}$ between two states of the material that are connected by an adiabatic switching process, as in Eq. (5). The formula amounts to replacing the time integral in Eq. (5) with a two-point formula.

The Berry phase $\gamma(\xi_1, \xi_2)$ in Eq. (37) – either continuous or discretized – is gauge-invariant modulo $2\pi$ for any given $(\xi_1, \xi_2)$. If (and only if) we choose the gauge in such a way that $\gamma(\xi_1, \xi_2)$ is a continuous function of $(\xi_1, \xi_2)$, then $\mathbf{G}_3 \cdot \mathbf{P}^{(\text{el})}$ is arbitrary modulo $2\pi e / V_{\text{cell}}$. Finally, we notice that if $\mathbf{R}$ is the most general lattice vector, one has $\mathbf{G}_i \cdot \mathbf{R} = 2\pi n$, with $n$ integer: ergo the polarization quantum (for each spin occupancy) is $e\mathbf{R}/V_{\text{cell}}$. A moment's reflection shows that even the classical nuclear term is affected by the same ambiguity.

The original definition of $\Delta\mathbf{P}$ as the time integral of its derivative, as in Eq. (5), is not affected by any quantum ambiguity. The Berry-phase theory shows that $\Delta\mathbf{P}$ can be alternatively cast as a two-point formula, thus requiring the evaluation of two Berry phases only (of the initial and final state): the trade-off is the quantum ambiguity. Usually this is not a problem when evaluating $\Delta\mathbf{P}$, since its value is typically much smaller than the quantum $e\mathbf{R}/V_{\text{cell}}$, for crystal cells of moderate size. If there is any doubt about the quantum choice, one can add some intermediate points between the initial and final ones.

## 5.2    Formulation in Terms of Wannier Functions

The independent-particle (or mean-field) ground state is a Slater determinant of doubly occupied orbitals; any unitary transformation of the occupied states among themselves leaves the determinantal wave function invariant (apart for an irrelevant phase factor), and hence it leaves invariant any ground-state property.

For an insulating crystal, the Bloch orbitals of completely occupied bands can be transformed to localized Wannier orbitals (or functions) WFs. This is known since long time (Wannier 1937), but for many years the WFs have been mostly used as a formal tool; they became a popular topic in computational electronic structure only after the seminal work of Marzari and Vanderbilt (1997); the classical review on the topic is by Marzari et al. (2012).

The transformation of the Berry phase formula in terms of WFs provides an alternative, and perhaps more intuitive, viewpoint. The formal transformation was known since the 1950s, although the physical meaning of the formalism was not understood until the advent of the modern theory of polarization.

The unitary transformation which defines the WF $w_{m\mathbf{R}}(\mathbf{r})$, labeled by band $m$ and unit cell $\mathbf{R}$, within our normalization is

$$|w_{m\mathbf{R}}\rangle = \frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \, \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}} \, |\psi_{m\mathbf{k}}\rangle \; . \tag{38}$$

If one then defines the "Wannier centers" as $\mathbf{r}_{m\mathbf{R}} = \langle w_{m\mathbf{R}}|\mathbf{r}|w_{m\mathbf{R}}\rangle$, it is rather straightforward to prove that Eq. (33) is equivalent to

$$\mathbf{P}^{(\mathrm{el})} = -\frac{e}{V_{\mathrm{cell}}} \sum_{m=1}^{n_{\mathrm{b}}} \mathbf{r}_{m\mathbf{0}}. \tag{39}$$

This means that the electronic term (per spin channel) in the macroscopic polarization $\mathbf{P}$ is the dipole of the Wannier charge distributions in the central cell, divided by the cell volume. The nuclear term is obviously similar in form to Eq. (39); the sum of twice Eq. (39) plus the nuclear term is charge neutral.

WFs are severely gauge-dependent, since the phases of the $|\psi_{m\mathbf{k}}\rangle$ appearing in Eq. (38) can be chosen arbitrarily; further ambiguity arises from band crossings. However, the sum of their centers in Eq. (39) is gauge-invariant modulo a lattice vector. Therefore $\mathbf{P}^{(\mathrm{el})}$ in Eq. (39) is affected by the same "quantum" indeterminacy discussed above.

The modern theory, when formulated in terms of WFs, becomes much more intuitive and in a sense vindicates the venerable Clausius-Mossotti viewpoint: in fact, the charge distribution is partitioned into localized contributions, each providing an electric dipole, and these dipoles yield the electronic term in $\mathbf{P}$. However, it is clear from Eq. (38) that the *phase* of the Bloch orbitals is essential to arrive at the right partitioning. Any decomposition based on charge only is severely nonunique and does not provide in general the right $\mathbf{P}$, with the notable exception of the extreme case of molecular crystals.

In the latter case, in fact, we may consider the set of WFs centered on a given molecule; their total charge distribution coincides – in the weakly interacting limit – with the electron density of the isolated molecule (possibly in a local field). This justifies the elementary Clausius-Mossotti viewpoint. It is worth mentioning that the dipole of a polar molecule is routinely computed in a supercell geometry via the single-point Berry phase discussed below. The dipole value coincides with the one computed in the trivial way in the large supercell limit. Finite-size corrections, due to the local field (different in the two cases), can also be applied (Dabo et al. 2008).

The case of alkali halides – where the model is often phenomenologically used – deserves a different comment (Resta 2010). The electron densities of isolated ions (with or without fields) are quite different from the corresponding WFs charge distributions, for instance, because of orthogonality constraints: hence the Clausius-Mossotti model is *not* justified in its elementary form, despite contrary statements in the literature. We stress once more that $\mathbf{P}$ cannot be determined – even in principle – from a knowledge of the microscopic charge density of the polarized crystal.

## 5.3 The Single-Point Berry Phase

First-principle calculations for large systems, which simulate, e.g., liquids, are routinely performed in a supercell formalism and diagonalizing the Hamiltonian

at $\mathbf{k} = 0$ only (the $\Gamma$ point). The rationale beyond this is that the reciprocal cell of a large supercell is small, and any BZ integral can be approximately evaluated exploiting the mean-value theorem, i.e.

$$\int_{BZ} d\mathbf{k}\, f(\mathbf{k}) \simeq \frac{(2\pi)^3}{V_{cell}} f(0). \tag{40}$$

The Berry phase cannot be evaluated in this way, because the Berry connection is not gauge-invariant. The problem was solved by Resta (1998), where it was shown that even polarization can be evaluated in a single-point formalism.

Suppose we have a large cubic supercell of side $L$. Then the electronic term of polarization in the $z$ direction is (for each spin occupancy)

$$P_z^{(el)} = -\frac{e}{2\pi L^2} \gamma^{(el)} = \frac{e}{2\pi L^2} \mathrm{Im}\, \ln \det S^{(z)}, \tag{41}$$

where the overlap matrix elements are

$$S_{mm'}^{(z)} = \langle u_m | e^{-i2\pi z/L} | u_{m'} \rangle = \langle \psi_m | e^{-i2\pi z/L} | \psi_{m'} \rangle, \tag{42}$$

and $|u_m\rangle \equiv |\psi_m\rangle$ are the eigenstates at $\mathbf{k} = 0$. Eq. (41) directly follows from the one-dimensional formulation, Eqs. (26) and (32), in the single point case; alternatively, it also follows from Eqs. (36) and (37) when a single-point discretization is adopted. As usual, the nuclear contribution must be added to the electronic term.

There is nonetheless an outstanding difference between the one-dimensional and the three-dimensional cases: in the former case, the polarization quantum is $e$; in the latter case, the quantum is $e/L^2$. Since polarization is defined in the large-sample limit, the vanishing of the quantum implies that polarization "itself" is ill-defined for a three-dimensional noncrystalline sample, at variance with the one-dimensional (and quasi one-dimensional) case. Eq. (41) is very useful, though: see Sect. 5.4.

## 5.4    First-Principle Infrared Spectra

The main ingredient of the infrared spectrum is the imaginary part of the dielectric function $\varepsilon''(\omega)$. This can be obtained from the equilibrium fluctuations of the system at temperature $T$. When the fluctuations are evaluated within PBCs, the formula for a classical system is

$$\varepsilon''(\omega) = \frac{2\pi\omega}{3V k_B T} \int_{-\infty}^{\infty} dt\, e^{-i\omega t} \langle \mathbf{d}(t) \cdot \mathbf{d}(0) \rangle, \tag{43}$$

where $k_B$ is the Boltzmann constant, $\mathbf{d}$ is the instantaneous dipole of the sample, and $V$ is its volume; the brackets indicate a statistical average. The PBCs choice

goes under the name of Ewald-Kornfeld (Kornfeld 1924; Neumann 1983) in the molecular-dynamics jargon.

Since the pioneering works of Silvestrelli et al. (1997) and of Debernardi et al. (1997), first-principle infrared spectra of liquids and amorphous systems are routinely evaluated from Eq. (43), where the dipole $\mathbf{d} = V\mathbf{P}$ is provided by the single-point Berry phase, Eqs. (41) and (42) (plus the classical term), and its fluctuations are computed via a Car-Parrinello simulation on a cubic supercell of volume $V = L^3$. The formula, as given here, refers to classical nuclei and does not include quantum corrections.

The integral in Eq. (43) is discretized over small intervals $\Delta t$, and its evaluation needs polarization *differences* only. In fact at any discretized time $n\Delta t$, the polarization is

$$\mathbf{P}(n\Delta t) = \mathbf{P}(0) + [\mathbf{P}(\Delta t) - \mathbf{P}(0)] + [\mathbf{P}(2\Delta t) - \mathbf{P}(\Delta t)] + \dots$$
$$+ [\mathbf{P}(n\Delta t) - \mathbf{P}((n-1)\Delta t)]. \tag{44}$$

For a Car-Parrinello time step $\Delta t$ of usual magnitude, each of the terms in square parenthesis is much smaller than the polarization quantum $e/L^2$ at typical supercell sizes. This feature overcomes the quantum ambiguity.

## 6    Overview of Magnetization Theory

The magnetization of a homogeneous sample carries the intuitive meaning of magnetic dipole per unit volume. At the nonrelativistic (and semi-relativistic) level, it is the sum of a spin and an orbital contribution. Experimentally, magneto-mechanical experiments, based on the Einstein-de Haas effect, provide the two terms separately (Meyer and Asch 1961). The spin term is conceptually trivial: in absence of time-reversal symmetry, the electronic spin density is nonzero, and spin magnetization is proportional to the macroscopic average of the spin density. In the crystalline case, electronic structure codes routinely compute the spin density, which is a lattice-periodic function: its cell average yields the spin magnetization. Here we are concerned with orbital magnetization only, indicating it with the symbol $\mathbf{M}$.

The modern theory addresses $\mathbf{M}$ in zero macroscopic $\mathbf{B}$ field, where the time-reversal symmetry is broken by some internal microscopic field, e.g., through the spontaneous development of ferromagnetic order or via spin-orbit coupling to a background of ordered local moments; in the crystalline case, the Hamiltonian is lattice periodic.

The starting date of the modern theory is 2005; important developments are much more recent. Originally, the theory addressed crystalline systems, and $\mathbf{M}$ was expressed as a Brillouin zone integral for insulators, more generally as a Fermi-volume integral for both insulators and metals. The integrand is based on $\mathbf{k}$-derivatives of Bloch orbitals; the $\mathbf{M}$ expression looks therefore superficially kind of similar to the integrand in $\mathbf{P}$ (i.e., the Berry connection). It was early realized,

however, that – at variance with the case of **P** – the integrand is gauge-invariant, and **M** is free from any "quantum" ambiguity. The overwhelming consequences of these two features have been fully realized only since 2013 onward and will be emphasized below. For instance, tinkering with the boundary of a finite sample may alter the value of **P** (Sect. 4.2), but not of **M**. After 2013 the theory may deal with **M** in noncrystalline systems and even in inhomogeneous ones (e.g., heterojunctions). At the time of writing (2017), there is no theory for correlated ground-state wave functions. The magnetization formula for crystalline systems of noninteracting electrons was generalized to finite temperatures as well. We are not dealing with the topic here: we refer to the original literature or to a previous review by Resta (2010).

As we previously did for the case of **P**, the presentation is based on the most recent findings (Bianco and Resta 2013; Marrazzo and Resta 2016; Resta 2018) and does not follow the historical development of the theory.

## 7    Magnetization Theory

### 7.1    Ground-State Projector

In the independent-electron framework (in a mean-field sense), all ground-state properties are embedded in the one-particle density matrix $\mathscr{P}$, also called ground-state projector. For the sake of simplicity, we give once more the formulas for spinless electrons (or per spin channel).

First we address a bounded sample, where the occupied orbitals are square-integrable: this case is usually called "open boundary conditions" (OBCs). If $|\varphi_j\rangle$ are the single-particle orbitals with eigenvalues $\varepsilon_j$, the ground-state projector is

$$\mathscr{P} = \sum_{\varepsilon_j < \mu} |\varphi_j\rangle\langle\varphi_j|, \tag{45}$$

where $\mu$ is the Fermi level.

We are considering here a macroscopically homogenous system, either disordered or crystalline (in the latter case a crystallite cut from the bulk). If $O$ is any operator defining a physical property, the corresponding intensive ground-state observable is given by a trace per unit volume

$$\frac{\langle O \rangle}{V} = \text{Tr}_V\{\mathscr{P}O\} = \frac{1}{V}\int d\mathbf{r}\,\langle\mathbf{r}|\mathscr{P}O|\mathbf{r}\rangle, \tag{46}$$

in the large-$V$ limit. The electronic contribution to **P** and orbital magnetization **M** – Eqs. (1) and (2) – are simple observables in this class. For instance, magnetization is

$$\mathbf{M} = -\frac{e}{2c}\mathrm{Tr}_V\{\mathscr{P}\mathbf{r} \times \mathbf{v}\}, \tag{47}$$

where $\mathbf{v} = i[\mathscr{H}, \mathbf{r}]/\hbar$ is the velocity operator.

The orbitals, and hence the projector, depend of the choice of the gauge in the Hamiltonian $\mathscr{H}$. Once the gauge in $\mathscr{H}$ is fixed, the projector is gauge-invariant, in the sense that it is invariant by unitary transformations of the occupied orbitals among themselves; the many-electron wave function (i.e., the Slater determinant) is gauge-invariant as well.

If instead we address an unbounded crystalline sample within PBCs, the ground-state projector is cast as a BZ integral in terms of the Bloch orbitals $|\psi_{j\mathbf{k}}\rangle = e^{i\mathbf{k}\cdot\mathbf{r}}|u_{j\mathbf{k}}\rangle$; here they are normalized to one over the unit cell of volume $V_{\mathrm{cell}}$. The ground-state projector is then given by

$$\mathscr{P} = \frac{V_{\mathrm{cell}}}{(2\pi)^3}\sum_j \int_{\mathrm{BZ}} d\mathbf{k}\,\boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}})|\psi_{j\mathbf{k}}\rangle\langle\psi_{j\mathbf{k}}|, \tag{48}$$

where $\varepsilon_{j\mathbf{k}}$ are the band energies and $\boldsymbol{\theta}$ is the step function. This expression applies to both insulators ($\mu$ in a gap) and metals ($\mu$ across a band).

The PBCs projector is a lattice-periodical operator, commuting with the translation group:

$$\langle\mathbf{r}|\mathscr{P}|\mathbf{r}'\rangle = \langle\mathbf{r}+\mathbf{R}|\mathscr{P}|\mathbf{r}'+\mathbf{R}\rangle, \tag{49}$$

where $\mathbf{R}$ is a lattice vector. It is also "nearsighted" Kohn (1996), i.e.

$$\langle\mathbf{r}|\mathscr{P}|\mathbf{r}'\rangle \to 0 \quad \text{for } |\mathbf{r}-\mathbf{r}'| \to \infty; \tag{50}$$

the decay is quasi-exponential (i.e., exponential times a power) in insulators (He and Vanderbilt 2001) and power law in metals.

In the PBCs framework, an intensive observable of the electronic ground state is still expressed as a trace per unit volume, where Eq. (46) is replaced by

$$\mathrm{Tr}_V\{\mathscr{P}O\} = \frac{1}{V_{\mathrm{cell}}}\int_{\mathrm{cell}} d\mathbf{r}\,\langle\mathbf{r}|\mathscr{P}O|\mathbf{r}\rangle, \tag{51}$$

but in order for this to make sense, even $O$ must be a lattice-periodical operator, i.e.

$$\langle\mathbf{r}|O|\mathbf{r}'\rangle = \langle\mathbf{r}+\mathbf{R}|O|\mathbf{r}'+\mathbf{R}\rangle. \tag{52}$$

This clearly rules out $\mathbf{P}$ and $\mathbf{M}$, if we wish to make use of Eqs. (1) and (2), where the position operator $\mathbf{r}$ (unbounded and nonperiodical) plays a dominant role.

Finally we observe that, in both the OBCs and PBCs cases, the ground-state projector can be formally written as

$$\mathscr{P} = \boldsymbol{\theta}(\mu - \mathscr{H}). \tag{53}$$

All ground-state properties must be invariant by a translation of the energy zero (bar possibly the energy itself); Eq. (53) perspicuously shows that $\mathscr{P}$ enjoys such property. More generally, any ground-state observable is – at least in principle – a function of $\mathscr{H} - \mu$.

## 7.2    The Magnetization of a Bounded Sample

For a bounded sample, we may safely adopt the definition of Eqs. (2) and (46); it is however expedient to write the velocity operator in the equivalent form $\mathbf{v} = i[(\mathscr{H} - \mu), \mathbf{r}]/\hbar$, whence

$$\mathbf{M} = -\frac{ie}{2\hbar cV} \mathrm{Tr} \{\mathscr{P}\mathbf{r} \times (\mathscr{H} - \mu)\mathbf{r}\}, \tag{54}$$

since $\mathbf{r} \times \mathbf{r} = 0$. Insofar as the system remains finite, the appearance of $\mu$ in Eq. (54) looks irrelevant. But our choice has the virtue that $\mathbf{M}$ is *explicitly* a function of $\mathscr{H} - \mu$: this is essential in the thermodynamic limit for metals, where the spectrum becomes dense around $\mu$.

So far, we have identically transformed the textbook definition of Eq. (2) into the equivalent Eq. (54): this is still plagued by the same original drawback: the $\mathbf{r}$-space integral includes an extensive contribution from the boundary. Next we are going to tame the position operator by performing a transformation similar in spirit to an integration by parts, where the same integrated value obtains from two very different *integrands*. Eventually, the trace will be boundary-insensitive in the large-$V$ limit.

Using the cyclic properties of the trace, the Cartesian components of $\mathbf{M}$ are

$$M_\gamma = \frac{ie}{2\hbar cV} \varepsilon_{\gamma\alpha\beta} \mathrm{Tr} \{(\mathscr{H} - \mu)r_\alpha \mathscr{P}r_\beta\}. \tag{55}$$

where $\varepsilon_{\gamma\alpha\beta}$ is the antisymmetric tensor and the sum over repeated indices is implicit (here and throughout). The following lemma is then very useful. Let $O$ be any Hermitian operator commuting with $\mathscr{P}$. Then

$$\mathrm{Tr} \{O [r_\alpha, \mathscr{P}] [r_\beta, \mathscr{P}]\} = -\mathrm{Tr} \{O\mathscr{P}r_\alpha r_\beta\} - \mathrm{Tr} \{O(2\mathscr{P} - I)r_\alpha \mathscr{P}r_\beta\}. \tag{56}$$

We apply this lemma by identifying $O$ with the operator $|\mathscr{H} - \mu| = (\mathscr{H} - \mu)(I - 2\mathscr{P})$ to get

$$M_\gamma = -\frac{ie}{2\hbar cV} \varepsilon_{\gamma\alpha\beta} \mathrm{Tr} \{|\mathscr{H} - \mu| [r_\alpha, \mathscr{P}] [r_\beta, \mathscr{P}]\}, \tag{57}$$

where we have used $(I - 2\mathscr{P})^2 = I$.

If we now define the vector field

$$\mathfrak{M}(\mathbf{r}) = -\frac{ie}{2\hbar c} \langle \mathbf{r} | |\mathscr{H} - \mu| [\mathbf{r}, \mathscr{P}] \times [\mathbf{r}, \mathscr{P}] | \mathbf{r} \rangle, \tag{58}$$

the previous main result can be cast in the very compact form

$$\mathbf{M} = \frac{1}{V} \int d\mathbf{r} \, \mathfrak{M}(\mathbf{r}), \tag{59}$$

where we remind that the formula as it stands applies to spinless electrons. As proved here, the integrated value in Eq. (59) is identical to Eqs. (2) and (54) at any sample size; the key difference is that the *integrands* are quite different: Eqs. (2) and (54) are dominated by boundary contributions, while Eq. (59) is free from such drawback. Indeed, Eq. (59) is a *local* definition of magnetization: if the bounded sample is a crystallite (cut from a bulk crystal), then a definition of **M** equivalent to Eq. (59) in the large-sample limit is

$$\mathbf{M} = \frac{1}{V_{\text{cell}}} \int_{V_{\text{cell}}} d\mathbf{r} \, \mathfrak{M}(\mathbf{r}), \tag{60}$$

where $V_{\text{cell}}$ is a crystal cell in the center region of the crystallite. Obviously, a similar property *does not* hold for the original integral (Eq. (2)). Owing to the locality property, the definition of Eq. (60) can also deal – with obvious modifications – with noncrystalline or inhomogeneous samples, like heterojunctions.

In all of the previous equations, the large-sample limit is understood; it has been demonstrated (Bianco and Resta 2013; Marrazzo and Resta 2016) that the convergence of Eq. (60) is much faster than the convergence of Eqs. (2), (54), and (59). Simulations based on a model Hamiltonian in two dimensions have proved that the convergence of Eqs. (2), (54), and (59) is of the order $1/L$, where $L$ is the linear dimension of the sample, in both insulators and metals. Instead the convergence of Eq. (60) is exponential in insulators and $L^{-\alpha}$, with $\alpha > 1$, in metals. The difference between the two owes to the different "nearsightedness" of $\mathscr{P}$, mentioned above (Kohn 1996; He and Vanderbilt 2001).

### 7.3 The Magnetization of an Unbounded Crystalline Sample

The definition of the vector field $\mathfrak{M}(\mathbf{r})$, Eq. (58), applies as it stands even to an unbounded sample within PBCs. In the crystalline case, the $\mathscr{P}$ projector therein is expressed in terms of Bloch orbitals as in Eq. (48). It is easy to verify that the operator $[\mathbf{r}, \mathscr{P}]$ commutes with the lattice translations, and therefore $\mathfrak{M}(\mathbf{r})$ is a lattice-periodical function. In this sense the commutator with $\mathscr{P}$ effectively "tames" the nasty, unbounded, position operator $\mathbf{r}$. The expression for **M** as a trace per unit volume is therefore formally identical to Eq. (60), found above for a *bounded*

sample. We show next how to express it as a BZ integral in terms of Bloch orbitals; in metals the BZ integral is actually a Fermi volume integral, owing to the $\theta$ function entering the $\mathscr{P}$ definition (Eq. (48)).

We start rewriting Eq. (48) as

$$\langle \mathbf{r} | \mathscr{P} | \mathbf{r}' \rangle = \frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \ e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \langle \mathbf{r} | \mathscr{P}_{\mathbf{k}} | \mathbf{r}' \rangle \tag{61}$$

$$\mathscr{P}_{\mathbf{k}} = \sum_j \theta(\mu - \varepsilon_{j\mathbf{k}}) |u_{j\mathbf{k}}\rangle \langle u_{j\mathbf{k}}|. \tag{62}$$

The $\mathscr{P}_{\mathbf{k}}$ projector is gauge-invariant in the generalized Marzari-Vanderbilt sense (Marzari and Vanderbilt 1997; Marzari et al. 2012), i.e., it is invariant for any unitary transformation of the occupied $|u_{j\mathbf{k}}\rangle$ at the given $\mathbf{k}$; it is also periodic in $\mathbf{k}$ (even when the Chern invariant is nonzero). Therefore taking the $\mathbf{k}$-gradient inside the integral, we get

$$0 = i(\mathbf{r} - \mathbf{r}') \langle \mathbf{r} | \mathscr{P} | \mathbf{r}' \rangle + \frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \ e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \langle \mathbf{r} | \nabla_{\mathbf{k}} \mathscr{P}_{\mathbf{k}} | \mathbf{r}' \rangle; \tag{63}$$

$$[\mathbf{r}, \mathscr{P}] = \frac{i V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \ e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \nabla_{\mathbf{k}} \mathscr{P}_{\mathbf{k}}. \tag{64}$$

The Hamiltonian $\mathscr{H}$ can also be written as a BZ integral, hence

$$|\mathscr{H} - \mu| = \frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \ e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} |\mathscr{H}_{\mathbf{k}} - \mu|, \tag{65}$$

where $\mathscr{H}_{\mathbf{k}} = e^{-i\mathbf{k} \cdot \mathbf{r}} \mathscr{H} e^{i\mathbf{k} \cdot \mathbf{r}}$.

We thus get the relevant operator identity:

$$|\mathscr{H} - \mu| [r_\alpha, \mathscr{P}] [r_\beta, \mathscr{P}] = -\frac{V_{\text{cell}}}{(2\pi)^3} \int_{\text{BZ}} d\mathbf{k} \ e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} |\mathscr{H}_{\mathbf{k}} - \mu| (\partial_{k_\alpha} \mathscr{P}_{\mathbf{k}})(\partial_{k_\beta} \mathscr{P}_{\mathbf{k}}). \tag{66}$$

Notice that the three BZ integrals entering the product on the l.h.s. – from Eqs. (64) and (65) – eventually contract to a single BZ integral. This owes to the fact that both $\langle \mathbf{r} | \mathscr{H}_{\mathbf{k}} | \mathbf{r}' \rangle$ and $\langle \mathbf{r} | \nabla \mathscr{P}_{\mathbf{k}} | \mathbf{r}' \rangle$ are lattice-periodical in $\mathbf{r}$ and $\mathbf{r}'$ *separately*.

The ultimate formula (Resta 2018) for the orbital magnetization of a crystalline system is then, after Eqs. (58) and (60)

$$\mathbf{M} = \frac{ie}{2\hbar c} \int_{\text{BZ}} \frac{d\mathbf{k}}{(2\pi)^3} \text{Tr} \{ |\mathscr{H}_{\mathbf{k}} - \mu| (\nabla_{\mathbf{k}} \mathscr{P}_{\mathbf{k}}) \times (\nabla_{\mathbf{k}} \mathscr{P}_{\mathbf{k}}) \}. \tag{67}$$

## 7.4 Insulators and Metals

Our main magnetization formula (Eq. (67)) holds for both insulators and metals: the latter case requires further clarification. We start from the $\mathscr{P}_\mathbf{k}$ definition, Eq. (62), and we further adopt a gauge where $|u_{j\mathbf{k}}\rangle$ is a differentiable function of $\mathbf{k}$ (this is always possible, even for topologically nontrivial solids): then

$$
\nabla_\mathbf{k}\mathscr{P}_\mathbf{k} = \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}})(|\nabla_\mathbf{k}u_{j\mathbf{k}}\rangle\langle u_{j\mathbf{k}}| + |\nabla_\mathbf{k}u_{j\mathbf{k}}\rangle\langle u_{j\mathbf{k}}|)
$$
$$
- \sum_j \delta(\mu - \varepsilon_{j\mathbf{k}})\nabla_\mathbf{k}\varepsilon_{j\mathbf{k}}\,|u_{j\mathbf{k}}\rangle\langle u_{j\mathbf{k}}|. \tag{68}
$$

The second line vanishes in insulators but is singular in metals. Nonetheless the singularity does not affect Eq. (67), given that it cancels in the antisymmetrized product. We may therefore safely neglect the second line of Eq. (68) in the following. The integrand in Eq. (67) is a continuous function of $\mathbf{k}$ in insulators and piecewise continuous in metals; Eq. (67) is indeed a well-defined Fermi-volume integral in both cases. As for the first line of Eq. (68), we notice that, while $\nabla_\mathbf{k}\mathscr{P}_\mathbf{k}$ is gauge-invariant and Hermitian, the operators $|\nabla_\mathbf{k}u_{j\mathbf{k}}\rangle\langle u_{j\mathbf{k}}|$ and $|u_{j\mathbf{k}}\rangle\langle\nabla_\mathbf{k}u_{j\mathbf{k}}|$ are in general gauge-dependent and non-Hermitian: in fact the trace of $|\nabla_\mathbf{k}u_{j\mathbf{k}}\rangle\langle u_{j\mathbf{k}}|$, times $i$, is nothing else than the Berry connection of band $j$, i.e., the essential ingredient of polarization theory (see Sect. 5).

At this point we wish to make contact with the original formula of magnetization theory (Xiao et al. 2005; Thonhauser et al. 2005; Ceresoli et al. 2006), as reported in the previous reviews (Resta 2010; Thonhauser 2011),and implemented in a few first-principle calculations:

$$
M_\gamma = -\frac{ie}{2\hbar c}\varepsilon_{\gamma\alpha\beta}\sum_{\varepsilon_{j\mathbf{k}}<\mu}\int_{\mathrm{BZ}}d\mathbf{k}\,\langle\partial_{k_\alpha}u_{j\mathbf{k}}|(\mathscr{H}_\mathbf{k} + \varepsilon_{j\mathbf{k}} - 2\mu)|\partial_{k_\beta}u_{j\mathbf{k}}\rangle. \tag{69}
$$

It is important to observe that Eq. (69) requires the so-called Hamiltonian gauge, i.e., the $|u_{j\mathbf{k}}\rangle$ are eigenstates of $\mathscr{H}_\mathbf{k}$: unitary mixing of them – à la Marzari-Vanderbilt (Marzari and Vanderbilt 1997; Marzari et al. 2012) – is *not* permitted. Our more general Eq. (67), instead, is fully gauge-invariant.

In order to prove the equivalence, it is expedient to introduce a lemma. Let $O_\mathbf{k}$, with eigenvalues $o_{j\mathbf{k}}$, be any operator which commutes with $\mathscr{H}_\mathbf{k}$, i.e.

$$
O_\mathbf{k} = \sum_j |u_{j\mathbf{k}}\rangle o_{j\mathbf{k}}\langle u_{j\mathbf{k}}|. \tag{70}
$$

Then the following identity holds:

$$\text{Tr}\{O_{\mathbf{k}}(\partial_{k_\alpha}\mathscr{P}_{\mathbf{k}})(\partial_{k_\beta}\mathscr{P}_{\mathbf{k}})\} = \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}}) o_{j\mathbf{k}} \langle \partial_{k_\alpha} u_{j\mathbf{k}} | \partial_{k_\beta} u_{j\mathbf{k}} \rangle \tag{71}$$

$$+ \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\beta} u_{j\mathbf{k}} | O_{\mathbf{k}}(I - 2\mathscr{P}_{\mathbf{k}}) | \partial_{k_\alpha} u_{j\mathbf{k}} \rangle.$$

This identity is somewhat reminiscent of Eq. (56) and is proved via a straightforward although somewhat tedious calculation.

We now identify $O_{\mathbf{k}}$ with $|\mathscr{H}_{\mathbf{k}} - \mu| = (\mathscr{H}_{\mathbf{k}} - \mu)(I - 2\mathscr{P}_{\mathbf{k}})$ and we get

$$\text{Tr}\{|\mathscr{H}_{\mathbf{k}} - \mu|(\partial_{k_\alpha}\mathscr{P}_{\mathbf{k}})(\partial_{k_\beta}\mathscr{P}_{\mathbf{k}})\} = \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}})(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\alpha} u_{j\mathbf{k}} | \partial_{k_\beta} u_{j\mathbf{k}} \rangle$$

$$\tag{72}$$

$$+ \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\beta} u_{j\mathbf{k}} | (\mathscr{H}_{\mathbf{k}} - \mu) | \partial_{k_\alpha} u_{j\mathbf{k}} \rangle,$$

where we have exploited $(I - 2\mathscr{P}_{\mathbf{k}})^2 = I$. Antisymmetrization yields

$$\varepsilon_{\gamma\alpha\beta} \text{Tr}\{|\mathscr{H}_{\mathbf{k}} - \mu|(\partial_{k_\alpha}\mathscr{P}_{\mathbf{k}})(\partial_{k_\beta}\mathscr{P}_{\mathbf{k}})\}$$

$$= \varepsilon_{\gamma\alpha\beta} \sum_j \boldsymbol{\theta}(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\alpha} u_{j\mathbf{k}} | (2\mu - \varepsilon_{j\mathbf{k}} - \mathscr{H}_{\mathbf{k}}) | \partial_{k_\beta} u_{j\mathbf{k}} \rangle, \tag{73}$$

and substitution into Eq. (67) concludes our proof.

## 8    Conclusions

Macroscopic polarization $\mathbf{P}$ and orbital magnetization $\mathbf{M}$ are phenomenologically known as intensive ground-state properties of condensed matter. Their elementary definitions, Eqs. (1) and (2), are very similar and are affected by the same drawback: the unboundedness of the position $\mathbf{r}$ therein. Because of this feature, the elementary definitions *cannot* be adopted to address macroscopic systems: Eqs. (1) and (2) are incompatible with periodic Born-von Kármán boundary conditions, which are at the root of all condensed matter theory and which make bulk physical properties accessible to computation (for both crystalline and noncrystalline materials).

The two very important observables $\mathbf{P}$ and $\mathbf{M}$ have remained problematic for many years; the nasty position operator $\mathbf{r}$ has been effectively "tamed" in the early 1990s in the case of $\mathbf{P}$ and since 2005 onward in the case of $\mathbf{M}$. In both cases the formulas adopted by modern condensed matter physics, as presented in detail throughout this chapter, do not bear any resemblance to Eqs. (1) and (2). In the special case of a crystalline system of independent electrons, both $\mathbf{P}$ and $\mathbf{M}$ are expressed as reciprocal-space integrals, where no reference to the position operator $\mathbf{r}$ is made. The integrands therein look superficially – and only superficially – rather

similar; here we have emphasized instead the key features which make the intensive observables **P** and **M**, as defined by the modern theories, profoundly different between themselves.

The qualitative difference came out as a big surprise, given the close similarity of Eqs. (1) and (2); we may spell out such difference as follows. Macroscopic polarization **P** is a Berry phase of the electronic ground-state wave function and does not admit any local representation: there is no "polarization density" to speak of. Orbital magnetization **M** can be defined – similarly to **P** – as a reciprocal-space integral, but, at variance with **P**, it also admits a local representation with a well-defined density in coordinate space. The modern theory of magnetization may even address macroscopically inhomogeneous systems (e.g., heterojunctions), which are *not* accessible to the modern theory of polarization.

The modern theory of polarization is nowadays a mature topic. Its formalism, presented here in detail in Sect. 5, is implemented as a standard option in most density-functional-theory electronic structure codes, based on first-principle ingredients. Because of this, there have been hundreds of applications to the most diverse materials, starting with the most common ferroelectrics and piezoelectrics. The accuracy and predictive power are remarkable, of the order of 5%–10% for nonproblematic materials. An extension of the theory – associated to Car-Parrinello simulations – has also provided very accurate infrared spectra for amorphous and liquid materials, including the paradigmatic case of water.

The modern theory of orbital magnetization is instead much less popular; there are several reasons for this. Bulk magnetization is the sum of an orbital term and a spin term: the latter is the dominant one in the most common materials. In the paradigmatic ferromagnetic metals Fe, Co, and Ni, the orbital contribution to the net magnetization is between 5% and 10%. Furthermore in most materials, the orbital magnetization is due to very localized $d$ orbitals, whose orbital moment can be evaluated semiquantitatively via some crude approximation. Finally, a technical complication concerns pseudopotential implementations: the core electrons do not contribute to electrical polarization but contribute instead to orbital magnetization. Therefore core-reconstruction corrections have to be added to the formulas presented here, whenever implemented in a plane-wave pseudopotential framework.

It is expected that the modern theory of polarization, in the different variants described here, will remain a staple of electronic structure theory for years to come. As for the modern theory of magnetization, its appeal for addressing real materials from first principles is limited so far. It will be enhanced if some all-electron implementations become available and if materials where the orbital term is the dominant one are discovered.

Tommaso Rizzo

## Contents

**Abstract**

Supercooled liquids become increasingly sluggish upon cooling down to the glass temperature $T_g$ where they can no longer be studied in equilibrium on the laboratory scale and behave as off-equilibrium amorphous solids, i.e., glasses. Simple activated dynamics account for the behavior of so-called strong liquids, but deviations from Arrhenius behavior are observed in fragile ones and have defied explanation for decades. Technical advances in experiments have steadily unveiled more facets of the puzzling phenomenology of fragile liquids including notably two-step relaxation, stretched exponentials, superposition principles, and dynamical heterogeneities. Theoretical efforts have developed mainly around the idea that some sort of finite-temperature critical phenomenon is at play, the key role in the discussion being played by two different critical points. The first one is thought to occur above $T_g$, and therefore it is not really a phase transition

but rather a dynamical crossover. Numerical studies have shed much light on its nature, and nowadays it is largely believed to be the outcome of the smoothing of a sharp singularity spuriously predicted by mode-coupling theory. The existence of a dynamical crossover is largely accepted, and what is disputed is whether that is the end of the story.

Those who believe this is not the case typically put forward the classic hypothesis of a true thermodynamic phase transition to an amorphous glass state at some finite temperature below $T_g$. Originally suggested by elementary extrapolations of experimental data, this putative critical point is nowadays supposed to be a complex and fascinating object, notably the locus of a configurational entropy crisis accompanied by a divergent static correlation length. The quest to establish its existence, reinvigorated by the discovery of the glass/spin-glass analogy, is very much open but has produced nonetheless significant advances both at the theoretical and numerical level. Opponents of the thermodynamic transition scenario include notably those who advocate for dynamic facilitation, as realized in kinetically constrained models, to explain physics solely in terms of a dynamical crossover. Understanding dynamics between the crossover temperature and $T_g$ would help assess both the range of validity of a description in terms of the crossover and whether something qualitatively different must be invoked close to $T_g$ and below. Here the essential missing piece of information is the nature and spatial extent of the activated processes that should rule the dynamics: at the theoretical level, a consistent, beyond phenomenological, theory of these dynamical processes has still to be developed; at the experimental level, current techniques do not have enough spatial resolution; finally numerical simulations have been typically confined to higher temperatures due to hardware speed limitations but are beginning to access the crossover region and may provide some guidance in the coming years.

## 1    Introduction

In spite of decades of experimental, theoretical, and numerical studies, the glass problem is very much open: the community agrees only on a few statements while all the rest is strongly debated. In the following an introductory critical discussion will be given of some of the theoretical and numerical results inspired by the idea that some sort of critical phenomena determines the puzzling phenomenology of supercooled liquids. The reader should be aware that this covers only a part, although significant, of the literature of this field. In the spirit of the handbook, this contribution is not intended as a general and exhaustive review but rather as an, hopefully stimulating, introduction to some of the main open questions. The interested reader will find in the references a number of more technically detailed review papers and books (Gotze 2009; Cavagna 2009; Wolynes and Lubchenko 2012; Berthier et al. 2011; Berthier and Biroli 2011).

This line of research has evolved over the years around the existence of two critical temperatures: the crossover temperature and the Kauzmann temperature. The first critical temperature occurs upon supercooling the liquid when it still can be studied in equilibrium, and its existence is largely agreed upon and can be considered part of the phenomenology. The problem is that it does not mark a genuine phase transition but rather a dynamical crossover; thus it is difficult to make sharp and universal statements about it. In this context mode-coupling theory (MCT) captures the initial steps of the dynamical slowing down but fails spectacularly because it predicts a sharp transition instead of a crossover, and the main open problem is to extend it to the crossover region and below. From the point of view of material modeling and simulations, it is a particularly important problem, because the resolution of current experiments cannot provide guidance for its solution. On the other hand, microscopic details are fully under control in numerical simulation, but hardware constraints limit them to considerably higher temperatures than those reached by experiments. Nevertheless many believe that the crossover region is attainable with present or near-future technology and hope to finally understand this regime in the coming years.

It is fair to say that our shared understanding of the physics of glasses ends with MCT slightly before the glass crossover. Below it we only know that some kind of activated dynamic should set in. In this context a fascinating but strongly debated hypothesis is the occurrence, at very low temperatures, of a genuine thermodynamic transition from the liquid to an amorphous glass state. This line of research has inspired a variety of novel analytical and numerical techniques; the idea is that the information on slow dynamics can be obtained without performing molecular dynamic simulations but rather by studying the equilibrium configurations of appropriately constrained systems. From the analytical point of view, the advantage is that one can perform static computations that are typically easier than full-fledged dynamical ones. From the numerical point of view, the advantage is that equilibrium configurations can be obtained through more efficient algorithms than molecular dynamics. This is a field where numerical work has been going on in the last 15 years, and significant recent developments include algorithms to reach temperatures that even experiments cannot. Nevertheless evidences for a genuine phase transition are still not decisive; besides this information has not shed light into the fundamental question of why dynamics becomes so slow.

This work is organized as follows. In order to define the problem, the main dynamical features of realistic supercooled liquids as obtained from experiments will be summarized in Sect. 2. In Sect. 3 the MCT scenario will be presented, and it will introduce a discussion of the extent to which the phenomenology can be explained in terms of an avoided MCT-like transition. Section 4 is devoted to the existence of a genuine phase transition occurring in the regime that is not accessible by experiments and to the conceptual, technical, and numerical developments it has inspired. Conclusions will be drawn in the last section.

## 2    Phenomenology of Supercooled Liquids

The main properties of supercooled liquids, as observed in experiments, are (1) power law to exponential crossover, (2) two-step relaxation, (3) complex dynamics (stretched exponentials), and (4) dynamical heterogeneities (violation of the Stokes-Einstein relationship (SER)). These are dynamical properties that a consistent theory of glasses should necessarily explain. In addition there are the so-called thermodynamics/dynamics correlations whose significance in relationship to the experimental dynamical features is more disputed.

The power law to exponential crossover is the oldest property that has been observed and possibly the most important. Upon slowly cooling a liquid crystallizes at the melting temperature. If one is able to further lower the temperature avoiding crystallization, a supercooled liquid is obtained. Upon further cooling, the relaxation time or equivalently the viscosity of the supercooled liquid increases up to a value where the viscosity is equal to a (conventional) value of the order of the laboratory timescale. This point defines the glass transition temperature $T_g$. It should be clear that nothing special happens at $T_g$ from the point of view of the system; it is just the lowest temperature where the system can reach equilibrium in a timescale accept-able to humans. Obviously there is nothing strange in dynamic slowing down upon lowering the temperature; for instance, this occurs if dynamics proceeds through elementary events that require to overcome a constant free energy barrier $E$. In this case Arrhenius behavior is observed, with the logarithm of the relaxation time (or equivalently the inverse of the viscosity) increasing as the inverse of the temperature:

$$\tau_\alpha \propto e^{-\frac{E}{k_B T}} \tag{1}$$

Strong liquids exhibit by definition Arrhenius behavior upon supercooling, while fragile liquids exhibit a different behavior: when the logarithm of the viscosity is plotted vs. the inverse temperature in the so-called Angell's plot (1995), the data do not follow a straight line (see Fig. 1). In the early stages of supercooling, the viscosity of fragile liquids increases slowly and can be fitted by the tail of a power law diverging at some finite temperature. This temperature, however, marks a dynamical crossover: close to it the viscosity deviates from the power law and does not diverge; however it begins to increase in a more pronounced way that can only be fitted with functional forms depending exponentially on the temperature variations. Overall the data of fragile liquids exhibit a more or less pronounced bending with respect to the straight line Arrhenius behavior, and the slope at $T_g$ provides a quantitative definition of kinetic fragility (note that this terminology has nothing to do with the brittleness properties of the corresponding glass). Experimental data above $T_g$ have been fitted by many different functions, including some that, upon extrapolation, predict a divergence of the relaxation time at some finite temperature below $T_g$, notably the Vogel-Fulcher-Tammann (VFT) law:

$$\tau_\alpha = \tau_0 \exp\left[\frac{DT_0}{T - T_0}\right] \tag{2}$$
**Fig. 1** Phenomenology of supercooled liquids. (**a**) Strong liquids like silica ($SiO_2$) follow a straight line on the Angell's plot, while fragile liquids like glycerol and *ortho*-terphenyl (OTP) exhibit a bending (Ediger et al. 1996). (**b**) The self-intermediate scattering function $F_s(q; t)$ for $q = 6.1$ at various temperatures from a numerical simulation of a binary mixture, from Flenner and Szamel (2013). The dashed line is a stretched exponential. (**c**) The susceptibility spectrum of supercooled CKN (Li et al. 1992) is broader than that of a single exponential (solid line); correspondingly the relaxation can be only fitted by a stretched exponential. (**d**) Diffusion coefficient $D$ versus viscosity $\eta$ for experimental and numerical simulation data from Rizzo and Voigtmann (2015). Dashed lines indicate $D \propto \eta^{-1}$ (Stokes-Einstein relation) and a fit with $D \propto \eta^{-0.65}$ (fractional SE relation). A large circle marks the crossover temperature. Inset: $D \cdot \tau$ with simulation data

This leads to the two following essential questions: what causes the power law to exponential behavior in fragile liquids? Will the relaxation time eventually diverge at a finite temperature below $T_g$?

Models of supercooled liquids are often defined in terms of spherical particles interacting with pairwise potentials, and the typical dynamical observable is the intermediate scattering function:

$$F(q, t) \equiv \frac{1}{N} \langle \rho_q(t)\rho_{-q}(0) \rangle \tag{3}$$

where the square brackets mean thermal average, $\rho_q$ is the Fourier component of the density,

$$\rho_q \equiv \sum_{j=1}^{N} e^{i\,q\,r_j} \tag{4}$$

and $r_j$ is the position of particle $j$. The intermediate scattering function is equivalent, by means of Fourier transforms, to the dynamic structure factors and the van Hove function. At $t = 0$ the intermediate scattering function is equal to the static structure factor and relaxes to zero at large times. In experiments this quantity is accessible through a number of techniques (Richert 2012; Lunkenheimer et al. 2012). Observation of the two-step relaxation requires measurements on a huge range of timescales. The main relaxation, associated with the viscosity, is called the $\alpha$ process hence the name $\tau_\alpha$ for the relaxation time. However, there is an additional timescale $\tau_\beta$ over which $F(q, t)$ develops a plateau when plotted vs. $log(t)$ and the system appears to be essentially frozen. The $\beta$ scale is orders of magnitude smaller than $\tau_\alpha$, but it is considerably larger than the microscopic timescale. In Fig. 1b the phenomenon is displayed as measured in a numerical simulation for the relaxation of the self-intermediate scattering function (the Fourier transform of the single-particle displacement). The origin of the two-step relaxation is often attributed to the emergence of caging (Gotze 2009). The idea is that when dynamics is sufficiently slow, the environment of a given particle appears to be frozen, and therefore the particle itself is caged and will in turn cage its neighbors.

Caging is observed clearly in numerical simulations of hard-sphere systems (Kob 1999), but its origin is not completely understood. In these systems the temperature can be always reabsorbed into a rescaling of times, and the only nontrivial external parameter to be changed is the density. It seems natural that upon increasing the density at some point dynamics will slow down because of reduced volume effects. The problem with this interpretation is that caging is observed already at rather low density, and it appears abruptly in a rather narrow range of densities, meaning that if one inspects instantaneous configurations it is rather difficult to tell the difference between a configuration from a system that displays caging and one from a system that does not. This is an aspect of the so-called structure vs. dynamics problem. In other words the question is whether slow dynamics can be traced back to some structural property of the instantaneous equilibrium configurations. We may ask if there is some observable that can be measured on a given configuration that will correlate with the fact that relaxation from that configuration will exhibit caging or not. This is a fundamental question in the field, and the negative answer amounts to say that glassiness is a completely dynamical problem; this issue will be discussed again later on.

In simple Arrhenius dynamics relaxation decays exponentially in time. Relaxation in fragile liquids instead is complex, meaning that can only be typically

fitted with a stretched exponential form $\exp(-t^b)$. In experiments this result in the broadening of the susceptibility spectra that are related to the Fourier transform of the relaxation (see Fig. 1c). Much as the two-step relaxation, this is not at all trivial. As soon as the relaxation is controlled by independent microscopic events occurring in a uniform environment, the decay is necessarily exponential, while in order to have a stretched exponential behavior, one must either invoke spatial fluctuations in the environment or a moderately large correlation length implying that the relaxation events are not elementary or involve many particles. Which hypothesis is correct, if any of the two, is at present unknown. *Superposition principles* are an additional nontrivial feature of the relaxation. Strictly speaking they amount to say that the temperature dependence of the relaxation is only encoded in the timescale $\tau_\alpha$, meaning that one can write

$$F(q, t) = C_q(t/\tau_\alpha) \qquad (5)$$

for some function $C_q(t)$. This property is verified approximately by many supercooled liquids in some temperature range; see Gotze (2009) for a more detailed discussion of experimental data.

In the last 20 years dynamical heterogeneities (Ediger 2000; Berthier et al. 2011) have emerged as a fundamental property of fragile liquids. In short the idea is that approaching $T_g$ if one look at the liquid at the microscopic level there will be regions where dynamics is orders of magnitude faster than in the rest of the system. The above generic statement can, and often is, misinterpreted if one does not give it a more quantitative formulation. This is given by the so-called violation of the Stokes-Einstein relationship (SER) connecting the viscosity with the inverse of the diffusion constant of a given particle. The SER is verified at high temperatures, but violations are observed approaching $T_g$ and starting somewhere near the crossover temperature (see Fig. 1d). The SER can be justified assuming that each particle perform a kind of Brownian motion in a homogeneous environment. Conversely violations should occur in a situation in which, even if the SER is satisfied locally, the environment is not homogeneous and the local viscosity has strong fluctuations in such a way that the inverse of its average is different from the average of its inverse. Once again the precise mechanism leading to SER violations is not agreed on, but they are definitively considered a hallmark of complex dynamics. MCT helps to clarify that dynamical heterogeneities should not be confused with dynamical fluctuations; indeed MCT has diverging dynamical fluctuations but no SER violation.

In addition to the above dynamical features, a consistent part of the literature points toward the so-called thermodynamics/dynamics correlations connecting dynamical quantities like the viscosity with thermodynamical quantities (the entropy) measured by calorimetry. They are often invoked in the context of theories that advocate for the existence of a genuine phase transition below $T_g$, and they will be discussed in more details in Sect. 4.

# 3     The Crossover Temperature

## 3.1     Mode-Coupling Theory

Mode-coupling theory (Gotze 2009) starts from the exact microscopic equations for the dynamic structure factor of simple monoatomic liquid models and then makes a certain number of approximations. The outcome is a set of closed equations that can be solved numerically once the static structure factor is provided as input. Before discussing MCT predictions, let us stress that there is at present a very poor understanding of the approximations involved. The only justification comes a posteriori as the results display a significant agreement with the behavior of actual systems (again with some caveats), and the problem is complicated by the fact that some of the approximations involved cannot even be tested directly. Therefore, in spite of the fact that MCT starts from the exact microscopic dynamics, it is fair to say that it is essentially a black box whose internal operation is unknown. Efforts to understand it have been limited in the past, and more work should be devoted to this essential open problem. Instead research activity has essentially ignored this issue focusing on the empirical development of a sort of operating manual of the theory and applying the resulting procedure to a variety of models and systems again with impressing results.

There is a broad agreement that many supercooled fragile liquids can be modeled by simple liquids with pairwise interactions, including hard-sphere (HS) systems. However in two and three dimensions, monoatomic systems tend to crystallize easily and cannot be supercooled to very low temperature; therefore one must consider, at least, binary mixtures (Kob 1999). Mode-coupling equations can be extended to binary systems of hard or soft spheres, and the resulting equations can be solved to obtain the dynamic structure factor giving as input the static structure factor typically obtained from numerical simulation.

The theory predicts that at a given value of the control parameter (temperature or pressure), dynamical arrest occurs meaning that the infinite time limit of the dynamic structure factor does not decay to zero as it should in the liquid phase but tends to a constant momentum-dependent value, called the non-ergodicity parameter. As we said already it is known that this prediction is completely wrong, and in order to understand why, in spite of this dramatic failure, MCT is still considered highly valuable; we have to discuss its predictions upon approaching the transition temperature $T_{MCT}$.

First of all, MCT predicts that the decay of the dynamic structure factor proceeds in a two-step fashion as seen in experiments, with both scales $\tau_\beta$ and $\tau_\alpha$ diverging as power law of $\tau \equiv T_{MCT} - T$. More precisely at the critical temperature $T = T_{MCT}$, $F(q, t)$ approaches the nonzero long-time limit $F_c(q)$ in a power-law fashion with a nontrivial exponent $a$: $F(q, t) \approx F_c(q) + c/t^a$. The exponent $a$ controls the divergence of the $\beta$ scale through

$$\tau_\beta \propto |\tau|^{\frac{1}{2a}}. \tag{6}$$

For temperatures slightly larger than $T_{MCT}$, $F(q, t)$ reaches the plateau value $F_c(q)$ in a finite time that defines the scale $\tau_\beta$. For times of the order of $\tau_\beta$, it remains close to the plateau value up to deviations of order square root of $\tau \equiv T_{MCT} - T$ before eventually leaving the plateau on the scale $\tau_\alpha \propto |\tau|^{-\gamma}$. The decay on the $\alpha$ scale satisfies both the superposition principle and the stretched exponential form with exponent $\exp[-t^b]$, in striking agreement with experiments. Furthermore the exponent $\gamma$ is related to $a$ and $b$ through

$$\gamma = \frac{1}{2a} + \frac{1}{2b} \tag{7}$$

and the two exponents $a$ and $b$ can be both expressed as

$$\lambda = \frac{\Gamma^2(1-a)}{\Gamma(1-2a)} = \frac{\Gamma^2(1+b)}{\Gamma(1+2b)} \tag{8}$$

where $\lambda$ is the so-called parameter exponent for which MCT provides quantitative predictions.

Data from numerical simulations of a variety of models are consistent with this scenario in some range of temperatures (Kob 1999; Gotze 2009). In particular, it is often possible to estimate the critical temperature, the exponents, and the ergodicity-breaking parameter $F_c(q)$ and compare them with the quantitative predictions of MCT. One should bear in mind that these estimates from realistic systems data are intrinsically arbitrary because in principle MCT scalings are only well defined close to the dynamical arrest transition, but in practice the transition does not occur. In practice this ambiguity is reflected by the fact that the critical temperature depends on the observable and also on the nature and range of the fit. In spite of this intrinsic ambiguity, it turns out that the range of variations of the critical temperature is often sufficiently small for the whole procedure to make sense. This happens for most models and experimental systems, and indeed this *experimental* MCT critical temperature (or density) is almost always reported in any study of supercooled liquid. Furthermore the value of the ergodicity-breaking parameter can be obtained from the data, and it is often in excellent quantitative agreement with the predictions of MCT. The values of the critical exponents are more ambiguous but still are in good agreement with the predictions of MCT. In particular it seems that there is good consistency between the exponents $a$ and $b$ that control the $\beta$ regime with the exponent $\gamma$ that controls the $\alpha$ regime. This is a manifestation of the nontriviality of the double-step relaxation, in the sense that processes occurring on large but comparatively very different timescales are related. It is worth mentioning that MCT predictions appear to be somewhat meaningful even below the critical temperature $T_{MCT}$ where the theory predicts that $F(q, t)$ have a nonzero long-time limit increasing as $\sqrt{\tau}$ for $T$ smaller than $T_{MCT}$. It turns out that in many experimental systems and numerical simulations a square root increase of the plateau value can be actually observed notwithstanding the fact that $F(q, t)$ will eventually leave the plateau at variance with MCT predictions.

Overall the comparison between numerical simulations and theory suggests a scenario in which ideal MCT predictions are accurate except very close to the critical temperature where the theory needs some substantial modification. Unfortunately this scenario is too optimistic in the sense that the effective MCT temperature, the one for which MCT fits do describe actual data, is definitively different from the value of the critical temperature obtained from the solutions of the MCT equations itself (Kob 1999). This discrepancy is model-dependent but seems rather universal; typically it is more pronounced in soft sphere models than in HS, but its origin is unclear. As a result, it is often said that the MCT critical temperature is wrong, but it should be clear that there are two essentially different aspects of it being wrong. In a weak sense it is wrong because its value does not compare well with the value used to fit numerical data. The theory overestimates this value, and in practice in order to obtain reasonable fits, one must plug into the MCT equations the structure factors from higher temperatures. In a strong, more fundamental, sense MCT is wrong because there is no true critical temperature in experiments and numerical simulations.

The above discussion on the critical temperature allows to introduce the quantitative vs. qualitative MCT scenario. There are some features of MCT that are more universal and are found also outside the original domain of the theory, i.e., supercooled simple liquid models in physical dimension. The most striking instance is the case of spin glasses displaying one step of replica symmetry breaking (1RSB) in Parisi's scheme (Mezard et. al. 1988). These systems are utterly different from a liquid at the microscopic level; notably they are defined on a lattice, and they have quenched disordered interactions, and yet, as discovered by Kirkpatrick and Thirumalai (1987), their dynamics shares the very same phenomenology of MCT, namely, dynamic arrest characterized by two-step relaxation with power-law divergent timescales. Furthermore in the $\beta$ regime, where the correlation stays near the plateau, dynamics obeys the very same critical equation of MCT, i.e., a universal quadratic dynamical equation that does not depend on the microscopic details of the model. Thus one should always bear in mind that there are qualitative, much more general, MCT predictions and quantitative MCT predictions that are only limited to supercooled liquid models. In MCT literature this distinction is often not very clear.

An important instance of the qualitative/quantitative difference is the case of simple supercooled liquids in large dimension. This problem has been investigated extensively over the years under the expectation that in infinite dimension the crossover should become a true transition and the problem should become solvable. These studies culminated recently with the exact and complete solution (Charbonneau et al. 2016) that confirmed that the qualitative MCT scenario is correct (e.g., the relationship between the exponents holds), while the quantitative values of the critical temperature and of the exponents are wrong.

Another striking instance of the universality of the qualitative MCT scenario is provided by cooperative kinetically constrained models (KCM) (Ritort and Sollich 2003; Chandler and Garrahan 2010) that will be briefly discussed in the next

section. Remarkably the Fredrickson-Andersen model, when studied on the (mean-field) Bethe lattice, displays a dynamical arrest transition in agreement with the qualitative MCT scenario (Berthier and Biroli 2011). Note that this statement is only based on numerical observations, and justifying it analytically is a fascinating open problem.

We are now in position to discuss the failures and successes of MCT in connection with the phenomenology of real supercooled liquids presented in the previous section. The two-step relaxation scenario is a significant success together with the presence of stretched exponentials in the relaxation. The main failure is the prediction of a true phase transition which in reality is a crossover; however MCT is at least consistent with the initial power-law behavior. Another significant failure of MCT is that even close to the critical temperature, it does not display the SER violations associated with dynamical heterogeneities. By means of the microscopic MCT equations, one can indeed obtain predictions for the diffusivity. Remarkably the lack of SER violation is confirmed by the exact solution in infinite dimension (Charbonneau et al. 2016). The fact that SER holds in MCT does not mean that dynamical fluctuations are finite within the theory. Actually one can argue that close to $T_{MCT}$ the theory predicts both diverging dynamical fluctuations and diverging dynamical correlation length. This can be shown by means of an extension called inhomogeneous MCT (Berthier and Biroli 2011) although care must be taken in extracting the critical exponents as simple scaling arguments lead to incorrect results (Rizzo 2014). Given that the dynamical arrest transition does not occur, these divergences are also unrealistic and are not often emphasized in the MCT literature.

A few comments on the spurious divergence of the dynamical correlation length are in order. In the early days of MCT, it was not clear what was the origin of dynamical arrest, and some authors believed that no diverging correlation length was involved (see, e.g., Ediger et al. 1996). One can argue on physical ground that for ergodic statistical mechanics systems, a finite-temperature dynamical transition must be necessarily associated with a diverging correlation length (these arguments can be made rigorous in the case of spin-glass models (Berthier and Biroli 2011)). This observation may appear not so important in the case of the MCT crossover because in the end no dynamical arrest transition is present, but it is important when discussing the possibility of a true transition occurring at some finite temperature below $T_g$ as we will see in the following section. Another point worth mentioning is that while diverging fluctuations must be necessarily accompanied by a diverging correlation length, a simple increase of fluctuations does not imply an increasing correlation length. This is important to assess the relevance of experimental measurements of nonlinear susceptibilities. The increase of fluctuations reported in these experiments is sometimes interpreted as an indication of an increase of the correlation length (Albert et al. 2016), overlooking the fact that the connection between the two quantities requires additional assumptions. Actually a recent theory of the crossover provides a counterexample in which increasing dynamical fluctuations are accompanied by a decreasing correlation length (Rizzo 2014).

## 3.2    Toward a Theory of the Crossover

The understanding of supercooled liquids ends slightly above the crossover temperature and everything occurring below is disputed. While MCT is definitively wrong at low temperatures, its success at moderate supercooling suggests that one should amend it in order to describe the crossover region and then move to even lower temperatures. Efforts in this direction have been going on for a long time, but none is considered fully satisfactory and will not be discussed in detail. People tried often to modify the theory at the microscopic level. In general it turns out to be rather easy to remove the sharp transition, but this typically leads to a simple exponential relaxation thus spoiling the stretched exponential which is one of the great successes of MCT, not to mention that these modifications are always ad hoc and phenomenological. Note that MCT also starts from the microscopic first-principle description and then makes some uncontrolled approximations, however there is no evident logical connection between the approximations made and the final results, and in this sense MCT approximations are not considered ad hoc.

A different possibility is that in order to describe the physics at the crossover and go beyond MCT, one should use instead a mesoscopic effective theory that is accurate on a coarse-grained scale over which the microscopic details of the model are unimportant. This is the way to proceed in the case of a genuine second-order phase transition because they are characterized by a divergent correlation length. Applications of these ideas in the context of the crossover appear counterintuitive, since in the end the correct theory should tell us that there is no divergence of the correlation length. Nevertheless one should note that in order for a mesoscopic effective theory description to be valid, one does not need a diverging correlation length; it is enough for it to be large compared to the microscopic scale. On the other hand it is largely agreed that dynamics in the crossover region is cooperative meaning that the dynamical correlation length, while not diverging, is indeed large (Berthier and Biroli 2011; Harrowell 2011).

The mesoscopic theory can be shown to be equivalent to a solvable model of dynamical stochastic equations. Quite interesting the resulting model displays all the hallmark of supercooled liquid, namely, the power law to exponential crossover, two-step relaxation, stretched exponential, and dynamical heterogeneities in the form of SER violations (Rizzo 2014). Most importantly it is not a phenomenological theory because these features are not the outcome of ad hoc assumptions. On the other hand, by definition, there is no way to tell from the mesoscopic theory itself if it is appropriate to describe a specific system. For that one should start from a first-principle microscopic description and apply coarse-graining in a rigorous way. This implies that in principle this description could be accurate for one system but not for another system. It is also important to note that the validity of a mesoscopic description for a given supercooled liquid model could also be assessed explicitly by means of a numerical simulation. This requires to accurately measure dynamical fluctuations and correlation lengths to check if the order parameter after coarse-graining is sufficiently smooth to be described by an effective theory.

The technology to measure dynamical correlations and fluctuations was developed some 20 years ago motivated by the experimental observations of dynamical heterogeneities (Berthier and Biroli 2011), and it is known that extracting these quantities from numerical simulations is quite demanding.

## 4 Dynamics vs. Thermodynamics: The Kauzmann Temperature

The idea of a genuine phase transition occurring below originated with Kauzmann's analysis of calorimetric experimental data (Kauzmann 1948). He noticed that while at the melting temperature the entropy of the crystal is lower than that of the liquid, it decreases less upon cooling in such a way that, by extrapolation, they should become equal at a temperature $T_K < T_g$. In order to avoid the paradox of an amorphous state having lower entropy of the crystal, he considered various possibilities including that the liquid had a genuine phase transition to a thermodynamically stable glass state at $T_K$. Nowadays Kauzmann's observation is not considered a paradox anymore: in the late 1950s computer simulations showed, to the surprise of many, that an isolated liquid of hard spheres does crystallize, and this occurs precisely because the crystal state has a higher entropy than the disordered state! This is understood in terms of a balance between short-range and long-range entropies: the crystal has a smaller long-range contribution to the entropy but has a larger local contribution because the particles have locally more room than in the amorphous state (Ackerson 1993). As we said already, crystallization is actually a major problem in numerical simulations of supercooled liquids, and it is typically avoided using binary mixtures or more polydisperse systems.

In spite of the fact that Kauzmann 's observation is not really a paradox, the debate over the existence of a genuine phase transition is still going on to this day. Interestingly Kauzmann himself was against this hypothesis and believed that the paradox would be solved by some dynamical mechanism. The main problem being that it is not possible to study the supercooled liquid below $T_g$. Another important aspect of the discussion is the observation of thermodynamics/dynamics correlations (Adam and Gibbs 1965). Adam and Gibbs pointed out that for many experimental systems VFT fits of viscosity data yield a critical temperature $T_0$ compatible with the $T_K$ extrapolated from calorimetric data. In particular if one plots the logarithm of the viscosity (a dynamical quantity) as a function of the inverse of the excess entropy , i.e., the difference between the entropy of the supercooled liquid and that of the crystal (a thermodynamic quantity), they appear to be correlated.

To complete the picture, Goldstein (1969) started with the observation that approaching $T_g$ relaxation from a given initial configuration proceeds in a two-step fashion; first each particle explores its cage and then escapes from it. Then he argued that the motion inside a cage defines a sort of metastable state and the final relaxation can be seen as a jump from one metastable to another. If one further argues that the entropy of the metastable state corresponds to a kind of vibrational

contribution (essentially analogous to the crystal entropy), it follows that the excess entropy is a measure of the number of metastable states, called the configurational entropy. The decrease of the configurational entropy thus explains the slowing down of dynamics because the system in order to relax has less and less metastable states to escape to.

It is important to realize that while the excess entropy is a well-defined object that can be measured experimentally, the configurational entropy is not. Entropy is a static equilibrium concept and thus cannot be applied to a metastable state that can only be observed on a finite time window. More practically this is reflected by the fact that there is no unique definition of it. On the other hand, Kirkpatrick, Thirumalai, and Wolynes (KTW) pointed out that the previously mentioned mean-field spin-glass models are indeed characterized by the presence of many metastable states below a temperature $T_{MCT}$ and the corresponding configurational entropy vanishes at some lower temperature $T_K$ (Kirkpatrick and Thirumalai 1987). At the mean-field level there is simply no dynamics beyond $T_{MCT}$, and they put forward the idea that in physical dimension the mean-field picture should be modified invoking nucleation arguments as in the classic Becker-Doring theory.

Classical nucleation theory describes the decay of a metastable phase to the stable phase of lower free energy in terms of the expansion of droplets of the stable phase. The surface tension tends to shrink the droplet, while the bulk free energy difference tends to expand it. The two forces depend on the radius of the droplet and balance at some critical radius $r_c$: droplets larger than $r_c$ will expand, while smaller droplets will shrink and disappear. The time to nucleate a critical droplet naturally increases with the size of the critical radius which in turn increases and diverges at the coexistence point where the free energy difference is zero and both phases are stable; correspondingly the lifetime of the metastable state diverges exponentially. The idea of KTW is to use nucleation arguments to describe the dynamics of supercooled liquids using the configurational entropy in place of the free energy difference. This offers an explanation of the thermodynamics/dynamics correlations and of the exponential VFT-like divergence of the relaxation time. Furthermore the nucleation argument implies that there is a diverging correlation length, which was already advocated by Adam and Gibbs that suggested that dynamics is driven cooperatively rearranging regions (CRR) of increasing size upon approaching $T_g$.

The existence of an actual phase transition at $T_K$ is an appealing topic because it is a sharp statement, either true or false. On the other hand the nontrivial phenomenology we need to explain is observed *above* $T_g$, and thus a consistent part of the community does not consider it particularly relevant. At any rate, even if a genuine glass transition occurred below $T_g$, one should still have to prove that the physics observed above $T_g$ is a consequence of its presence. Instead many believe that the physics of supercooled liquid can be explained solely in terms of a crossover temperature that was discussed in the previous section. Note that in the context of mean-field theories, the existence of a $T_K$ requires logically the presence of a crossover at a higher temperature while the opposite is not true: models exist for which there is an MCT singularity, but the configurational entropy does not vanish at any finite temperature.

The opposite view that dynamics may be completely unrelated to thermodynamics is supported by the so-called Kinetically constrained models (Ritort and Sollich 2003; Chandler and Garrahan 2010). They are defined in terms of binary variables (that can be viewed as spins) on a lattice. The variables do not interact and thus the thermodynamics is trivial at all temperatures. Dynamics instead must obey some constraint, for instance, in the well-known Fredrickson-Andersen model, each spin must have at least $k$ neighbors in the up state in order to flip. It turns out that dynamically these models display many of the phenomenological features of supercooled liquids, notably a power law to exponential crossover and two-step relaxation. Since no thermodynamics transition may occur in these models, their physics is typically interpreted solely in terms of the existence of a crossover temperature. Furthermore on the Bethe lattice they seem to display a sharp MCT-like transition, and the aforementioned dynamical features can clearly be associated with this transition being avoided on lattices in three and two dimensions (Berthier et al. 2011). The main open problem is that these models lack a clear microscopic connection with the original liquid models, and it is not exactly clear how the constraints on the dynamics should emerge from the (unconstrained) microscopic Hamiltonian dynamics. In practice this is also reflected by the impossibility of obtaining some sort of quantitative prediction. Another problem is that it seems difficult to rationalize the Adam-Gibbs phenomenological correlations between dynamics and excess entropy using these models, although, as we said before, one may question their overall relevance.

An additional interesting open problem is inherently associated with facilitation dynamics. At low temperatures one expects that in a supercooled liquid there are large regions that are essentially frozen for a large amount of times and eventually relax. One possible mechanism inducing the relaxation is the expansion/motion of a mobile region from outside the blocked region into it, but one can also think of relaxation led by thermally activated rare events. However this second mechanism is impossible in KCM where relaxation can only propagate from the borders of the blocked region. Thus knowing what is the mechanism at work in actual supercooled liquids could help discriminate between competing theories, but at present this is unclear.

From a practical point of view, the idea of a genuine thermodynamics transition is appealing because one can study it in a purely static framework. In the context of numerical simulations, one is no longer bound to use a physical algorithm to thermalize the system, and more efficient algorithms can be devised. For instance, particle-swap algorithms have been used in the last 15 years and recently have produced spectacular results for specially designed polydisperse hard-sphere mixtures that were thermalized up to densities corresponding to the laboratory timescale and even below (Berthier et al. 2017).

Underlying any static study in the context of supercooled liquids is the key question of whether nontrivial information can be extracted solely from the instantaneous equilibrium configurations. At first one would say that the answer is no, after all one of the striking features of supercooled liquid models of hard or soft spheres is precisely the fact that if one looks at the instantaneous configurations

at various temperatures (or densities) approaching the crossover, one cannot detect any significant change that could justify the dramatic increase of the relaxation time. Nevertheless, guided by the supercooled liquid/spin-glass analogy advocated by KTW, various authors have suggested that nontrivial information can be obtained solely from the equilibrium configurations by applying appropriate procedures (Wolynes and Lubchenko 2012).

The general idea is that one has to use an equilibrium configuration of the original system (the reference configuration) to define a new system and then show that nontrivial information can indeed be red off the equilibrium configurations of the new system. The first procedure that was introduced is the so-called Franz-Parisi potential that counts the equilibrium configurations that are at some fixed distance from the reference configuration. At the mean-field level, the potential has a minimum as a function of the distance at the maximal distance but, upon lowering the temperature, develops a secondary minimum at $T_{MCT}$. The difference in height between the primary and the secondary minimum is the configurational entropy that will eventually vanish at a lower temperature . This mean-field picture must be modified in finite dimension by applying a Maxwell construction as in ordinary first-order phase transition: one expects that the potential first develops a constant-slope segment close to the crossover temperature with the slope eventually going to zero at $T_K$.

Another interesting procedure is to measure the so-called point-to-set length (Berthier and Biroli 2011). In this case the particle positions are frozen in the reference configuration except inside a spherical cavity that it is then thermalized again. One expects that when the cavity is very large the bulk should be insensitive to the constraint at the boundaries, while if the cavity is sufficiently small, the center of the cavity should be stuck in a metastable state (stabilized by the frozen boundary). The point-to-set length is defined as the length that separates these two regimes, and mean-field theory predicts that it should diverge at $T_K$. This length should provide a way to actually measure the size of CCRs thus rephrasing the KTW idea of a diverging correlation length in a way that is amenable to be tested in simulations.

Finally we can mention random pinning that amounts to freeze a finite fraction of the particles of the reference configuration and equilibrate again the remaining free particles (Berthier and Biroli 2011). In this case the existence of genuine phase transition can be linked to the presence of a line of first-order transitions in the temperature-concentration plane. Different geometries, e.g., the freezing/pinning of an infinite wall of the system, have also been studied. Note that in both the pinning and cavity procedure, it can be shown that the configuration in which the free particles have the same positions they had in the reference configuration is an equilibrium configuration for the constrained system, which is a considerable advantage because one does not need to equilibrate the system again.

In the last 20 years the above procedures have been applied to various systems, and the most spectacular results are those obtained recently by the swap algorithms (Berthier et al. 2017). In these studies both the Franz-Parisi potential and the

point-to-set length were measured in equilibrium for values of the density even higher than the glass density $\rho_g$. Their behavior was found to be compatible (through extrapolation) with the presence of an actual phase transition at some $\rho_K$. Unfortunately, as it will be discussed in the following, while being a tremendous improvement with respect to earlier studies, it seems that these results are not enough to assess convincingly the validity of the scenario.

One problem is that the degree of extrapolation that one has to make on the actual data is still significant, and if one thing can be learned from the extensive literature on glasses is that extrapolations are always debated. Another problem concerns the point-to-set length itself and emerged from the early numerical studies of this quantity. Measurements of this quantity indicate a rather small value that increases slowly; thus, while a divergence at lower temperature cannot be ruled out, it is not particularly remarkable. Given that the growth and eventual divergence of this quantity should be the driving mechanism behind the growth of the relaxation time, we have a problem because this length is small while the relaxation time is increasing exponentially. Therefore it is further postulated that the relationship between the static length and the relaxation time is exponential due to some kind of activation mechanism. To this day however, a solid theoretical foundation of these statements is lacking.

The connection with dynamic raises an additional problem. As we discussed in the previous section, the dynamical correlation length should diverge at $T_{MCT}$. In the region where it can be measured, it exhibits a significant growth, while obviously being nondivergent. However in the region where both can be measured, the dynamical correlation length is definitively larger than the point-to-set length and appears to be growing more strongly, such that extrapolation suggests that their difference would be even more pronounced at lower temperatures. In other words the static length does not seem to be relevant for dynamics in the region where dynamics is already nontrivial.

In order to complete the discussion on the relevance of static methods, one must add that unphysical algorithms may allow to assess the validity of supercooled liquid models. As we said already the problem of crystallization becomes less severe increasing the dimension, but in three and two dimensions one is necessarily forced to consider at least binary mixtures. Recent numerical studies suggest that even if they do not crystallize at the temperatures reached by state-of-the-art molecular dynamics simulations they will be at lower temperatures accessible at present only by unphysical algorithms. Furthermore while up to now the knowledge of low-temperature equilibrium configurations has not shed light into the central problem of why dynamics slows down, they could be used to study the emergence of various anomalies in the glassy state observed in experiments. Besides understanding why swap algorithms are successful may shed light into why physical dynamics is instead so slow.

Some comments are important on the analogy between spin glasses and super-cooled liquids suggested almost 30 years ago by KTW. On general ground systems with a completely different microscopic structure can be expected to share some

common behavior if they have a sufficiently large correlation length, such that the relevant physics occurs on a scale insensitive to microscopic details. In this light the fact that static length measured is typically small is troublesome. Furthermore many problems concerning these spin-glass models are still open irrespective of their eventual connection with supercooled liquids. First of all there is no numerical evidence that any of these spin models actually displays an entropy crisis transition with a discontinuous order parameter in finite dimension: the fate of the MF transition in finite dimensional system has still to be firmly established. Various failures to identify such a model have been rationalized by noticing that short-length fluctuations, already present on finite-connectivity mean-field lattices, are responsible for the absence of the transition rather than long-length fluctuations that would be a more general and harmful mechanism. Thus the quest for a good candidate is still a fascinating open problem.

Besides the numerics, an additional problem is that there is no precise and well-established analytical treatment of finite dimensional effects. In particular the connection between statics and activated dynamics is not well established even at the mean-field level, i.e., that of nucleation theory for metastability and phase coexistence. Furthermore, in order to agree with experimental data, the phenomenological expressions require the use of non-mean-field exponents that nobody knows at present how to compute. Note that these are all well-defined problems that should be addressed and solved irrespectively of their relevance to supercooled liquids.

We have seen that the static approaches offer a considerable advantage at the algorithmic level, but there are also major advantages at the analytic level, because dynamics is typically more difficult than statics. The spin-glass/structural glass analogy suggests that one has to use the replica method (Mezard and Parisi 2012) that indeed provides a way to compute static objects like the Franz-Parisi potential and the point-to-set length. In finite dimension the replica method predicts a MCT-like transition that should be considered a spurious mean-field modification of what is in reality a crossover. This follows from the fact that, as in MCT, one must resort to some approximation scheme. As we said before, MCT provides nevertheless good quantitative estimates for quantities like the ergodicity-breaking parameter and the (pseudo)critical exponents. On the contrary current approximation schemes in the replica method studies yield predictions of considerable lower quality. On the other hand, as we said in the previous section, the replica method has been used successfully to study supercooled liquids in infinite dimension. This is an instance, albeit special, of a system where the connection between dynamics and thermodynamics can be demonstrated starting from first-principle microscopic methods, to be contrasted with KCM models, where, at present, there is no explicit microscopic derivation of the assumption that dynamics is facilitated. Still, the essential problem remains to describe how the ideal MCT transition becomes a crossover in finite dimension, and it is not even clear if the mechanism at work in large but finite dimension is the same in dimension two and three.

# 5 Conclusions

The body of work presented in the previous sections may be summarized as follows: there is an accepted transition which is not really a genuine critical point, and then there is another transition that is really critical but whose existence is highly debated.

State-of-the-art molecular dynamics simulations can equilibrate a few super-cooled liquid models down to temperatures close and slightly below the crossover temperature. While there is no precise way to substantiate these claims as we are dealing with a crossover and not a sharp critical point, there is, nevertheless, a widespread belief in the community that the next generation of numerical studies will be able to probe the crossover region and beyond for a variety or models. This makes all the more urgent to go beyond MCT and develop a comprehensive theory of the crossover with qualitative and quantitative predictive power.

Additional motivation to tackle this problem comes from other critical phenomena that have not been discussed here. In particular in the context of MCT, higher-order glass-glass transitions have been predicted and also detected numerically to some extent (Gotze 2009). Actually, the ability to predict these singularities prior to observation has convinced many of the value of MCT and of the fact that one should try to correct its shortcomings instead of throwing it away altogether. Much as the MCT transition, these higher-order singularities are expected to become smooth crossovers in realistic systems, and it seems reasonable that their understanding would benefit from any development in the former. Similarly, the study of liquids in high dimension (Charbonneau et al. 2016) has suggested the existence of even more exotic critical points, notably full replica-symmetry-breaking critical points as observed in mean-field spin glasses. At present the relevance of these transitions in realistic models is unclear. Be as it may, they are intrinsically mean field in nature, and their existence in realistic models poses a number of conceptual problems. Actually they may be observed only after the MCT crossover has occurred, and it is likely their fate in finite dimension could be fully understood only once the crossover problem has been solved.

As for the debate on the existence of a genuine glass transition below $T_g$, the bottom line is that the static objects that should manifest critical behavior, e.g., static length scales, are compatible with a singularity, but their divergence is too mild and not particularly remarkable in the range where they can be measured in current numerical simulations. On the other hand their connection with the truly remarkable dynamical features is still speculative and should be established more rigorously. Nevertheless this is a field in which progress has been made steadily in the last decades and more is expected to come.

If we had to single out one fundamental open question from the previous discussion, that would be the nature of the activated process below the crossover temperature and above $T_g$. Measurements of increasing dynamical correlation lengths unambiguously show that kinetic fragility, i.e., the power-law-to-exponential crossover is induced by the dynamics becoming cooperative. The problem is what happens at lower temperatures: do correlation lengths continue to increase? Can dynamics

be described solely in terms of the crossover, or can we identify some feature that necessarily requires some other mechanism approaching $T_g$? Currently, experiments do not have enough spatial resolution to shed light on these questions while the timescales involved are too large for numerical simulations, but both problems could be overcome in the future through some breakthrough.

**Abstract**

The next set of 12 chapters provides an overview of the new advances since the first edition of the *Handbook of Materials Modeling* in 2005 regarding the description of the ground-state and excited-state electronic structure of complex many-body systems by ab initio electronic structure methods. In this section we present contributions aiming to providing an up-to-date description and illustration of the main theoretical methods used by the electronic structure community for the study of problems of actual materials, of prediction of properties, and for the design of novel materials.

## 1     Introduction

Back in September 2015, I was contacted by Wanda and Sidney, who proposed me the idea of joining the editorial board of the second edition of the *Handbook*

A. Rubio (✉)

*of Materials Modeling* as well as being the editor in charge of one section on electronic structure and ab initio methods, which should work as a fundamental point of reference for the following chapters within the volume. I thought this was an excellent idea. After a lot of hard and excellent work by the contributors to this section, I am delighted to welcome you to the introduction of the section on "Electronic structure of materials by ab initio methods" in the *Handbook of Materials Modeling (2nd edition, Vol. 1)*.

A large part of research in condensed matter science is related to the characterization of the electronic, structural, and bonding properties of interacting many-electron systems. An accurate description of the electronic structure and its response to external probes is essential to the understanding of the behavior of systems ranging from atoms, molecules, and nanostructures to complex materials. Solving for the electronic structure of an interacting electron system (in terms of the many-particle Schrodinger equation) has an intrinsically high complexity: while the problem is completely defined in terms of the total number of particles N and the external potential V(r), its solution is a task of exponentially increasing complexity. Fortunately, in the study of either ground- or excited-state properties of interacting many-body systems, we seldom need the full solution to the Schrodinger equation. When one is interested in structural properties, the ground-state total energy is sufficient. In other cases, we want to study how the system responds to some external probe; thus, the knowledge of a few excited-state properties is needed.

In the last two decades, we have seen a continuous but impressive improvement in the accuracy of the approximate methods to deal with many-body electronic systems together with a tremendous increase of computing power as well as improved numeral algorithms. In this realm, ab initio computational sciences have become a fundamental tool to understand, discover, and predict materials properties, as well as to guide experimental efforts along those lines. Therefore, in this set of chapters, we aim to lay out the fundamental concepts providing the basis for the development of increasingly more realistic models and more powerful multi-scale simulation methods as they are being applied nowadays in the materials science community. We address in particular the development and application of a broad range of experimental and computational methods to describe the electronic, optical, and magnetic properties of matter, including nonadiabatic ultrafast phenomena and non-equilibrium dynamical processes at different size and time scales. This section plays a pivotal role in the whole structure of the *Handbook of Materials Modeling* by providing the fundamentals of the methodologies used in the two volumes. In particular, it has close ties with this volume's sections on atomistic simulations, materials informatics, molecular dynamics-thermodynamics, and magnetism-spintronics. Furthermore, it offers complementary information to many of the sections in the second volume of the Handbook that focus on applications to demonstrate and expand the capabilities of current models and simulation methods, in particular the one dealing with photovoltaics from first-principles.

At the simplest level of treating the many-electron problem, the Hartree-Fock theory (HF) is obtained by considering the wave function to be a single Slater determinant. In this way the N-body problem is reduced to N one-body

problems with a self-consistent requirement due to the dependence of the HF effective potential on the wave functions. By the variational theorem, the HF total energy is a variational upper bound of the ground-state energy for a particular symmetry. The HF eigenvalues may be used as estimates of the true excitation energies. The HF theory is far from accurate because the wave function of a system in general cannot be written as a single determinant for the ground state and Koopman's theorem is in general a poor approximation. On the one hand, a rigorous method is to employ the many-particle Green's function approach in which the poles of the one-particle and two-particle Green's function give the quasiparticle energies and optical transition energies, respectively. On the other hand, within the density-functional theory (DFT), the ground-state energy of an interacting system of electrons in an external potential can be written as a functional of the ground-state electronic density. When comparing to conventional quantum chemistry methods, this approach is particularly appealing since it does not rely on the complete knowledge of the N-electron wave function but only on the electronic density. However, although the theory is exact, the energy functional contains an unknown quantity called the exchange-correlation energy, $E_{xc}[n]$, that has to be approximated in practical implementations. For excited-state properties, the DFT has been extended to a time-dependent formalism (TDDFT) and applied with success to the calculations of optical properties and excited-state dynamics of finite and extended systems. However, the commonly used adiabatic functionals in DFT and TDDFT encounter problems when studying correlated materials and spectroscopic properties of extended systems and excitation energies in molecules. Of course, when going to more complex systems, the key to describe and model most physical effects in chemistry and materials is not achieving "chemical accuracy" but being able to theoretically describe and capture the relevant physical-chemical processes.

When describing light-matter interactions, those theoretical tools have a certain range of validity as they often treat electromagnetic radiation and matter on a different level of approximation. Photons are usually only treated as an external perturbation that probes matter without any further influence and vice versa. The standard theoretical modeling can thus be insufficient when photon and matter degrees-of-freedom become equally important (as in the case of polariton condensates). Indeed, these matter-only approaches can be viewed as approximations to a density functional or Green's function formulation of nonrelativistic quantum electrodynamics (QED). In my group we have recently introduced a novel quantum-electrodynamical density-functional approach (QEDFT) to describe such complex dynamics of interacting electrons, photons, and phonon systems all on the same theoretical footing (Ruggenthaler et al. 2018; Flick et al. 2015, 2017). QEDFT is a novel framework to deal with electron-photon interactions from first-principles (opening up the fields of cavity QED-chemistry and QED materials). Hybridizing light strongly with the electronic structure of the system, novel effects appear providing a promising route for new design of material, for example, Floquet engineering (quantum topological matter), valley Hall effect in 2D materials, chiral plasmonics, or phonon-driven spin-magneto valleytronics. Moreover, hidden

aspects of photon-matter interaction can be revealed with new tailored spectroscopic tools (Ruggenthaler et al. 2018; Flick et al. 2015, 2017).

## 2 Contributed Chapters to "Electronic Structure of Materials by Ab Initio Methods"

The carefully chosen contributions presented here handle fundamental aspects of the different frameworks to deal with static and dynamical properties of many-body interesting systems (from molecules to solids). We touch up on basic ideas coming from traditional quantum chemistry methods, condensed matter approaches based on different flavors of many-body perturbation theory as well as static and time-dependent density (and density matrix) functional approaches. Thus, the articles collected in this section cover a wide and impressive range of topics in the fields of chemistry, physics, and material science.

In the next 12 chapters (and in some of the 4 plenary presentations), we provide an in-depth discussion of the basic concepts of density-functional theory and the development of exchange and correlation functionals (▶ Chap. 11, "Recent Developments in Density Functional Approximations," L. Li and K. Burke), which are able to cope with strong correlations, charge transfer phenomena (▶ Chap. 12, "Charge Transfer in Molecular Materials," T. Zhu, T. Van Voorhis, P. de Silva) and dispersion (van der Waals) (▶ Chap. 13, "Van der Waals Interactions in Material Modelling," J. Hermann and A. Tkatchenko) forces within a DFT formalism and beyond, both in the static as well as in time-dependent domains (touching on the efficient ab initio modeling of pump probe spectroscopies (▶ Chap. 14, "Pump-Probe Photoelectron Spectra," U. De Giovannini)). After having presented the approach to solve the many-body problem from a density-functional perspective, we change gear and address the recent exciting developments in correlated many-body techniques based on Green's functions methods, including new developments on the GW+BSE framework for fermions (▶ Chap. 15, "Modeling Excited States of Confined Systems," L. Hung and S. Öğüt) and coupled fermion-boson systems (▶ Chaps. 16, "Many-Body Calculations of Plasmon and Phonon Satellites in Angle-Resolved Photoelectron Spectra Using the Cumulant Expansion Approach," F. Caruso, C. Verdi, F. Giustino, and ▶ 17, "Non-equilibrium Green's Functions for Coupled Fermion-Boson Systems," D. Karlsson and R. van Leeuwen), non-equilibrium dynamical mean field approaches (▶ Chap. 18, "Non-equilibrium Dynamical Mean-Field Theory," M. Eckstein), quantum (▶ Chap. 19, "Correlations and Effective Interactions from First Principles Using Quantum Monte Carlo," L. Wagner), and diagrammatic Monte Carlo approaches (▶ Chap. 20, "Diagrammatic Monte Carlo and GW Approximation for Jellium and Hydrogen Chain," K. Van Houcke, IS Tupitsyn and NV. Prokof'ev) as well as coupled cluster and quantum chemistry schemes (▶ Chap. 21, "Coupled Cluster and Quantum Chemistry Schemes for Solids," A. Grüneis). This section ends with a contribution on how those different electronic structure methods could be combined with optimal control theory in order

to design protocols that allow one to achieve specific predefined targets (▶ Chap. 22, "Optimal Control Theory for Electronic Structure Methods," A. Castro), i.e., bring a system into a specified electronic state, maximize a higher order response function, improve the yield of a chemical reaction, etc. Those methods are just several selected from a lot of examples, given to illustrate the current status in ab initio calculations. Yet work needs to be done toward the inclusion of higher order vertex effects into the many-body description of electron-electron and electron-phonon interactions in order to have a more general ab initio theory of the spectra of weak and strongly correlated electronic systems.

## 3      Final Concluding Remarks

In conclusion, this section is a journey through some of the recent advances in solving the many-body electronic problem in complex materials, which have been enabled by major theoretical and methodological developments. Some of the methods and ideas discussed are very recent and will clearly evolve in the next years. Also, I want to mention here three other schemes that have emerged as powerful tools to deal with correlated many-body systems that have not been addressed by any of the chapters in this section, just to name a few: density-matrix renormalization group (Schollwöck 2011) and embedding methods (Wouters et al. 2016), stochastic method for DFT (Cytter et al. 2018) and many-body schemes (Neuhauser et al. 2014), auxiliary field quantum Monte Carlo (Motta and Zhang 2017), (the recent advances on this topic are reviewed in ▶ Chap. 7, "Ab Initio Electronic Structure Calculations by Auxiliary-Field Quantum Monte Carlo" by S. Zhang in this volume) machine learning for many-body problems (Carleo and Troyer 2017), quantum electrodynamical density-functional theory (Ruggenthaler et al. 2018; Flick et al. 2015). This is just an indication of the dynamism and wealth of ideas and methodologies being explored in our community to enable to tackle the many-body problem in realistic interacting quantum materials. This is clearly an exciting field of research.

Especially in this field, we have been witness of a real knowledge transfer from academia to society in the last years, with the rise and establishment of many start-up companies based on such accumulated knowledge (we are clearly entering the age of big data analytics in many fields arounds us, and computational materials science has joined the wave since the start). In this context, the whole Handbook and in particular this fundamental section on electronic structure will play an important role in further enabling and strengthening such synergy between fundamental research and society.

I don't want to take more space and much rather would like to leave you enjoying the reading of the next articles in which many experts have laid out the fundamentals of the electronic structure methods being in use now, which will shape the field of chemistry and condensed matter physics in the next years. I hope you will find those contributions interesting and relevant for your scientific work or scientific curiosity.

# 1    Introduction

Each year, at least 30,000 papers are published using density functional theory to perform electronic structure calculations (Pribram-Jones et al. 2015). Almost all solve the Kohn-Sham (KS) equations (Kohn and Sham 1965) self-consistently and use some approximation for the exchange-correlation (XC) energy as a functional of the (spin)-densities, $E_{XC}[n]$. This chapter surveys some of the more popular approximations. Some background is covered in Burke (2012), which is more focused on chemistry.

## 1.1    Commonly Used Approximations

The original approximation was suggested by Kohn and Sham themselves (Kohn and Sham 1965), namely, the local density approximation (LDA), in which the XC energy density at each point in the system is replaced by that of a uniform electron gas with the density at that point. The exchange contribution was first written by Bloch (1929), with correlation now well-known from quantum Monte

Carlo simulations of the uniform gas (Ceperley and Alder 1980), parametrized in simple formulas (Vosko et al. 1980; Perdew and Wang 1992). LDA is remarkably accurate for geometries but typically overbinds molecules by about 1 eV per bond, making it relatively useless for thermochemistry (Jones and Gunnarsson 1989).

The next step in complexity is the generalized gradient approximation (GGA), which creates an energy density using both the density and its gradient at each point (Burke et al. 1997). The basic concept and its first realization were given already in the pioneering work of Ma and Brueckner (1968). This was carefully refined in the work of Langreth, leading to the Langreth-Mehl functional (Langreth and Mehl 1981, 1983). Perdew pioneered the use of real-space cutoffs to create GGA's, leading to the PW86 functional (Perdew and Wang 1986). The highpoint of this detailed construction was the PW91 functional (Perdew 1991; Perdew et al. 1992; Burke et al. 1997), and in 1993, it was shown that they yield useful accuracy for binding energies, i.e., errors of about 6–10 kcal/mol (1 eV = 23 kcal/mol) (Gill et al. 1992). The most commonly used GGA in materials today is a simplification of the PW91 form called PBE (Perdew et al. 1996a), while in chemistry it is BLYP, with B88 exchange (Becke 1988) and Lee-Yang-Parr correlation (Lee et al. 1988). Both these are trained on noble gas atomic energies, yielding more accurate energies for those atoms (Elliott and Burke 2009; Burke et al. 2016).

The last standard step is to create a hybrid of GGA with the exact exchange energy from a Hartree-Fock calculation, by replacing a fraction, $a$, of the GGA exchange with the Hartree-Fock (HF) exchange, as first suggested by Becke (1993). This fraction is 20% in the famous B3LYP functional, (which stands for Becke, 3-parameter, Lee-Yang-Parr), the most commonly used approximation in chemistry today (Becke 1993; Lee et al. 1988; Vosko et al. 1980; Stephens et al. 1994). Its analog is PBE0 (Perdew et al. 1996b; Ernzerhof and Scuseria 1999) which uses 25% mixing.

At least 80% of all DFT calculations currently being performed use one of the approximations mentioned above. One can think of more sophisticated approximations using more ingredients of the density, as in Jacob's ladder (Perdew and Schmidt 2001). An important principle of progress in making density functional approximations is to ensure that (almost) everywhere, each level of approximation performs at least, as well as the previous level, and also improves some features, making the previous level obsolete (except to save computational time). One should avoid having different functionals for different purposes.

## 1.2   Beyond Ground-State DFT

What has been described above is generic ground-state DFT in the non-relativistic limit and for collinear magnetic fields. The single largest use of DFT beyond this domain is using time-dependent DFT (TDDFT) (Runge and Gross 1984; Maitra et al. 2004; Maitra 2016) in the linear response regime to extract electronic transition frequencies (Casida 1996; Petersilka et al. 1996). As much as 10% of all DFT publications include TDDFT estimates of excitations. Such calculations

almost all use the adiabatic approximation for the XC kernel and so are uniquely determined by the choice of ground-state approximation. Most such calculations are for molecules (Burke et al. 2005), as a nonlocal contribution is needed to yield details of bulk semiconductor spectra correctly (such as exciton binding energies), and that contribution is missing from the commonly used functionals mentioned above (Onida et al. 2002; Martin et al. 2016).

Other extensions include magnetic DFT for non-collinear fields, relativistic DFT (Engel and Dreizler 2011) and even QED (Flick et al. 2015), DFT at finite temperatures using the Mermin theorem (Smith et al. 2018), coupling between nuclei and electrons (Requist and Gross 2016), and so on. Again, standard ground-state approximations are used unless a particular effect requires going beyond these, such as extracting double excitations (Maitra et al. 2004).

## 2  Recent Developments

This section is devoted to developments over the past 20 years.

### 2.1  RPA-Type Functionals

The famous adiabatic-connection fluctuation-dissipation formula of DFT yields $E_{XC}$ in terms of the a frequency and coupling constant and spatial integral over the density-density response function (Langreth and Perdew 1975; Harris and Jones 1974; Gunnarsson and Lundqvist 1976). This can be extracted directly from the KS response function, constructed from the occupied and unoccupied orbitals, and the XC kernel of TDDFT (Gross and Kohn 1985). Ignoring the kernel yields RPA, also known as direct random-phase approximation (RPA) (Furche 2001; Langreth and Perdew 1977, 1975; Chen et al. 2017) or TD-Hartree. This scheme thus yields a fifth-rung (in Jacob's ladder) approximation that can be costly to evaluate, but the relative burden is always decreasing (Furche 2008; Eshuis et al. 2010). Direct RPA overcorrelates systems, because it includes only "bubble" diagrams in the many-body expansion of the energy, and misses other contributions at higher-order that reduce correlation. It also has difficulties with self-interaction, because it yields finite correlation energies even for only one electron. These two effects yield inaccuracies in the dissociation energies of molecules. Recent progress has included various approximations to the XC kernel to yield improved energetics and computational cost savings. A very recent development, using the exact frequency-dependent exchange kernel, and a clever and physically motivated resummation of higher-orders, appears to overcome stability problems and even allows the binding curve of $N_2$ to be accurately calculated (Erhard et al. 2016; Burke 2016) (which is difficult even in coupled-cluster theory, due to the multireference nature of the wave function at large separations).

## 2.2   Weak Interactions

Tremendous progress has been made in the last two decades for including weak, van der Waals (vdW) interactions into DFT calculations. The standard functionals model covalent, ionic, and metallic bonds reasonably well but fail for longer, weaker bonds. Because of their semilocal nature, they cannot yield weak-binding that falls off as $R^6$, where $R$ is the separation between two atoms or molecules. Thus corrections must be added to the standard functionals to capture these effects. There are three main schemes for doing this.

In the domain of explicit nonlocal density functionals, there is the sequence of approximations originally developed by Langreth and Lundqvist and co-workers (Dion et al. 2004). These approximations are derived nonempirically, remarkably starting from contributions to the uniform gas correlation energy. The original was from 2004, and an improved parameterization was given in vdW2 (Klimeš et al. 2009). These explicit density functionals can be applied to all materials, from molecules to solids, but have been designed assuming the system has a gap (not a metal) (Berland et al. 2015).

At the extreme opposite end of the scale, there are the parametric schemes of Grimme and co-workers (Grimme 2006), commonly referred to as DFT-D. These are not explicit density functionals, but rather additional energies that include estimates of the $C_6$ (and higher-order) coefficients in the asymptotic expansion of the vdW energy between atoms, combined with a damping factor to keep the contributions finite as the separation reduces. Such schemes require empirical parameters for each atom for a given standard XC approximation but can yield highly accurate energy curves for small weakly bound molecules (Burns et al. 2017).

In between is the scheme developed by Tkatchenko and Scheffler, which requires only one parameter for a given XC functional and produces accurate add-on corrections to DFT energies (Tkatchenko and Scheffler 2009). This has been expanded to incorporate collective electrostatic effects so that metals and materials in many dimensions and on different length scales can be treated (Hermann et al. 2017). A final scheme is that begun by Becke and Johnson, which uses the dipole moment of the exchange hole to determine $C_6$ (and higher) coefficients (Johnson and Becke 2006).

Of course, more expensive treatments, such as RPA mentioned above, automatically include approximations to the vdW forces.

## 2.3   Meta-GGAs

The third rung of Jacob's ladder is the meta-GGA, which adds a new ingredient beyond that of the density and its gradient. This is most often chosen to be the (positive) kinetic energy density of the KS orbitals. The aim for a good meta-GGA is to aim for the accuracy of hybrids without the computational overhead of the exact exchange contribution. The cost of exact exchange is relatively manageable in molecular calculations with atom-centered basis functions but can often be

prohibitive when using periodic boundary conditions and plane-wave basis sets. Running a range-separated hybrid (see next section) can sometimes take 1000 times longer than a typical GGA in a materials calculation.

Perdew and co-workers and many others have spent several decades developing meta-GGAs, with many flawed attempts (Sun et al. 2015). But the most recent effort, called strongly constrained and appropriately normed semilocal density functional (SCAN), has passed many standard tests and appears very promising to join the pantheon of commonly used functionals. The G3 dataset (Curtiss et al. 2005) is a standard set of chemical bonds that LDA overbinds by about 3 eV (typically about 1 eV/bond). PBE reduces this to about 1 eV, while SCAN reduces this to about 1/4 eV. SCAN also has errors that are 2–3 times smaller than PBE on the S22 dataset (Jurecka et al. 2006) of weakly bonded systems. At the same time, SCAN reduces errors in lattice parameters on the LC20 data (Sun et al. 2011) set from about 0.05Å in PBE to about 0.01Å. SCAN also yields better water properties than PBE (Perdew et al. 2017). On the other hand, the underestimation of chemical barrier heights by PBE is only mildly improved, by about a factor of 30% (whereas hybrids are often 2–3 times better). Thus, for many properties, SCAN yields accuracies similar to hybrid functionals but at a fraction of the computational cost (for materials codes).

## 2.4    Range-Separated Hybrids

The theory behind range separation is an exact one, developed first by Andreas Savin (Toulouse et al. 2009; Savin 1996; Leininger et al. 1997). One simply writes the Coulomb repulsion as a sum of a short-ranged contribution (decaying more rapidly than the inverse of the separation) and a long-ranged contribution, which has no Coulomb singularity at zero separation. One can then include one contribution as an interaction in some generalization of the KS equations and have the redefined XC contribution accounting for the other. This is all formally exact, and exact XC functionals exist for such schemes (though they differ from their regular KS counterparts).

But a plethora of choices now await. The first is the length scale on which the range separation is performed, often denoted $1/\omega$. This is a continuous parameter, and since approximations will be made to the corresponding $E_{XC}$, the results are sensitive to it. Just like the fraction of exact exchange in global hybrids, there is always a temptation to adjust it.

Furthermore, the separation into long- and short-ranged contributions can occur for the exchange contribution (most common), the correlation, or both. Finally, one may wish to treat the short-ranged contribution with an approximate functional or, in other situations, the long-ranged contribution! For example, a vexing problem in TDDFT is to accurately calculate charge-transfer excitations of well-separated donor-acceptor complexes. Including long-ranged Fock exchange exactly works very well for this problem (Stein et al. 2009). On the other hand, the very successful HSE06 functional (Heyd et al. 2003) is a range-separated hybrid, in which the long-

ranged exchange is treated with an approximate functional, but the short-ranged exchange is treated exactly, to model screening in an extended insulator (Janesko et al. 2009). This particular hybrid typically yields accurate gaps for moderate-gap semiconductors and insulators (Perdew et al. 2017).

## 2.5   Gaps of Solids

A crucial failure of the standard approximations is their inability to predict gaps of semiconductors and insulators. The LDA underestimates the gap of bulk Si by a factor of 2 and makes Ge a metal, and GGAs fare little better. From very early on, a great strength of the GW method  (Aryasetiawan and Gunnarsson 1998) has been its ability to provide accurate and reliable gaps.

To understand this issue, it is important to first note that the KS gap of a periodic solid does *not* match the fundamental gap of the solid (Perdew et al. 1982; Perdew 1985). All indications suggest that in fact LDA and GGA yield reasonably accurate KS gaps (i.e., close to the KS gap found with the exact ground-state functional) (Grüning et al. 2006). But, unlike LDA and GGA, the exact functional allows access to the fundamental gap, which is just $I - A$, the difference between the ionization energy and electron affinity of a system. Consider a very large but finite cluster of material. One can then add and subtract an electron to find $I$ and $A$ and deduce the exact gap. In fact, modern methods exist for doing this in a periodic calculation (Stadele et al. 1999). But in LDA or GGA, the added electron or hole delocalizes over the entire system and, because of their lack of a derivative discontinuity, $I - A$ collapses to the HOMO-LUMO KS energy difference, i.e., the KS gap.

A great success of the past two decades has been the accurate calculation of moderate gaps using hybrid functionals such as HSE06 (Heyd et al. 2003). This is achieved by going to a generalized KS scheme (Seidl et al. 1996), in which the orbital-dependent part of the functional is treated as in HF theory, not pure KS theory (which would require treating it with optimized effective potential (OEP) methods (Kümmel and Kronik 2008)). By having an orbital-dependent potential, one can show that the generalized Kohn-Sham (GKS) gap of such a calculation does match $I - A$, and because of the orbital-dependence, an approximate derivative discontinuity is included. Thus the GKS gap in such a calculation is the approximate fundamental gap and is wider than the corresponding KS gap. This is how hybrid functionals and meta-GGAs yield wider and generally more accurate gaps than GGA's (Perdew et al. 2017).

## 3   Challenges and Hopes

Here we review some of the more depressing failures of our current approximations.

## 3.1    Strong Correlation

The failure of DFT with standard approximations for strongly correlated systems
has been known since before its invention, as HF has problems for $H_2$ when it is
stretched (Heitler and London 1927). The problem can be analyzed and related to
localization/delocalization errors of the standard approximations when integer (or
half-integer) numbers of electrons localize on different sites (Cohen et al. 2008).
This is often called static correlation in quantum chemistry and involves the KS gap
between two states becoming very small and the exact many-body wave function
becoming an (almost) equal mixture of two Slater determinants.

It is important to note that the difficulties lie only with the failure of approx-
imations under these circumstances, rather than the KS scheme itself. This can
be beautifully illustrated with the two-site Hubbard model, for which it is trivial
to construct the exact KS system, even when strongly correlated (Carrascal and
Ferrer 2012). Even in realistic cases (albeit in 1d), the KS equations for a strongly
correlated system always can be made to converge to the exact ground energy and
density if the exact XC functional is used (Wagner et al. 2013). But of course many
of the features of the KS system do not resemble those of the physical system under
such conditions (Carrascal et al. 2015). This point is often confused by practitioners
of many-body theory. The differences between KS response functions and the many-
body analogs for strongly correlated systems is not a signal that a density functional
approximation is failing to yield accurate energies for such systems.

But strong correlation in solids is even more difficult than static correlation
in molecules. To see this simply, consider chains of uniformly spaced H atoms.
As the spacing is increased, an electron localizes on each site. For $H_2$, the true
wave function combines two Slater determinants. But for $H_4$, there are four such
determinants, and a DFT calculation with, say LDA, will break symmetry into four
different solutions, one of which will have lowest energy (Wagner et al. 2014). As
the number of atoms in the chain grows, so does the number of nearly degenerate
solutions, separated by spin excitations of very small energy. In the thermodynamic
limit, these become infinite, and the usual quantum chemical starting point of a
single Slater determinant becomes hopeless (Qiu et al. 2017). Because this is such
an important problem, vast amounts of research have been performed studying this
limit, especially by the group of Weitao Yang (Zheng et al. 2011), but also by
Scuseria (Motta et al. 2017) and Becke (Johnson and Becke 2017).

## 3.2    The Role of Empiricism

The most practical systematic approach to the construction of density functionals
has that been championed by Perdew: combine exact conditions that are relevant
to a given level of approximation with appropriate norms, such as the uniform gas

or hydrogen atom, to create approximations of tremendous generality (Medvedev et al. 2017). A key aspect of this approach is that, as one rises on Jacob's ladder, each successive approximation works better than the previous one (or at least is no worse) under almost all circumstances (and the cases where it does not are usually very informative). Thus, for a given computational cost, there is a single (or at least, very similar) obvious choice that is rarely worse than using a lower rung. Use of appropriate norms may appear empirical, but it can be understood as choosing parameters in the approximations to capture limits that have not been fully derived as yet but in principle could be. The extremely successful B88 exchange functional (Becke 1988; Elliott and Burke 2009) can be viewed as incorporating appropriate norms (exchange energy of atoms).

On the other hand, the profusion of inexpensive computing resources has led to many databases with either experimental results or those of high-level computational chemistry against which new approximations can be tested. It has also led to empirical fitting of density functional approximations with many parameters, as championed by Truhlar and co-workers (Zhao and Truhlar 2008, 2006; Zhao et al. 2006). This approach typically produces more accurate approximations than those of Perdew et al. for the systems and properties fitted and for related systems and properties. But it does not yield single universal approximations that generically improve over previous steps on the ladder. Such approximations can fail badly when applied beyond their range of applicability.

An entirely new approach to functional approximation is to use machine-learning to learn from accurate data (Snyder et al. 2012; Rupp et al. 2012; Bartók et al. 2010). This differs from the earlier approaches, because it automatically includes highly nonlocal contributions, as captured for example, in the kernel which measures density separations by integrals over the entire system (Snyder et al. 2012; Li et al. 2016b; Vu et al. 2015; Snyder et al. 2013). Recent advances include the first KS-MD simulation with an ML-DFT approximation to bypass solving the KS equations (Brockherde et al. 2017) and accurate approximation of the full interacting functional (including XC) (Li et al. 2016a) even for strong correlation and even for extended systems (but so far, only in 1d, because of the cost of generating accurate data).

## 3.3 New Horizons

An entirely new arena for DFT which has grown immensely in the last decade or so is applications to warm dense matter (Smith et al. 2018), with temperatures significant on the electronic scale (about 100,000 K), but not so high that Thomas-Fermi theory (or classical behavior) dominates. Applications range from modeling planetary interiors to inertial confinement fusion. This field is so "hot" that even the input to thermal LDA, the XC energy of a uniform gas as a function of temperature, is only now being calculated at high accuracy (Groth et al. 2017).

## Contents

### Abstract

Charge transport in materials has an impact on a wide range of devices – LEDs, PVs, batteries, fuel cells, circuits, and sensors all prominently exploit charge transfer characteristics of the underlying materials. As material design becomes more sophisticated, molecular components are playing a larger role in these

applications, so that an understanding of charge migration in molecular systems is increasingly relevant. Here, we present a concise review of the principles of charge transfer in molecular materials. After a brief summary of the key concepts of Marcus theory, we discuss the key molecular and material properties that influence charge transfer and how they can be accounted for. Using organic PV and LED materials as a case study, we illustrate how these concepts can be used to better understand the microscopic properties that underpin device function in real devices.

# 1      Introduction

Charge transfer in materials is a central step in a host of technologies. In photovoltaic cells, charge separation turns sunlight into electricity (Sariciftci et al. 1992). In batteries, long-lived charge transfer stores electrical energy (Goodenough and Park 2013). In fuel cells, electron transfer converts chemical energy into mechanical work (Wang et al. 2011). In LEDs, charge recombination turns electrical current into visible light (Nakamura et al. 1994). In $CO_2$ sequestration, charge transfer harnesses electrical energy to perform a chemical transformation (Appel et al. 2013).

In each of these technological settings, the molecular picture of charge transfer is increasingly important. In many cases, such as fuel cells, at least one of the active phases is molecular in nature so that the need for a molecular description is obvious. In other cases, the motivation for a molecular picture is driven by the increasing success of molecular semiconductors. Whether one considers perovskite photovoltaics (Kojima et al. 2009) or organic LEDs (Tang and VanSlyke 1987), material discovery is consistently demonstrating that molecular materials are able to outperform traditional network solids in a variety of technological settings.

In this review, we discuss charge transfer in these types of molecular materials from a quantum chemical perspective. Whereas charge transport in inorganic semiconductors is typically described in terms of band theory (Kittel 2005) and delocalized charge carriers, in molecular systems, one typically employs Marcus theory (Marcus 1956; Hush 1961) in which localized charge carriers hop from one location to another. We begin by summarizing the basic principles of this Marcus picture, emphasizing its physical underpinnings and limitations. Next, we outline how modern quantum chemical tools can quantitatively simulate charge transfer within the Marcus framework. Finally, we use some examples involving organic solar cells and organic LEDs to illustrate the utility of these ideas and suggest directions for future research efforts.

# 2      Marcus Picture of Charge Transfer

*The Marcus picture describes electron (or hole) transfer from one localized center (the donor) to another localized center (the acceptor)* (Marcus 1956). Hence, by its very nature, the Marcus picture assumes that electrons localize on individual

centers. The resulting hopping-like picture of charge transport is thus fundamentally irreconcilable with the band theory of transport common in solid-state physics. Broadly speaking, the localized picture is expected to be appropriate in more disordered materials, because disorder drives quantum-mechanical localization (Anderson 1958). Molecular systems are only held together by weak intermolecular forces, making them highly defective compared to inorganic network solids. The resulting rugged energy landscape tends to localize charges, making the Marcus picture the default approach in molecular materials (Coropceanu et al. 2007).

The two electronic states in which the electron is localized on one center or the other are called *diabatic states* (Mead and Truhlar 1982; Van Voorhis et al. 2010). Typically, one envisions localization on a single molecule, although submolecular localization (e.g., within a polymer) or super-molecular localization (e.g., to a single aggregate) is also possible. In any case, charge transfer between the centers is driven by fluctuations in the energies of the diabatic states. Again, molecular materials differ from their inorganic counterparts in this respect. Whereas inorganic network solids tend to be inflexible, organic materials are comparatively soft and deformable, leading to relatively large, dynamic fluctuations in the energies of the diabatic states. These fluctuations in turn drive efficient charge transfer. As illustrated in Fig. 1a, these fluctuations can arise both from intramolecular reorganization (e.g., changes in bond lengths or torsion angles) and intermolecular reorganization (e.g., molecular reorientation or polarization), but the result is the same in either case: dynamic changes in the donor and acceptor energies occasionally lead to configurations where the two states are degenerate and charge transfer can occur rapidly. The rate of charge transfer is thus partly determined by the probability of obtaining one of these rare degenerate configurations.

For any given system, identifying the geometric changes that govern these fluctuations (the so-called reaction coordinate) is a task unto itself (Marcus 1993). However, the structural changes that accompany electron transfer tend to be rather system-specific – the reaction coordinate for electrochemistry in solution (Blumberger and Sprik 2006), for example, might be very different than for hole transfer in a polymer (Brédas et al. 2004). This variability tends to complicate the discussion of electron transfer in different systems that are otherwise physically and mathematically analogous. As a result, it is common to instead use the energy gap, $q \equiv \Delta E = E_{Donor} - E_{Acceptor}$, as a universal reaction coordinate (Warshel 1982; Tachiya 1993). Clearly this gap will be negative for configurations where the electron would prefer to be on the donor (the "reactant") and positive for configurations that favor the acceptor (the "product") and so fulfills the key purpose of the reaction coordinate: it distinguishes the product from the reactant.

Now, consider the probability, $P(\Delta E)$, of observing a given energy gap in our system. Roughly speaking, the rate of charge transfer will be given by (Marcus 1964):

$$k_{CT} \propto \left| \left\langle \Psi_{Donor} \left| \widehat{H} \right| \Psi_{Acceptor} \right\rangle \right|^2 P(\Delta E = 0) \tag{1}$$
**Fig. 1** (**a**) The reaction coordinate in electron transfer involves molecular rearrangements and polarization that go from stabilizing charge on the "donor" (left) toward stabilizing charge on the acceptor (right). (**b**) The free energies of the system when the charge is on the donor (red) or acceptor (blue) resemble two parabolas that intersect at the transition state for charge transfer. Assuming the curves are exactly parabolic leads to the Marcus non-adiabatic rate expression

where the first term on the right-hand side is the electronic coupling between the donor and acceptor. One can derive Eq. 1 starting from Fermi's golden rule assuming nuclear motion is classical (Barbara et al. 1996), but the physical justification is clear. Charge transfer between two localized states is governed by the product of two factors: (1) the probability of attaining a configuration where donor and acceptor are degenerate ($P(\Delta E = 0)$) and (2) the probability of quantum-mechanical tunneling between donor and acceptor ($\propto \left| \langle \Psi_{\text{Donor}} \left| \widehat{H} \right| \Psi_{\text{Acceptor}} \rangle \right|^2$).

Visualization of the electronic coupling is challenging, but a qualitative picture of the probability is straightforward. If the electron is on the donor, we will tend to observe configurations in which $\Delta E$ will be negative. That is, $P_{donor}(\Delta E)$ will tend to be peaked at some negative value of $\Delta E$. Meanwhile, the opposite will be true of the acceptor: $P_{acceptor}(\Delta E)$ will tend to be peaked at some positive value of $\Delta E$. Thus, if we consider the free energy of each species (where $G_x(\Delta E) \equiv -kT \ln P_x(\Delta E)$), then we will obtain a picture similar to Fig. 1b: two free energies with minima at different points along the reaction coordinate that cross at the transition state ($\Delta E = 0$). Visually, these two curves resemble parabolas, and one typically makes the linear response approximation that these curves actually are parabolic, in which case the rate can be expressed in closed form:

$$k_{CT} \propto \left| \langle \Psi_{\text{Donor}} \left| \widehat{H} \right| \Psi_{\text{Acceptor}} \rangle \right|^2 e^{-\frac{(\Delta G + \lambda)^2}{4\lambda kT}} \qquad (2)$$

Equation 2 is the celebrated Marcus rate for non-adiabatic electron transfer. It expresses the rate in terms of three physical parameters: (1) the electronic coupling $V_{DA} \equiv \langle \Psi_{Donor} | \hat{H} | \Psi_{Acceptor} \rangle$, (2) the free energy difference ($\Delta G$) between donor and acceptor, and (3) the reorganization energy ($\lambda$) that measures the degree of structural relaxation that accompanies electron transfer.

As can be seen from the discussion above, there are a number of approximations built in to Eq. 2. There are therefore various extensions to the Marcus expression that can be considered:

- **Strong coupling**: By invoking Fermi's golden rule, one implicitly assumes that the electronic coupling, $V_{DA}$, is small. One can extend Eq. 2 to include higher-order terms in the coupling – effects like superexchange (Siddarth and Marcus 1993; Cheng et al. 2017) and even the adiabatic limit (Marcus and Sutin 1985; Jortner and Bixon 1988). In the context of materials, these higher-order terms eventually connect the Marcus picture to the traditional band picture of transport (Nan et al. 2009; Shuai et al. 2014).
- **Variable coupling**: In the above, we have assumed that the electronic coupling is a single number, whereas in reality, it will depend on molecular structure. Variation of the electronic coupling can influence the rate (Difley et al. 2010), and these variations can have a crucial impact in highly ordered molecular crystals (Troisi and Orlandi 2006a, b; Vehoff et al. 2010).
- **Beyond linear response**: The linear response approximation in Marcus theory can be justified heuristically using the central limit theorem, but for many systems, the free energy curves are markedly non-parabolic. In these cases, corrections for anharmonicity are available (Yeganeh and Ratner 2006), although less widely explored in molecular solids.

We will not dwell much on these extensions in what follows, in part because the extensions of Eq. 2 are typically system-specific. That is to say, whereas Eq. 2 applies universally to any system that satisfies a handful of physical approximations, the ways in which individual systems violate Eq. 2 are highly nonuniversal. Thus, in order to maintain a focused review, we will direct our attention toward computational realization of Eq. 2, leaving the discussion of extensions to other work.

## 3 Computational Realization

### 3.1 Calculations of Charge-Localized States and Electronic Couplings

Marcus theory provides a closed form expression for the charge transfer (CT) rate. Its practical use hinges on the possibility of calculating diabatic charge-localized states and electronic couplings. Standard electronic structure methods diagonalize some effective Hamiltonian; therefore, they generate adiabatic states

that are approximations to the true eigenstates of the Hamiltonian for the donor (A)-acceptor (B) system. In the diabatic basis, the Hamiltonian is not diagonal anymore, and the electronic coupling is simply its off-diagonal term:

$$V_{AB} = \left\langle \Psi_A \left| \widehat{H} \right| \Psi_B \right\rangle = \left\langle \Psi_{Donor} \left| \widehat{H} \right| \Psi_{Acceptor} \right\rangle \tag{3}$$

Since strict diabatization of the adiabatic basis is in general not possible (Mead and Truhlar 1982), a number of practical methods to generate charge-localized states have been developed. The practical concerns are computational feasibility and the cost of the diabatization procedure as well as accuracy of the resulting electronic couplings. The conceptually simplest method relies on modeling of the donor-acceptor complex as a two-level system (Newton 1991). The eigenvalues of the Hamiltonian are given by the expression:

$$E_{0,1} = \frac{1}{2} \left( E_A + E_B \pm \sqrt{(E_A - E_B)^2 + 4|V_{AB}|^2} \right) \tag{4}$$

In the case of a symmetric dimer ($E_A = E_B$), the expression simplifies, and the electronic coupling is just half of the energy gap between the adiabatic states:

$$|V_{AB}| = \frac{1}{2} (E_1 - E_0) \tag{5}$$

Therefore, for a symmetric donor-acceptor system, no explicit diabatization is needed, and the coupling can be computed just from the knowledge of the ground and first excited state energies. This can be simplified even further if the one-electron approximation is considered and adiabatic energies $E_0$, $E_1$ are replaced by orbital energies $\epsilon_{LUMO}$, $\epsilon_{LUMO+1}$ for electron and $\epsilon_{HOMO-1}$, $\epsilon_{HOMO}$ for hole transfer.

In a general case, one has to decide on the definition of a charge-localized state that will be further used in calculations of couplings and driving forces. Within the fragment orbital (FO) approach (Senthilkumar et al. 2003), diabatic states are defined by the orbitals of isolated molecules. In the simplest variant, the frozen orbitals of neutral molecules are considered, so only relevant frontier orbitals participate effectively in the electron transfer process, and the coupling element is

$$V_{AB}^{FO} = \left\langle \phi_A^{HOMO/LUMO} \left| \widehat{h} \right| \phi_B^{HOMO/LUMO} \right\rangle \tag{6}$$

where $\widehat{h}$ is the effective one-electron Hamiltonian constructed from the fragment orbitals. HOMOs or LUMOs of the A/B fragments are considered for hole and electron transfer, respectively. Such approach is computationally very efficient; however, it neglects the effect of relaxation of orbitals upon charging/discharging and mutual polarization of fragments. Several flavors of the FO method have been proposed to address these shortcomings (Schober et al. 2016), which still rely on separate calculations for fragments, but take account of the correct number of electrons in the construction of the reference states and the Hamiltonian.

More accurate calculations of diabatic states should fully take into account the mutual interactions of the donor and acceptor fragments in their proper oxidation states. Since minimization of the total energy leads to the adiabatic ground-state wave function, one needs to impose some sort of a constraint that enforces an excess electron or a hole to localize on the desired fragment. This is achieved in constrained density functional theory (CDFT) (Wu and Van Voorhis 2005, 2006; Kaduk et al. 2012) through minimization of the total energy functional under an additional constraint that the charge densities of fragments integrate to the predefined numbers of electrons. Since there is no unique way to partition the electron density into fragments, a weight function $w(r)$ is introduced to define a charge constraint on fragment A:

$$N_A = \int w_A\left(r\right)\rho\left(r\right)dr \tag{7}$$

While there is much freedom in the definition of the weight function, in the majority of implementations, it is based on Becke grid weights (Becke 1988) or Hirshfeld density partitioning (Hirshfeld 1977). Despite this ambiguity, the electronic couplings computed with CDFT states show only limited sensitivity to the choice of the weight function (Goldey et al. 2017).

In CDFT, the energy is minimized subject to the constraint by finding a stationary point of the following Lagrangian:

$$W\left[\rho, V_A\right] = E\left[\rho\right] + V_A\left(\int w_A\left(r\right)\rho\left(r\right)dr - N_A\right) \tag{8}$$

This leads to Kohn-Sham equations that need to be solved to obtain a KS charge-localized state:

$$\left(-\frac{1}{2}\nabla^2 + v_H\left(r\right) + v_{xc}\left(r\right) + V_A w_A\left(r\right)\right)\phi_i\left(r\right) = \epsilon_i\phi_i\left(r\right) \tag{9}$$

where $v_H$ is the Hartree potential, $v_{xc}$ is the exchange-correlation potential, and $V_A w_A$ is the constraining potential that enforces the proper charge on fragment A. Since the optimal Lagrange multiplier $V_A$ is not known a priori, it has to be optimized together with the electron density. In practice, this is done by adding an extra optimization loop to enforce Eq. 7 at each SCF cycle. The resulting diabatic state is a Kohn-Sham determinant, which formally is only an auxiliary mathematical object used to represent the electron density. This poses a challenge for the calculation of electronic couplings (Eq. 3), which require knowledge of the actual wave functions of the diabatic states. Since diabatic states are eigenstates of the Hamiltonian with the constraining potential, the coupling can be rewritten in the following way (Wu and Van Voorhis 2006):

$$V_{AB} = \langle \Psi_A \, | \widehat{H} | \, \Psi_B \rangle = \frac{F_A + F_B}{2} \langle \Psi_A \mid \Psi_B \rangle - \frac{1}{2} \langle \Psi_A \, | V_A w_A \, (\boldsymbol{r}) + V_B w_B \, (\boldsymbol{r}) | \, \Psi_B \rangle \tag{10}$$

where $F_{A/B} = E_{A/B} + V_{A/B} N_{A/B}$ are energies of the diabatic states interacting with the constraining potential. In this form, the dependence of the electronic coupling on the wave functions is reduced only to the overlap and one-body terms. At this point, it is assumed that the Kohn-Sham determinant is a reasonable approximation to the wave functions, which turns out to work well in practice.

Another DFT-based approach to compute charge-localized states and electronic couplings takes advantage of splitting of the donor-acceptor complex into two distinct but interacting Kohn-Sham subsystems. In subsystem DFT (sDFT) (Cortona 1991; Jacob and Neugebauer 2014), the starting point is the partitioning of the electron density into fragments:

$$\rho_{AB} \, (\boldsymbol{r}) = \rho_A \, (\boldsymbol{r}) + \rho_B \, (\boldsymbol{r}) \tag{11}$$

Each of the subsystem densities is a ground-state solution of Kohn-Sham equations with constrained electron density (KSCED) (Wesolowski and Weber 1996), where interactions with the other subsystem are described through a local embedding potential:

$$\left( -\frac{1}{2} \nabla^2 + v_{\mathrm{KS}} \left[ \rho^{A/B} \right] (\boldsymbol{r}) + v_{emb} \, [\rho_A, \rho_B] \, (\boldsymbol{r}) \right) \phi_i^{A/B} \, (\boldsymbol{r}) = \epsilon_i \phi_i^{A/B} \, (\boldsymbol{r}) \tag{12}$$

where $v_{\mathrm{KS}}[\rho^{A/B}](\boldsymbol{r})$ is a regular Kohn-Sham potential for the subsystem $A/B$ and $v_{emb}[\rho_A, \rho_B](\boldsymbol{r})$ is the embedding potential which is a nonsymmetric bifunctional that couples the equations for both densities. In practice, the equations are solved one at a time while keeping the density of the other subsystem frozen until both densities converge. Such implementation of sDFT is closely related to frozen density embedding (FDE) theory (Wesolowski and Warshel 1993), and both terms are often used interchangeably in the literature.

The key feature of sDFT that allows for generating diabatic states is the non-uniqueness of the density partitioning in Eq. 11. In particular, the number of electrons assigned to subsystems A and B is completely arbitrary, so conceptually it is straightforward to construct a state with a predefined charge. It is not immediately clear why these charge-constrained states remain localized when the total energy of the donor-acceptor system is minimized. Since KSCED equations yield the exact density of the total system, the number of electrons assigned to subsystems A and B should not matter at convergence as the initial fragment densities would polarize and delocalize in order to add up to the correct one. Nevertheless, sDFT proved to be an efficient computational tool to generate charge-localized states (Pavanello and Neugebauer 2011; Pavanello et al. 2013) provided that initial densities are chosen as isolated fragments with proper charges and each state is expanded in an atomic basis set that is centered only on the given fragment's nuclei. Such choice biases

the solution toward the targeted diabatic states, and restricted basis prevents the undesired delocalization of their densities while letting them mutually polarize each other.

Computing of electronic couplings is problematic due to the use of Kohn-Sham determinants instead of wave functions of interacting electrons. In the mean-field approximation, the couplings can be rewritten as a functional of transition density and wave function overlaps:

$$V_{AB} = E\left[\rho^{AB}\right] det\left(\mathbf{S}^{AB}\right) \tag{13}$$

Here $\mathbf{S}^{AB}$ is a transition orbital overlap matrix with elements:

$$\mathbf{S}_{kl}^{AB} = \left\langle \phi_k^A \middle| \phi_l^B \right\rangle \tag{14}$$

and $\rho^{AB}(\mathbf{r})$ is the scaled transition density:

$$\rho^{AB}(\mathbf{r}) = \sum_{kl} \phi_k^A(\mathbf{r}) \left(S^{AB}\right)_{kl}^{-1} \phi_l^B(\mathbf{r}) \tag{15}$$

By assuming that Kohn-Sham orbitals can be used to approximate the diabatic states and using an approximate functional to evaluate $E[\rho^{AB}]$, electronic couplings between sDFT diabats are readily available through Eq. 13.

## 3.2    Incorporating Environmental Effects

Charge transfer reactions usually occur in condensed phases, and the environment can have a significant effect on electronic structure of reactants and the resulting charge transfer parameters. In fact, the environment's degrees of freedom play a crucial role in the CT process; their fluctuations make two diabatic states transiently isoenergetic, at which point the electron hop happens. On average, the environment stabilizes localized charges through polarization of its electron density, alignment of multipole moments, and geometric deformation (polaron formation). For these reasons, accounting for the presence of the environment in computational studies of CT is of fundamental importance. The methods for including embedding effects can be divided into explicit and implicit models, depending whether surrounding molecules are present explicitly in the simulations or are replaced by a dielectric continuous medium.

The Marcus rate expression involves two thermodynamic properties associated with the CT reaction, the driving force $\Delta G$ and the reorganization energy $\lambda$. The driving force is the difference between the free energies of the initial and final diabatic states, so the role of the environment model is to describe the stabilization of the charges after the environment's degrees of freedom have been equilibrated.

Calculations of the reorganization energies are more complicated as it is a non-equilibrium property, which requires calculations of the energy of one diabatic state in the equilibrium structure of the other. It is particularly challenging for the outer sphere component of $\lambda$, which is associated with the rearrangement of surrounding molecules, and its treatment depends on the type of the model used.

In modern implicit environment models (Cramer and Truhlar 1999; Tomasi et al. 2005), the molecule or the reactive complex is placed inside a cavity resembling its molecular shape. The cavity is constructed either as a union of van der Waals spheres or is enclosed inside an isosurface of the molecule's electronic density. All the space outside of the cavity is filled with a continuous medium characterized by its dielectric constant $\epsilon$, which is usually assumed to be frequency independent. The presence of the molecular system inside the cavity induces charges in the dielectric, which generate an effective reaction field interacting with the embedded electron density. The free energy of interactions with the environment can be calculated by solving the Poisson equation for the apparent charge on the surface of the cavity. The surface charge generates a Coulomb potential:

$$\phi_\sigma \left( \boldsymbol{r} \right) = \int \frac{\sigma \left( \boldsymbol{r}_s \right)}{\left| \boldsymbol{r} - \boldsymbol{r}_s \right|} \, d\boldsymbol{r}_s \tag{16}$$

which is then added to the Hamiltonian of the embedded molecule. In the self-consistent reaction field (SCRF) family of approaches, the equations for the electronic structure of the embedded system and the surface charge on the cavity are solved iteratively until convergence. The converged electron density and electrostatic potential are used to compute the electrostatic contribution to the embedding free energy:

$$\Delta G_{es} = \frac{1}{2} \int \phi_{reac} \left( \boldsymbol{r} \right) \rho \left( \boldsymbol{r} \right) d\boldsymbol{r} \tag{17}$$

where the reaction field $\phi_{reac}(\boldsymbol{r})$ is the difference between electrostatic potentials of a molecule in the cavity and vacuum. Apart from the electrostatic component, the free energy of cavitation and dispersion/repulsion interactions can be accounted for in implicit models. These contributions are usually highly parametrized to fit to experimental or other theoretical data.

The implicit models used most frequently in computational studies of charge transfer reactions in condensed phases are the polarizable continuum model (PCM) (Miertuš et al. 1981) in its several variants (Mennucci 2012), conductor-like screening model (COSMO) (Klamt and Schüürmann 1993; Klamt 2011), and the SMx family of models (Kelly et al. 2005; Marenich et al. 2007, 2009), where the latter are based on solution of the generalized Born instead of the Poisson equation. The common advantage of these methods is that they are computationally very efficient and account for the majority of important effects resulting from interaction with the environment. However, they rely on many fitted parameters, so transferability and accuracy are often an issue. Also, the specific interactions

between the molecules, e.g., hydrogen bonding, are not accounted for in continuum models. Another challenge of modeling of CT reactions with implicit environment is that they assume thermodynamic equilibrium, and there is no direct way to freeze environment's geometric relaxation in calculations of reorganization energies. Extensions of implicit models to non-equilibrium structures assume that the bulk dielectric constant has a slow and fast ($\epsilon_\infty$) component (Aguilar 2001), where the latter is associated with electronic polarization only (high-frequency component). Then, $\epsilon_\infty$ can be used in calculations of reorganization energies, which is a qualitative yet efficient approach.

While implicit models are efficient, they necessarily ignore the fact that the environment is composed of individual molecules. Conversely, in explicit environment models, the molecular system of primary interest is surrounded by a number of discrete molecules that constitute its environment. Various models differ by how interactions between different parts of the total system are treated. The conceptually simplest approach is to do calculations on the whole supersystem without singling out its individual components. Since a very large number of environment molecules often number, this approach can become impractical due to steep computational scaling of conventional electronic structure methods. Additionally, it may be difficult to disentangle the properties of the embedded system and the environment if their states begin to mix. This can be further exacerbated by errors of the computational method, e.g., delocalization error of approximate density functionals. These problems can be alleviated by the use of subsystem and embedding methods that perform calculations on individual components, while including the interactions with the others.

One of the fragment-based approaches that has been successfully used in CT simulations is subsystem DFT, which has been already discussed in the context of generating diabatic states. It is straightforward to generalize the density partitioning (Eq. 11) to an arbitrary number of subsystems:

$$\rho\left(\boldsymbol{r}\right) = \sum_{i}^{N_{sub}} \rho_i\left(\boldsymbol{r}\right) \tag{18}$$

where each subsystem density $\rho_i(\boldsymbol{r})$ typically represents one molecule. For each molecule, KSCED equations (Eq. 12) are solved, where the embedding potential is a functional of its density and the density of all the remaining fragments. Since the orbitals of the supersystem are never calculated, the method scales linearly with the number of solvent molecules and relatively large clusters can be simulated. It is also straightforward to calculate diabatic states of CT complexes interacting with their environment by assigning the desired number of electrons to two of the subsystems representing donor and acceptor molecules.

Further reduction of the computational cost of explicit models can be achieved by employing hybrid quantum mechanics/molecular mechanics (QM/MM) methods (Warshel and Levitt 1976; Field et al. 1990; Lin and Truhlar 2007). The supersystem is partitioned into the embedded fragment, usually the solute molecule or the donor-

acceptor complex, and the environment. The active subsystem is treated at the quantum-mechanical level (e.g., DFT), while the environment is described by a classical force field which does not explicitly account for the presence of electrons. The Hamiltonian for the total system is therefore partitioned into the QM, MM, and interaction terms:

$$H_{total} = H_{QM} + H_{MM} + H_{QM/MM} \qquad (19)$$

where $H_{QM}$ is the Hamiltonian accounting for interactions of nuclei and electrons of the embedded fragment, $H_{MM}$ accounts for interaction of MM atoms, and $H_{QM/MM}$ couples these two subsystems. The wave function of the quantum subsystem is optimized by minimizing the energy of the total system; therefore the polarization of the embedded subsystem by the environment is taken into account through the electrostatic term in the interaction Hamiltonian. The final interaction energy is given by the expression that accounts for coulomb interaction between solute and MM atoms represented by point charges and the additional empirical term representing van der Waals interactions:

$$
\begin{aligned}
E_{QM/MM} = & -\int \sum_{i \in MM} \frac{q_i}{|\boldsymbol{R}_i - \boldsymbol{r}'|} \rho\left(\boldsymbol{r}'\right) d\boldsymbol{r}' \\
& + \sum_{i \in MM} \sum_{j \in QM} \frac{q_i Z_j}{|\boldsymbol{R}_i - \boldsymbol{R}'|} + \sum_{i \in MM} \sum_{j \in QM} V_{vdW}\left(\boldsymbol{R}_i, \boldsymbol{R}_j\right)
\end{aligned}
\qquad (20)
$$

In simulations of charge transfer parameters, it is important to also include the polarization of the environment due to the presence of the donor-acceptor complex. The relaxation of the environment's electron density is the major contribution to the overall outer sphere reorganization energy and is chiefly responsible for the stabilization of charged diabatic states. Including this effect in QM/MM calculations requires the use of a polarizable force field in the MM part. A simple yet effective way of including polarization of MM atoms is based on Drude oscillators (Lamoureux and Roux 2003), i.e., fictitious charged and massless particles that are harmonically bound to nuclei. Drude particles are free to move around the atom to which they are anchored in response to the electric field of other atoms and Drude particles as well as the electron density of the QM region. The energy associated with Drude particles is

$$E_{Drude} = \sum_i \frac{1}{2} k_i^D |\boldsymbol{d}_i - \boldsymbol{r}_i|^2 + \sum_{ij} \frac{q_i^D q_j}{|\boldsymbol{d}_i - \boldsymbol{r}_i|} + \sum_{ij} \frac{q_i^D q_j^D}{|\boldsymbol{d}_i - \boldsymbol{d}_i|} \qquad (21)$$

Every Drude particle is characterized by its charge $q_i^D$ and spring constant $k_i^D$, which determine the atomic polarizability $\alpha_i = \frac{(q_i^D)^2}{k_i^D}$. In practice, often a constant value is assumed for the spring constant and the charges of Drude particles are fitted to reproduce molecular polarizability or atomic polarizabilities obtained through the

distributed multipole analysis (Stone 1981). Since the position of Drude particles and the electron density of the QM region depend on each other, calculations cycle between the optimization of the wave function and the position of Drude charges until self-consistency is reached.

### 3.3    Effects of Configurational and Energetic Disorder

Charge transfer reactions between molecular systems often occur in disordered and fluctuating environments like liquids, polymers, or glasses. Therefore, when simulating CT processes, it is usually not sufficient to consider only one configuration of the molecules surrounding the reaction center. This is especially true for charge-transporting molecular materials, where macroscopic properties like conductivity inherently depend on the morphology of the material. When a charge hops between molecular sites, the energetic landscape it experiences changes with the position and time. Incorporating these effects in molecular simulations requires a significant amount of computational resources but is often indispensable to understand macroscopic charge transport.

The overall disorder at any given instant of time has two primary sources. The dynamic disorder results from coupling of the electronic structure to the vibrations. Since vibrational modes of distinct molecules are not necessarily in phase, the molecules in the ensemble have different geometries and experience different local environments. This leads to a heterogeneity in CT parameters and resulting instantaneous CT transfer rates, which are a time-dependent property. If only dynamic disorder is present in the system, the distributions of these parameters sampled over time are identical for all the sites in the ensemble. In contrast, if there is static disorder present in the system, some of the sites have different time distributions of the CT parameters. The difference between the dynamic and static disorder is not always unambiguous as it depends on the time scale over which the properties are sampled. For ergodic systems, every molecule will eventually visit the entire phase space, so all the disorder in the ensemble is dynamic. However, in the context of CT reactions, the distinction between the two types of disorder is based on the time scale set by the charge transfer rate – motion that is slower than charge transfer effectively appears static to the transferring electron. In practice, it means that much of the disorder in molecular materials is inherently static, which may result from factors like sites being kinetically trapped in different local minima, presence of impurities, defects, phase boundaries, etc. The disorder of CT parameters can be further divided into the energetic and positional disorder. The former, which is also called the diagonal disorder, is manifested by the distribution of energies of diabatic states (site energies). The positional (off-diagonal) disorder gives rise to the heterogeneity of electronic couplings between different diabats. Static disorder typically reduces charge mobility of the material as the polaron encounters higher-energy barriers and often needs to move via percolation pathways. Large static disorder may also lead to charge trapping and subsequent chemical degradation of the material. In contrast, dynamic disorder is

fundamental for a charge hop to occur as the vibrations make the diabatic states transiently isoenergetic. Also, electronic couplings are very sensitive to the nuclear configuration so dynamic positional disorder affects how effectively the charge can be transferred between sites.

Atomistic computational studies of CT processes in a disordered material require the knowledge of its morphology under experimental conditions. Realistic configurations can be obtained from classical molecular dynamics (MD) simulations carried out in NVT or NPT ensembles. After initial equilibration, the snapshots of the MD trajectory are sampled at regular intervals, and these instantaneous configurations are used in subsequent QM calculations of CT parameters. In the hopping regime, only two molecular sites at a time are involved in charge transfer, but the environment has an important effect on the calculated values. Since nuclear configurations of the environment are sampled in the MD trajectory, explicit environment models can be directly used for every snapshot. In particular, polarizable QM/MM methods are well suited for such calculations (Difley et al. 2010) as they balance computational efficiency and inclusion of important physical effects. Sampling the energy landscape of the relevant diabatic states allows to compute the distribution of energy gaps, which can then be used to calculate free energy differences through the thermodynamic perturbation or thermodynamic integration methods (Frenkel and Smit 2002). In the linear response approximation, the energy gaps are assumed to be normally distributed, and the driving force for CT is expressed as the average energy gap in the reactant and product ensembles:

$$\Delta G = \frac{\langle \Delta E \rangle_A + \langle \Delta E \rangle_B}{2} \qquad (22)$$

while the reorganization energy is half of the difference between mean energy gaps

$$\lambda = \frac{\langle \Delta E \rangle_A - \langle \Delta E \rangle_B}{2} \qquad (23)$$

Analytical rate expressions enable calculation of the CT reaction rate between specific donor and acceptor sites. However, in a disordered material, there is a distribution of charge hopping rates which vary for different pairs of molecules involved in the CT reaction. To simulate the evolution of charge carriers, the material can be mapped to a lattice of molecular sites with assigned hopping rates between them. The mapping can be done based on atomistic simulations, where every molecule in an MD snapshot is represented by a lattice site and Marcus rates are calculated for every pair of nearest neighbors. Such approach reflects the realistic morphology of a material but is computationally demanding due to the large number of CT parameters that need to be computed. A simpler method that enables to study charge transport through a disordered medium is to assume a distribution of CT parameters and draw from this distribution to assign hopping rates based on some rate expression. In the Gaussian disorder model (GDM) (Bässler 1993), site energies $\epsilon$ are assumed to be normally distributed:

$$\rho\left(\epsilon\right) = \left(\sqrt{2\pi\sigma^2}\right)^{-1} exp\left(-\frac{\epsilon^2}{2\sigma^2}\right) \tag{24}$$

and the hopping rate between neighboring sites $i$ and $j$ is of the Miller-Abrahams type (Miller and Abrahams 1960):

$$v_{ij} = v_0\, exp\left(-2\gamma r_{ij}\right) \begin{cases} exp\left(-\frac{\epsilon_j - \epsilon_i}{kT}\right), & \epsilon_j > \epsilon_i \\ 1, & \epsilon_j < \epsilon_i \end{cases} \tag{25}$$

where the parameters $v_0$ and $\gamma$ are the frequency factor and the inverse localization radius of the charge wavefunction. Extensions of GDM (Pasveer et al. 2005; Bouhassoune et al. 2009; Kordt and Andrienko 2016) have been developed to account for effects like correlations of site energies or finite charge-carrier density. Evolution of a charge carrier in terms of site occupations $\{p_i\}$ is given by the following master equation:

$$\frac{\partial p_i}{\partial t} = \sum_j p_j \omega_{ji} - \sum_j p_i \omega_{ij} \tag{26}$$

In a general case, Eq. 26 cannot be solved analytically. Instead, charge dynamics can be directly simulated with the kinetic Monte Carlo (KMC) method (Bortz et al. 1975), which propagates the carrier by constructing a Markov chain based on predefined probabilities of transitions between different states (site occupations). Averaging of independent KMC trajectories allows to calculate macroscopic properties like charge mobility, diffusivity, charge density, and current (Kwiatkowski et al. 2008).

## 4 Computational Results

To illustrate how quantum chemistry methods can help with understanding charge transfer processes, we focus on their applications to organic semiconductors (OSCs). OSC materials hold promise for photovoltaic devices due to their low manufacture cost and for light-emitting diode devices because of their great optical properties and flexibility. In order to improve the efficiency of organic photovoltaics (OPVs) and organic light-emitting diodes (OLEDs), it is crucial to understand processes such as charge separation at the interface, charge recombination, charge transfer, and exciton diffusion in these devices. Therefore, we review some of the recent work on modeling OSC devices, with an emphasis on our work using QM/MM simulation techniques.

## 4.1    Band Gaps

Band gaps are the most fundamental property for understanding charge transfer in OSC devices. Especially, the optimization of OPV materials relies on estimating their band gaps, for which experimental techniques are time-consuming and have limited accuracy (Hüfner 2003; Zahn et al. 2006). Estimating band gaps by running DFT calculations on single molecules is inaccurate because it ignores the disordered environment in OSC devices. As discussed in Sect. 3.2, to incorporate the disordered and polarizable effects of the environment, it is necessary to use implicit solvent model (e.g., PCM) or explicit solvent model (e.g., QM/MM).

Recently, Kohn et al. (2017) modeled the PPV-PCBM and P3HT-PCBM OPV devices and compared the accuracy of different methods on bulk OSC band gaps. The authors first performed an MD simulation using OPLS force field (Jorgensen et al. 1996) to sample the bulk structures of PPV, P3HT, and PCBM. DFT calculations were then employed to compute ionization potential (IP) and electron affinity (EA) of the chosen OSC molecule from MD snapshots. The environment was treated in three different ways: as absent (vacuum), as point charges (non-polarizable QM/MM), and as point charges with corresponding Drude particles (polarizable QM/MM). The authors showed that non-polarizable QM/MM improved the estimation of both IP and EA values of PCBM by 0.5 eV over the vacuum but did not correct IP/EA values of P3HT and PPV. Adding Drude particles in polarizable QM/MM significantly improved the band gaps of all three OSC materials: the EA values of PCBM, PPV, and P3HT were closer to experimental values by 0.8 eV, 0.4 eV, and 0.9 eV, respectively. It was thus suggested that inclusion of environmental polarizability is crucial for obtaining quantitative description of OSC band gaps. This result is consistent with many earlier studies on OPVs and OLEDs (Difley et al. 2010; Yost et al. 2011, 2014; Yost and Van Voorhis 2013).

A later study by de Silva and Van Voorhis (2018) applied the same methods to an OLED emission layer consisting of PIC-TRZ2 and mCP. The authors found it is important to include polarizable environment while computing the band gaps of PIC-TRZ2 and mCP and showed this could be achieved by the polarizable QM/MM or PCM methods. However, this study found that although PCM can obtain quantitative mean values of band gaps, it failed to produce correct distributions of energy levels due to the lack of explicit environment. Therefore, the polarizable QM/MM method is a more accurate method to predict both mean values and distributions of band gaps of OSC materials.

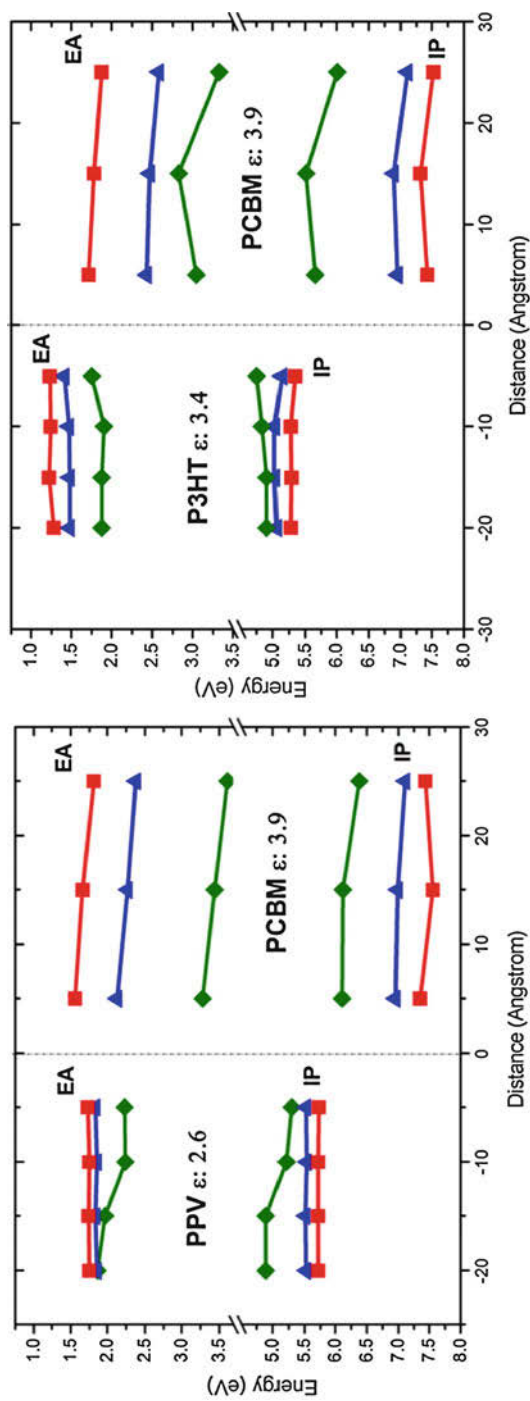
In OSC devices, most of the important charge transfer processes happen at organic/organic interfaces, where the polarizable environment changes compared to the bulk. The change of polarization can affect the band gaps significantly. Such behavior is referred to band bending at the organic/organic interface in OPVs and is crucial for understanding charge separation mechanisms (Ishii et al. 1999). Quantum chemical simulations on several OPV devices have been performed to illustrate how band gaps change at the interface (Verlaak et al. 2009; Linares et al. 2010; Yost et al. 2011; Idé et al. 2013; Yost and Van Voorhis 2013). Figure 2 shows a recent study using QM/MM simulations on PPV-PCBM and P3HT-P3BM interfaces (Kohn


**Fig. 2** Band structures as a function of distance from the interface at the PPV-PCBM (left) and the P3HT-PCBM (right) interfaces with different treatment of the environment: as a vacuum (red), as static point charges (blue), or as static point charges with Drude particles (green) (Kohn et al. 2017)

et al. 2017). This study demonstrated polarization effects that result in notable band bending near the interface. For example, IP/EA values of PPV change by about 0.3 eV from the bulk to the interface suggested by the polarizable QM/MM method, which cannot be captured if the polarizable environment is ignored in simulations. Based on this result, the authors concluded that band bending at the PPV-PCBM interface promotes charge separation, while polarization effects inhibit charge separation in the P3HT-PCBM system.

## 4.2  Localization/Delocalization

In addition to band bending, another explanation for charge separation at the organic/organic interface in OPVs focuses on the role of delocalization of the charges in the charge-separated state (Nayak et al. 2013; Bässler and Köhler 2015). As donor materials in OPV devices are normally polymers, the hole state can delocalize easily over the donor, decreasing its Coulombic interaction with the electrons (McMahon et al. 2011; Castet et al. 2014). As a result, the hole-electron binding energy is reduced, and the charge separation at the interface becomes more efficient. Although the OPV acceptor materials are mostly fullerene-based, the delocalization of electrons over multiple fullerene units have also been reported (Jamieson et al. 2012; Savoie et al. 2014).

Kohn et al. (2017) have recently examined how the change of disorder and polarization at the interface affects delocalization in the hole electronic states in PPV-PCBM and P3HT-PCBM systems. Based on their QM/MM simulation results, they performed a normalized inverse participation ratio (NIPR) analysis, which counts the effective fraction of the polymer over which a hole state is spread. NIPR was computed as:

$$\text{NIPR} = \frac{1}{N} \frac{1}{\sum_{i \in \text{sites}} P_i^2} \tag{27}$$

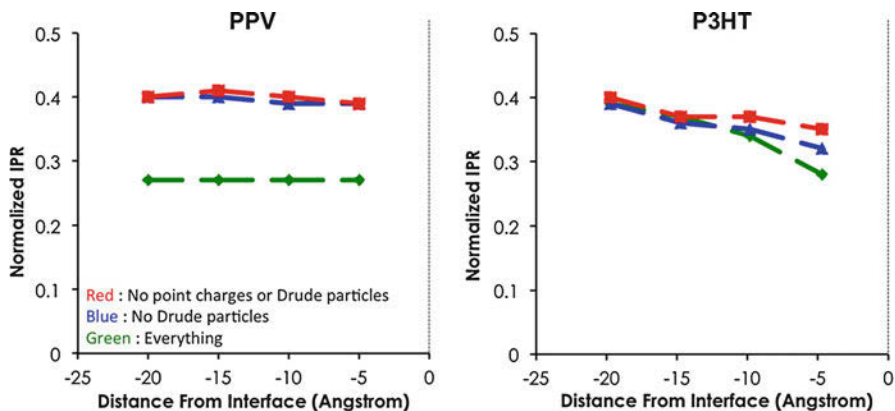
where $P_i$ is the Mulliken population of the hole on each monomer $i$ and $N$ is the number of monomers in the polymer. The NIPR therefore indicates the extent of hole delocalization: for a polymer in which the hole is equally distributed over all $N$ monomers, NIPR $= 1$, and for a polymer in which the hole is only localized on one monomer, NIPR $= \frac{1}{N}$. Their NIPR results for hole states in PPV (14-mer) and P3HT (20-mer) are shown in Fig. 3, as a function of the distance from the interface. As can be seen, the NIPR for PPV does not change when the PPV chain is closer to the interface, suggesting the hole delocalization on PPV is insensitive to the PPV-PCBM interface. However, this is not the case for P3HT (which is more disordered than PPV): the hole distribution becomes obviously more localized when P3HT is closer to the P3HT-PCBM interface, indicated by the smaller NIPR values. The authors explained that this behavior arises from the interfacially induced disorder that disrupts the conjugation and causes a form of Anderson localization, which was also observed in other theoretical studies on P3HT (McMahon and Troisi


**Fig. 3** Normalized inverse participation ratios (NIPRs) for the hole states in the electron-donating polymers, PPV and P3HT, with different treatment of the environment: as a vacuum (red), as static point charges (blue), or as static point charges with Drude particles (green) (Kohn et al. 2017)

2010; Barford et al. 2010). The authors pointed out although the localization of hole states at the interface provides a driving force for charge separation, this effect is overpowered by the polarization of the electronic environment in the investigated systems. Therefore, they suggested considerations of electrostatic effects should take priority when designing new OPV devices.

Polarization effects from the environment show great importance in describing the hole delocalization. For PPV, the effect of static point charges added in the non-polarizable QM/MM is negligible because of PPV's less disordered structure. However, adding Drude particles in the polarizable QM/MM localizes the hole states in PPV by more than 30%. Such effects are smaller in P3HT: improved treatment of the polarizable environment increases the degree of localization but only reduces the hole size by about 15%. The authors thus concluded that the hole delocalization of disordered materials (such as P3HT) may be well described without the use of a polarizable environment.

## 4.3 Energetic Disorder

In OSC devices, the charge transport normally can be well described by a hopping mechanism. The charge hopping rates are mostly affected by alignment of electronic transport levels of individual sites (site energies) (Coropceanu et al. 2007). As a result of amorphous structures of OSC materials, there is an energetic disorder in site energies. As discussed in Sect. 3.2, there are two different sources of energetic disorder, static and dynamic energetic disorder, and they affect the charge transport properties in different ways. For example, as pointed out by Tummala et al. (2015), static disorder is always detrimental for charge transport, while dynamic disorder can sometimes lead to an enhancement of the transport properties via a

phonon-assisted contribution to charge-carrier mobility. Therefore, it is important to separately estimate the effects of static and dynamic disorder on charge transport in OSCs.

However, widely used disorder models like the Gaussian disorder model (Bässler 1993) and its extensions (Novikov et al. 1998; Bouhassoune et al. 2009; Kordt and Andrienko 2016) do not make an explicit distinction between these two types of disorder. Meanwhile, many charge transport simulation studies use parametrizations that assume all the disorder to be static (Rühle et al. 2011; Friederich et al. 2015; Yavuz et al. 2015). Only very recently, there are studies simulating static and dynamic energetic disorder in OSC devices. Tummala et al. (2015) investigated the energetic disorder in fullerene systems, including $C_{60}$, $C_{70}$, $PC_{61}BM$, and $PC_{71}BM$, using combined MD and DFT calculations. They found in the $C_{60}$ and $C_{70}$ bulk amorphous structures, the extent of static disorder is comparable to that of dynamic disorder. However, in the case of $PC_{61}BM$ and $PC_{71}BM$, the static disorder increases significantly and is twice as large as the dynamic disorder, due to the conformational changes from the phenyl-butyric acid methyl ester adducts.

de Silva and Van Voorhis (2018) performed combined MD and polarizable QM/MM simulations to study energetic disorder in emission layers of two OLED devices, where PIC-TRZ2 (guest) is dispersed into two different host matrices: mCP and UGH2. From sampling 20 different guest and host sites and their time evolution over 100 MD snapshots, the authors obtained the overall energetic disorder. The choice of the host matrix significantly affects the degree of energetic disorder in site energies for both guest and host components. For example, the standard deviations of EA levels of host and guest in mCP are in the range of 0.15–0.16 eV, while in UGH2 the standard deviations are only 0.10 eV. The authors performed further analysis of ensemble and time distributions of site energies to decompose the total disorder into static and dynamic contributions. Similar to the results of Tummala et al., they showed the dynamic disorder and static disorder are on the same order of magnitude. More interestingly, they found the larger disorder of guest and host molecules in PIC-TRZ2@mCP film is caused by the increase in the static component. The dynamic disorder is not affected by the choice of host, but there is a twofold increase in the static disorder when mCP is used as the host instead of UGH2. The authors thus concluded that polarity is the dominant factor for static disorder, while dynamic disorder does not depend significantly on intermolecular interactions.

## 4.4 Reaction Coordinate

In host-guest OLED devices, guest (emitter) molecules can be treated as impurities because they are dispersed into host molecules at a low concentration. The host-guest interactions have been shown to be important for improving the OLED device performance (Tao et al. 2011; Einzinger et al. 2017). It is then interesting to investigate if the impurities affect the energy levels of their neighboring host molecules, which may further influence the charge transfer efficiency from the host

to the guest. This is similar to band bending at the organic/organic interfaces in OPVs, which can facilitate or inhibit the charge separation processes. As OPV devices normally consist of layers of donor and acceptor molecules, it is easy to define the geometrical distance from a position in the bulk to the interface. Such geometrical distance is then used as the reaction coordinate to study the energy level changes (Yost et al. 2011; Yost and Van Voorhis 2013; Kohn et al. 2017). However, distance between molecules is poorly defined in OLEDs because the molecules are about the same size ($\sim$1 nm) as the space between their centers of mass (1–5 nm). In addition, since many guest molecules exist in the emission layer, it is ambiguous to determine which host-guest distance to use for a specific host molecule. Therefore, a new reaction coordinate is needed to indicate the effective distance between guest molecules and a specific host molecule.

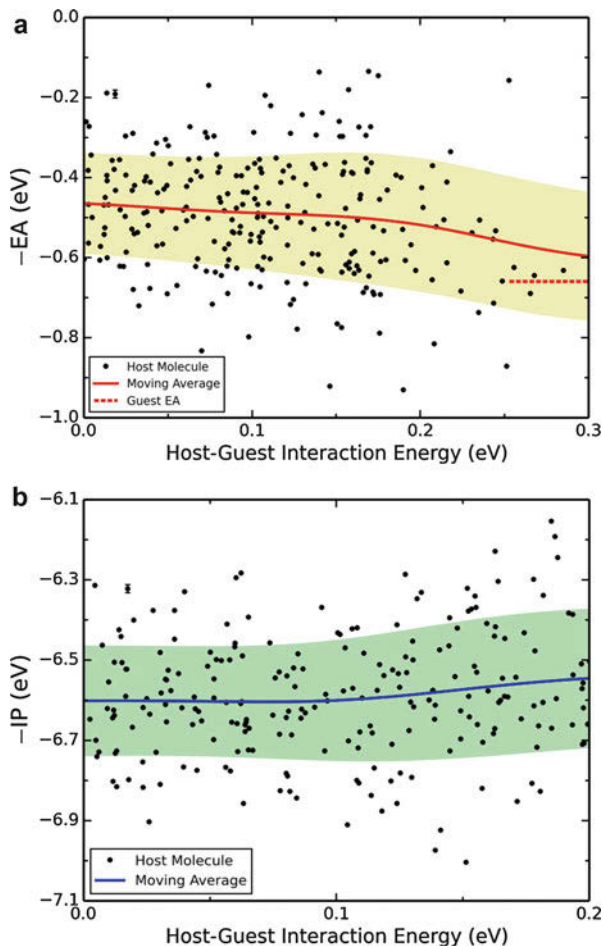
Zhu and Van Voorhis (2016) introduced a new reaction coordinate while studying a phosphorescent OLED host-guest system consisting of BTDF and Ir(ppy)$_3$ using combined MD and polarizable QM/MM simulations. In order to investigate the charge recombination process from the host to the guest, the authors used the "host-guest interaction energy" as the reaction coordinate to evaluate the effect of impurities on the host energy levels. For a specifically chosen host molecule, the host-guest interaction energy is defined as the change of its IP/EA values ($\Delta$IP/$\Delta$EA) with or without the electrostatic interactions with all guest molecules in the system:

$$\Delta IP = |IP\,(on) - IP\,(off)|$$
$$\Delta EA = |EA\,(on) - EA\,(off)| \tag{28}$$

where "off" means point charges and Drude particles on all guest molecules were set to 0 in the MM part of the Hamiltonian in the polarizable QM/MM simulation and "on" means all MM parametrized force field values are kept. Because the electrostatic interaction between two molecules is inversely proportional to their distance, this "host-guest interaction energy" can be used to directly measure the effective distance: the larger host-guest interaction energy means closer distance between the chosen host molecule and all guest molecules.

The IP and EA values of the host as a function of the host-guest interaction energy are shown in Fig. 4. The authors showed that EA of the host increases by about 0.1 eV when the host is closer to guest molecules, while IP of the host stays almost the same. Meanwhile, there are broader distributions of IP/EA at closer host-guest distances, suggesting guest molecules result in slightly more disordered molecular environment. Based on these results, the authors concluded that the change in EA distributions makes the electron transfer from the host to the guest less efficient. This study thus suggests the impurity effect on host energy levels caused by guest molecules is minor in OLEDs. This is also confirmed by a later study of de Silva and Van Voorhis (2018), where they observed no guest impurity effect on host energy levels for PIC-TRZ2@mCP system. The authors explained that such effect is completely suppressed by both static and dynamic energetic disorder in host materials.

**Fig. 4** Left: Distribution of electron affinities of BTDF as a function of the host-guest interaction energy ΔEA. Right: Distribution of ionization potentials of BTDF as a function of the host-guest interaction energy ΔIP. The colored regions indicate the standard deviations. (Zhu and Van Voorhis 2016)



## 4.5    Charge Transfer State

OPV devices need a large driving force to break up excitons and create separate electrons and holes. This driving force is provided by the offset of HOMO/LUMO energy levels of two different OSC materials at their interface. A charge transfer state is formed after the exciton breakup, and the binding energy of the CT state is still around 10 kT, a prohibitively high-energy barrier at room temperature (Zhu et al. 2009). Despite this problem, high interfacial charge separation efficiencies are shown in many OPVs (Kippelen and Brédas 2009; Park et al. 2009; Few et al. 2015). One proposed mechanism is that some of the excess exciton energy might be used to create a "hot" CT state, where the carriers have sufficient kinetic energy to overcome the dissociation barrier. This mechanism is supported by several

theoretical and experimental studies (Dimitrov et al. 2012; Jailaubekov et al. 2012; Bakulin et al. 2013). Tamura and coworkers (Tamura and Burghardt 2013) simulated the exciton dissociation in a TFB/F8BT dimer using a model Hamiltonian and found a significant increase in the free charge formation rate when going through a higher-energy, vibrationally excited CT state. Later work by Shen et al. (2015) using the QM/MM simulation also showed in DTDCTB/fullerene solar cells, the rate of exciton dissociation via the higher-energy CT state is much faster than that of exciton dissociation via the CT ground state.

However, contradictory studies have shown that "cold" CT states can form free charges just as efficiently as "hot" CT states (Vandewal et al. 2013; Bässler and Köhler 2015; Gautam et al. 2016). The experimental study of Lee et al. (2010) on the formation of hot CT states showed that the charge separation efficiency is independent of whether the CT state was formed with excess energy. To understand how charge separates from a cold CT state, it is important to accurately estimate the binding energy of CT states at the organic/organic interface:

$$E_{bind} = \left( E_{IP}^{Donor} - E_{EA}^{Acceptor} \right) - E_{CT} \tag{29}$$

where $E_{CT}$ is the energy of the CT state, $E_{IP}^{Donor}$ and $E_{EA}^{Acceptor}$ are IP of the donor and EA of the acceptor. Time-dependent DFT is known to underestimate CT state energies, while CDFT is shown to be an effective tool to accurately describe CT states and can easily incorporate the environment into the calculations. A restricted open-shell Kohn-Sham approach has also been shown to work well for intramolecular CT states (Hait et al. 2016).

Yost et al. (2011) performed combined MD and polarizable QM/MM simulations on the $H_2Pc$/PTCBI OPV interface. The authors computed the interfacial CT states on a number of nearest-neighbor CT pairs using CDFT and found the CT states have a broader energy distribution than first excited states of either $H_2Pc$ or PTCBI, suggesting the CT states are more sensitive to the electrostatic environment. Through further analysis on the CT binding energy, they found $E_{bind}$ has a clear $R^{-1}$ decay as a function of intermolecular distance, shown in Fig. 5. The average $E_{bind}$ for the closest pairs is 0.2 eV, while averaging over all of the nearest-neighbor pairs gives a $E_{bind}$ of 0.15 eV. There is also a scatter of 0.1 eV within each CT pair due to thermal fluctuations, which is expected to facilitate the initial charge separation at the organic-organic interface. In addition to the CT binding energy, the authors also simulated energy levels at the $H_2Pc$/PTCBI interface, where the band offset is shown to be 0.25 eV larger than the bulk value. The authors thus concluded that the interfacial CT states have higher average energy than fully separated charges in bulk materials but are locally bound at the interface. This study suggested that it is possible for bound interfacial CT states to dissociate in a barrierless fashion without involving "hot" CT states.
**Fig. 5** Distribution of the $H_2Pc$/PTCBI interfacial CT state binding energies. The coordinate R is a linear combination of intermolecular distances. Each different color/shape combination represents distinct dimer pairs in the simulation cell (Yost et al. 2011)

## 4.6    Charge Mobility

A major factor that limits the efficiency of OPVs is the low charge mobility of OSC materials. The charge mobility at room temperature of most conductive OSC materials is a few tens of $cm^2\ V^{-1}\ s^{-1}$, an order of magnitude smaller than the value of inorganic semiconductors (Ostroverkhova et al. 2006; Troisi 2011). To understand this limit and design more conductive OSCs, one needs to be able to accurately estimate the charge mobility. The simulation of charge mobility in OSCs requires the evaluation of charge transfer rates and a subsequent analysis of the solution of the master equation. Here, we only highlight the computational efforts on charge transfer rates. For the use of kinetic Monte Carlo simulation and coarse-grained lattice models to obtain the charge mobility, we direct the reader to the review by Andrienko and coworkers (Kordt et al. 2015).

To compute the charge transfer rates following Marcus theory, one needs to simulate the band gap, reorganization energy, and electronic coupling of OSC materials, which requires the knowledge of diabatic states and the Hamiltonian of the involved dimer. Semiempirical methods such as ZINDO have also been shown to be useful in computing electronic coupling in a faster manner compared to first principle calculations (Kirkpatrick 2008; Vehoff et al. 2010). However, a more accurate and general method to construct diabatic states is CDFT. Difley et al. (2010) performed CDFT calculations in polarizable MM environment to simulate the charge transfer rates in $Alq_3$ crystalline structure. The authors found the electronic coupling can vary by as much as a factor of 5 as a function of time,

indicating significant dynamic heterogeneity of the hopping rate on the nanosecond time scale. The electronic coupling was also shown to depend strongly on the relative orientation and distance of the involved $Alq_3$ dimer. The authors further found that although the reorganization energy for the electron transfer is larger than the hole transfer, the considerably larger electronic coupling of the electron transfer is enough to overcome the difference in activation barriers. As a result, the electron transfer rate is shown to be larger than the hole transfer, which qualitatively agrees with the experimental observation that $Alq_3$ is a good electron transport material. However, the authors also pointed out one must apply mesoscopic simulations to obtain quantitative predictions on charge mobility (Kwiatkowski et al. 2008) because of the heterogeneity of the charge transfer rates. This study thus suggests it is crucial to include dynamic and static disorder and construct diabatic states accurately when computing the charge transfer rates.

## 5    Conclusion

We have here presented a brief review of the principles of charge transfer in molecular materials. The essential principles of electron transfer can be understood using arguments from Marcus theory – an approximate model that was originally designed for solution-phase electrochemistry but which has seen a shocking degree of success describing charge transfer in widely disparate areas. Next, we highlighted the main ingredients in any computational model: (1) a method to compute localized charge states and their couplings (here chosen to be CDFT), (2) a method to account for environment effects (here chosen to be QM/MM), and (3) a means of differentiating between static and dynamic disorder of the system. Then, using organic LED and PV materials as illustrations, we showed how careful consideration of charge transfer reveals a wealth of information about the system: the behavior of band gaps near heterojunction interfaces; the delocalization length of charge carriers; the effective binding energy of electrons and holes; and the charge mobility of materials.

Moving forward, there are a number of exciting directions for exploration. How do oppositely charged carriers in host-guest complexes interact with one another, and how does that interaction mediate charge recombination? In polymeric systems, how does the dynamic localization and delocalization of charge impact charge transport? How do charges interact with bound electron-hole pairs, like excitons, and how can we understand the rate of exciton-charge annihilation? And finally, how can we combine the molecular and solid-state pictures of charge transport in order to appropriately describe *hybrid* organic-inorganic devices involving molecules and traditional semiconductors simultaneously? All of these are intriguing research directions, and we are at the auspicious moment of history where such questions can and will be answered in the coming years.

# Van der Waals Interactions in Material Modelling

**13**

Jan Hermann and Alexandre Tkatchenko

## Contents

**Abstract**

Van der Waals (vdW) interactions stem from electronic zero-point fluctuations and are often critical for the correct description of structure, stability, and response properties of molecules and materials, including biomolecules, nanomaterials, and material interfaces. Here, we give a conceptual as well as mathematical overview of the current state of modeling vdW interactions,

focusing in particular on the consequences of different approximations for practical applications. We present a systematic classification of approximate first-principles models based on the adiabatic-connection fluctuation-dissipation theorem, namely the nonlocal density functionals, interatomic methods, and methods based on the random-phase approximation. The applicability of these methods to different types of materials and material properties is discussed in connection with availability of theoretical and experimental benchmarks. We conclude with a roadmap of the open problems that remain to be solved to construct a universal, efficient, and accurate vdW model for realistic material modeling.

# 1 Introduction

van der Waals (vdW) interactions stem from electronic zero-point (and possibly thermal) fluctuations in electronic matter (Langbein 1974; Parsegian 2005). Therefore, vdW interactions scale rapidly with system size and are often critical for the correct description of structure, stability, and response properties of molecules and materials, including biomolecules, nanomaterials, and material interfaces. This makes proper description of vdW interactions a crucial aspect of modern material modelling. This is especially important in the context of electronic-structure calculations using approximate density functionals. Such functionals are normally semilocal ("short sighted") in the electronic density, meaning that nonlocal vdW interactions are poorly or not at all described by these functionals.

From a classical electrostatic perspective, electrons repel each other. However, quantum-mechanical correlation effects typically act to minimize the electric repulsion between electrons. This *correlation* in the electronic motion results in instantaneous effective multipoles that interact via electrostatic forces, attracting different regions toward each other. When there is no significant overlap between two interacting regions of electronic matter, we usually speak of the long-range electron correlation, which is the underlying microscopic cause of vdW interactions. (As Margenau put it already in 1939, "the term 'van der Waals force' is not one of very precise usage," which holds to this date. Here, we will use the term exclusively to refer to the electron correlation part of noncovalent interactions.)

In many approaches to material modelling, ranging from empirical to those based on first principles, the models that describe the short-range and long-range parts of the electron correlation are constructed separately, because each requires a different set of considerations. This chapter discusses currently used approaches to the calculation of the long-range correlation energy – the vdW energy – with special focus on the case when the short-range part of the correlation energy (and other total energy components) is calculated within the density functional theory (DFT). We begin with a conceptual understanding and importance of vdW interactions in materials (Sect. 2), which has motivated the recent rapid development of new vdW models presented in the subsequent sections. This is followed by a brief conceptual overview of existing and widely used vdW models (Sect. 3), which can serve

either as a stand-alone short synopsis or as an introduction to the subsequent more detailed exposition. We then continue with a more theoretical presentation of current approaches to modelling vdW interactions, first introducing a general framework for discussing vdW models (Sect. 4), followed by a classification of current approaches within that framework (Sect. 5). None of the existing vdW models is the best choice for every system, and a close attention must be paid to their accuracy and areas of applicability (Sect. 6). We conclude with an outline of outstanding problems in the topic of modelling vdW interactions from first principles of quantum mechanics (Sect. 7).

## 2    Role of van der Waals Interactions in Materials

Functional materials are becoming increasingly smaller in size and more heterogeneous in composition. These two aspects of novel nanomaterials lead to the emergence of nontrivial quantum-mechanical effects that depend on size and topology and which may ultimately determine the properties of a material of interest. One important consequence of this evolution beyond traditional materials, the functionality of which was largely regulated by bulk observables, is that noncovalent interactions play an increasingly important role in determining the structure, stability, and ensuing function of homogeneous and heterogeneous nanostructured materials. van der Waals interactions, which exhibit nontrivial scaling behavior with system size (Dobson et al. 2006; Ruzsinszky et al. 2012; Gobre and Tkatchenko 2013), are often the dominant part of such noncovalent interactions. In general, vdW interactions have already been recognized as playing an instrumental role in determining the structure, stability, and functionality of biological materials, supramolecular and sensor chemistry, pharmaceuticals, dye-sensitized solar cells, and many other systems. More recently, the field of "van der Waals heterostructures" has moved into the forefront (Geim and Grigorieva 2013) and has already led to fundamental advances in the study of low-dimensional materials and to a number of novel technological applications.

In this context, the importance of understanding and accurately modelling vdW interactions in realistic materials can hardly be overemphasized. However, our ability to model these ubiquitous quantum mechanical effects has been severely impeded by the prohibitively high computational cost of explicitly correlated quantum chemical methods and the lack of efficient approximations to the many-electron correlation problem for large systems (Szabo and Ostlund 1996). In fact, most successful approximations employed for modelling vdW interactions in materials rely on the rather crude lowest-order pairwise additive approximation, which is only exact in the weak polarization limit and at large interatomic distances. For condensed-phase systems with a moderate to large polarizability density, such pairwise approximations can often lead to qualitatively incorrect predictions of structural, energetic, and response properties.

The structure and binding in organic materials is often driven by vdW interactions, in combination with other contributions such as repulsion, electrostatics,

and induction. Therefore, accurate modelling of vdW interactions is critical for understanding the properties of organic materials. In recent years, substantial progress has been achieved in the theoretical prediction of structures and stabilities of molecular crystals by using vdW-inclusive DFT approaches. Today, the structures of (simple) organic molecular crystals can be predicted with an accuracy of 2–3% and cohesive energies to 1–2 kcal/mol. Proper description of vdW correlations becomes even more relevant when one looks at the relative energetics of molecular systems, which are essential to predict the polymorphic behavior of molecular crystals.

While the crucial role of vdW interactions in organic materials is well established, our understanding of the relative importance of these ubiquitous interactions in semiconductors, ionic solids, and metals is still in development. The contribution of the long-range vdW energy to the cohesive energy of elemental and binary semiconductors and ionic solids amounts to 0.2–0.3 eV/atom, which is around 8% of the cohesive energy (Zhang et al. 2011). The contribution of vdW energy to the bulk modulus is even more pronounced, reaching up to 22% for Ge and GaAs. Notably, the inclusion of vdW interactions in DFA calculations allows to simultaneously improve the performance for lattice constants, cohesive energies, and bulk moduli, when compared to experiment. Similar conclusions have been reached for a wide variety of hard solids. Because vdW interactions typically have larger contributions to relative energetics than absolute ones, one expects significant effects for phase transition pressures and phase diagrams of most solids.

The properties of many materials are substantially affected by the presence of simple and complex defects. For example, the properties of semiconductors are largely determined by neutral and charged interstitials and vacancies (Freysoldt et al. 2014). The formation of defects entails a modification of polarization around defect sites, and this can have a substantial effect on the contribution of vdW energy to the stability and mobility of defects. For instance, the inclusion of interactions in DFT improves the description of defect formation energies, significantly changes the barrier geometries for defect diffusion, and brings migration barrier heights into close agreement with experimental values (Gao and Tkatchenko 2013). In the case of Si, the vdW energy substantially decreases the migration barriers of interstitials and impurities by up to 0.4 eV, qualitatively changing the diffusion mechanism. Moving beyond point defects, it is to be expected that more complex neutral and charged multiatom defects and dislocations will lead to even stronger nonlocal polarization effects and intricate dependence of vdW interactions on the nature of defects.

Hybrid inorganic/organic systems (HIOS) are relevant for many applications in catalysis, light-emitting diodes, single-molecule junctions, molecular sensors and switches, and photovoltaics. The predictive modelling and understanding of the structure and stability of such hybrid systems are an essential prerequisite for tuning their electronic properties and functions. The bonding in HIOS is often determined by a delicate balance between covalent bonds, hydrogen bonds, charge transfer, Pauli repulsion, and vdW interactions. Yet the latter are at the edge of what is possible with current vdW approaches, because the inorganic substrate is often a

metal or a doped semiconductor, which is difficult to model due to the delocalized nature of metallic single-particle excitations.

## 3 Overview of Existing van der Waals Models

A common starting point for virtually all existing vdW models is an exact expression for the electron correlation energy that can be constructed from the ACFD theorem (Gunnarsson and Lundqvist 1976; Langreth and Perdew 1977). The essential idea of this expression is an interpolation between a reference noninteracting mean-field system and the fully interacting many-body system. The starting quantity from which the correlation energy can be calculated is some form of a response function (nonlocal polarizability, dielectric function, density response function), which describes the linear response of the system to external electric field. This quantity can be calculated either from first principles, using some mean-field electronic-structure theory such as the Hartree–Fock (HF) method or Kohn–Sham DFT (KS-DFT), or constructed semiempirically using approximate models. The former approach is less ambiguous, but the complexity of such ab initio response functions demands large computational cost and even then requires substantial approximations to the interelectronic interactions. In contrast, the latter approach leads to efficient methods, in which much of the complexity of the electronic structure can be treated effectively by suitable parameterization of the model response functions. In both cases, either the response functions or the interelectronic interactions (or both) are treated approximately, leading to deviations from the in-principle exact ACFD correlation energy.

Essentially all existing methods for modelling vdW interactions can be derived by following various approximations to the ACFD theorem. Two major classes of approximations that can be identified in existing vdW models are the coarse-graining of the response functions and truncation of the many-body expansion. In their full form, the response functions are two-point spatial functions, specifying a response of a system at some point to the perturbation in the electric field in another point. Such a description enables the calculation of the electron correlations across the whole range of interelectronic distances, including the short-range intra-atomic as well as long-range intermolecular correlations. This level of detail is largely unnecessary for the calculation of the vdW energy, which comprises only the long-range part of the electron correlation energy. Therefore, a common approach is to coarse-grain the response functions into finite-size fragments – typically atoms – and to evaluate only the long-range correlations between the fragments, while the short-range intrafragment interactions are captured in the effective response properties of the fragments. The second common approximation involves the truncation of the many-body expansion. The closed-form ACFD expression can be expanded as an infinite sum of terms that involve repeated couplings of the noninteracting response functions. Ordering these terms by the number of times a response function occurs in them, the electron correlation energy starts at second order (two occurrences) and continues to infinity. The physical interpretation of the

$n$-th order is such that $n$ electronic fluctuations interact via the long-range Coulomb potential to yield a contribution to the correlation energy. The magnitude of the contribution of the individual orders to the vdW energy decreases with the growing order, which motivates the common approximation of truncating the infinite sum at some order, usually second or third. Using only the lowest second order results in the large class of pairwise methods, which neglect any many-body effects in vdW interactions.

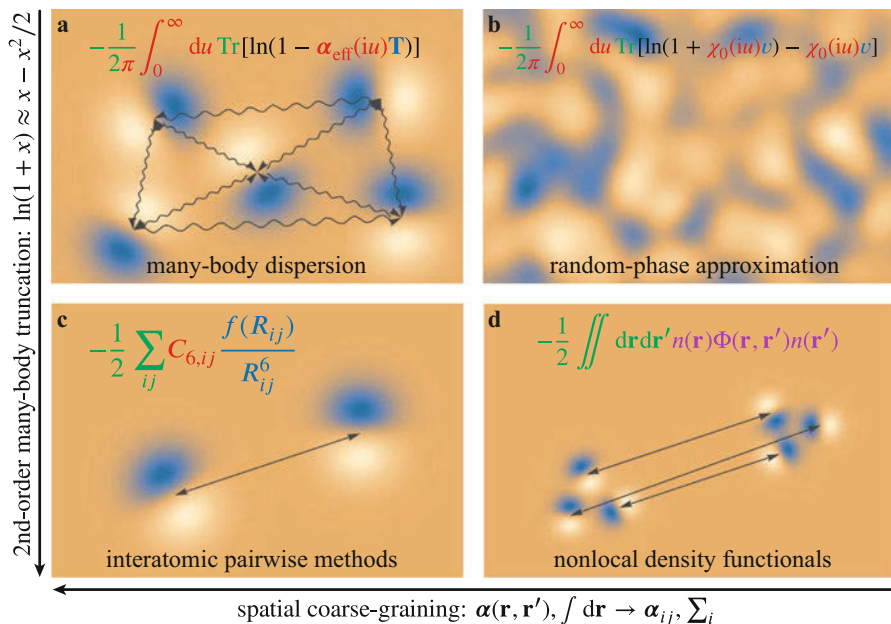

**Fig. 1** Classification of different approaches to modelling vdW interactions based on their approximations to the adiabatic-connection fluctuation–dissipation (ACFD) formula. The light yellow and blue illustrate density fluctuations, and the arrows denote interactions between them. General formulas for each method class are shown, with colors denoting parts with the same origin in the ACFD formula: summation of all interactions in the system (green), encoding of the response properties (red), and the interaction potentials (blue). In random-phase approximation (RPA), both the noninteracting frequency-dependent density response function, $\chi_0(\mathbf{r}, \mathbf{r}', u)$, and the electronic Coulomb interaction, $v(\mathbf{r}, \mathbf{r}') = |\mathbf{r} - \mathbf{r}'|^{-1}$, are nonlocal spatial quantities, and their multiplication should be interpreted as $[\chi_0 v](\mathbf{r}, \mathbf{r}', u) = \int d\mathbf{r}'' \chi_0(\mathbf{r}, \mathbf{r}'', u) v(\mathbf{r}'', \mathbf{r}')$. The RPA itself neglects the exchange–correlation screening of the Coulomb interaction and is not illustrated in this figure. In many-body dispersion (MBD), the response function and potential are coarse-grained and expressed as the nonlocal polarizability matrix, $\boldsymbol{\alpha}_{ij}(u)$, and dipole matrix, $\mathbf{T}_{ij}$, which are multiplied as ordinary matrices. Nonlocal functionals truncate the many-body expansion (expressed as the logarithm in RPA and MBD) at second order, and the response function and interaction potential are intermingled (violet) in the nonlocal kernel, $\Phi(\mathbf{r}, \mathbf{r}')$. Interatomic pairwise models, coarse-grained and truncated at second order, integrate the frequency-dependent polarizability into the so-called $C_6$ coefficients, while the square of the dipole potential yields the $R^{-6}$ power law

Organizing existing vdW models into a 2-by-2 matrix based on whether they use the coarse-graining and/or the many-body truncation approximations (Fig. 1) provides a concise classification that allows for an efficient discussion of the general behavior of these models. The class of methods that do not coarse-grain nor truncate the many-body expansion are based exclusively on the ab initio noninteracting response functions obtained from the HF or KS-DFT methods. This requires other approximations to the interelectronic interactions in the ACFD formula, which make its evaluation tractable (though still computationally demanding). The most straightforward of these approaches is the so-called random-phase approximation (RPA), in which the complex interaction between electronic fluctuations is replaced with the bare Coulomb potential. In contrast, the other three vdW model classes use model noninteracting response functions (usually polarizability), in which the electronic fluctuations are usually assumed to be localized. In nonlocal density functionals, the response function is modelled as a semilocal polarizability functional of the electron density, which is coupled between all pairs of points in space, resulting in a double spatial integral. The many-body dispersion (MBD) approach models the response of atomic fragments as that of harmonic oscillators, which enables efficient evaluation of the ACFD formula without any truncation of the many-body expansion. Finally, interatomic pairwise models use both the coarse-graining and the truncation to provide a particularly simple formula for the vdW energy, in which the response functions are expressed in the form of the so-called dispersion $C_6$ ($C_8$, $C_{10}, \dots$) coefficients.

Within each of the four classes of vdW models, there are multiple instances that differ in more subtle details. These include the particular parametrization of the model response functions or the mechanisms that separate the short-range and long-range parts of the electron correlation. These differences influence the performance of the individual methods but do not change their general behavior for different types of molecules and materials, which will be discussed in more detail in Sect. 6. These individual models together with a more rigorous mathematical formulation of this overview are presented in the following two sections.

## 4   Long-Range Electron Correlation

The ACFD theorem yields an in-principle exact expression for the electron correlation energy and serves as a basis for the various approximate vdW models discussed in this chapter. The present and the following sections give a brief introduction to the mathematical formulation of this topic, which can be found in greater detail elsewhere (Hermann et al. 2017). The ACFD formula expresses the vdW energy in terms of the response of an electronic system to an external electric field, which is introduced in the remainder of this section, while the formula itself and the various approximations to it are discussed in the following section.

## 4.1    Response Functions and Polarizability

The polarization of electronic matter under the influence of a time-periodic external electric field, $\mathbf{E}_\Delta = -\nabla v_\Delta$, with a given frequency, $u$, can be expressed by the change in the electron density, $\Delta n$, from the unpolarized state ($\mathbf{E}_\Delta = 0$). In the linear regime, this change is related to the corresponding potential, $v_\Delta$, via the density response function,

$$\Delta n\left(\mathbf{r}, u\right) = \int \mathrm{d}\mathbf{r}' \chi\left(\mathbf{r}, \mathbf{r}', u\right) v_\Delta\left(\mathbf{r}', u\right) \tag{1}$$

Alternatively, the polarization state can be described by the polarization density, $\mathbf{P}$, which can be interpreted as a dipole density and which gives the polarized charge density via divergence,

$$\Delta n\left(\mathbf{r}, u\right) = \nabla \cdot \mathbf{P}\left(\mathbf{r}, u\right) \tag{2}$$

The polarization density is related to the electric field via the (nonlocal) dipole polarizability, $\boldsymbol{\alpha}$, (Hunt 1983),

$$\mathbf{P}\left(\mathbf{r}, u\right) = -\int \mathrm{d}\mathbf{r}' \boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}', u\right) \mathbf{E}_\Delta\left(\mathbf{r}', u\right) \tag{3}$$

In general, the response of the electron density is anisotropic, $\mathbf{E}_\Delta$ and $\mathbf{P}$ are not aligned, and the polarizability must be a tensor. The relation between the density response function and dipole polarizability is obtained by taking the divergence of Eq. 3, integrating by parts, using the definitions of $\mathbf{E}_\Delta$ and $\mathbf{P}$, and comparing to Eq. 1,

$$\begin{aligned}
\chi\left(\mathbf{r}, \mathbf{r}', u\right) &= -\nabla \cdot \nabla' \cdot \boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}', u\right) \\
&= -\sum_{\iota\zeta} \frac{\partial^2}{\partial r_\iota \partial r'_\zeta} \alpha_{\iota\zeta}\left(\mathbf{r}, \mathbf{r}', u\right) \quad (\iota, \zeta = x, y, z)
\end{aligned} \tag{4}$$

Whereas the electron density and the density response functions interact electrically via the Coulomb operator, the polarization density and dipole polarizability interact via the dipole operator,

$$\mathbf{T}\left(\mathbf{R}\right) = \nabla \otimes \nabla' v\left(\left|\mathbf{r} - \mathbf{r}'\right|\right)\Big|_{\substack{\mathbf{r}=\mathbf{R} \\ \mathbf{r}'=\mathbf{0}}} = \frac{-3\mathbf{R} \otimes \mathbf{R} + R^2 \mathbf{I}}{R^5} \tag{5}$$

For instance, the electrostatic Coulomb self-interaction of $\Delta n$, with its corresponding $\mathbf{P}$, can be expressed in two equivalent ways,

$$\begin{aligned}
J\left[\Delta n\right] &= \tfrac{1}{2} \iint \mathrm{d}\mathbf{r}_1 \mathrm{d}\mathbf{r} \Delta n\left(\mathbf{r}_1\right) v\left(\left|\mathbf{r}_1 - \mathbf{r}_2\right|\right) \Delta n\left(\mathbf{r}_2\right) \\
&= \tfrac{1}{2} \iint \mathrm{d}\mathbf{r}_1 \mathrm{d}\mathbf{r}_2 \mathbf{P}\left(\mathbf{r}_1\right) \cdot \mathbf{T}\left(\mathbf{r}_1 - \mathbf{r}_2\right) \mathbf{P}\left(\mathbf{r}_2\right)
\end{aligned} \tag{6}$$

The description of the response via the density response function and dipole polarizability is equivalent, and likewise the ACFD formula can be expressed using both. The density response functions are directly accessible from ab initio electronic-structure calculations, whereas the dipole polarizability is better suited for the formulation of approximate models. The reason for this is that the density response function has a complex nodal structure, as it describes depletion of the electron density at some points and its accumulation elsewhere. In contrast, the corresponding polarizability is a smooth rotation-free vector field which encodes that underlying nodal structure implicitly in terms of its local behavior via the divergence operators in Eq. 4. This is true even in the case of a delocalized density response that is characteristic of gapless or near-gapless systems. Therefore, the strength of the response is translated directly into the magnitude of the polarizability, whereas it is translated only indirectly into the magnitude of the gradient of the density response function.

For illustration, consider two one-dimensional (1D) Gaussian charge densities located at $\pm 1$ (as crude model of atoms) and two model density response functions, local and nonlocal (Fig. 2). In one dimension, the dipole polarizability is a scalar and uniquely determined by integrating over the density response function,

$$\alpha^{1D}(x, y) = \int_{-\infty}^{x} dx' \int_{-\infty}^{y} dy' \chi^{1D}(x', y') \tag{7}$$

Even in these trivial models, the density response function changes sign around atoms and has a nontrivial nodal structure, whereas the polarizability is positive everywhere. Furthermore, the delocalized density response translates into a polarizability that is still localized but over a larger region spanning both atoms.

## 4.2   Harmonic Oscillator Model of Polarizability

When the dipole polarizability is localized, as in the examples in the previous section, it can be relatively accurately represented as an effective local polarizability, $\alpha^{\mathrm{eff}}(\mathbf{r}, u)$, formally obtained by integrating over some neighborhood, $M(\mathbf{r})$, around each point, $\mathbf{r}$,

$$\alpha^{\mathrm{eff}}(\mathbf{r}, \mathbf{r}', u) \approx \delta(|\mathbf{r} - \mathbf{r}'|) \int_{M(\mathbf{r})} d\mathbf{r}'' \alpha(\mathbf{r}, \mathbf{r}'', u) \equiv \delta(|\mathbf{r} - \mathbf{r}'|) \alpha^{\mathrm{eff}}(\mathbf{r}, u) \tag{8}$$

A wide variety of approaches to model the spatial dependence of $\alpha^{\mathrm{eff}}$ exist, which will be discussed in the following sections.

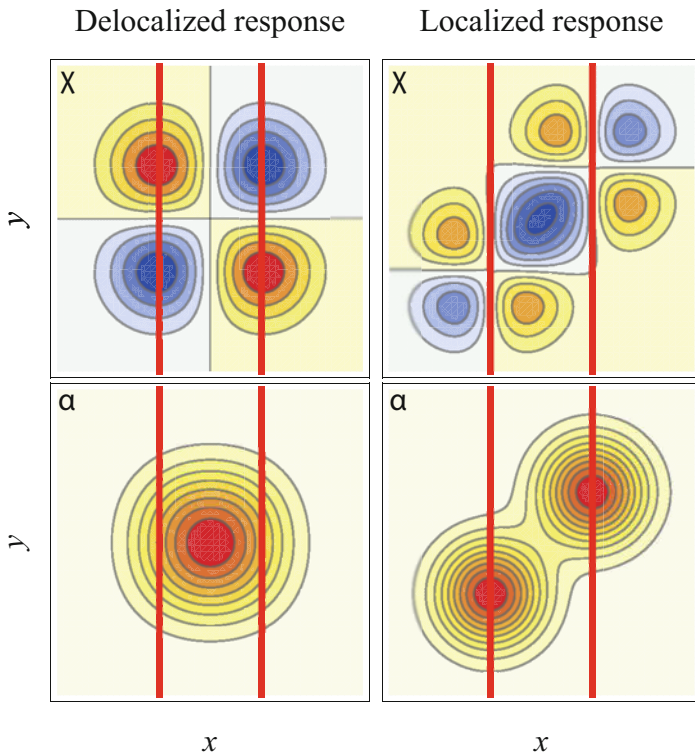
The frequency dependence, on the other hand, is very often modelled by that of a charged harmonic oscillator (HO) – a Drude oscillator. Having been Fourier-transformed from the time domain, the frequency-dependent polarizability is a complex-valued function, with the real and imaginary parts encoding the


**Fig. 2** Density response function, $\chi(x, y)$, compared to nonlocal dipole polarizability, $\alpha(x, y)$. The figure considers two different model one-dimensional two-particle systems with particle coordinates $x$ and $y$. The left and right systems have a delocalized and localized response, respectively. The columns encode the response of the two systems in two different but equivalent ways – as a density response function (top), $\chi(x, y)$, and as a nonlocal dipole polarizability (bottom), $\alpha(x, y)$. The red and blue colors correspond to positive and negative values. The red lines denote the positions of the two responding Gaussian charge densities on the $x$-axis

nondissipative and dissipative parts of the response, respectively. The frequency dependence of the imaginary part of the polarizability encodes the full optical (electromagnetic) absorption spectrum. This is equivalent to knowing the full energy spectrum of the corresponding Hamiltonian, which is a much harder problem than calculating the ground-state energy. Accordingly, the ACFD formula for the electron correlation energy contains the polarizability only under the integral sign over all frequencies, and it is sufficient to model the spectrum only such that its sum total is represented accurately, which is conveniently achieved with the so-called Wick rotation,

$$\int_0^\infty \mathrm{d}u \, \mathrm{Im} \, \alpha(u) = \int_0^\infty \mathrm{d}u \, \alpha(\mathrm{i}u) . \tag{9}$$

In contrast to the full absorption spectrum, Im $\alpha(u)$, which is a complicated and highly system-dependent function of the frequency, the imaginary-axis part of $\alpha$, $\alpha(iu)$, is a real-valued monotonically decreasing function, which has the same general shape for all kinds of systems. Together with the localized nature of the polarizability, this justifies the use of the harmonic oscillator to model the frequency dependence of the polarizability of more complex electronic systems. The polarizability of a harmonic oscillator is a simple function with two parameters, the static polarizability, $\alpha_0$, and the resonance frequency, $\omega$,

$$\boldsymbol{\alpha}^{\mathrm{HO}}(iu) = \frac{q^2\omega^2}{m\left(\omega^2 + u^2\right)} \equiv \frac{\boldsymbol{\alpha}_0\omega^2}{\omega^2 + u^2} \tag{10}$$

Consider a system of nonoverlapping bodies of electronic matter interacting via the usual electronic Coulomb force (described equivalently either by the Coulomb or dipole potential). Putting aside the internal structure of these bodies for now, their interaction energy, $E_{\mathrm{int}}$, consists of the electrostatic part (including induction) and the (long-range) electron correlation part, $E_{\mathrm{c}}$ – the vdW energy. The ACFD formula for $E_{\mathrm{c}}$ derives its name from two parts: first, the correlations in the electronic fluctuations can be expressed in terms of the response of the bodies to an external field via the so-called *fluctuation–dissipation* theorem (Landau and Lifschitz 1980, sec. §124). Second, $E_{\mathrm{int}}$ is the difference in the total energy of the system when the Coulomb potential between the interacting bodies is switched on ($\lambda = 1$) and switched off ($\lambda = 0$). This difference can be alternatively expressed as an integral over from 0 to 1 while keeping the system at its ground state for all $\lambda$, in this way *adiabatically connecting* the noninteracting and interacting cases. Putting these two parts together, the ACFD theorem gives $E_{\mathrm{c}}$ in terms of the total polarizability of the nonoverlapping subsystems,

$$-\frac{1}{2\pi}\int_0^\infty du \iint d\mathbf{r}d\mathbf{r}' \int_0^1 d\lambda \operatorname{Tr}\left[\boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}', iu; \lambda\right) \mathbf{T}^{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}'\right)\right] \tag{11}$$

where $\mathbf{T}^{\mathrm{int}}(\mathbf{r}, \mathbf{r}')$ is set to zero for $\mathbf{r}, \mathbf{r}'$ from the same subsystem.

## 4.3    Range Separation in Density Functional Theory

The distinction between the short-range and long-range parts of the electron correlation energy becomes blurred in realistic systems at equilibrium geometries, where the overlaps between (or within) the interacting subsystems cannot be neglected. Some ab initio electronic-structure methods can treat both parts on an equal basis, but those are often computationally demanding and not applicable to large systems. It is therefore more common that the short-range and long-range parts are treated with different models, which must be somehow seamlessly joined, to avoid both omitting or double counting of some midrange part of the correlation.

Notably, one of the most successful of such approaches is the combination of the density functional theory (DFT) in semilocal approximation for the short-range correlation and explicit vdW models for the long-range correlation.

The ACFD formula can be derived within the density functional for the total correlation energy of a general electronic system (see Callen and Welton 1951; Parr and Yang 1989, Sect. 8.6; Kohn et al. 1998), not only for the interaction energy of nonoverlapping bodies as in the previous section. In this form, it yields the exchange–correlation (XC) energy, $E_{xc}$, the exchange part stemming from the antisymmetry of the electronic wave function,

$$
\begin{aligned}
E_{xc} &= -\frac{1}{2\pi} \int_0^\infty du \iint d\mathbf{r} d\mathbf{r}' \int_0^1 d\lambda \, \chi \left( \mathbf{r}, \mathbf{r}', iu; \lambda \right) v \left( \mathbf{r}, \mathbf{r}' \right) \\
&= -\frac{1}{2\pi} \int_0^\infty du \iint d\mathbf{r} d\mathbf{r}' \int_0^1 d\lambda \, \mathrm{Tr} \left[ \boldsymbol{\alpha} \left( \mathbf{r}, \mathbf{r}', iu; \lambda \right) \mathbf{T} \left( \mathbf{r}, \mathbf{r}' \right) \right]
\end{aligned} \tag{12}
$$

Within time-dependent DFT, the true response functions can be further expressed in terms of the response functions of the KS noninteracting system, corresponding to $\lambda = 0$, as a Dyson screening equation,

$$
\chi \left( iu; \lambda \right) = \chi \left( iu; 0 \right) + \chi \left( iu; 0 \right) \left( v + f_{xc} \left( iu; \lambda \right) \chi \left( iu; \lambda \right) \right) \tag{13}
$$

where $f_{xc}$ is the so-called XC kernel, in general an unknown system-dependent nonlocal function. In approximate vdW models, the XC effects contained in the kernel are usually incorporated implicitly into the effective polarizability,

$$
\boldsymbol{\alpha} \left( iu; \lambda \right) \approx \boldsymbol{\alpha}^{\mathrm{eff}} \left( iu \right) + \boldsymbol{\alpha}^{\mathrm{eff}} \left( iu \right) \mathbf{T} \boldsymbol{\alpha} \left( iu; \lambda \right) \tag{14}
$$

The XC energy can be formally divided into a short-range (sr) and long-range (lr) part by separating the double spatial integral in Eq. 12 into two parts using some range-separating function, $f$, which should decay at least exponentially fast for large distances,

$$
\begin{aligned}
\iint d\mathbf{r}_1 d\mathbf{r}_2 &= \iint d\mathbf{r}_1 d\mathbf{r}_2 \left( 1 - f \left( \mathbf{r}_1, \mathbf{r}_2 \right) \right) + \iint d\mathbf{r}_1 d\mathbf{r}_2 f \left( \mathbf{r}_1, \mathbf{r}_2 \right) \\
&\equiv \iint_{sr} d\mathbf{r}_1 d\mathbf{r}_2 + \iint_{lr} d\mathbf{r}_1 d\mathbf{r}_2
\end{aligned} \tag{15}
$$

In practice, the short-range part is calculated via some semilocal XC functional, for which the corresponding $f$ is system-dependent and in general unknown. On the other hand, most vdW models have $f$ explicitly built in, and the aim is to find explicit $f$ for the vdW method that matches the implicit $f$ of a given XC functional. This is in general an unsolved problem, and most current approaches resort to a varying degree of empiricism.

The most radical difference in the range separation to semilocal DFT and vdW methods runs along the border between systems with uniform and nonuniform electron density. The vdW force between atomic bodies held together by covalent, ionic, or metallic binding is always caused by the long-range electron correlation, but not all effects of the long-range correlation are considered to be a vdW force.

In metals, the electrons from the nonconducting bands are localized on atoms, which form nonuniform islands in the sea of approximately uniform electron density of the conducting electrons (Tao et al. 2010). Here, the long-range correlation between the conducting electrons contributes to the metallic binding. In nonmetals, however, all electrons are nonconducting, the electron density is nowhere uniform, and long-range correlation is mostly associated with vdW interactions. The electronic structure within a single uniform subsystem differs qualitatively in many aspects from that in a nonuniform system. In a uniform system, the exchange effects, the KS density response function, and the XC kernel decay only algebraically with distance (they are long-ranged) as a result of the conducting electrons, whereas they decay exponentially (they are short-ranged) in nonuniform systems (Ge and Lu 2015). (The true density response function decays algebraically in both cases because of electron correlation.) Correspondingly, semilocal and hybrid XC functionals capture both short-range and long-range part of the XC energy in uniform systems but only the short-range part in the nonuniform systems. The vdW interactions can be therefore associated with all long-range electron correlation except for that between conducting electrons within a single uniform subsystem, which is fortunately covered by semilocal and hybrid density functionals. The nonuniform situations include interactions between conducting electrons in disjoint metallic bodies; interactions of conducting electrons with localized electrons, either in the same metallic body or in other bodies; and all interactions between localized electrons.

The consequences of the differences between uniform and nonuniform systems for the range separation can be summarized as follows:

$$
\begin{array}{l}
\text{uniform :} \\
E_{\mathrm{xc}} \quad = \quad \overbrace{\underbrace{E_{\mathrm{x}}^{\mathrm{sr}} + E_{\mathrm{c}}^{\mathrm{sr}}}_{\text{semilocal/hybrid}} + \underbrace{E_{\mathrm{x}}^{\mathrm{lr}}}_{\approx 0} + \underbrace{E_{\mathrm{c}}^{\mathrm{lr}}}_{\text{vdW}}}^{\text{semilocal/hybrid}} \\
\text{nonuniform :}
\end{array} \tag{16}
$$

With the caveat about the uniform systems, the vdW interactions can then be associated with the long-range XC energy. In this setup, care must be taken about the potential double counting of the long-range XC energy in uniform systems from the semilocal or hybrid functionals and from the long-range ACFD formula. This double counting does not matter in situations when the result of a calculation is an energy difference, such as when calculating the adsorption energy of a molecule on a metal surface. But it may pose a problem in other cases, for instance, when investigating a lattice expansion of a metal.

## 5    Classification of van der Waals Functionals

Most existing models of long-range correlation can be described in terms of various approximations to the range-separated effective-polarizability version of the ACFD formula (Eqs. 12 and 14) (Hermann et al. 2017). One of them is the already

discussed local representation of the effective polarizability. Two other general and common approximations are spatial coarse-graining of the system and truncation of the many-body expansion of the vdW energy.

## 5.1 Coarse-Graining of Response Functions

Given a set of functions, $w_p(\mathbf{r})$, that partition space into fragments, $\sum_p w_p(\mathbf{r}) \equiv 1$, and respective centers of the fragments, $\mathbf{R}_p$, each spatial function or operator, such as the dipole polarizability, can be represented as a sum over the partitioned components, $\boldsymbol{\alpha}_{pq}$, which can be in turn expanded in the basis of solid harmonics (multipole expansion), $\alpha_{pq,ll'mm'}$, around the centers (Stone 2013),

$$\boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}', u\right) = \sum_{pq} w_p\left(\mathbf{r}\right) w_q\left(\mathbf{r}'\right) \boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}'u\right) \equiv \sum_{pq} \boldsymbol{\alpha}_{pq}\left(\mathbf{r}, \mathbf{r}', u\right) \rightarrow \alpha_{pq,ll'mm'} \tag{17}$$

(Here, $l$, $l'$ start from 1, because the expanded quantity is a tensor. The corresponding expansion of the scalar density response function, $\chi$, would start from $l = l' = 0$.) The dipole potential is expanded correspondingly. Unlike the Fourier transformation, the multipole expansion is not invertible, but like the Fourier transformation, it introduces a correspondence between spatial integrals and infinite sums,

$$\mathbf{P}\left(\mathbf{r}, u\right) = -\int d\mathbf{r}' \boldsymbol{\alpha}\left(\mathbf{r}, \mathbf{r}', u\right) \mathbf{E}\left(\mathbf{r}', u\right) \iff \mathbf{P}_{p,lm}(u)$$
$$= -\sum_{q,l'm'} \alpha_{pq,ll'mm'}(u) E_{q,l'm'} \tag{18}$$

The motivation for this multipole reformulation is that because both $\mathbf{T}_{\text{eff}}$ and $\mathbf{T}_{\text{lr}}$ are long-ranged and their moments decay increasingly faster for higher $l$'s; all the matrix multiplications (infinite sums) converge quickly and can be approximated well by finite sums.

The feasibility of the coarse-graining and multipole expansions is dictated by the choice of the fragments and the response properties of the system. In a nonuniform system, the nonlocal effective polarizability is exponentially localized on atoms, and atom-centered fragments are a natural basis of a quickly converging multipole expansion. In a uniform system, the effective polarizability is long-ranged, diffused, and there are no natural centers for the multipole expansion, leading to large higher moments and slow convergence or even divergence of the expansion. In principle, this problem is mitigated in combination with the KS-DFT, because the long-range XC energy within the uniform systems is captured by the semilocal or hybrid functional, and the multipole convergence of the correlation energy due to the interaction with a separate uniform or nonuniform system is helped by larger

separations between the fragments. But such an interplay is not well understood, and none of the coarse-grained models discussed in this chapter take advantage of this cancellation.

## 5.2 Truncation of Many-Body Expansion

After inserting the Dyson screening equation into the ACFD formula, the coupling-constant integration can be carried out analytically either when using the effective-polarizability formulation or by approximating the XC kernel with some form that depends on explicitly. In both cases, the $\lambda$-integration results in a logarithm expression such as

$$E_{xc} \approx -\frac{1}{2\pi} \int_0^\infty du \iint d\mathbf{r} d\mathbf{r}' \, \mathrm{Tr} \left[ \ln \left( 1 - \boldsymbol{\alpha} \left( \mathbf{r}, \mathbf{r}', iu; \lambda = 0 \right) \mathbf{T} \left( \mathbf{r}, \mathbf{r}' \right) \right) \right] \qquad (19)$$

The operator logarithm is defined as an infinite series, and writing it out explicitly in terms of individual orders leads to a many-body decomposition of the XC energy,

$$\begin{aligned}
E_{xc} = &\frac{1}{2\pi} \int_0^\infty du \iint d\mathbf{r} d\mathbf{r}' \, \mathrm{Tr} \left[ \boldsymbol{\alpha} \left( \mathbf{r}, \mathbf{r}', u; 0 \right) \mathbf{T} \left( \mathbf{r}, \mathbf{r}' \right) \right] \\
&- \frac{1}{4\pi} \int_0^\infty du \iiint \int d\mathbf{r} d\mathbf{r}' d\mathbf{r}'' d\mathbf{r}''' \, \mathrm{Tr} \left[ \boldsymbol{\alpha} \left( \mathbf{r}, \mathbf{r}', u; 0 \right) \mathbf{T} \left( \mathbf{r}', \mathbf{r}'' \right) \right. \\
&\left. \boldsymbol{\alpha} \left( \mathbf{r}'', \mathbf{r}''', u; 0 \right) \mathbf{T} \left( \mathbf{r}''', \mathbf{r} \right) \right] + \frac{1}{6\pi} \cdots + \ldots
\end{aligned} \qquad (20)$$

The term "many-body" is best motivated in the coarse-grained models where the individual terms correspond to interactions between increasing number of fragments (bodies). (The order does not necessarily correspond to the number of bodies. At fourth order, for instance, some terms are a back-and-forth interaction between two bodies.) When constructed from the bare KS polarizability, the first order evaluates to the exact exchange, and the correlation energy starts at the second order. With any local approximation for the bare polarizability, the first term evaluates identically to zero, and the formula gives only the correlation energy. The long-range part of the second term is the leading term for vdW interactions and the basis of all nonlocal correlation functionals and coarse-grained pairwise methods discussed below. The third term corresponds to the Axilrod–Teller–Muto (ATM) three-body potential (Axilrod and Teller 1943; Mutō 1943) when coarse-grained to atoms.

## 5.3 Random-Phase Approximation

The approximations to the ACFD formula that are fully many-body and not coarse-grained can be based on the bare KS density response function. Because the KS

density response function can be calculated directly from the KS orbitals via the so-called Adler–Wiser formula, these approximations are usually formulated and evaluated in the $\chi \upsilon$-representation rather than the $\boldsymbol{\alpha T}$-representation. Furthermore, because the KS response has a well-defined short-range structure, this construction allows the evaluation of the total XC energy, not only its long-range part, so the use of these methods goes beyond long-range correlation energy. Here, we discuss the methods from the perspective of vdW interactions.

The simplest of these methods is the RPA itself, which amounts to setting the XC kernel in Eq. 13 to zero (Ren et al. 2012). The omitted XC kernel is short-ranged in nonuniform systems, but its omission influences both short-range and long-range correlation energy, because the short-range XC effects still influence the total polarizability of the system, which is manifested in the long-range correlation energy via the ACFD formula. As a result, although RPA does not suffer from any systematic errors in the long-range correlation energies, the overall accuracy is often worse than that of the many effective models discussed below (Olsen and Thygesen 2013b). This is further amplified in vdW systems in equilibrium geometries, where the short-range XC energy also contributes to the total interaction energy. Attempts at improvement go both ways, replacing the short-range correlation energy with a better model than RPA and improving the effective polarizability.

Kurth and Perdew (1999) suggested to correct the short-range correlation energy from RPA with that from a semilocal XC functional, in what they called the RPA+ method. Rather than explicitly range-separating the ACFD expression, RPA+ removes the RPA short-range part by subtracting correlation energy from a specially designed semilocal correlation functional, $E_c^{\text{GGA@RPA}}$, and reintroduces it back with a standard semilocal functional, $E_c^{\text{GGA}}$.

$$E_c^{\text{RPA+}} = E_c^{\text{RPA}} - E_c^{\text{GGA@RPA}} + E_c^{\text{GGA}} \tag{21}$$

$E_c^{\text{GGA@RPA}}$ is constructed in a similar way as standard functionals, but its uniform part is parameterized to reproduce the RPA energy of the electron gas rather than the true energy. RPA+ attempts to fix the short-range correlation energy of RPA, but the long-range part is unchanged, so the vdW force remains the same, and it is only the interaction due to electron-density overlap, which occurs at equilibrium, that can be possibly improved. Furthermore, the range separation in RPA+ is unsystematic in the sense that there is no guarantee that $E_c^{\text{GGA@RPA}}$ and $E_c^{\text{GGA}}$ have the same effective range.

Toulouse et al. (2004) formulated a range-separated version of the KS scheme, in which the XC functional is designed from the beginning to treat only the short-range part of the electron correlation. This leads to an alternative range separation of the ACFD formula, in which $\boldsymbol{\alpha}(\lambda)$ is not the polarizability of the wave function that minimizes $\langle \Psi | \widehat{T} + \lambda \widehat{V} | \Psi \rangle$ but rather of one that minimizes $\langle \Psi | \widehat{T} + \lambda \widehat{V}_{\text{lr}} | \Psi \rangle$ (Toulouse et al. 2009). In this scheme, the RPA of the Dyson-like equation results in a model in which the effective polarizability is still equal to the bare KS polarizability, like in normal RPA, but the effective dipole operator is only the

long-range part of the full operator. The underlying assumption then is that the dipole operator and the XC kernel partially cancel out at short range, giving a different estimate of the effective polarizability than normal RPA. This is supported by numerical evidence on select small systems. A similar scheme, proposed earlier by Kohn et al. (1998), also uses a range-separated version of the KS scheme, but instead of obtaining the true polarizability at the RPA level, $\chi(\lambda)$ is obtained for each $\lambda$ by explicitly perturbing the corresponding $\lambda$-scaled system with electric field.

A straightforward way to improve the RPA is to devise approximate XC kernels, which improves the short-range behavior of the polarizability and hence both short-range and long-range correlation energies. Extending the LDA to the time domain, the adiabatic LDA (ALDA) assumes that the XC kernel has no memory, leading to a frequency-independent local XC kernel. Unlike LDA, which is exact for the uniform electron gas (UEG), ALDA does not give the true XC kernel of the UEG (which is nonlocal in both time and space) and violates several known properties of the true XC kernel. Despite that, it is a useful approximation in TD-DFT calculations when one is interested only in a certain range of the frequency spectra. Still, it turns out not to be a good approximation in the ACFD formula, where it gives worse results than the absent XC kernel of the RPA (Lein et al. 2000).

Olsen and Thygesen (2012) constructed a correction to ALDA by fixing its large-$\mathbf{q}$ (short-range) behavior in the UEG to better reproduce the known exact behavior. Taking this renormalized ALDA (rALDA) kernel, transforming back to real space, and using the mean density in two points as the corresponding uniform density, this procedure gives a universal XC kernel. This construction is computationally no more demanding than RPA but improves upon RPA in almost every case tested (Olsen and Thygesen 2013a, 2014). The rALDA XC kernel gives a more realistic short-range screening of the bare KS polarizability, resulting in more accurate long-range correlation energies and better description of vdW systems.

A different path toward improving the accuracy of RPA can be taken using the many-body perturbation (MBPT) theory. This is possible because, as Gell-Mann and Brueckner (1957) showed, yet another equivalent definition of RPA is via a certain subset of Feynman diagrams, the so-called ring diagrams. Summing different subsets of the diagrams similar to those corresponding to RPA then leads to different RPA-like models and sometimes confusing terminology, when a certain modification of the XC kernel in RPA is equivalent to adding additional terms to the RPA XC energy that do not seem to be related to RPA (Scuseria et al. 2008; Jansen et al. 2010; Ángyán et al. 2011).

The second-order Møller–Plesset correlation energy (MP2) consists of the Coulomb direct and exchange terms, of which only the former is long-ranged. In this context, RPA can be understood as the sum of all MP2-like direct terms (ring diagrams) in the infinite MBPT expansion. Similarly, the MP2 exchange can be renormalized by replacing one of the Coulomb interactions with the RPA sequence of ring diagrams, leading to the second-order screened exchange (SOSEX). Furthermore, unlike in the Møller–Plesset perturbation theory, where the first order is guaranteed to be zero, single-electron excitations contribute to the XC energy in the MBPT based on KS orbitals. Combining RPA, SOSEX,

and RPA-renormalized single-excitation correction then results in the renormalized second-order perturbation theory (rPT2) (Ren et al. 2011, 2013). Although the MP2 exchange term is short-ranged, the renormalization in SOSEX is long-ranged, and the long-range correlation energy of rPT2 is different from that of RPA. The combined improvements of the short-range and long-range XC energy in rPT2 compared to RPA lead to improved accuracy in vdW binding energies.

## 5.4    Nonlocal van der Waals Density Functionals

The models of long-range correlation energy discussed in this section are in the class of approximations to the ACFD formula that truncate the many-body expansion at second order, but do not do any spatial coarse-graining. This leads to XC functionals that are characterized by nonlocal dependence of the XC energy density on the electron density via some nonlocal kernel, $\Phi$,

$$
\begin{aligned}
E_{\text{c}}^{\text{nl-df}} &= -\frac{1}{2} \int d\mathbf{r} d\mathbf{r}' n\left(\mathbf{r}\right) n\left(\mathbf{r}'\right) \Phi\left[n\right]\left(\mathbf{r}, \mathbf{r}'\right) \\
&= -\int d\mathbf{r}\, n\left(\mathbf{r}\right) \int d\mathbf{r}' \frac{1}{2} n\left(\mathbf{r}'\right) \Phi\left[n\right]\left(\mathbf{r}, \mathbf{r}'\right)
\end{aligned}
\tag{22}
$$

The effective polarizability is approximated with a local isotropic polarizability,

$$
\boldsymbol{\alpha}_{\text{eff}}\left(\mathbf{r}, \mathbf{r}', u\right) \approx \mathbf{I}\alpha_{\text{eff}}\left(\mathbf{r}, u\right) \delta\left(\mathbf{r} - \mathbf{r}'\right)
\tag{23}
$$

This results in the first-order term in the many-body expansion being zero, which means that such a functional cannot capture any exchange energy, which is intentional, since the nonlocal functionals are designed to capture only the long-range correlation energy. The locality of the effective polarizabilities reduces two of the four integrals in the second-order term, and the isotropy allows to take the polarizabilities out of the trace in Eq. 20.

A general form of the local effective polarizability used in many models is obtained from the polarizability of a harmonic oscillator by setting the ratio of the charge and mass to that of an electron, $q/m = 1$, and substituting the electron density for the charge,

$$
\alpha_{\text{tot}}^{\text{HO}}\left(\mathrm{i}u\right) = \frac{q^2/m}{\omega^2 + u^2} \rightarrow \alpha_{\text{eff}}\left[n\right]\left(\mathbf{r}, \mathrm{i}u\right) = \frac{n\left(\mathbf{r}\right)}{\omega_{\text{eff}}^2\left[n\right]\left(\mathbf{r}\right) + u^2}
\tag{24}
$$

Besides the obvious reason of modelling electrons, the charge–mass ratio of one is motivated by the $f$-sum rule for an electronic system that dictates that $\alpha_{\text{tot}}(\mathrm{i}u) \rightarrow N/u^2$ ($N$ is the number of electrons), which the form above automatically satisfies. (Strictly speaking, this is not necessary, because the rule does not need to be satisfied in any local form, and furthermore, the local effective polarizability is not supposed to integrate to the total polarizability without any long-range coupling.

However, the local form is a straightforward way to satisfy the global rule.) The local effective resonance frequency, $\omega_{\text{eff}}^2$, can be in general any functional of the electron density but is often approximated semilocally.

The approximated ACFD formula can then be recast in the form of a nonlocal density functional, where the nonlocal kernel is a functional of the effective resonance frequency and some (so far unspecified) range-separating function,

$$
E_{\text{c,lr}} \approx -\frac{1}{2} \iint \mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' n\left(\mathbf{r}\right) n\left(\mathbf{r}'\right) \frac{3}{\pi} \int_0^\infty \mathrm{d}u
$$
$$
\frac{1}{\omega_{\text{eff}}^2\left[n\right]\left(\mathbf{r}\right) + u^2} \frac{1}{\omega_{\text{eff}}^2\left[n\right]\left(\mathbf{r}'\right) + u^2} \frac{f\left(\mathbf{r}, \mathbf{r}'\right)}{\left|\mathbf{r} - \mathbf{r}'\right|^6}
\tag{25}
$$

The asymptotic behavior of the long-range correlation energy calculated in this way is fully specified by $\omega_{\text{eff}}$.

The first general functional of this form, referred to simply as the vdW density functional (vdW-DF), was developed by Dion et al. (2004). Although the derivation of vdW-DF starts from the ACFD formula, it follows quite a different direction than the framework in this chapter, and most of the approximations along the way are done in reciprocal space, until everything is transformed back to real space in the end. However, the final result can still be cast in the form of Eq. 25. The effective resonance frequency in the vdW-DF is constructed from a GGA-type XC energy density. The first equality is motivated by using $\omega_{\text{eff}}^2$ to calculate the XC energy of a slowly varying electron gas via the ACFD formula. The particular choice of the semilocal approximation to the XC energy density is rather arbitrary and completely independent of the semilocal functional potentially used to complete the vdW-DF at short range.

A serious disadvantage of the vdW-DF in light of other long-range correlation models is that its range-separating function is fixed by the underlying theory. Because of the construction in the reciprocal space, the parameter $A$ appears both in the effective resonance frequency and the range-separating function. Since the asymptotic behavior of any nonlocal functional depends only on $\omega_{\text{eff}}$, not the range-separating function, the parameter $A$ is essentially fixed, and there is no remaining freedom in the range-separating function that could be adjusted for a particular choice of a short-range semilocal functional in a full KS-DFT calculation.

The form of the range-separating function is complex due to the reciprocal-space formulation, but there are two underlying physical motivations for it. When the two oscillators given by the resonance frequencies $\omega_{\text{eff}}$ are close to each other such that their ground-state wave functions would overlap, the underlying model does not work anymore, the corresponding part of the XC energy must be covered by the semilocal functional, and the dipole coupling must be damped. This is effectively achieved by increasing the resonance frequency as $k^2$ in the reciprocal space. The second damping mechanism is that the nonlocal functional must evaluate to zero for the uniform electron gas, whose long-range correlation energy is already covered by a semilocal or a hybrid functional. This forces the range-separating function to

negative values at short range, to counterbalance the attractive contribution from the long range.

The complex form of vdW-DF was simplified in the VV09 functional, which used a substantially different form of $\omega_{\mathrm{eff}}$,

$$\omega_{\mathrm{VV}}^2 [n] (\mathbf{r}) = \frac{4\pi}{3} n (\mathbf{r}) + C \frac{|\nabla n|^4}{n^4} \tag{26}$$

Here, $4\pi n$ is the resonance frequency of the macroscopic (small-$\mathbf{q}$ limit) plasmon fluctuations of the uniform electron gas. The factor of 1/3 comes from the Clausius–Mossotti relation between the microscopic local polarizability and the macroscopic dielectric function. The density-gradient term is a local model of a bandgap obtained from considering the behavior of the electron density in the density tail of a finite system. The range-separating mechanism of VV09 is still constructed in reciprocal space. The latest attempt at a simplified formulation of the vdW-DF, named VV10, was constructed entirely in real space (Vydrov and Van Voorhis 2010). Both the resonance frequency and range-separating function of Eq. 25 have a simple form in VV10. The former is the same as in VV09, and the latter is constructed using the same mechanism of reduced polarizabilities of overlapped oscillators as in the original vdW-DF but in real space.

## 5.5    Pairwise Interatomic Models

The oldest approaches to fix the missing long-range electron correlation in HF or semilocal KS-DFT calculations are of the interatomic pairwise form,

$$E_{\mathrm{c,lr}} \approx -\frac{1}{2} \sum_{pq} C_{6,pq} \frac{f (\mathbf{R}_p, \mathbf{R}_q)}{|\mathbf{R}_p - \mathbf{R}_q|^6} \tag{27}$$

Here, $f$ is some range-separating (damping) function, $\mathbf{R}_q$ are the atom coordinates, and the so-called dispersion coefficients, $C_{6,pq}$, determine the asymptotic interaction between two atoms. This type of interatomic potential has origin in empirical force fields dating back to the Lennard–Jones potential, even before it was clear that the correct leading term of the vdW force is $1/R^6$. In the context of electronic-structure methods, it was first used by Hepburn et al. (1975) to correct interaction curves of rare-gas dimers from HF calculations. This approach was later extended to molecules and KS-DFT calculations, and the $C_6$ coefficients were extended to a wider range of systems (Halgren 1992; Mooij et al. 1999; Elstner et al. 2001; Wu and Yang 2002). Grimme (2004) then presented a parametrization of $C_6$ and $f$, termed DFT-D ("D" for dispersion), that could in principle be applied to any molecule or solid, in combination with any XC functional. This marked a start of routine addition of the long-range correlation energy to semilocal KS-DFT calculations.

The pairwise interatomic model of Eq. 27 can be obtained as a coarse-grained truncated approximation to the ACFD formula. The derivation follows the same course of second-order truncation and local approximation to the effective polarizability as nonlocal vdW density functionals but starting from the coarse-grained multipole-expanded ACFD formula (see Eq. 18),

$$E_{c,lr} \approx -\frac{1}{4\pi} \int_0^\infty du \, \mathrm{Tr}_{p,lm} \left( \boldsymbol{\alpha}_{\mathrm{eff}} (iu) \, \mathbf{T}_{lr} \boldsymbol{\alpha}_{\mathrm{eff}} (iu) \, \mathbf{T}_{lr} \right) \tag{28}$$

Here, the trace is over multipole moments and fragments, which are chosen to be atoms in most cases. (In this context, the formal definition of an atom in a molecule is given by some partition function.) Approximating the local effective polarizability as isotropic, $\alpha_{\mathrm{eff}, pll'mm'} = \delta_{ll'}\delta_{mm'}\alpha_{\mathrm{eff}, pl}$, the formula is reduced as in the case of nonlocal vdW XC functionals. The standard pairwise formula of Eq. 27 is recovered by keeping only the lowest dipole–dipole term ($l = l' = 1$, $K_{11} = 6$), where the expression for the corresponding dispersion coefficient is called the Casimir–Polder integral,

$$C_{6, pq} = \frac{3}{\pi} \int_0^\infty du \, \alpha_{\mathrm{eff}, p1} (iu) \, \alpha_{\mathrm{eff}, q1} (iu) \tag{29}$$

Some pairwise methods are formulated directly in terms of the dispersion coefficients, not the underlying polarizabilities, in which case approximate combination rules for calculating unknown heteronuclear coefficients from known homonuclear coefficients are useful. Such rules can be derived from the Casimir–Polder integral using some model polarizability. An often used rule is obtained from the harmonic-oscillator model,

$$C_{6, pq}^{\mathrm{HO}} = \frac{3}{\pi} \int_0^\infty du \frac{\alpha_p(0)\omega_p^2}{\omega_p^2 + u^2} \frac{\alpha_q(0)\omega_q^2}{\omega_q^2 + u^2} = \frac{2C_{6, pp}C_{6, qq}}{C_{6, pp}\frac{\alpha_q(0)}{\alpha_p(0)} + C_{6, qq}\frac{\alpha_p(0)}{\alpha_q(0)}} \tag{30}$$

Using the single-pole polarizability of the harmonic oscillator in situations where the true spectrum is more complex, such as in the equation above, is called the Unsöld (1927) approximation.

The models of Grimme, mentioned above, are different from the rest discussed in this section in that they are formulated only in terms of the geometry of a molecule, $\{\mathbf{R}p\}$, not the electron density. This makes them straightforwardly useful even for empirical short-range electronic models that do not produce any electronic density, but at the same time, it makes it much harder to achieve truly general models, because the electron density encodes much useful information about the system.

The first version of DFT-D used fixed homonuclear $C_6$ coefficients, the combination of Eq. 30 with all polarizability ratios set to 1 and a range-separating function constructed from vdW radii that did not go to 1 in infinity (Grimme 2004). The second version was a numerical reparametrization of the first one with a changed combination rule, which set the polarizability ratios equal to those of

the $C_6$ coefficients (Grimme 2006). In the first and second version, the atomic $C_6$ coefficients do not depend on the molecular environment, which is a crude approximation. The third version was an improvement in several regards (Grimme et al. 2010). The range separation was modified to obey the correct asymptotic behavior. An elementary dependence of the $C_6$ coefficients on the environment was included via geometrical factors estimating the coordination number of an atom. The dipole–quadrupole term ($l = 1$, $l' = 2$) was included, and a three-atom correction was suggested, which is the third-order triple-dipole term in the logarithm expansion of the coarse-grained ACFD formula. The corresponding dispersion coefficients, $C_8$ and $C_9$, are obtained by combination rules similar to those for the $C_6$ coefficient.

Soon after the first version of DFT-D and in stark contrast to it, Becke and Johnson (2005b) developed a method to calculate $C_6$ coefficients from first principles, using an approximation to the polarizability based on the dipole moment of the XC hole of the HF model, the exchange-hole dipole method (XDM). Their initial derivation was rather heuristic, with a wrong prefactor, but the final result can be in fact obtained directly from the Casimir–Polder integral using the fluctuation–dissipation theorem for the density response function and the Unsöld approximation (Ángyán 2007; Heßelmann 2009; Ayers 2009). A semilocal approximation to the XC hole by Becke and Roussel (1989) works as well as that from the HF model and with the additional benefit of reduced computational complexity (Becke and Johnson 2005a). To formulate a general interatomic pairwise method, the (local) dipole moment of the XC hole is coarse-grained using the partitioning scheme devised by Hirshfeld (1977). In this scheme, the atomic partition functions, $w_p$, are constructed from radially averaged electron densities of isolated atoms, $n^{\text{free}}$,

$$w_p^{\text{Hirsh}}(\mathbf{r}) = \frac{n_p^{\text{free}}(|\mathbf{r} - \mathbf{R}_p|)}{\sum_q n_q^{\text{free}}(|\mathbf{r} - \mathbf{R}_q|)} \tag{31}$$

The corresponding static dipole polarizabilities of the atomic fragments are calculated from free-atom dipole polarizabilities, assuming that they scale linearly with the Hirshfeld measure of a volume (Hirshfeld volume),

$$\alpha_{p1}(0) = \alpha_{p1}^{\text{free}}(0) \frac{V_p^{\text{Hirsh}}[n]}{V_p^{\text{Hirsh}}[n^{\text{free}}]} \tag{32}$$

$$V_p^{\text{Hirsh}}[n] = \int d\mathbf{r}\, n(\mathbf{r})\, w_p^{\text{Hirsh}}(\mathbf{r})\, |\mathbf{r} - \mathbf{R}_p|^3 \tag{33}$$

The fragment $C_6$ coefficients are then calculated from the fragment polarizabilities and coarse-grained XC hole dipole moment. The harmonic-oscillator combination rule is used to get the rest of the $C_6$ coefficients. The XDM can be extended to higher multipole dispersion coefficients by calculating higher multipole moments of the XC hole polarization around each atomic center (Becke and Johnson 2006; Johnson and Becke 2006).

A simple yet accurate interatomic pairwise method was developed by Tkatchenko and Scheffler (2009) (TS), who extended the free-atom scaling approach to all the atomic parameters, including the $C_6$ coefficients and the vdW radii, and thus formulated the calculation of interatomic pairwise vdW interactions into a true density functional. Assuming that the excitation energies of the atoms are independent of the volume, the Unsöld approximation and the Casimir–Polder integral dictate that the $C_6$ coefficients scale with the second power of the Hirshfeld volume ratio,

$$C_{6,pq} = C_{6,pq}^{\text{free}} \left( \frac{V_p^{\text{Hirsh}}[n]}{V_p^{\text{Hirsh}}\left[n^{\text{free}}\right]} \right)^2 \tag{34}$$

The free-atom reference values may not be the most effective choice in metals and some solids, whose electron density is often substantially different from the superposition of free-atom densities. Zhang et al. (2011) and Ruiz et al. (2012) used an adapted TS method, where the reference values are obtained from bulk macroscopic dielectric constant.

Sato and Nakai (2009, 2010) developed an atomic pairwise method based on the local effective polarizability functional from the vdW-DF-09 nonlocal functional. A system is described by the local effective polarizability given by the harmonic-oscillator formula with the resonance frequency from Eq. 26. The atomic fragments are defined using the partitioning functions from the scheme by Becke (1988), which is most often used to define atomic radial grids in KS-DFT calculations, but here it is used as an alternative to the Hirshfeld partitioning. The partitioned polarizability is used to calculate a coarse-grained representation of the system via multipole expansion and Casimir–Polder integrals up to the $C_{10}$ coefficient.

Silvestrelli (2008) formulated a pairwise method in which the coarse-grained fragments are not atoms but Wannier functions (WFs) (Marzari et al. 2012). Wannier functions are any set of localized one-electron wave functions that in principle form a complete basis. In finite molecular systems, they are called Boys orbitals. The Wannier functions of conducting and nonconducting electrons are localized algebraically and exponentially, respectively. In the vdW-WF method, each WF is approximated with a single spherically symmetric exponential function that has the same width (second central moment) as the true WF. The polarizability of the approximate WF is calculated with the polarizability functional of Andersson et al. (1996) (ALL). Here, $n_p$ is the electron density of the WF and $k$ is a nonempirical constant. The $C_6$ coefficients between the WFs are calculated from the Casimir–Polder integral, and the range-separating function is the same as in the TS method, with vdW radii of the WFs defined via an electron density cutoff (Silvestrelli et al. 2009). The vdW-WF scheme has two theoretical shortcomings: first, the partitioning of the total electron density is only approximate because of the use of the approximate WFs, and second, the ALL polarizability functional was designed for the total electron density, not one-electron densities.

Coarse-grained methods in which the fragment polarizabilities and $C_6$ coefficients are calculated directly, rather than obtained by explicit partitioning of some

continuous quantity, may be sensitive to a particular choice of the partitioning scheme. This motivated a series of modified Hirshfeld partitioning schemes that should capture better the redistribution of the electron density in a molecule with respect to free atoms. Steinmann and Corminboeuf (2010, 2011) adapted the XDM to use the self-consistent Hirshfeld scheme, which gives a more consistent description of ionic systems (Bultinck et al. 2007). Bučko et al. (2013, 2014) did the same with the TS method. The self-consistent Hirshfeld partitioning uses the same stockholder formula in Eq. 31 as the original scheme, but the reference densities are generalized and depend recursively on the partitioning, leading to equations that need to be solved iteratively (Verstraelen et al. 2012). A common form of the generalized reference densities, used in the modified XDM and TS methods, is a linear combination of free-atom and free-ion densities that maintains the charge of the Hirshfeld-partitioned atomic density. This scheme is complicated by the instability of many isolated anions, which requires addition of auxiliary negative charges, making the partitioning somewhat arbitrary.

## 5.6 Many-Body Dispersion

The fourth class of approximations to the ACFD formula covers nontruncated coarse-grained models. A common theme of all such models is to interpret the Unsöld approximation with its single resonance frequency literally and model a real molecular system as a collection of coupled charged oscillators. The corresponding Hamiltonian describes a system of distinguishable particles characterized by a charge, $q_i$, and a mass, $m_i$, each having its own harmonic potential defined by the resonance frequency, $i$, and a center, $\mathbf{R}_i$, interacting via the Coulomb force,

$$
\begin{aligned}
\widehat{H}_{\text{osc}} = & \sum_i \frac{\widehat{\mathbf{p}}_i^2}{2} + \sum_i \frac{1}{2} m_i \omega_i^2 |\widehat{\mathbf{r}}_i - \mathbf{R}_i|^2 \\
& + \sum_{i<j} q_i q_j \left( \frac{1}{|\widehat{\mathbf{r}}_i - \widehat{\mathbf{r}}_j|} - \frac{1}{|\widehat{\mathbf{r}}_i - \mathbf{R}_j|} - \frac{1}{|\mathbf{R}_i - \widehat{\mathbf{r}}_j|} + \frac{1}{|\mathbf{R}_i - \mathbf{R}_j|} \right)
\end{aligned}
\tag{35}
$$

The centers of the harmonic potentials additionally host a compensating charge of the opposite sign. If the centers are the same as those of the atoms, this Hamiltonian can be interpreted as a very crude approximation to the electronic Hamiltonian, in which all electrons of individual atoms are described by distinguishable psuedoelectrons that move in an effective potential which is the combined result of the nuclear potential and the mean field of the electrons. In particular, any exchange effects and hence charge transfer and delocalization are not considered. Expanding the Coulomb operator in a multipole series and keeping only the dipole term result in dipole-coupled oscillator Hamiltonian,

$$\widehat{H}_{\text{dosc}} = \sum_i \frac{\widehat{\mathbf{p}}_i^2}{2} + \sum_i \frac{1}{2} m_i \omega_i^2 |\widehat{\mathbf{r}}_i - \mathbf{R}_i|^2$$
$$+ \sum_{i<j} q_i q_j \left(\widehat{\mathbf{r}}_i - \mathbf{R}_i\right) \mathbf{T} \left(\mathbf{R}_j - \mathbf{R}_i\right) \left(\widehat{\mathbf{r}}_j - \mathbf{R}_j\right) \tag{36}$$

A useful property of this Hamiltonian is that it can be solved exactly by coordinate transformation into a system of uncoupled quasi-oscillators, which describe different collective oscillations. The ground-state wave function of such a system is then a simple product of the single-oscillator ground-state wave functions, and the ground-state energy is a sum of the single-oscillator ground-state energies, $E_0 = \sum_n \tilde{\omega}_n/2$. Drawing analogy with the RPA, the individual oscillators model the particle-like quasi-electrons in some coarse-grained way, while the coupled oscillations model the wavelike electron oscillations. This Hamiltonian has been used many times to obtain various qualitative properties of long-range electron correlation (Bade 1957; Bade and Kirkwood 1957; Mahan 1965; Lucas 1967; Renne and Nijboer 1967; Donchev 2006) but only recently to formulate general quantitative methods.

The relevance of the dipole-coupled oscillator model to the true electronic system can be derived directly from the coarse-grained ACFD formula by performing the frequency integration analytically (Tkatchenko et al. 2013). When truncated at the dipole term, the approximate long-range correlation energy is then equal to the difference in the ground-state energy between the dipole-coupled oscillators and noninteracting oscillators. The exact equivalence between the dipole-coupled oscillators and the approximated ACFD formula breaks when going beyond the dipole approximation. The effective Hamiltonian derived from the ACFD formula is always bilinear in the interaction and contains one oscillator per each fluctuating moment (dipole, quadrupole, etc.). In contrast, the coupled-oscillator Hamiltonian has always $3N$ coordinates, independent of the degree of the multipole expansion of the Coulomb operator, and the interaction terms above the dipole order are formed from nonlinear combinations of the coordinates, making the Hamiltonian unsolvable in closed form.

The use of the coupled-dipole approach to formulate general methods for the long-range correlation energy was initiated in the many-body dispersion (MBD) model developed by Tkatchenko et al. (2012). MBD reuses the effective dynamic polarizability as approximated in the TS pairwise method and combines it with a physically motivated effective dipole operator. Motivated by the Gaussian shape of the harmonic-oscillator ground-state wave function, the dipole potential in MBD, $\mathbf{T}_{\text{gg}}$, is derived from the screened Coulomb interaction between two Gaussian unit-charge densities (Mayer 2007), with widths derived from the corresponding dipole polarizabilities. In general, the dipole potential in the Dyson equation should be different from that in the ACFD formula and independent of the XC functional used for the short-range part of the correlation energy. To circumvent this obstacle, Ambrosetti et al. (2014b) separated $\mathbf{T}_{\text{gg}}$ into the long-range part and the short-range

remainder. The long-range correlation energy is then calculated in two steps. First, the effective polarizability is screened by the short-range dipole potential via the Dyson equation. Second, the dipole-coupled Hamiltonian is solved with the long-range dipole potential.

Silvestrelli (2013) developed another method inspired by MBD in which the oscillators do not model the response of the atoms but of Wannier functions. This Wannier-based MBD is to the pairwise vdW-WN method as what the range-separated MBD is to the pairwise TS method. Unlike in vdW-WN, here the polarizabilities of the Wannier functions are not calculated using a local polarizability functional but directly from the Hirshfeld volumes of the Wannier functions.

# 6    Applicability in Material Modelling

Most vdW models have been designed following some set of theoretical principles (as is common in DFT), rather than obtained by a straightforward application of systematic approximations (as is common in quantum chemistry). As a result, a careful attention must be paid to the evaluation of the accuracy of the models, to avoid any systematic bias, both within and between different classes of systems, and to know the level of uncertainty in predicted quantities that one may expect. In this regard, the systematic verification of a given DFT+vdW method is usually achieved through comparison against the results of higher-level (more costly and more accurate) theoretical methods or experimental results with sufficient resolution.

In the case of organic molecules and materials, several benchmark sets of binding energies of complexes and lattice energies of molecular crystals have been established that allow for systematic testing of vdW models. For smaller molecules, the reference data have been obtained by high-level correlated methods of quantum chemistry (Jurečka et al. 2006; Řezáč et al. 2011), for larger molecules by diffusion quantum Monte Carlo (Ambrosetti et al. 2014a) and for molecular crystals by extrapolating experimental lattice enthalpies to zero temperature (Otero-de-la-Roza and Johnson 2012; Reilly and Tkatchenko 2013b). Initially, the development of vdW models was largely driven by their performance for small molecules on the S22 and S66 benchmark sets, and currently most popular DFT+vdW methods are able to achieve accuracies of 10–20 meV (better than 10%). The remaining errors are due to inaccuracy in the asymptotic vdW coefficients, empirical parameters in damping functions, and errors in the XC functional. Because of such rather uniform performance of different methods for small molecules, the focus has shifted to assessing the performance for larger systems. Here, in fact, the differences are more prominent, because the vdW energy makes a much larger relative contribution to cohesion. For example, for polarizable supramolecular systems, such as the "buckyball catcher" complex, pairwise dispersion corrections overestimate the binding energy by 0.4–0.6 eV, whereas including many-body dispersion effects reduces this error to 0.1 eV.

For periodic molecular crystals, some coarse-grained DFT+vdW methods are able to achieve remarkable accuracy of 40–50 meV per molecule (5%), compared to experimental results (Reilly and Tkatchenko 2013a, b; Brandenburg and Grimme 2014). Since the difference in lattice energies between various available experiments is on the same order of magnitude, this highlights the mature state of vdW dispersion corrections to semilocal DFT. The nonlocal density functionals yield somewhat larger errors (Otero-de-la-Roza and Johnson 2012). Understanding the performance of different vdW-inclusive methods for large molecular systems is still a subject of ongoing research. Accurate description of vdW interactions becomes even more relevant for the relative energetics of molecular systems, which are essential to predict the correct polymorphic behavior of molecular crystals (Reilly et al. 2016).

Beyond organic materials, the performance of DFT+vdW methods have started to be tested only recently. Reference lattice and interlayer binding energies calculated with RPA exist for a range of bulk solids (Harl et al. 2010; Schimka et al. 2013) and layered materials (Björkman et al. 2012; Björkman 2012, 2014), but the accuracy of RPA on the organic systems is comparable to that of DFT+vdW methods. Alternatively, experimental data are available for many of these systems. Of the different material types, the performance of individual methods for semiconductors is usually comparable to that of the organic compounds. In contrast, the accuracy with which ionic solids and metallic materials are described differs greatly between vdW models. In some cases, this has motivated the development of different flavors of vdW models, each targeting a specific class of materials.

## 7    Toward the Ultimate van der Waals Model

Despite the numerous advances in recent years discussed in the previous sections, a general, accurate, and efficient vdW model is not yet available. Arguably, this is a result of each of the current vdW models having some theoretical deficiencies, some of which are shared by all the models. Therefore, and to stimulate the reader with potential research problems, we conclude this chapter with a list of theoretical features that are missing from some or all current vdW models. Furthermore, we discuss which types of materials do we expect to benefit from potential addition of such features.

- All current vdW models assume a localized noninteracting polarizability, which is appropriate for gapped electronic systems, but not for gapless ones. At the same time, it is not clear what is the importance of the delocalized part of the response to vdW interactions in different circumstances. For instance, one can expect that the delocalized fluctuations will be manifested more strongly in the case of two metallic objects and less in the case of a molecule adsorbed on a metallic surface. Developing a unified model that uses both the localized and delocalized parts of the electronic response would enable treating the widest possible range of systems from purely covalent to purely metallic.

- Most current interatomic approaches assume a single-oscillator frequency dependence of the polarizability. This may be adequate for lighter elements of the periodic table in which majority of the response comes from the valence electrons with similar response properties. However, the core shells contribute nonnegligibly to the polarizability of heavier elements, and in such cases the use of two oscillators to capture separately the response of inner-shell and valence electrons could be beneficial to accuracy.
- All current models of effective polarizability assume isotropic local response. Could the directionality of the density gradient be used to construct an anisotropic polarizability model? The part of anisotropy resulting from the long-range interactions (for instance, due to specific packing in a molecular crystal) is already captured in many-body vdW effects. But the part stemming from short-range interactions between neighboring atoms (such as in planar aromatic compounds) is currently neglected.
- The VV functional is perhaps the most accurate semilocal functional for the local polarizability, but it is still lacking in accuracy to some of the interatomic approaches. Could this be potentially remedied by including dependence on the kinetic energy density or the second derivative of the electron density? Are there some exact constraints and limits on the polarizability functional? Improvements of this type can be expected to improve the accuracy of the vdW models across the whole spectrum of materials.
- All methods that use vdW models are based on some empirical coupling of the short-range and long-range parts. The empiricism necessarily hinders generality and introduces bias toward the system on which the coupling was constructed. Many theoretical results are available about general properties of XC functionals yet none so far that would enable a more rigorous coupling between semilocal DFT and vdW models. This question is especially relevant in systems where long-range vdW interactions contribute only partially to the total interaction energy, such as smaller organic complexes or organic/inorganic systems.
- Except for the costly RPA-based methods, there is no general vdW model that would be simultaneously many-body while treating also higher multipole moments of the polarizability. Some pairwise interatomic models include higher multipole moments, and nonlocal vdW functionals do not need to because of the lack of coarse-graining, but none of them are fully many-body methods. The MBD methods, on the other hand, have not yet been extended beyond the dipole approximation. The inclusion of higher multipoles would be beneficial for two reasons. First, it should improve the accuracy of the vdW model for strongly polarizable systems at equilibrium geometries. Second, it would enable to systematically study a whole new class of vdW effects such as the dependence of vdW interactions on external electric fields, which cannot be done within the dipole approximation.

# Pump-Probe Photoelectron Spectra

# 14

Umberto De Giovannini

## Contents

**Abstract**

Pump-probe photoelectron spectroscopy provides a tool to observe excitations taking place in electronic systems as they evolve in time. This technique is frequently applied to study complex phenomena taking place in chemistry and solid-state physics. To properly capture the dynamics observed in the experiments, one needs to employ non-perturbative theories capable to describe the complete time evolution of large physical systems. After a pedagogical survey on the literature, in this chapter, we focus on TDDFT and illustrate how this theory can be formulated in a way that can capture the entire ionization dynamics in atoms, molecules, and solids.

## 1    Overview

Photoelectron spectroscopy (PES) is nowadays one the most prominent experimental tools employed to measure the electronic structure of matter in the solid, gas,

e-mail: umberto.degiovannini@gmail.com

and liquid phases. In this chapter we are concerned with the application of PES to two classes of electronic systems: *finite* systems, such as atoms and molecules in gas phase, and *infinitely* periodic systems, such as bulk crystals and surfaces. This spectroscopy is based on the photoelectric effect, the physical phenomenon where electrons are extracted from a sample by illuminating it with light of an appropriate wavelength which was first discovered by Hertz in 1887. Electrons emerging from this kind of process are normally called photoelectrons.

The fundamental equation governing photo-ionization is the Einstein law which states the energy balance between the kinetic energy of the ionized electrons $E_{kin}$, the energy of the photon $\hbar\omega$, and the ionization energy, or ionization potential, $I_p$, that keeps them bind to the sample. Depending on the context, this relation is expressed in slightly different ways. In atomic and molecular physics, it usually reads: $E_{kin} = \hbar\omega - I_p$. In solid-state and surface physics, it is customary to break down the ionization energy as the sum of the work function $\phi$ and the binding energy $E_b$ both measured from the Fermi energy as illustrated in Fig. 1. In this case the relation becomes $E_{kin} = \hbar\omega - \phi - E_b$. Obviously, the underlying mechanism remains the same.

From these basic considerations, the spectroscopic potential of the photoelectron observables is immediately apparent because, by measuring the kinetic energy of the ionized electrons and knowing the frequency of the field, one can obtain a picture of the electronic energy levels of the system. It must be noted, however, that this technique can only access the properties of occupied states. To measure empty states, one in principle can use the inverse process where an electron is captured by the material and emits a photon.

In the literature, it is customary to divide photoelectron spectroscopy in two main categories depending on the radiation used. We are dealing with ultraviolet PES, if the field is in the UV range and only ionizes valence electrons, while we have X-ray PES if the field is energetic enough to ionize inner shell electrons. However, based on the same physical process, there are theoretical details specific for each energy

**Fig. 1** Schematic of photoelectron spectroscopy in the case of (**a**) finite systems, such as atoms and molecules, and (**b**) infinitely periodic systems, i.e., bulk crystals

scale, most notably whether or not it is allowed to invoke the dipole approximation. The discussion of this chapter is concerned with photon energies up to the XUVs ($\approx 100$ eV) where the dipole approximation is well justified.

The intensity of the photoelectron current, or equivalently the probability rate to eject photoelectrons with a given velocity, is the observable quantity in the experiments. It can be estimated using Fermi's golden rule

$$I = \frac{2\pi}{\hbar} \sum_f \left| \left\langle f \left| \frac{e}{mc} \mathbf{A} \cdot \hat{\mathbf{p}} \right| i \right\rangle \right|^2 \delta(E_f - E_i - \hbar\omega). \tag{1}$$

In the equation, $|i\rangle$ is the many-body $N$-electrons ground state representing the system in its initial state, while $|f\rangle$ is the state describing a single ionization and is composed of $N - 1$ bound electrons plus one in the continuum with momentum $\mathbf{p}$.

By summing overall the possible final states that satisfy the energy conservation – the Einstein relation – imposed by the delta function, one recovers the full distribution in momentum, $I(\mathbf{p})$. This quantity goes under different names depending on the community of reference. In atomic and molecular physics, it is oftentimes called photoelectron angular distribution (PAD), while in the solid-state community, it goes under the name of angular-resolved photoelectron spectroscopy (ARPES) spectrum. The reasons for this apparent dichotomy originate from the differences in the experimental detectors and the specific spectroscopic information attainable in the different contexts. In solid-state physics, the usual assumption is that, during ionization, the photoelectron's momentum parallel to the surface is conserved and equal to the crystal momentum of the electrons in the sample, $\mathbf{p}_{\parallel} = \mathbf{k}_{\parallel}$. Therefore the intensity expressed as a function of the binding energy and the parallel momentum, $I(\mathbf{p}_{\parallel}, E_{\text{kin}})$, measures the dispersion of the energy levels of the system, i.e., the band structure. For molecules the physical content of $I(\mathbf{p})$ is still in the process of beginning to be fully understood, for instance, in planar molecules, it was shown to be linked with the molecular orbital spatial distribution (Puschnig et al. 2009).

The picture given by (1) is an idealization of the photoemission process that does not take into account electron-electron interaction and surface effects. In fact, the electrons in the system have to relax in order to screen the hole left behind after ionization, and, during this dynamical process, they can excite other modes of the sample. In solids, for instance, it is often possible to observe charge density oscillations – plasmons – or lattice vibrations, phonons, being excited by the ejected electrons on their way to the vacuum. These processes ultimately affect the kinetic energy distribution of the photoelectrons by introducing new peaks and by imposing a finite peak width that reflects the lifetime of the excitation. To include these effects in (1), the delta function has to be substituted by the more general spectral function $A(\omega, \mathbf{p})$. The spectral function is a many-body object which can be rigorously defined in terms of the one-particle Green's function, and it is usually calculated in the so-called *GW approximation*. For more details, we remind to the review article (Damascelli et al. 2003) and references therein.

After substituting the delta with the spectral function, to get the full ionization current from (1), one has to evaluate the dipole matrix elements. These terms contain the photoelectron current dependence on the external field properties such as photon polarization and energy and are crucial for the complete account of the experimental spectrum. To calculate the matrix elements, one needs to explicitly evaluate the continuum states of the Hamiltonian that constitutes the scattering-wave component – i.e., the ionized electron – of the final state $|f\rangle$. The simplest approximation often employed in the literature is to substitute the scattering wave with a plane wave $|\mathbf{p}\rangle$, so that the matrix element turns into a simple Fourier transform of the initial wavefunction: for one-electron systems, $\langle\mathbf{p}|\mathbf{A}\cdot\hat{\mathbf{p}}|i\rangle = \mathbf{A}\cdot\mathbf{p}\langle\mathbf{p}|i\rangle$. The quality of this approximation varies from system to system and is not always good especially for low-energy continuum states that are strongly affected by the electrostatic potential. For a better agreement to experiments, one has to turn to more sophisticated approaches. The time-reversed low-energy electron-diffraction – known as LEED – states (Pendry 1990) in solid-state physics and the B-spline basis (Bachau et al. 2001) in atomic and molecular physics are among the most popular expansions.

Non-perturbative approaches alternative to (1), like the direct solution of the time-dependent Schrödinger equation (TDSE), can also be used to model the full ionization process. This is a usual practice in the atomic strong-field community where the fields are so strong to allow multiphoton processes to take place and where the interference pattern formed by the photoelectrons ejected at different times in the pulse encodes a plethora of valuable information. In these cases, the photoelectron spectrum can be directly obtained by projecting the long time limit of the time-dependent wavefunction $|\Psi(t)\rangle$ on the continuum states: $I \propto \langle f|\Psi(t)\rangle$. Even in this approach, a detailed account of the continuum state is therefore needed, which oftentimes is already present in the basis used to integrate the TDSE.

Motivated by the need of a non-perturbative theory, the strong-field community developed methods to calculate the photoelectron probability that do not require any explicit knowledge of the continuum states; the resolvent technique (Catoire and Bachau 2012) and the t-SURFF method (Tao and Scrinzi 2012) are the most notable results of this effort. These methods have been successfully employed to calculate PES and PADs in atoms under strong and long wavelength pulses where electrons follow large rescattering trajectories before being released into the continuum (Blaga et al. 2009). Clearly, the application of a non-perturbative approach to the single photon ionization described so far is straightforward, even though the solution of the TDSE may not be very efficient or properly motivated. When PES is employed to study systems out of equilibrium, however, the non-perturbative approach becomes more necessary.

Time-resolved photoelectron spectroscopy extends PES to excited states in the time domain. In this extension the spectra are usually acquired in pump-probe setups where two laser pulses are directed onto the sample and where one of the pulses, the pump, creates an excitation in the system which is then observed by ionizing it with the probe. The presence of two pulses breaks the time translation symmetry, and therefore the spectra acquire an explicit dependence on the relative delay between the pulses. Recording different spectra as a function of this delay constitutes the

time-resolved spectrum from which one can access information about the dynamics of the excitation.

In pump-probe experiments, by selecting the length of the pulses, one can observe the time trace of different physical excitations. On the femtosecond scale, the scale of ionic motion, time-resolved measurements have been applied to study chemical reactions ranging from bond breaking in dimers to nuclear motion in large biological molecules. This line of research developed into the field of *femtochemistry* (Stolow et al. 2004) which culminated with the Nobel Prize in Chemistry to A. H. Zewail in 1999. With shorter pulses, one can further increase time resolution and observe even faster dynamics. The shortest time scale attainable today is the attosecond scale, the characteristic scale of the electronic excitations. It lays at the forefront of the research as it combines complex experiments with the theoretical challenges presented by the description of coherent electron dynamics (Lépine et al. 2014). In solid-state physics, the use of ultrafast time-resolved approaches started later than molecular physics but quickly caught up, and the last decade has seen these techniques applied to study many different processes such as, for instance, the exciton relaxation and excitation dynamics or the ultrafast charge migration and screening in insulators (Krausz and Stockman 2014).

Given the dynamical nature of the physical observables accessible via pump-probe PES, it is clear that any theoretical approach used to interpret the results of the experiments must be capable to account for the time evolution of the system. In this respect, we must first distinguish between two substantially different regimes depending on whether the pulses overlap or not. When the pulses overlap, the system is governed by a time-dependent Hamiltonian which explicitly contains the pump field and that can be quite different from the one of the samples in equilibrium. This is no longer the case when the two pulses do not overlap because the Hamiltonian is the same as the one in equilibrium.

In the nonoverlapping regime, the system finds itself into a state which, in the most general case, is in a superposition of different excited states of the equilibrium Hamiltonian. In this case one can still use (1) by choosing as initial state $|i\rangle$ the pump-generated wavepacket, $|\Psi(t)\rangle$, which is expanded in the basis of the exact excited states $|\Psi_i\rangle$ with eigenvalues $E_i$: $|\Psi(t)\rangle = \sum_i A_i e^{-i(E_i t/\hbar + \phi_i)}|\Psi_i\rangle$. Here $\phi_i$ and $A_i$ are, respectively, the phases and expansion coefficients of the wavepacket and are completely determined by the pump. The strength of this formulation is that, for isolated systems, the coefficients are time independent and therefore the time propagation can be carried out analytically. In practice, since the exact eigenstates are not easily available, one usually has to resort to approximate eigenstates of a simplified Hamiltonian, and therefore the coefficients become time dependent (Wu et al. 2011). Besides the specific approximations concerning the details of the physical system under study, one limitation of this approach is that the construction of the initial wavepacket can be accurately approximated only for a limited number of cases. To cover the most general situation, one needs to simulate the pump excitation process with a non-perturbative approach.

Non-equilibrium Green's function theory offers, in principle, a more general platform to formulate the out-of-equilibrium many-body problem (Kadanoff and

Baym 1962). In this context the most promising approach to date is based on the Kadanoff-Baym formulation for the lesser Green's function $G^<$ (Perfetto et al. 2016a). Given the computational cost of the implementation, this approach has been so far limited to simple systems, e.g., Perfetto et al. (2016b).

When pump and probe overlap, PES carries spectroscopic information about the pump-dressed system. The interest in this regime is that, since the pump field directly enters the Hamiltonian, it can give a handle to parametrically modify it. This modification can possibly result in new physical properties of the driven system that can be observed by PES (Hsieh et al. 2017). From the basic standpoint, the properties of the periodically driven system can be understood in the framework of Floquet theory. However, to properly account for the PES even in this regime, it appears necessary to simulate the full time-dependent evolution.

After this brief and non-exhaustive survey of the theoretical approaches available to model pump-probe PES, it emerges that, in order to include the largest possible spectrum of experimental conditions, one needs to simulate the full photo-ionization process as it develops in time. Our choice for this chapter is time-dependent density functional theory (TDDFT). TDDFT is an exact reformulation of the TDSE in terms of the time-dependent density which has been successfully used to model the dynamics of atomic, molecular, and solid-state systems. This flexibility offers the opportunity to illustrate the application of the theory to finite systems and infinitely periodic systems on equal footing.

In the remainder of this chapter, unless otherwise specified, we use Hartree atomic units where $\hbar = e = m_e = 4\pi\varepsilon_0 = 1$.

## 2    Real-Time TDDFT

Below, we briefly recall the relevant concepts of TDDFT, already introduced in the plenary ▶ Chap. 6 ,"TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter," and the specific features of the real-time approach that are instrumental for the description of pump-probe photoemission.

The central idea of TDDFT is to express the equation of motion for the time-dependent density, $n(\mathbf{r}, t)$, of an interacting many-body system as a set of equations for the density of a fictitious auxiliary system of noninteracting electrons – the *Kohn-Sham* (KS) system. The resulting equations – the time-dependent KS (TDKS) equations – are expressed in terms of the orbitals $\varphi_i$ of a single KS Slater determinant as follows:

$$i\frac{\partial}{\partial t}\varphi_i(\mathbf{r}, t) = H_{\text{KS}}(\mathbf{r}, t)\varphi_i(\mathbf{r}, t), \quad i = 1, \ldots, N/2, \tag{2}$$

$$H_{\text{KS}}(\mathbf{r}, t) = \frac{1}{2}\left(-i\nabla - \frac{\mathbf{A}(t)}{c}\right)^2 + v_{\text{KS}}[n](\mathbf{r}, t)$$

$$n(\mathbf{r}, t) = 2\sum_{i=1}^{N/2}|\varphi_i(\mathbf{r}, t)|^2. \tag{3}$$

To avoid nonessential complications in the notation, here we choose to describe systems with an even number of electrons $N$, so that each spatial orbital $\varphi_i$ is doubly occupied with two electrons of opposite spin. The time-dependent density $n(\mathbf{r}, t)$ corresponds both to the real and to the KS system, thanks to the action of the KS potential $v_{KS}$, which is composed of

$$v_{KS}[n](\mathbf{r}, t) = v_{ion}(\mathbf{r}, t) + v_H[n](\mathbf{r}, t) + v_{xc}[n](\mathbf{r}, t). \tag{4}$$

In the definition, the first term, $v_{ion}(\mathbf{r}, t)$, is the electron-ion potential provided by the nuclei, while the second term is the classical electrostatic, or Hartree, potential $v_H[n](\mathbf{r}, t)$, and the last term $v_{xc}[n](\mathbf{r}, t)$ is the so-called exchange and correlation potential, whose form is unknown and must be approximated.

For observables involving ionization, like PES, it is crucial to choose a functional capable to provide a good ionization energy. Exception made from hybrid functionals, containing the computationally expensive *exact-exchange* functional – i.e., the Fock operator – the large majority of functionals is unable to cancel the self-interaction component of the Hartree potential, self-interaction error, which results in an unphysical asymptotic exponential decay instead of the correct $\propto 1/r$ given by the electrostatic potential of a point charge. Overall this results in a systematic underestimation of the ionization energy. Many self-interaction correction (SIC) strategies have been developed over the years, but, owing to its simplicity, the average-density SIC (Legrand et al. 2002) has been so far the most adopted.

Another important aspect that has to be considered in order to properly describe ionization is charge removal. Any numerical implementations aiming at solving the TDKS equations have to deal with a finite basis set or simulation box which is incompatible with a correct description of ionization where, by definition, electrons are removed from a system and taken to infinity. To simulate the presence of an infinite surrounding vacuum space, it is customary to use absorbing boundaries. These boundaries act to prevent spurious reflections when the electronic density reaches the limit of the numerical representation mimicking the behavior of an open system. Note that, in the presence of these boundaries, the total charge is not conserved and the Hamiltonian is no longer Hermitian. The choice is between complex absorbing potentials and exterior complex scaling. While this last one is in principle superior, its numerical implementation is quite involved, and in practice very few codes use it. Complex potentials, though much easier to implement, pay the price of being not perfectly absorbing. This translates into having to deal with a window of kinetic energies for which the transparency is achieved that depends on the functional form of the potential and that has to be carefully tuned on the basis of the expected ionization dynamics (De Giovannini et al. 2015).

To simulate pump-probe spectra, one needs to couple the system with an external laser field. In (2), this coupling is expressed in the so-called *velocity gauge* with the field represented by a classical time-dependent vector potential $\mathbf{A}(t)$ in the dipole approximation. This means that the vector potential is taken to be constant in space, a good approximation as long as the field's wavelength is much larger than the spatial extension of the system – up to soft X-rays for systems smaller than 1 nm.

The use of the velocity gauge is uncommon in atomic and molecular physics where the coupling is usually expressed in terms of the electric field, $E \cdot \mathbf{r}$, in the so-called *length gauge*. The reason for this choice is functional to our scope. That is because the velocity gauge is compatible with both finite and periodic systems and, as we will show in the next section, it is particularly convenient to describe the coupling with ionized free electrons.

The choice of describing the coupling with a classical field instead of a quantized one is well justified in those cases, like in modern pump-probe experiments, where the laser fields employed have large fluences and are thus constituted by a large number of photons. In particular since $\mathbf{A}(t)$ is a general function of time, it is well suited to describe any linear combination of laser pulses and thus can perfectly account for any pump-probe configuration. It is important to stress that, given the nature of the pulses, it is not possible to invoke any linear response approach and the TDKS equations have to be integrated by real-time propagation. A large array of propagation options is available in the literature to perform this task (Castro et al. 2004).

The TDKS equations are general to any atomic and molecular system regardless of their shape and size and, in principle, are suited to describe systems, such as bulk crystals, which are microscopically infinite. Considering an infinitely extended $\varphi_i(\mathbf{r}, t)$ is of course not practical, but, exploiting the translation symmetry, it is possible to substantially simplify the formulation of the problem. Since the crystal periodically repeats in space, we can describe the infinite lattice with wavefunctions defined in a primitive cell, and using the Bloch theorem, we can express the KS orbitals as Bloch waves

$$\varphi_{i,\mathbf{k}}(\mathbf{r}, t) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{i,\mathbf{k}}(\mathbf{r}, t) \tag{5}$$

where $u_{i,\mathbf{k}}(\mathbf{r}, t)$ is a wavefunction with the periodicity of the lattice and $\mathbf{k}$ spans the first Brillouin zone (BZ) in reciprocal space.

By plugging the expression for the Bloch wave into (2), we arrive to a new set of TDKS equations only for the periodic component of the KS orbitals

$$i\frac{\partial}{\partial t} u_{i,\mathbf{k}}(\mathbf{r}, t) = \frac{1}{2}\left(-i\nabla + \mathbf{k} - \frac{\mathbf{A}(t)}{c}\right)^2 u_{i,\mathbf{k}}(\mathbf{r}, t) + v_{\mathrm{KS}}[n](\mathbf{r}, t) u_{i,\mathbf{k}}(\mathbf{r}, t),$$
$$i = 1, \ldots, N/2, \tag{6}$$

$$n(\mathbf{r}, t) = 2\sum_{i=1}^{N/2}\int_{BZ} d\mathbf{k} \, |\varphi_{i,\mathbf{k}}(\mathbf{r}, t)|^2 = 2\sum_{i=1}^{N/2}\int_{BZ} d\mathbf{k} \, |u_{i,\mathbf{k}}(\mathbf{r}, t)|^2. \tag{7}$$

These equations govern the time evolution of a generic nonmagnetic bulk insulator where each of the $N/2$ lowest-lying orbital states accommodates two electrons of opposite spin.
**Fig. 2** Scheme illustrating the geometries employed to calculate the photoelectron spectra for (**a**) finite and (**b**) infinitely periodic systems

## 3 Photoemission from Atoms and Molecules

The outcome of a ionization process is characterized by the total ionization probability $\mathscr{P}$: the probability to find a system, an atom, or a molecule, in a determined charged state after ionization. Given a spherical region $\Omega$ surrounding the system, like in Fig 2a, one can calculate $\mathscr{P}$ by integrating the charge density in its complement $\bar{\Omega}$, which is equivalent to the number of escaped electrons $N_{esc}(t)$, any time $t > t'$ after the ionization has taken place. In the long time limit, it follows from this definition that

$$\mathscr{P} = \lim_{t \to \infty} \frac{N_{esc}(t)}{N} = \lim_{t \to \infty} \frac{\int_{\bar{\Omega}} d\mathbf{r} \, n(\mathbf{r}, t)}{N}. \tag{8}$$

As we discussed at the beginning of this chapter, many important physical properties can be obtained only by looking at more *resolved* ionization observables than just the total probability. These include the energy-resolved or momentum-resolved photoelectron probabilities, $\mathscr{P}(E)$ and $\mathscr{P}(\mathbf{p})$, which can be obtained from $\mathscr{P}$ by direct differentiation

$$\mathscr{P}(E) = \frac{\partial \mathscr{P}}{\partial E} \text{ and } \mathscr{P}(\mathbf{p}) = \frac{\partial \mathscr{P}}{\partial \mathbf{p}}. \tag{9}$$

In order to use this definition, one needs to *expose* the functional dependence of $\mathscr{P}$ from the differentiating variable, $\mathbf{p}$ or $E$, and in what follows, we employ the flux of the ionization current through a closed surface to accomplish this task. This approach is based on the t-SURFF method, first introduced by Scrinzi (Tao and Scrinzi 2012) in the strong-field community for single-electron systems. Since here we are interested in many-electron systems described with TDDFT, we present the extended version of this method (Wopperer et al. 2017).

Note that the two quantities in (9) are not independent and one can recover one from the other using $E = \mathbf{p}^2/2$ – the free electron energy dispersion. In particular $\mathscr{P}(\mathbf{p})$, being resolved in momentum is the most general one. For this reason we can concentrate only on $\mathscr{P}(\mathbf{p})$, granted the other quantities can be derived from it by integration.

First we postulate that the KS Hamiltonian $\hat{H}(\mathbf{r}, t)$ describing a photo-ionization process can be factored out into two spatially separated components, one describing fully interacting electrons in an area surrounding the system, $\Omega$, and another one representing the asymptotic behavior of quasi-free electrons in the ionization region, $\bar{\Omega}$. In practice this is done assuming that the TDKS Hamiltonian (2) asymptotically reduces to a Volkov Hamiltonian in $\bar{\Omega}$:

$$
\hat{H}(\mathbf{r}, t) = \begin{cases} \hat{H}_{\mathrm{KS}}(\mathbf{r}, t) \text{ if } \mathbf{r} \in \Omega \\ \hat{H}_{\mathrm{V}}(\mathbf{r}, t) \text{ if } \mathbf{r} \in \bar{\Omega} \end{cases}. \tag{10}
$$

The Volkov Hamiltonian describes noninteracting free electrons driven by an external vector potential $\mathbf{A(t)}$ and is defined as

$$
\hat{H}_{\mathrm{V}}(\mathbf{r}, t) = \frac{1}{2}\left(-i\nabla - \frac{\mathbf{A(t)}}{c}\right)^2. \tag{11}
$$

Note that the partitioning (10) is an idealization since we are discarding the long-range tails of the Coulomb potential always present in the real systems. We are thus committing an error that is proportional to the radius of $\Omega$ and (10) that has to be considered as an approximation. The price that we pay is well compensated by the properties of the Volkov Hamiltonian. In particular the fact that it is analytically solvable and its time-dependent solutions – the Volkov waves – defined by

$$
\chi_{\mathbf{p}}(\mathbf{r}, t) = \frac{1}{(2\pi)^{\frac{3}{2}}} e^{i\mathbf{p}\cdot\mathbf{r}} e^{i\Phi(\mathbf{p}, t)} \text{ with } \Phi(\mathbf{p}, t) = \int_0^t \mathrm{d}\tau \left(\mathbf{p} - \frac{\mathbf{A}(t)}{c}\right)^2 \tag{12}
$$

are eigenstates of the momentum operator and form a complete set. This means that in $\bar{\Omega}$ we can expand the KS orbitals as a superposition Volkov waves

$$
\varphi_i(\mathbf{r}, t) = \int \mathrm{d}\mathbf{p}\, b_i(\mathbf{p}, t) \chi_{\mathbf{p}}(\mathbf{r}, t) \tag{13}
$$

and that, from (8) and (7), the number of escaped electrons can be written as

$$
N_{\mathrm{esc}}(t) = 2\sum_{i=1}^{N/2} \int_{\bar{\Omega}} \mathrm{d}\mathbf{r}\, |\varphi(\mathbf{r}, t)|^2 = 2\sum_{i=1}^{N/2} \int \mathrm{d}\mathbf{p}\, |b_i(\mathbf{p}, t)|^2. \tag{14}
$$

This provides us with an expression for $N_{\text{esc}}(t)$ with an explicit dependence on $\mathbf{p}$ that we can exploit to calculate the the resolved probability from (9)

$$\mathscr{P}(\mathbf{p}, t) = \frac{1}{N} \frac{\partial N_{\text{esc}}(t)}{\partial \mathbf{p}} = \frac{2}{N} \sum_{i=1}^{N/2} |b_i(\mathbf{p}, t)|^2 \tag{15}$$

from which the connection with the Volkov expansion coefficients $b_i(\mathbf{p}, t)$ is apparent. This result is consistent with the construction of the Hamiltonian (10) which serves the purpose of exposing the momentum dependence of the scattering states by approximating them with Volkov waves and offers the interpretation of the expansion coefficients as scattering amplitudes.

The second part of the problem is the evaluation $b_i(\mathbf{p}, t)$ from the knowledge of the TDKS orbitals. To this end we express $N_{\text{esc}}(t)$ as a flux integral of the current density $\mathbf{J}(\mathbf{r}, t)$. By applying the continuity equations for the volume $\bar{\Omega}$, we find that

$$N_{\text{esc}}(t) = -\int_0^t d\tau \oint_S d\mathbf{s} \cdot \mathbf{J}(\mathbf{r}, \tau), \tag{16}$$

where $d\mathbf{s}$ is the surface element vector pointing in the direction normal to the surface $S$ enclosing the region $\Omega$ as shown in Fig. 2a. The current density can be evaluated as an expectation value over the TDKS wavefunction as

$$\mathbf{J}(\mathbf{r}, t) = 2 \sum_{i=1}^{N/2} \langle \varphi_i(t)|\hat{\mathbf{j}}|\varphi_i(t)\rangle \text{ with } \hat{\mathbf{j}} = \text{Re}\left\{-i\nabla - \frac{\mathbf{A}(t)}{c}\right\} \tag{17}$$

being the single-particle current operator. If we expand the bra $|\varphi_i(t)\rangle$ in Volkov waves with (13), we have that

$$\mathbf{J}(\mathbf{r}, t) = 2 \sum_{i=1}^{N/2} \int d\mathbf{p}\, b_i(\mathbf{p})\langle \varphi_i(t)|\hat{\mathbf{j}}|\chi_{\mathbf{p}}(t)\rangle, \tag{18}$$

together with the conjugate expression obtained by expanding $\langle \varphi_i(t)|$. By plugging this equation and its conjugate into (16), we obtain a formula that we can directly confront to (14). From the comparison, it results that the Volkov expansion coefficients can be written as the surface flux integral of the projected single-particle current operator $\hat{\mathbf{j}}_{\mathbf{p},i}(\mathbf{r}, t) \equiv \langle \chi_{\mathbf{p}}(t)|\hat{\mathbf{j}}|\varphi_i(\tau)\rangle$ accumulated over time

$$b_i(\mathbf{p}, t) = -\int_0^t d\tau \oint_S d\mathbf{s} \cdot \langle \chi_{\mathbf{p}}(t)|\hat{\mathbf{j}}|\varphi_i(\tau)\rangle. \tag{19}$$

This formulation is particularly convenient since it only involves the evaluation of $\hat{\mathbf{j}}_{\mathbf{p},i}(\mathbf{r}, t)$ on the surface $S$ and, given

$$\hat{\mathbf{j}}_{\mathbf{p},i}(\mathbf{r}, t) = \frac{1}{2} \left\{ i\varphi_i(\mathbf{r}, t)\nabla\chi_{\mathbf{p}}^*(\mathbf{r}, t) - i\chi_{\mathbf{p}}^*(\mathbf{r}, t)\nabla\varphi_i(\mathbf{r}, t) - 2\frac{\mathbf{A}(t)}{c}\chi_{\mathbf{p}}^*(\mathbf{r}, t)\varphi_i(\mathbf{r}, t) \right\},$$

(20)

it is easy to see that it requires the evaluation of the gradient operator only on $S$. Furthermore, as long as the time integral runs for times longer than the complete ionization process, during the time propagation, electrons can seamlessly flow back and forth through the surface without producing any artifact in the final spectrum. This provides with the freedom to choose the radius of $\Omega$ only on basis of the quality of the approximation of (10) which in practice has to be converged case by case.

## 4     Photoemission from Crystal Surfaces

The t-SURFF formalism can be easily extended to include the description of electron photoemission from bulk crystals. Since the derivation largely overlaps with the one presented in the previous section, here we focus on the differences and remind the interested reader to De Giovannini et al. (2017) for the full derivation.

A crystal can be considered as a very large molecule with a highly ordered lattice structure; thus, in principle, one just needs to find a suitable geometry to calculate the flux of the ionization current. The need for a surface to calculate the flux immediately implies that the model must include the material termination from which the electrons can escape. Therefore, in contrast to the usual practice of solid-state physics where the crystal is considered as a periodically repeating lattice in all directions, we need to reduce the periodicity from three to two dimensions and explicitly introduce a surface. Given this arrangement, one can choose $S$ as an infinite plane oriented perpendicular to the nonperiodic dimension like in Fig. 2b and calculate the photoelectron probability with (15) and (19).

Further, to exploit the translational symmetry, one can use the periodic formulation of the TDKS equations (6) and (7) on a bidimensional primitive cell with lattice vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ spanning the surface. At this point we just need to adapt the t-SURFF equations to the new periodic boundary conditions.

These boundary conditions impose slight but crucial modifications to the Volkov waves. First, applying the Bloch theorem to the Volkov Hamiltonian results into a decomposition of the momentum $\mathbf{p}$ in the definition of (12). Indeed, given the Bloch factorization (5), the plane-wave momentum $\mathbf{p}$ can be seen as a sum of a bidimensional crystal momentum $\mathbf{k}$ plus a reciprocal lattice vector $\mathbf{G}$ – a component of the spatial Fourier transform on the unit cell: $\mathbf{p} = \mathbf{k} + \mathbf{G}$. Because of periodicity, the component of $G$ parallel to the surface, $\mathbf{G}_{\parallel}$, can assume only discrete values, while the perpendicular one, $\mathbf{G}_{\perp}$, is continuous. Second, $\chi_{\mathbf{p}}(\mathbf{r}, t)$ must be normalized to the unit cell area such that the Volkov wave definition (12) becomes

$$\chi_{\mathbf{p}}(\mathbf{r}, t) = \sqrt{\frac{2\pi}{a_1 a_2}} e^{i\mathbf{p}\cdot\mathbf{r}} e^{i\Phi(\mathbf{p}, t)} = \sqrt{\frac{2\pi}{a_1 a_2}} e^{i(\mathbf{k}+\mathbf{G})\cdot\mathbf{r}} e^{i\Phi(\mathbf{k}+\mathbf{G}, t)},$$

(21)

while the definition of the phase $\Phi(\mathbf{p}, t)$ is unmodified.

With this prescription, we can expand each KS orbital for a given $\mathbf{k}$ with Volkov waves at the same $\mathbf{k}$. The Volkov expansion given by (13) turns into

$$\phi_{i,\mathbf{k}}(\mathbf{r}, t) = \int d\mathbf{G}\, b_i(\mathbf{k} + \mathbf{G}, t)\chi_{\mathbf{k}+\mathbf{G}}(\mathbf{r}, t), \tag{22}$$

where the decomposition of the momentum $\mathbf{p}$ explicitly appears.

The expansion coefficients $b_i(\mathbf{p}, t)$ even in this case act as scattering amplitudes and are central to the definition of $\mathscr{P}(\mathbf{p}, t)$. In fact using the expansion (22), it is possible to derive the same expression for the photoelectron probability given by (15). The difference in the derivation is that, likewise for the definition of the charge density of a periodic system (7), the equations for the number of escaped electrons $N_{\mathrm{esc}}(t)$ (14) and the current density $\mathbf{J}(\mathbf{r}, t)$ (18) have to be integrated over the full BZ. Once the connection between photoelectron probability and expansion coefficients is established, we are left with the problem of calculating the coefficients.

Like in the nonperiodic case, the expansion coefficients can be defined with an expression involving a flux integral of the current density. This results in an equation identical to (19), only for $\phi_{i,\mathbf{k}}(\mathbf{r}, t)$. This formula can be further simplified using the Bloch factorizations of $\chi_{\mathbf{p}}(\mathbf{r}, t)$ and $\phi_{i,\mathbf{k}}(\mathbf{r}, t)$ to obtain an equation containing only the periodic components of the orbitals $u_{i,\mathbf{k}}(t)$ and plane waves $|\mathbf{G}\rangle$ with the periodicity of the lattice

$$b_i(\mathbf{p} = \mathbf{k} + \mathbf{G}, t) = -\int_0^t d\tau \oint_S d\mathbf{s} \cdot \langle \mathbf{G}|\hat{\mathbf{j}}|u_{i,\mathbf{k}}(t)\rangle e^{i\Phi(\mathbf{k}+\mathbf{G}, t)}. \tag{23}$$

This final expression is well suited for the periodic TDKS equations (6) and (7) and any numerical implementation designed to solve them.

## 5   Applications

Nowadays TDDFT can be used to calculate the photoelectron spectrum of a large variety of material complexes and laser configurations. Given the general form in which the field $\mathbf{A}(t)$ enters the TDKS equations, the formalism trivially includes the special case where the system is simultaneously irradiated by a pump and a probe laser pulses with a given time delay, $\tau$, just by employing a field of the form

$$\mathbf{A}(t) = \mathbf{A}_{\mathrm{pump}}(\omega_P, t) + \mathbf{A}_{\mathrm{probe}}(\omega, t + \tau). \tag{24}$$

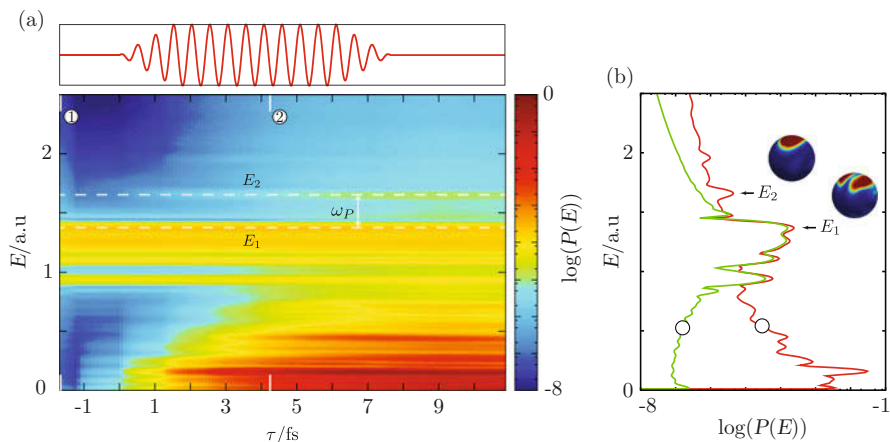
Likewise in the experiments where, in order to expand the dependence on $\tau$, one has to repeat the measure for every value of the delay, in the simulations, one needs to perform a separate calculation for every different configuration of pulses.


**Fig. 3** Pump-probe photoelectron spectrum of ethylene. The time-resolved photoelectron spectrum (**a**) is calculated by performing a different simulation for each value of $\tau$. The spectra at fixed time delays (**b**) can be further analyzed expanding the angular dependence of electrons ionized with a fixed kinetic energy displayed as spheres in the inset. (Reproduced from De Giovannini et al. 2013)

As an example, consider the case of an ethylene molecule pumped by a laser pulse resonant with the energy of transition between the HOMO – the highest occupied molecular orbital – and the LUMO, the lowest empty molecular orbital. The plot in Fig. 3a is obtained by calculating several energy-resolved photoelectron spectra $\mathscr{P}(E)$ and illustrates how the resonant excitation takes place as function of $\tau$. The appearance of a population on the excited state is clearly observable as an increase of the photoelectron probability for the energy $E_2$ – corresponding to the LUMO energy – which survives for delay times longer than the pump pulse.

Having access to the full $\mathscr{P}(\mathbf{p})$ provides a higher level of detail that can be used to further inspect the excitation process. For instance, for a fixed $\tau$, one can analyze the angular distribution of the photoelectrons emerging with a given kinetic energy: $\mathscr{P}(p = \sqrt{2E}, \theta, \phi)$. The plot in Fig. 3b shows how by applying this analysis to the HOMO and LUMO energies, $E_1$ and $E_2$, it is possible to observe the correlation between the nodal structure of the spatial orbitals and the angular distribution of the photoelectrons.

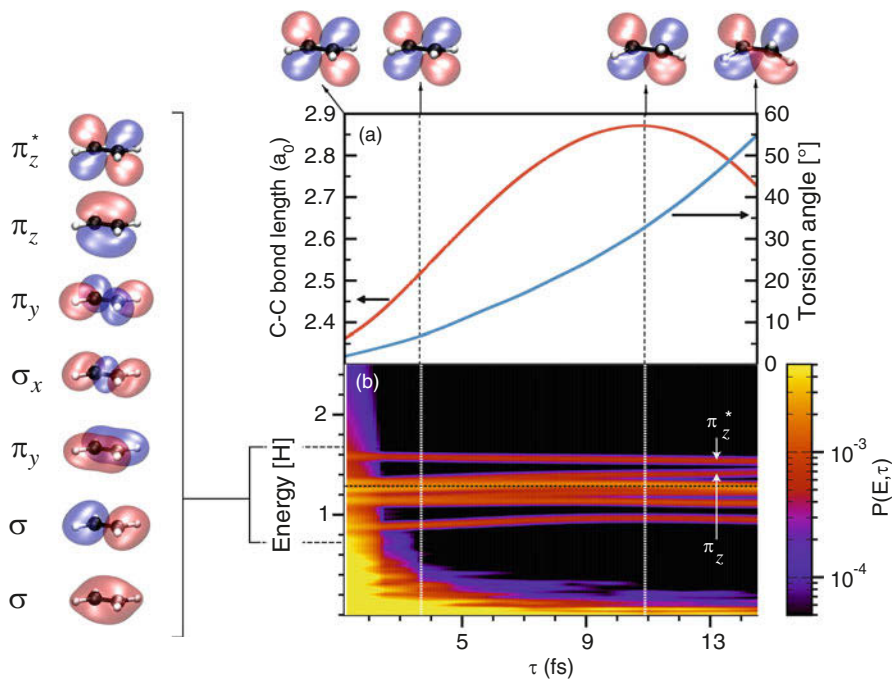
So far we discussed molecular models where the only role of the nuclei is to provide the source of the external potential, but a full molecular problem involves the entire electron-nuclear wavefunction. The simplest strategy is the so-called Ehrenfest dynamics in which the ions are fully classical and are coupled to the electrons via the density (see plenary ▶ Chap. 6, "TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter"). To illustrate how the ion dynamics can reflect in the photoelectron spectrum in Fig. 4, we present the time-resolved photoelectron spectrum of ethylene initialized into an excited state where one electron is promoted from the HOMO to the LUMO. Given


**Fig. 4** Pump-probe photoelectron spectrum of ethylene with moving ions. At time zero the system is initialized by promoting one electron from the HOMO ($\pi_z$ bonding) to the LUMO ($\pi_z^*$ antibonding), and the evolution is monitored by probing the system at different time delays. The time evolution of the molecular geometry (**a**) is reflected in the time-resolved spectrum (**b**). (Reproduced from Crawford-Uranga et al. 2014)

the antibonding nature of the LUMO orbital – of $\pi^*$ symmetry – the excitation initiates an ionic motion on the C-C bond which results in the combination of a vibrational and a torsional mode shown in Fig. 4a. This nuclear motion is reflected in the electronic configurations, and their time evolution can be monitored with time-resolved PES by probing the system at different time delays as in Fig. 4b. In particular, one can observe how the peaks corresponding to the HOMO, $\pi_z$, and the LUMO, $\pi_z^*$, move in energy toward each other as the torsion angle increases. A fact easy to interpret by looking at the shape of the orbitals, depicted in the inset of the figure, and noticing that in the limit of 90° torsion $\pi_z$ and $\pi_z^*$ become degenerate.

Of course the TDDFT methodology described so far is by no means limited to small molecules. For instance, in Wopperer et al. (2017), the photoelectron spectrum of $C_{60}$ was easily simulated for a single strong-field laser pulse. In practical calculations, the largest part of the computational burden is carried by the amount of vacuum needed to account for ionization, i.e., the size of the region $\Omega$. This computational cost scales with the third power of the radius of $\Omega$, while the TDKS equations have a much lighter linear scaling with the total number of electrons $N$.
**Fig. 5** Pump-probe ARPES on monolayer hBN. The ARPES spectrum (**a**) of the system in equilibrium is modified by pumping it with a laser pulse resonant with the gap at K. The resulting pump-probe ARPES spectrum (**b**) displays finite electron populations of the electrons in the conduction band across the gap. The band structure is plotted as dashed lines. (Reproduced from De Giovannini et al. 2017)

Therefore the size of the system itself is not critical for a relatively large number of atoms ($\approx$50).

The scaling with the volume of $\Omega$ is less severe for periodic systems. Indeed, since the vacuum only extends in one dimension, the computational cost scales linearly. In this kind of calculations however, the number of points needed to sample the reciprocal space – the k-points – constitutes an additional dimension that one needs to take into account. Thus even though the primitive cell contains only few atoms, the cost of the simulation can be considerable. Nevertheless the simulation of pump-probe photoelectron spectra for periodic systems can be reduced to a manageable task.

As an example in Fig. 5, we present the photoelectron spectrum of monolayer hexagonal boron-nitride (hBN). The ARPES spectrum can be directly obtained from the photoelectron distribution as $\mathscr{P}(\mathbf{p}_\parallel, E)$. This is in perfect agreement with the band structure shown in Fig. 5a. The ARPES spectrum is modified by pumping the system with a pulse resonant with the gap and by probing it after the pump has been switched off, Fig. 5b. Granted the fact that ARPES probes only occupied states, the appearance of a signal in correspondence of the conduction band at K is a clear indication of the population transfer operated by the pump.

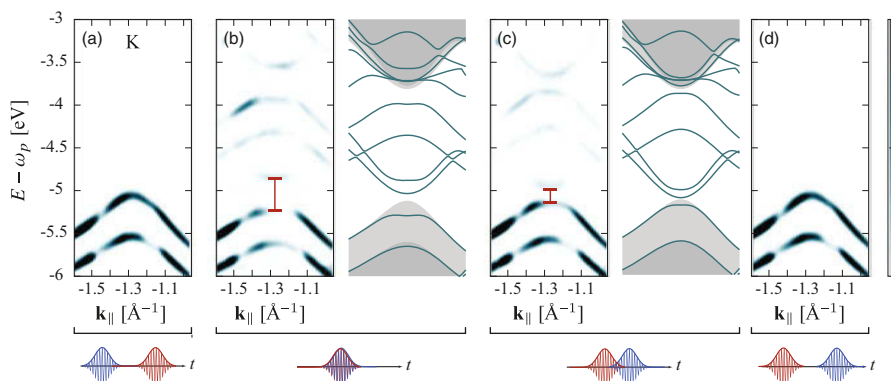
For the sake of clarity, in this chapter, we restricted the discussion to a simplified formulation, and it is however important to keep in mind that the general theory can handle more complex systems than simple nonmagnetic insulators. For instance, it can easily describe systems with non-negligible spin-orbit coupling, such as monolayer $WSe_2$, and in highly out-of-equilibrium configurations, like the example in Fig. 6. Similar to the former case, the system is pumped with a laser resonant with the bandgap at K but is probed at different time delays in such a way to explore different overlap configurations between the pump and the probe fields.


**Fig. 6** Pump-probe ARPES on monolayer WSe$_2$ strongly driven out of equilibrium. The spectra are obtained with different pump-probe configurations: (**a**) the probe comes before the pump, (**b**) the probe is fully contained in the pump, (**c**) the pump and the probe only partially overlap, and (**d**) the probe comes after the pump. The photon-dressed bands are reported for comparison in panels (**b**) and (**c**). Pump (red) and probe (blue) configurations are depicted as cartoons below each panel. (Reproduced from De Giovannini et al. 2016)

When the pump field is strongly coupled with the electrons, the system can undergo a transition into a state where quasiparticles formed by the dressing of photons to electrons emerge as new eigenstates. This is typically accompanied by a proliferation of the energy levels like the one observed in the Autler-Townes effect in atomic physics. The same dressing mechanism can be observed in Fig. 6b, c where the ARPES signal in correspondence of the conduction band becomes deformed and splits in two – this feature is indicated by the red marker bar in the figure. This is a highly out-of-equilibrium feature that can be properly understood in the context of the Floquet theory – for details, see De Giovannini et al. (2016).

## 6    Conclusions

From the standpoint of the experiments, pump-probe photoelectron spectroscopy nowadays appears as a mature field where the key tools are established and have been tested and available in many laboratories around the world. The perspective of the field is the application of this toolset to investigate new dynamical processes in a vast array of system going from atoms to large molecules and bulk crystals.

This roadmap raises important challenges for the theory, some of which can be tackled within TDDFT. Using the versatility of TDDFT, the goal of this chapter was to present an overview of this vast field by covering finite and infinite systems on the same ground.

Clearly, the accuracy in the description of the photoemission process presented here is affected by the same restrictions involved with the approximation of the exchange and correlation functionals in TDDFT. Future developments aimed at

improving these functionals to overcome present limitations, such as the description of static and dynamic correlations or long-range interactions, will positively affect photoelectron observables. Much-needed developments in this direction will make possible the description of exciton dynamics in solids or double-excitation phenomena such as Fano resonances which currently lay beyond the reach of the application of the theory.

We conclude mentioning that the code to perform real-space and real-time TDDFT simulations of pump-probe photoelectron spectra with the techniques presented in this chapter is freely available to the public (Andrade et al. 2015).

### Abstract

The many-body perturbation theory methods based on the $GW$ approximation and the Bethe-Salpeter equation (BSE) provide a first-principles route to modeling one- and two-particle excitations in a variety of bulk and molecular systems. This chapter reviews the current status of $GW$-BSE methods in the context of confined systems. We describe methods for basis set convergence, which allow sufficient numerical precision for accurate benchmarking of $GW$ and BSE theory and study various theoretical approximations within $GW$. The differences in

various flavors of $GW$ and $GW$-BSE, including perturbative, self-consistent, and vertex-corrected implementations, are compared in the context of benchmark sets of $sp$-bonded aromatic molecules and Group IB and IIB transition metal atoms and ions with filled $d$ shells.

# 1    Introduction

From a historical perspective, excited-state descriptions of materials have lagged behind descriptions of the ground state. This is especially true for density functional theory (DFT) methods where the initial formalism was developed to describe only ground-state properties. However, studies during the last three decades on time-dependent density functional theory (TDDFT) and Green's function methods, such as the $GW$ approximation and the Bethe-Salpeter equation (BSE), have provided new methodologies to examine excited-state properties within similar frameworks as the ground state (Hedin 1965; Hybertsen and Louie 1986; Strinati 1988; Rohlfing and Louie 2000; Onida et al. 2002; Casida 2009). Developed in the mid-1960s by Hedin, the $GW$ approximation allows one to solve for the interacting one-particle Green's function, whose poles are associated with vertical ionization potentials and electron affinities as measured in photoemission and inverse photoemission experiments. The BSE, on the other hand, allows one to construct an interacting two-particle correlation function from one-particle Green's functions; the poles of the two-particle Green's function are associated with neutral excitations such as those observed in optical absorption experiments. Developments in TDDFT, also used to simulate neutral excitations, are covered in greater detail in another chapter of this *Handbook* ▶ Chap. 6, "TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter".

Since the overview of $GW$ and BSE methods in the first edition of the *Handbook of Materials Modeling* (Louie and Rubio 2005), many-body perturbation theory methods based on the $GW$-BSE formalism have become standard tools to simulate the excited state of materials. However, while certain theoretical methods underlying the $GW$ approximation and the BSE are well established, the accuracy of such methods in predicting properties of real systems is still being assessed and improved. Recent benchmarks for various bulk materials, nanostructures, and molecules are now available to quantify the trade-off between cost and accuracy for approximations within $GW$ and the BSE. In this chapter, we discuss how theoretical and numerical approximations affect the accuracy of excited-state energies for confined systems, e.g., nanoclusters and molecules.

The physical properties of confined systems can deviate from those of extended systems; specifically, stronger self-interaction effects and less delocalized wave functions would be expected (especially in atoms and small molecules). Therefore, any conclusions from benchmarks of TDDFT, $GW$, and the BSE on the solid state might not be completely applicable to confined systems. Nevertheless, in the past 10 years, multiple $GW$ and $GW$-BSE benchmarks specifically focused on molecules have been reported to quantify the accuracy of different levels of

theory (Ma et al. 2010; Rostgaard et al. 2010; Ke 2011; Faber et al. 2011; Qian et al. 2011; Blase and Attaccalite 2011; Ren et al. 2012; Baumeier et al. 2012; Marom et al. 2012; Bruneval and Marques 2013; Pham et al. 2013; Caruso et al. 2013; Atalla et al. 2013; Koval et al. 2014; Boulanger et al. 2014; Körbel et al. 2014; Hirose et al. 2015; Wang 2015; Krause et al. 2015; Bruneval et al. 2015; Jacquemin et al. 2015; van Setten et al. 2015; Hung et al. 2016, 2017; Knight et al. 2016; Blase et al. 2011, 2016). Several of these benchmarks also compare software packages to validate the different implementations. In general, $GW$-BSE methods have proven to be rather accurate for modeling charged and neutral excitations, particularly for excitations between orbitals with $s$ and $p$ character. For systems containing transition metal elements, however, computations using the $GW$-BSE formalism face greater challenges, since the enhanced electron correlations inherent in such systems necessitate the use of more sophisticated approaches beyond simple perturbative implementations. Understanding the level of theory needed to achieve a reasonable balance between accuracy and computational demand is therefore a crucial step in enhancing the predictive power of the $GW$-BSE formalism and extending its applicability to a wider range of materials.

In Sect. 2, we begin by reviewing the theory and implementation of the $GW$-BSE framework, including descriptions of prevalent approximations. In Sect. 3, we discuss methods that improve the numerical convergence of energies, which enables the theoretical accuracy of $GW$-BSE to be accurately compared. In Sect. 4, we apply various flavors of $GW$-BSE methods, including perturbative (one-shot) $G_0W_0$, $GW$ calculations performed with a simple vertex derived from the local density approximation (LDA) of DFT, and self-consistent $GW$ (in the form of quasiparticle and eigenvalue self-consistency), as well as the ensuing BSE calculations. Our examples are centered on a set of six aromatic molecules comprising benzene ($C_6H_6$), thiophene ($C_4H_4S$), 1,2,5-thiadiazole ($C_2H_2N_2S$), naphthalene ($C_{10}H_8$), benzothiazole ($C_7H_5NS$), and tetrathiafulvalene (TTF, $C_6H_4S_4$) and Group IB and IIB atoms in three valence electron configurations: $d^{10}$ ($Cu^+$, $Ag^+$, $Zn^{2+}$, and $Cd^{2+}$), $d^{10}s^1$ ($Cu^0$, $Ag^0$, $Zn^+$, and $Cd^+$), and $d^{10}s^2$ ($Cu^-$, $Ag^-$, $Zn^0$, and $Cd^0$). We conclude with a brief summary in Sect. 5.

## 2    Many-Body Perturbation Theory and Implementation

In this section, we present the theory behind the $GW$-BSE framework and an implementation that uses a transition-space representation of excited states. The transition-space (spectral) basis is efficient for confined systems due to their discrete energy levels. It also allows the exact integration of $GW$ self-energies, unlike the contour deformation (Godby et al. 1988) and plasmon pole (Hybertsen and Louie 1986) techniques commonly used with a plane-wave basis. The framework described throughout this section is presented in more detail in Tiago and Chelikowsky (2006).

## 2.1    One-Particle Excitations: The $GW$ Approximation

Electron or hole injection into a system (e.g., processes occurring during ionization or anion formation) is considered single-particle excitations. The energies of these processes are associated with the poles of the one-particle Green's function $G$, which can be expressed as the Dyson equation:

$$G(1, 2) = G_0(1, 2) + \int d(34) G_0(1, 3) \Delta \Sigma(3, 4) G(4, 2). \tag{1}$$

Here, $(1) \equiv (\mathbf{r}_1, \sigma_1, t_1)$ is a many-body notation for the spatial, spin, and time coordinates, and $G_0$ is a mean-field Green's function. While $G_0$ traditionally denotes the noninteracting Green's function (from a Hartree calculation), here we use it to indicate any mean-field calculation, expressed in general as DFT with some exchange-correlation potential $V_{xc}$. Equation 1 also includes the term $\Delta \Sigma$, which is the difference between the self-energy $\Sigma$ and the mean-field exchange-correlation potential.

In Hedin's equations (Hedin 1965), the interacting one-particle Green's function can be determined self-consistently with four other equations that define the polarizability $\chi$, screened Coulomb interaction $W$, self-energy $\Sigma$, and vertex function $\Gamma$:

$$\chi(1, 2) = -i \int d(34) G(1, 3) G(4, 1^+) \Gamma(3, 4; 2), \tag{2}$$

$$W(1, 2) = V_H(1, 2) + \int d(34) V_H(1, 3) \chi(3, 4) W(4, 2), \tag{3}$$

$$\Sigma(1, 2) = i \int d(34) G(1, 3) W(4, 1^+) \Gamma(3, 2; 4), \tag{4}$$

$$\Gamma(1, 2; 3) = \delta(1, 2)\delta(1, 3) + \int d(4567) \frac{\delta \Sigma(1, 2)}{\delta G(4, 5)} G(4, 6) G(7, 5) \Gamma(6, 7; 3), \tag{5}$$

where $1^+$ denotes that $t_1 \to t_1 + \eta$ for some positive infinitesimal $\eta$, $V_H$ is the bare Coulomb potential, and $\delta(1,2)$ is the Dirac delta function.

Hedin's equations are too computationally demanding to model realistic systems. Accordingly, an approximation is taken to reduce the three-point vertex function to

$$\Gamma(1, 2; 3) = \delta(1, 2)\delta(1, 3), \tag{6}$$

which removes the need to evaluate a four-point integral. This vertex approximation gives rise to the naming of the $GW$ approximation, since the expression to compute $\Sigma$ becomes an integral over only $G$ and $W$.

For the implementation of a $GW$ self-energy calculation using a quasiparticle, transition-space basis, the self-energy $\Sigma$ is partitioned into two contributions: a bare exchange part $\Sigma^x$ and a correlation part $\Sigma^c$. The bare exchange self-energy matrix element between quasiparticles $j$ and $j'$ can be written as a sum over occupied states:

$$\langle j|\Sigma^x|j'\rangle = -\sum_n^{\text{occ.}} K^x_{njnj'}, \tag{7}$$

where the exchange kernel is

$$K^x_{vcv'c'} = \int d\mathbf{r} \int d\mathbf{r}' \varphi_v(\mathbf{r})\varphi_c(\mathbf{r}) V_H(\mathbf{r},\mathbf{r}')\varphi_{v'}(\mathbf{r}')\varphi_{c'}(\mathbf{r}'), \tag{8}$$

and $\varphi$ are real-valued quasiparticle wave functions. Since only states $j$, $j'$, and occupied states contribute to this finite summation, the exact value of $\Sigma^x$ (given the basis) can always be computed.

In contrast, the energy-dependent $\Sigma^c$ is expressed as a double infinite sum over quasiparticles $n$ and transitions $s$:

$$\langle j|\Sigma^c(E)|j'\rangle = 2\sum_n^{\infty}\sum_s^{\infty} \frac{V^s_{nj} V^s_{nj'}}{E - \varepsilon_n - \omega_s \eta_n}, \tag{9}$$

where $\eta_n$ is $-1$ for occupied state $n$ (quasihole) and $+1$ for empty state $n$ (quasielectron), and

$$V^s_{nj} = \sum_v^{\text{occ.}}\sum_c^{\text{empty}} K^x_{njvc} \left(\frac{\varepsilon_c - \varepsilon_v}{\omega_s}\right)^{1/2} Z^s_{vc}, \tag{10}$$

where $\varepsilon_n$ are quasiparticle eigenvalues (poles of $G$), $v$ is the index over occupied states, and $c$ is the index over empty states. The transition energies $\omega_s$ (poles of $W$) and eigenvectors with components $Z^s_{vc}$ are from the solution of Casida's equations (Casida 2009).

A cutoff in the infinite sums (over the number of empty states and transitions) therefore must be chosen when computing $\Sigma^c$. As is discussed in Sect. 3, great care must be taken to ensure numerical convergence of the correlation self-energy.

Once $\Sigma^x$ and the energy-dependent $\Sigma^c$ are summed to obtain the total self-energy, the quasiparticle energy $E^{\text{QP}}$ is determined from the Dyson equation for $G$ (Eq. 1), expressed in the quasiparticle basis as

$$\left[-\frac{1}{2}\nabla^2 + V_H(\mathbf{r}) + V_0(\mathbf{r}) + \Delta\Sigma(E^{\text{QP}}_j)\right]\varphi^{\text{QP}}_j = E^{\text{QP}}_j \varphi^{\text{QP}}_j, \tag{11}$$

where $V_0$ is a local external potential with contributions from the ionic potential and the mean-field exchange-correlation potential. In the case of self-consistency, we solve for the $E^{\text{QP}}$ that satisfies Eq. 11 at each iteration. Depending on the level of

self-consistency, the quasiparticle wave functions $\varphi^{\text{QP}}$ may also be updated, but in a separate step. In that case, the full self-energy matrix – not just the diagonal terms – must be computed at each iteration.

### 2.1.1 Vertex Approximations

Multiple works have addressed the issue of improving the description of the vertex beyond that of conventional $GW$ (Eq. 6) while still maintaining a computationally efficient form. These alternate vertex functions may include higher-order terms (Ummels et al. 1998; Maebashi and Takada 2011; Grüneis et al. 2014; Stefanucci et al. 2014) or capture the response of density functionals (Del Sole et al. 1994; Marini and Rubio 2004; Bruneval et al. 2005). In this chapter, we include benchmarks using a vertex derived from a local density functional approach, in which the polarizability $\chi$ is expressed within TDDFT and a consistent level of approximation is achieved by replacing the vertex function with

$$\Gamma_{\text{LDA}}(1, 2; 3) = \delta(1, 2)\delta(1, 3) - i\delta(1, 2) f_{\text{xc}}(1) \times$$
$$\int d(45) G(1, 4) G(5, 1^+) \Gamma_{\text{LDA}}(4, 5; 3), \tag{12}$$

where $f_{xc} = \delta V_{xc}/\delta\rho$ and $V_{xc}$ is the LDA exchange-correlation potential. Although a three-point vertex is needed to accurately describe certain physical properties (Romaniello et al. 2009; Grüneis et al. 2014), this two-point form of the vertex allows computations that cost only a prefactor more than conventional $GW$.

### 2.1.2 Levels of Self-Consistency

Because of the computational cost, $GW$ predictions often are presented as a perturbative (one-shot) result, which is computed by adding only one cycle through Hedin's equations onto the initial mean-field starting point instead of a fully self-consistent procedure. This amounts to solving Eq. 11 for quasiparticle energies only, with quasiparticle wave functions set to the mean-field (e.g., DFT) wave functions. With this so-called $G_0W_0$ approximation, there is a significant dependence of the predicted quasiparticle energies on the starting mean-field description.

Even when a self-consistent result is reported, the level of self-consistency must be specified. Some self-consistent calculations are only eigenvalue self-consistent (ev$GW$), where the "diagonal approximation" is applied so that quasiparticle wave functions remain fixed at the mean-field wave functions and only eigenvalues are updated. A higher level of self-consistency is achieved with quasiparticle self-consistent $GW$ (QS$GW$), where the wave functions are optimized as well. In QS$GW$ (Faleev et al. 2004), the $GW$ self-energy is used to construct a better approximation for the mean-field effective potential, which is in turn used to build a new set of mean-field Green's functions. Using the new Green's functions, the cycle (including updates to $W$) is repeated until self-consistency is reached between the mean-field and new $G_0W_0$ Green's functions. Note that even though QS$GW$ allows

updates to the wave functions, it is different from full self-consistency. Both ev$GW$ and QS$GW$ results are presented in Sect. 4.

## 2.2   Two-Particle Excitations: $GW$-BSE and TDDFT

The promotion of an electron into an excited state is considered a two-particle excitation, due to the coexistence of both an electron and a hole. The BSE expresses the two-particle correlation function $L$ as (Strinati 1988)

$$L(1, 2; 1', 2') = G(1, 2')G(2, 1') + \int d(3456)G(1, 3)G(4, 1')$$

$$K(3, 5; 4, 6)L(6, 2; 5, 2'), \tag{13}$$

where $G$ is, as before, the one-particle Green's function, and the electron-hole interaction kernel is expressed as

$$K(3, 5; 4, 6) = -i\delta(3, 4)\delta(5, 6)V_H(3, 6) + \frac{\delta\Sigma(3, 4)}{\delta G(6, 5)}. \tag{14}$$

Assuming that $G$ is represented using quasiparticles and that electron-hole excited states are long-lived, the BSE can be written as a generalized eigenvalue problem with block matrix form (Rohlfing and Louie 2000):

$$\begin{pmatrix} A & B \\ -B & -A \end{pmatrix} \begin{pmatrix} X_l \\ Y_l \end{pmatrix} = \Omega_l \begin{pmatrix} X_l \\ Y_l \end{pmatrix}, \tag{15}$$

where $\Omega_l$ is the energy of electron-hole excitation $l$.

From the definition of the BSE kernel (Eq. 14), it is clear that $G$ determines the quality of ensuing BSE predictions. When $G$ is obtained from the $GW$ approximation (as in the $GW$-BSE framework) and neglecting dynamical effects, the BSE kernel can be split into an exchange part $K^x$ (Eq. 8) and a direct part:

$$K^d_{vcv'c'} = K^x_{vv'cc'} + 4\sum_s \frac{V^s_{vv'} V^s_{cc'}}{\omega_s}, \tag{16}$$

and the block submatrices for $GW$-BSE corresponding to the spin-conserving excitations (and ignoring spin-orbit interactions) are

$$A_{\uparrow\uparrow,\uparrow\uparrow} = A_{\downarrow\downarrow,\downarrow\downarrow} = D + K^x + K^d,$$

$$B_{\uparrow\uparrow,\uparrow\uparrow} = B_{\downarrow\downarrow,\downarrow\downarrow} = K^x + K^d,$$

$$A_{\uparrow\uparrow,\downarrow\downarrow} = B_{\uparrow\uparrow,\downarrow\downarrow} = A_{\downarrow\downarrow,\uparrow\uparrow} = B_{\downarrow\downarrow,\uparrow\uparrow} = K^x, \tag{17}$$

where

$$D_{vcv'c'} = (E_c - E_v)\delta_{cc'}\delta_{vv'}, \tag{18}$$

with $c$, $c'$ being indices for empty states, $v$, $v'$ being indices for occupied states, and $E_c$ and $E_v$ being their quasiparticle energies. If the ground state is not spin polarized, its neutral singlet (and triplet) excitations can be computed with a basis set two times reduced. Singlet excitations correspond to a BSE Hamiltonian with

$$
\begin{aligned}
A &= D + 2K^x + K^d, \\
B &= 2K^x + K^d.
\end{aligned} \tag{19}
$$

In addition, when a vertex function is used in $GW$ calculations, a corresponding vertex contribution must also be added to the BSE kernel to maintain a consistent level of theory. The LDA vertex term

$$K^f_{vcv'c'} = 2\sum_s \frac{V^s_{vv'}F^s_{cc'} + F^s_{vv'}V^s_{cc'}}{\omega_s}, \tag{20}$$

is added to the BSE Hamiltonian wherever $K^d$ contributes for $GW\Gamma_{\mathrm{LDA}}$-BSE calculations. Here, $F^s_{nj}$ has the same form as $V^s_{nj}$ (Eq. 10) with $K^x_{njvc}$ replaced by $K^{\mathrm{LDA}}_{njvc}$, where LDA exchange-correlation kernel $K^{\mathrm{LDA}}$ is defined as

$$K^{\mathrm{LDA}}_{vcv'c'} = \int d\mathbf{r}\varphi_v(\mathbf{r})\varphi_c(\mathbf{r})f_{xc}(\mathbf{r})\varphi_{v'}(\mathbf{r})\varphi_{c'}(\mathbf{r}). \tag{21}$$

The BSE can also use a lower level of approximation for $G$, constructing it directly from wave functions and energies ($\varphi$ and $\varepsilon$) corresponding to the Kohn-Sham DFT electronic structure, with the self-energy in the BSE kernel (Eq. 14) approximated by $\Sigma(1,2) \approx V_{\mathrm{xc}}(1)\delta(1,2)$. This form of the BSE is in fact linear-response TDDFT in Casida's formalism. The eigenvalue equation can be written as

$$R^{1/2}\left[R + 4(K^x + K^{\mathrm{LDA}})\right]R^{1/2}Z_s = \omega_s^2 Z_s. \tag{22}$$

Here, the matrix $R$ is diagonal with entries $R_{vcv'c'} = \delta_{vv'}\delta_{cc'}(\varepsilon_c - \varepsilon_v)$. Compared to $GW$-BSE, TDDFT offers a computationally more efficient method for calculating absorption spectra of confined systems ▶ Chap. 6, "TDDFT and Quantum-Classical Dynamics: A Universal Tool Describing the Dynamics of Matter".

As a final note, the BSE frameworks outlined above represent $G$ in the diagonal approximation. However, past work has shown that off-diagonal terms can alter $G_0W_0$ and $G_0W_0$-BSE energies by more than 1 eV, especially for unoccupied states in finite systems or when occupied states are poorly described within DFT (Rohlfing and Louie 2000; Kaplan et al. 2015). In this chapter, we include the off-diagonal terms with the expression

$$D_{vcv'c'} = \delta_{vv'} \sum_{\bar{c}} \varepsilon_{\bar{c}} \langle c|\bar{c}\rangle \langle \bar{c}|c'\rangle$$

$$- \delta_{cc'} \sum_{\bar{v}} \varepsilon_{\bar{v}} \langle v|\bar{v}\rangle \langle \bar{v}|v'\rangle, \tag{23}$$

where $c$ and $v$ are indices for the original Kohn-Sham DFT electronic structure and the overbar indicates energies and wave functions of the diagonalized quasiparticle basis. The equation above is used in place of Eq. 18 when solving the BSE. Note that the expression above corresponds to the case where the occupied-state subspace and the unoccupied-state subspace are diagonalized separately and the electron density remains unchanged (Tiago and Chelikowsky 2006; Hung et al. 2017).

## 3 Numerical Convergence

The typical target for theoretical accuracy in $GW$ and BSE is ∼0.1 eV. Therefore, the necessary numerical accuracy must also be near ∼0.1 eV. This level of accuracy in the computation of charged and neutral excitation energies of confined systems requires one to pay particular attention to convergence issues within the $GW$-BSE framework. We focus here on the evaluation of the correlation self-energy (Eq. 9), where summations over empty states converge slowly and become the bottleneck of the computation. More generally stated, this is where convergence relative to basis set size is most difficult. The challenge in obtaining the convergence of excited-state energies with basis set size has motivated the development and testing of techniques to accelerate convergence or approximate the complete basis set limit. These include extrapolation (Sharifzadeh et al. 2012; Klimeš et al. 2014; Hung et al. 2014), the extrapolar method (Anglade and Gonze 2008; Bruneval and Gonze 2008; Berger et al. 2010), Lanczos-chain techniques (Rocca et al. 2008; Umari et al. 2010), construction of more efficient basis sets (Samsonidze et al. 2011; Jiang and Blaha 2016), sampling fewer high-energy states (Gao et al. 2016), and approximations for the missing basis set contributions (Tiago and Chelikowsky 2006; Kang and Hybertsen 2010; Deslippe et al. 2013).

The methods that approximate missing basis set contributions are based on adding a "static remainder" correction to the $GW$ correlation self-energy. This correction is derived from the static limit of the $GW$ approximation, which is known as the Coulomb-hole-screened-exchange (COHSEX) approximation, and is added to summation over quasiparticles (Eq. 9) truncated at some quasiparticle index $N$. In work by Tiago and Chelikowsky (2006), the COHSEX correction is given by the difference between the total COHSEX $\Sigma^c$ calculated using a completeness relation and the COHSEX $\Sigma^c$ in sum-over-states form, truncated at the same index $N$. More recent work shows that a correction of half that difference is a better approximation (Kang and Hybertsen 2010; Deslippe et al. 2013).

While the static remainder already improves convergence for most confined systems, it is important to note that it only enhances the convergence of the

summation over quasiparticle states. In addition, numerical convergence must also be sought with respect to the infinite summation over transitions $s$ in the expression for $\Sigma^c$. We focus here on methods of extrapolation to achieve that convergence.

To approach the complete basis set limit with respect to transitions $s$ via extrapolation, one can calculate the $GW$ energies with increasing number of quasiparticle states $N$ and increasing number of transitions $s$ between those states. The converged $GW$ energy is then obtained by fitting $E_\infty$ and coefficients $c_1$ and $c_2$ to

$$E(N) = E_\infty + \frac{c_1}{N + c_2}, \tag{24}$$

where the $1/N$ dependence has been suggested (Gulans 2014) as arising from the electron-electron cusp condition. With atom-centered Gaussian-type basis sets that are more common in quantum chemistry methods, similar extrapolation and fitting schemes can be used. Since all quasiparticles and transitions that exist within a given basis are included in the computation, extrapolation is performed across basis sets of increasing size. With Dunning basis sets, the $GW$ energies at the complete basis set limit are obtained by fitting the extrapolated energy $E_\infty$ and coefficient $c_1$ to

$$E(X) = E_\infty + c_1 X^{-\alpha} \tag{25}$$

where $X = 3, 4$, or $5$ ranging from aug-cc-PVTZ, aug-cc-PVQZ, or aug-cc-PV5Z, respectively. An $X^{-3}$ dependence – equivalent to the $N^{-1}$ scaling where $N$ is the number of basis functions – is commonly used for extrapolating the correlation energy with Dunning basis sets (Bruneval 2012; Kaplan et al. 2016). However, a smaller exponent ($\alpha \approx 2$) has been empirically shown to provide a better fit for quasiparticle energies computed on finite basis sets (Truhlar 1998; Bruneval et al. 2016).

In this chapter, the majority of computations use the RGWBS software suite (Tiago and Chelikowsky 2006), with numerical convergence achieved with a combination of the half COHSEX remainder and extrapolation. Results from BerkeleyGW (Deslippe et al. 2012) are converged with a combination of sampling high-energy states and extrapolation. Results from MolGW (Bruneval et al. 2016) use extrapolation.

## 4 Simulating Atoms and Molecules

### 4.1 Numerical Validation

Software packages make a variety of choices in their numerical implementation that may affect the final computed $GW$ results. We compare the RGWBS software suite with BerkeleyGW and MolGW and find that the numerical error is fairly well controlled. RGWBS, which represents wave functions on a uniform real-space grid,

**Fig. 1** Error of $G_0W_0$ IPs relative to experiment. Computations use two software packages: black circles are RGWBS (real-space framework), and orange squares are BerkeleyGW (plane-wave framework)

and BerkeleyGW, which has a plane-wave basis, are compared in Fig. 1 across the aromatic molecule test set (Hung et al. 2016). The frontier orbitals differ by no more than 80 meV, and only five IPs differ by more than 100 meV despite the different basis sets and other numerical approximations. A similar comparison has also been made comparing MolGW, which represents wave functions with Gaussian bases, with RGWBS for transition metal atoms and ions, with differences at the complete basis set limit near ~0.2 eV (Hung et al. 2017).

Figure 1 also shows that, often, $G_0W_0$ with a LDA or generalized gradient approximation (GGA) starting point is sufficient for good agreement with experiment in $sp$-bonded systems (see Sect. 4.3 below). As has also been noted in earlier work, we observe that the error in $G_0W_0$ energies is insensitive to the type of orbital, correcting from DFT where the energies of orbitals with $\sigma$ character are significantly

less accurate than those of $\pi$ orbitals (Hybertsen and Louie 1986; Qian et al. 2011; Marom et al. 2012).

## 4.2    Starting-Point Dependence

Among the various approximations, the effect of the mean-field starting point on the quasiparticle energies of molecules has perhaps been the most studied. In multiple benchmarks, hybrid functional mean-field starting points have been consistently observed to produce better agreement between $G_0W_0$ and experiment as seen in benchmarks referenced in Sect. 1. Here we only briefly touch on one set of examples illustrating the starting-point dependence.

The effect of the amount of exact exchange in the mean-field starting point on $GW$ predictions is shown in Fig. 2 for the Zn atom and ions. Computations in MolGW are performed where none, half, or all of the exchange density functional is replaced with a corresponding amount of exact exchange (Hung et al. 2017). At the DFT level, the lowest unoccupied molecular orbital (LUMO) becomes less bound with increasing amounts of exact exchange, while the highest occupied molecular orbital (HOMO) is more bound. The $G_0W_0$ results decrease or even reverse the trend observed at the DFT level, and the changes in trends are most evident at the ev$GW$

**Fig. 2**  DFT (left), $G_0W_0$, and ev$GW$ (right) quasiparticle energies of Zn, $Zn^+$, and $Zn^{2+}$ with mean-field starting points of 0% exact exchange (GGA), 50% exact exchange, and 100% exact exchange (HF). Dashed lines indicate the experimentally measured IPs

level of theory. This example illustrates that the starting-point dependence persists even if eigenvalues are iterated to self-consistency. The starting-point contribution may only be removed with optimization of the quasiparticle wave functions as well.

## 4.3    Combining $\Gamma$ and Self-Consistency

The LDA-derived vertex approximation has, in the past, been generally associated with a near-constant shift of all energies compared to conventional $GW$ values. We see the same trend for our test set of aromatic molecules (Fig. 3). Compared to $G_0W_0$ ionization potentials (IPs), $G_0W_0\Gamma_{LDA}$ predictions are consistently shifted downward by $\sim 0.7$ eV. The electron affinities (EAs) are similarly shifted downward

**Fig. 3** Shift of quasiparticle energies from predictions at $G_0W_0$, for $GW$ variants including self-consistency and vertex corrections, for the aromatic molecule set
by ∼0.7 eV for $G_0W_0\Gamma_{\mathrm{LDA}}$ compared to $G_0W_0$. As a result, going from $G_0W_0$ to $G_0W_0\Gamma_{\mathrm{LDA}}$ barely affects the fundamental gap.

Figure 3 also shows that quasiparticle self-consistency makes the occupied orbitals more bound compared to the perturbative calculations. The first IP is slightly shifted upward, and deeper orbitals exhibit a greater shift. In contrast, EAs move in the opposite direction from IPs and become more negative compared to perturbative results. Quasiparticle self-consistency therefore increases the fundamental gap by 0.8–0.9 eV.

The two trends of the near-constant shift of eigenvalues after applying $\Gamma_{\mathrm{LDA}}$ and the opening of the $GW$ gap upon self-consistency agree with other benchmark studies for both confined and extended systems. In addition, these trends are also observed when both the LDA vertex and self-consistency are applied in combination through QS$GW\Gamma_{\mathrm{LDA}}$. The IPs predicted by QS$GW\Gamma_{\mathrm{LDA}}$ remain nearly a constant shift below those predicted by standard QS$GW$ with an energy difference ∼0.8 eV, and the EAs computed via QS$GW\Gamma_{\mathrm{LDA}}$ are on average ∼0.8 eV lower than those computed with QS$GW$. Again, the fundamental gap, predicted with $\Gamma_{\mathrm{LDA}}$, is essentially unchanged from the gap of conventional QS$GW$.

For the IPs, these benchmarks show a cancellation between the effects of vertex corrections and $GW$ self-consistency, as reported in earlier work (Shirley 1996; Ummels et al. 1998). For EAs, on the other hand, we see that the vertex and self-consistency effects are still roughly the same magnitude, but they shift in the same direction from $G_0W_0$ predictions, such that QS$GW\Gamma_{\mathrm{LDA}}$ compounds their effects instead of canceling them out. The comparable magnitudes of self-consistency and vertex corrections are likely coincidental, although it may be worth studying whether such cancellations for IP predictions are inherent to the physical properties of aromatic or $sp$-bonded molecules.

In benchmarks relative to experiment, we find that despite the greater effort in $\Gamma_{\mathrm{LDA}}$ and self-consistent computations, $G_0W_0$ predictions are closest to measured IPs. Experimental measurements exist for IPs up to 15 eV in most of the molecules, and $G_0W_0$ energies all lie within 0.6 eV of measured values with a mean absolute error less than 0.3 eV (Figs. 1 and 4). Predictions of IPs from $G_0W_0\Gamma_{\mathrm{LDA}}$ are too low, consistent with a benchmark of single atoms (Morris et al. 2007). The quasiparticle self-consistent results reverse the trend: an increase of the QS$GW$ IPs from perturbative values results in decreased accuracy, but the increase in QS$GW\Gamma_{\mathrm{LDA}}$ IPs improves agreement with experiment – although not to the extent of improving on the $G_0W_0$ values.

Experimental comparisons for EAs are only available for benzene and naphthalene, which are reported in Table 1 together with our $GW$ predictions. In contrast to the IPs, it is $G_0W_0\Gamma_{\mathrm{LDA}}$ and QS$GW$ that best predict the EAs. Interestingly, EAs from $G_0W_0\Gamma_{\mathrm{LDA}}$ are in good agreement with coupled-cluster [CCSD(T)] calculations, although both are too negative relative to experiment. It is unclear whether these differences are due to the difficulties in experimental measurements or an inaccurate representation of the unoccupied orbitals in the calculations. For instance, the limited basis set used in the higher-order corrections of CCSD(T) may

**Fig. 4** Error for the first IP (top) and the mean absolute error of orbitals with IPs up to 15 eV (bottom), relative to experiment for each molecule

**Table 1** First EA in eV with comparison to electron transmission spectroscopy (ETS) measurements (Burrow et al. 1987) and CCSD(T) (Hajgató et al. 2008) calculations

| Molecule | Orbital | ETS | CCSD(T) | $G_0W_0$ | $G_0W_0\Gamma_{LDA}$ | QS$GW$ | QS$GW\Gamma_{LDA}$ |
|---|---|---|---|---|---|---|---|
| Benzene | $1e_{2u}$ ($\pi^*$) | −1.12 | −1.526 | −0.84 | −1.55 | −1.33 | −2.12 |
| Naphthalene | $2b_{1g}$ ($\pi^*$) | −0.19 | −0.477 | 0.38 | −0.30 | −0.15 | −0.93 |

numerically bind the wave functions, and similarly, our perturbative calculations use a DFT-LDA electronic structure, a theory which over-binds the unoccupied orbitals.

When we take the difference of predicted IP and EA for each molecule, we find that the fundamental gaps of benzene and naphthalene computed using QS$GW$ (11.01 and 8.61 eV, respectively) and QS$GW\Gamma_{LDA}$ (10.98 and 8.57 eV) are nearly identical to fundamental gaps determined from experimental IPs and CCSD(T) EAs (10.98 and 8.62 eV). However, we also see that no single variant of $GW$ studied here is best for the absolute IPs and EAs. For perturbative calculations, $G_0W_0$ is more accurate for IPs, and $G_0W_0\Gamma_{LDA}$ is more accurate for EAs, while among self-consistent calculations (which reduce or eliminate starting-point dependence), QS$GW\Gamma_{LDA}$ is more accurate for IPs, and QS$GW$ is more accurate for EAs. This example simulating real molecules confirms an earlier prediction derived from model systems: a two-point DFT-derived vertex can alleviate self-screening errors felt by occupied orbitals, but only a three-point vertex can be expected to treat both occupied and unoccupied orbitals accurately (Romaniello et al. 2009).

Concerning self-consistency, these results contrast with multiple benchmarks which show improved spectral properties for molecules after eigenvalue, QS, or fully self-consistent $GW$ (Dahlen and van Leeuwen (2005), Stan et al. (2006), and Stan et al. (2009) and some references in Sect. 1). These computations are performed using various numerical implementations. Therefore, for self-consistent

*GW*, numerical considerations such as the choice of a quasiparticle basis for self-consistency and the basis set chosen to represent wave functions must be better understood before a consensus can be reached on the theoretical accuracy of self-consistent *GW* for molecules.

Eigenvalue self-consistency and the LDA vertex are also used to compute *GW* quasiparticle energies of Cu, Ag, Zn, and Cd atoms in neutral and charged configurations, with comparison to experiment in Fig. 5. Similar to QS*GW* with the aromatic molecules, ev*GW* widens the fundamental gap, although not all quasiparticle energies are affected to the same degree. The ev*GW* energies for the HOMOs with *s* character ($d^{10}s$ and $d^{10}s^2$ valence) remain fairly similar to perturbative values. However, the energies of the LUMOs (all of which have *s* character) increase, and energies of the HOMO with *d* character ($d^{10}$ valence) decrease. The resulting *d* quasiparticle energies from ev*GW* are less accurate than in $G_0W_0$, and there is no systematic improvement for *s* or *p* states. Again, the

**Fig. 5** Error of *GW* quasiparticle energies for Cu, Ag, Zn, and Cd atoms and ions, relative to experiment for various flavors of *GW*. The reference valence electron configurations are given in bold on the right
worsened quasiparticle energies differ from the majority of self-consistent $GW$ benchmarks (see list of benchmarks in Sect. 1), but similar results were observed in earlier studies of azabenzenes and small transition metal molecules (Marom et al. 2012; Körbel et al. 2014).

A more unusual result is observed for the LDA-vertex-corrected $GW$ benchmarks. Unlike the aromatic molecule test set (and other earlier studies), the energy change associated with the vertex correction is not constant but rather ranges between 0.6 and 1.1 eV. The variation is not due to differences in angular momentum character – indeed, the energy differences for $d$-states are $\sim$0.8 eV, in the middle of the observed range. However, the LDA-derived vertex function's sensitivity to the local wave function amplitude is showcased by the character of orbitals on single atoms, which range from localized to diffuse. We observe that the LDA vertex affects the quasiparticle energies most dramatically for the HOMO corresponding to the $d^{10}s \leftarrow d^{10}$ and the $d^{10}s^2 \leftarrow d^{10}s$ excitations; the quasiparticle wave functions used in computing these states are overly delocalized due to the use of the LDA exchange-correlation functional. In contrast, the LDA vertex changes the quasiparticle energies the least for the LUMO corresponding to the $d^{10}s \rightarrow d^{10}s^2$ excitation; this wave function is overly localized by the LDA exchange-correlation functional.

Despite the increased versatility of the LDA vertex in this context, the inclusion of $\Gamma_{\mathrm{LDA}}$ still does not improve agreement with experiment, and $G_0W_0$ remains the best predictor of ionization energies for these single atoms. Eigenvalue self-consistency and the LDA vertex correction together also do not exhibit any fortuitous cancellation of effects for this test set.

These benchmarks show that, although self-consistent $GW$ solutions have certain theoretical advantages, such as starting-point independence, fulfillment of energy and momentum conservation laws, and consistent values for observables when using different partitioning functions (Baym 1962), they do not necessarily perform well for the spectral properties of confined systems. In fact, for fully self-consistent $GW$, inaccuracies in computed values are unavoidable as long as the vertex approximation remains. This is the same as for extended (bulk) systems, where ground-state properties are in general accurately represented by self-consistent $GW$, but band energies can be less accurate than perturbative calculations, and valence bandwidths are too large (Ku and Eguiluz 2002; Kutepov et al. 2009).

## 4.4   $GW$-BSE

When computing two-particle interactions within the $GW$-BSE framework, the initial errors in the quasiparticles predicted via $GW$ (and DFT) may be propagated, amplified, or canceled out. Therefore, the level of theory best for $GW$-BSE must be confirmed in benchmarks separate from the $GW$ approximation alone.

We begin with a quick check of numerical convergence in the top row of Fig. 6, which contains TDDFT (with LDA exchange-correlation) spectra for the aromatic molecules in our test set computed in two different-sized simulation cells. For
**Fig. 6** The absorption cross section for each of the molecules as predicted by various levels of theory (with Gaussian broadening of 0.1 eV). The TDLDA$_{big}$ calculations are performed in simulation cells with radii of 20 bohr, while TDLDA$_{small}$ simulation cells have radii that are either 12 bohr (for benzene, thiophene, and 1,2,5-thiadiazole) or 14 bohr (for naphthalene, benzothiazole, and TTF). $GW$-BSE calculations are performed in the smaller simulation cells

both cell sizes, the lowest-energy excitations are in agreement; deviations are only observed for the higher-energy excitations that involve transitions to regions farther from the atomic cores. This suggests that the simulation cell size is numerically converged for the lower-energy, localized excitations. Figure 6 also illustrates the trends in the $GW$-BSE energies (in the diagonal approximation) occurring due to self-consistency and the vertex function. The spectra from perturbative $GW$-BSE ($G_0W_0$-BSE and $G_0W_0\Gamma_{LDA}$-BSE) are all redshifted compared to the other spectra.

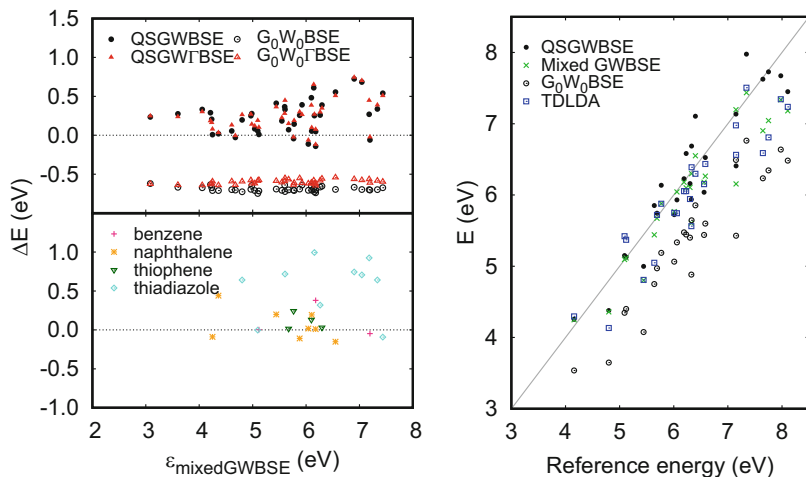
The trends due to self-consistency and the vertex approximation are also reflected in the detailed comparison of $GW$-BSE predictions of low-lying valence (localized) singlet excitations, in the top left panel of Fig. 7. All calculations are presented as the difference from mixed $GW$-BSE predictions, which we explain later in this section. In these benchmarks, the choice of vertex only minimally changes excitation energies. This is unsurprising, since as mentioned in the previous section, the energy differences between quasiparticles (both holes and quasielectrons) upon adding the LDA vertex essentially amount to a rigid shift, while energy differences between quasiparticle levels remain unchanged. The small differences in transition energies upon inclusion of $\Gamma_{LDA}$ – increasing an average of 0.09 eV for perturbative $GW$-BSE and 0.02 eV for QS$GW$-BSE – are attributed to the inclusion of $\Gamma_{LDA}$ in the BSE kernel. In contrast, self-consistency in $GW$-BSE has a large effect on excitation energies. QS$GW$-BSE has an average 0.91 eV increase of singlet excitation energies over $G_0W_0$-BSE, and QS$GW\Gamma_{LDA}$-BSE has an average 0.84 eV increase compared to $G_0W_0\Gamma_{LDA}$-BSE.


**Fig. 7** Left: with mixed $GW$-BSE predictions as reference, the top panel plots the difference between vertical valence excitation energies predicted by several variants of $GW$-BSE; the bottom panel is the difference between mixed $GW$-BSE and literature values computed using quantum chemistry methods (see text for references). Right: the difference between TDDFT and $GW$-BSE predictions and literature "reference" values

A comparison of $GW$-BSE and TDDFT predictions relative to best previous theoretical results for the aromatic molecules is shown in the right panel of Fig. 7. For benzene, naphthalene, and thiophene, the best previous theoretical values were computed including contributions from singles, doubles, and triples excitations (Falden et al. 2009; Fliegl and Sundholm 2014; Stenrup 2012). The mean absolute difference across these three molecules is 0.78 eV for $G_0W_0$-BSE, 0.68 eV for $G_0W_0\Gamma_{LDA}$, 0.25 eV for QS$GW$-BSE, 0.24 eV for QS$GW\Gamma_{LDA}$-BSE, and 0.25 eV for TDDFT. For 1,2,5-thiadiazole, the cited calculation only includes singles and doubles excitations (Palmer 2008), and the mean absolute difference is larger at 1.26 eV for $G_0W_0$-BSE, 1.14 eV for $G_0W_0\Gamma_{LDA}$, 0.33 eV for QS$GW$-BSE, 0.29 for $GW\Gamma_{LDA}$-BSE, and 0.61 for TDDFT. We observe that BSE calculations that build on perturbative $GW$ calculations produce singlet excitation energies that are too small by 0.7–0.8 eV compared to previous theoretical computations of benzene, naphthalene, and thiophene. On the other hand, QS$GW$-BSE and QS$GW\Gamma_{LDA}$-BSE have mean signed differences that are negative for benzene but positive for naphthalene and thiophene.

In Figs. 6 and 7, we also mention a "mixed $GW$-BSE" method. This is where we apply the BSE to a mixed set of $GW$ quasiparticles: occupied orbitals are associated with $G_0W_0$ quasiparticle energies, unoccupied orbitals have $G_0W_0\Gamma_{LDA}$ quasiparticle energies, and the screened interaction is computed using LDA quantities without vertex contributions. The quasiparticle wave functions in this case are given by the DFT wave functions. The mixed $GW$-BSE calculation is motivated by the observation in the previous section that $G_0W_0$ energies have the best agreement with

experimental values for IPs, while $G_0W_0\Gamma_{LDA}$ energies are better for EAs. Through this construction, mixed $GW$-BSE has an optical gap larger than perturbative $GW$-BSE calculations, which better matches reference values. For this set of molecules, the mean signed difference between mixed $GW$-BSE and previous theoretical results is approximately $-0.1$ eV, but we emphasize that this observed cancellation of effects is not necessarily transferable across different physical systems.

Also in Figs. 6 and 7, TDDFT predictions for localized valence excitations of $sp$-bonded molecules are shown to be in good agreement with higher-level quantum chemistry calculations. However, TDDFT with the LDA functional cannot properly simulate excitations such as charge-transfer and Rydberg excitations, where long-range interactions become important (Tozer and Handy 1998; Casida et al. 1998). In such cases, TDDFT functionals that better account for exchange and correlation interactions must be used to produce good optical spectra for molecules (Refaely-Abramson et al. 2011; Leang et al. 2012; Laurent and Jacquemin 2013). This reliance on specific exchange-correlation functionals contrasts with the self-consistent $GW$-BSE framework, which – assuming an adequate starting point – treats all excitations on equal footing.

We now turn to predictions from variants of the $GW$-BSE method for optical excitations in the Group IB and IIB atoms and compare them with spin-orbit-averaged experimental absorption energies and TDDFT eigenvalues. We focus on low-lying, spin-conserving excitations promoting electrons from the HOMO to the unoccupied valence $s$ or $p$ shells. Here, we also move beyond the diagonal approximation (Eq. 18), which was used for all $GW$-BSE energies computed for the above aromatic molecules, and determine BSE eigenvalues while also accounting for off-diagonal terms of the $GW$ self-energy. Figure 8 and Table 2 summarize the $GW$-BSE error relative to experiment, with the rectangles in Fig. 8 indicating the ranges from minimum to maximum error across the Cu, Ag, Zn, and Cd test set.

In the diagonal approximation, perturbative $GW$-BSE eigenvalues underestimate absorption energies, with improvements in accuracy for self-consistent $GW$-BSE, a trend consistent with other recent $GW$-BSE benchmarks of confined systems. The inclusion of the LDA vertex increases the predicted energies of optical excitations; however, without self-consistency (BSE@$G_0W_0\Gamma_{LDA}$@LDA), this still underestimates excitation energies. This is the same trend as observed for the aromatic molecules above, where perturbative $GW$-BSE excitation energies are too small, and some amount of self-consistency must be incorporated for better agreement with reference energies.

With the inclusion of off-diagonal terms, however, the predicted absorption energies increase for all variants of $GW$-BSE. This effect occurs because the low-lying LDA (and GGA) unoccupied orbitals are overly localized, and off-diagonal terms help delocalize the quasiparticles. With this energy increase, eigenvalue self-consistency no longer improves accuracy for all calculations. BSE@ev$GW$@LDA deteriorates in accuracy compared to BSE@$G_0W_0$@LDA, but BSE@ev$GW$@GGA is the most accurate variant of conventional $GW$ tested, with errors no more than $0.5$ eV. We also find that the computationally efficient BSE@$G_0W_0\Gamma_{LDA}$@LDA provides excellent agreement with experiment that is

**Fig. 8** Error of $GW$-BSE predictions relative to experimental absorption energies from a $d^{10}$ (first four sets of bars), $d^{10}s$ (fifth set), or $d^{10}s^2$ (sixth set) electron configuration to the configuration listed along the horizontal axis. Rectangles matching the legend indicate the error range across the Cu, Ag, Zn, and Cd test set, with fainter colored bars providing a guide for the eye

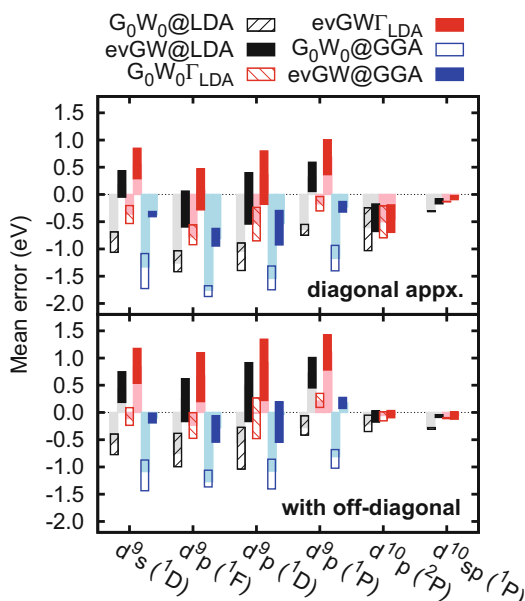

**Table 2** Mean error of $GW$-BSE eigenvalues (including off-diagonal terms) associated with excitations from the HOMO to the lowest empty $s$ or $p$ quasiparticle, relative to experimental energies

| | | BSE@ | | | | BSE@ | |
|---|---|---|---|---|---|---|---|
| | TDDFT | $G_0W_0$ | evGW | $G_0W_0\Gamma_{LDA}$ | evGW$\Gamma_{LDA}$ | $G_0W_0$ | evGW |
| Transition | @LDA | @LDA | | | | @GGA | |
| $d^{10}s^2 \to d^{10}sp$ ($^1$P) | −0.03 | −0.29 | −0.07 | −0.10 | −0.06 | – | – |
| $d^{10}s \to d^{10}p$ ($^2$P) | 0.51 | −0.21 | −0.09 | −0.05 | −0.04 | – | – |
| $d^{10} \to d^9p$ ($^1$P) | −1.48 | −0.28 | 0.72 | 0.21 | 1.11 | −0.81 | 0.18 |
| $d^{10} \to d^9p$ ($^1$D) | −1.90 | −0.56 | 0.50 | −0.01 | 0.92 | −1.08 | −0.03 |
| $d^{10} \to d^9p$ ($^1$F) | −1.95 | −0.75 | 0.25 | −0.23 | 0.67 | −1.27 | −0.28 |
| $d^{10} \to d^9s$ ($^1$D) | −1.54 | −0.56 | 0.44 | −0.11 | 0.84 | −1.08 | −0.10 |

comparable to BSE@ev$GW$@GGA. While further study is needed, at least for the Group IB and IIB test set, DFT-derived vertex corrections combined with off-diagonal terms allow an accurate calculation of BSE energies from less exact $GW$ quasiparticles.

## 5    Summary

Computational advances now make it feasible – if still expensive – to perform $GW$ calculations at varying levels of theory, and researchers have begun to understand the intricate approximations used to model the excited state from first principles.

In this chapter, we discussed many-body perturbation theory methods that allow the simulation of the excited state in confined systems. We overviewed an efficient implementation of $GW$, BSE, and TDDFT that uses a transition-space basis to describe excitations and presented benchmarks of excitations in atoms and molecules, comparing approximations taken in theory and implementation. Since the accuracy of variants of $GW$ and $GW$-BSE can be compared only after knowing the numerical accuracy for context, we discussed the impact of finite basis sets, including methods to estimate quasiparticle energies at the complete basis set limit.

Using test sets of aromatic molecules and transition metal atoms and ions, we examined the impact of self-consistency within $GW$ as well as the vertex approximation. In our benchmarks involving self-consistency, we found worsened accuracy compared to $G_0W_0$ results but caution that the performance of these and other benchmarks may still be influenced by numerical approximations, not just theory. For the LDA-derived vertex, the results presented here generally agreed with past work, where the vertex shifted both occupied and unoccupied states to lower energies compared to conventional $GW$. However, while all past results reported shifts of a near-constant magnitude, the LDA vertex applied to transition metal atoms resulted in shifts whose magnitude varied according to the diffusivity of associated orbitals. We also addressed the off-diagonal terms of the self-energy. These did not necessarily improve accuracy in $GW$ predictions (such as in QS$GW$) but did contribute to improved descriptions of neutral excitations within the perturbative $GW$-BSE framework.

# Many-Body Calculations of Plasmon and Phonon Satellites in Angle-Resolved Photoelectron Spectra Using the Cumulant Expansion Approach

# 16

Fabio Caruso, Carla Verdi, and Feliciano Giustino

## Contents

### Abstract

The interaction of electrons with crystal lattice vibrations (phonons) and collective charge-density fluctuations (plasmons) influences profoundly the spectral properties of solids revealed by photoemission spectroscopy experiments. Photoemission satellites, for instance, are a prototypical example of quantum

emergent behavior that may result from the strong coupling of electronic states to plasmons and phonons. The existence of these spectral features has been verified over energy scales spanning several orders of magnitude (from 50 meV to 15–20 eV) and for a broad class of compounds such as simple metals, semiconductors, and highly doped oxides. During the past few years, the cumulant expansion approach, alongside with the $GW$ approximation and the theory of electron-phonon and electron-plasmon coupling in solids, has evolved into a predictive and quantitatively accurate approach for the description of the spectral signatures of electron-boson coupling entirely from first principles, and it has thus become the state-of-the-art theoretical tool for the description of these phenomena. In this chapter we introduce the fundamental concepts needed to interpret plasmon and phonon satellites in photoelectron spectra, and we review recent progress on first-principles calculations of these features using the cumulant expansion method.

# 1 Introduction

The emergence of satellites in photoemission spectroscopy provides direct evidence of the electronic coupling to bosonic excitations in solids. Satellites are spectral features that reflect the simultaneous excitation of a hole and of a boson, and they are separated from the quasiparticle peak by a multiple of the boson energy. The origin of these features may be understood based on simple considerations on the energy scales involved in the photoemission process. When a photon with energy $\hbar\omega$ is absorbed by an electron with binding energy $\varepsilon_i$, if no boson modes are excited in the system, energy conservation requires the condition $\hbar\omega = \varepsilon_i + \Phi + E_{\text{kin}}$ to be satisfied, where $\Phi$ is the work function of the system and $E_{\text{kin}}$ is the kinetic energy of the photo-emitted electron. In photoemission, by measuring $E_{\text{kin}}$ and $\Phi$, the electron binding energy can thus be inferred. If, in addition to the creation of a hole, a fraction of the absorbed photon energy is transferred to the system in the form of bosonic modes, such as plasmons and phonons, the energy conservation condition is modified as follows: $E_{\text{kin}} = \hbar\omega - \varepsilon_i - nE_{\text{b}} - \Phi$, where $E_{\text{b}}$ is the energy of the boson and $n$ an integer. Since $\hbar\omega$ and $\Phi$ are constants, the kinetic energy distribution of the photo-emitted electrons will be peaked at the energies corresponding to (i) the binding energy of electrons $\varepsilon_i$ and (ii) the sum of the binding and boson energies $\varepsilon_i + nE_{\text{b}}$, and it may thus provide direct information regarding the coupling of electrons to bosonic modes in solids.

The presence of satellites in the photoemission spectra of solids was first predicted by a theoretical analysis of the spectral function of the homogeneous electron gas by Lundqvist (1967), Hedin and Lundqvist (1970), and Langreth (1970) and subsequently verified experimentally for the core electrons of simple metals (Baer and Busch 1973). Recently, the availability of energy resolutions of the order of 25–50 meV in angle-resolved photoelectron spectroscopy (ARPES) made it possible to observe new low-energy signatures of electron-boson coupling in experiments. In particular, high-resolution ARPES measurements of graphene

by Bostwick et al. (2010) have revealed plasmon-induced satellite structures with characteristic energies of the order of ~1 eV. More recently, polaronic satellites at energies of the order ~100 meV from the band edges have been observed in doped oxides, for example, by Moser et al. (2013) and Wang et al. (2016). At variance with valence-plasmon satellites, which typically appear at energies between 5 and 15 eV below the Fermi energy and have been known since the early days of photoemission spectroscopy, low-energy satellites are a manifestation of the coupling between low-energy bosonic modes and electronic carriers near the band edges. In addition to the formation of satellites, the coupling to bosons may lead to the emergence of photoemission kinks (Lanzara et al. 2001; Damascelli et al. 2003) and to a renormalization of energy levels (Logothetidis et al. 1992; Giustino et al. 2010; Poncé et al. 2015) and carrier lifetimes (Eiguren et al. 2002; Park et al. 2007).

In this chapter we will discuss the state-of-the-art techniques for the description of plasmon and polaron satellites and their application to the prediction and interpretation of photoemission spectroscopy experiments.

## 2   The Localized Electron Model

To illustrate how the interaction between electrons and bosons may lead to the emergence of satellites in photoemission spectra, we consider in the following the exactly solvable model of a "localized electron" in a solid interacting with a boson bath. The latter can be regarded as a set of phonons, plasmons, or any other bosonic excitations that may be approximately represented as a set of uncoupled harmonic oscillators. The localized electron is assumed to be dispersionless, that is, its energy $\varepsilon$ is independent of the crystal momentum, and its interaction with other electrons in the system is neglected. Instances in which the electron energy levels exhibit a weak dependence on momentum, and can thus be approximated as nondispersive, are, for example, core electrons in solids, localized impurity levels, and $4f$ electrons. On the other hand, electron-electron interactions are typically strong and non-negligible in three-dimensional solids, which poses limitations to the applicability of this model to real physical systems. This simplified model, however, is remarkably successful in describing the emergence of bosonic satellites in the spectral properties and is in good qualitative agreement with more advanced theories, whereby the electron-electron interaction is accounted for. This is demonstrated, for instance, by the generalization of the localized electron model reported by Langreth (1970).

The localized electron model is described by the following electron-boson coupling Hamiltonian:

$$\hat{H} = \hat{H}_e + \hat{H}_b + \hat{H}_{int} = \varepsilon \hat{c}^\dagger \hat{c} + \sum_{\mathbf{q}} \hbar \omega_{\mathbf{q}} \hat{b}_{\mathbf{q}}^\dagger \hat{b}_{\mathbf{q}} + \sum_{\mathbf{q}} g_{\mathbf{q}} \hat{c}^\dagger \hat{c} (\hat{b}_{\mathbf{q}} + \hat{b}_{-\mathbf{q}}^\dagger), \qquad (1)$$

where $\hat{c}^\dagger$ and $\hat{c}$ are fermionic creation and annihilation operators for the localized electron, respectively, which satisfy the ordinary anti-commutation relations.

Similarly, the operators $\hat{b}_{\mathbf{q}}^{\dagger}$ and $\hat{b}_{\mathbf{q}}$, respectively, create and annihilate a boson with energy $\hbar\omega_{\mathbf{q}}$ and momentum $\mathbf{q}$ and satisfy bosonic commutation relations. The absence of two-particle interaction terms in the Hamiltonian reflects the fact that both electron-electron and boson-boson interactions are neglected. The localized electron interacts with the boson bath with the coupling strength $g_{\mathbf{q}}$.

As we are primarily interested in the effects of the electron-boson interaction on the photoemission intensity, the relevant quantity that we want to compute is the electron spectral function:

$$A(\omega) = -\frac{1}{\pi}\mathrm{Im}\,G^{\mathrm{ret}}(\omega), \qquad (2)$$

with the single-particle retarded Green's function $G^{\mathrm{ret}}$ defined as:

$$G^{\mathrm{ret}}(t) = -i\,\langle\Psi_0|\,\{\hat{c}(t),\hat{c}^{\dagger}(0)\}\,|\Psi_0\rangle\,\theta(t), \qquad (3)$$

where $\{\,,\,\}$ denotes the anticommutator, $\Psi_0$ the electronic ground state, and the time-dependence of the operators is accounted for in the Heisenberg picture. As shown by Langreth (1970), the Green's function associated to the Hamiltonian in Eq. (1) can be calculated exactly. In fact, by applying a unitary transformation, Eq. (1) is recast in the form of a shifted harmonic oscillator Hamiltonian for which eigenvalues and eigenvectors are known (Mahan 2000). The spectral function for a localized electron can thus be expressed as (Langreth 1970):

$$A(\omega) = \sum_{n=0}^{\infty} \frac{e^{-a}a^n}{n!}\delta(\hbar\omega - \varepsilon - a\hbar\omega_{\mathrm{b}} + n\hbar\omega_{\mathrm{b}}), \qquad (4)$$

where $a = \sum_{\mathbf{q}} g_{\mathbf{q}}^2/(\hbar\omega_{\mathrm{b}})^2$ and for simplicity the energy of the boson mode has been replaced by its average value $\hbar\omega_{\mathrm{b}}$.

In the small coupling limit, that is for $g_{\mathbf{q}} \to 0$, the spectral function reduces to the case of a noninteracting electron $A(\omega) = \delta(\hbar\omega - \varepsilon)$, and the Dirac delta function is peaked at the quasiparticle energy. For finite coupling strengths, the structure of the spectral function in Eq. (4) reveals that the effect of the interaction between electrons and bosons on the spectral properties of the system is twofold. First, the quasiparticle energy of the localized electron is shifted by $a\hbar\omega_{\mathrm{b}}$. This process is analogous, for example, to the well-known band-gap renormalization of semiconductors and insulators due to the electron-phonon interaction (Allen and Heine 1976; Giustino 2017), and it results from the *dressing* of the bare quasiparticle via the interaction with the boson modes. Second, the spectral function exhibits a series of additional features at lower energies which are separated from the quasiparticle peak by multiples of the boson energy $\hbar\omega_{\mathrm{b}}$. These spectral features arise from the simultaneous excitation of the localized electron and of one or more bosons with energy $\hbar\omega_{\mathrm{b}}$.
**Fig. 1** (**a**) Spectral function of the localized electron model evaluated using Eq. (4) for a nondispersive electron with binding energy $\varepsilon$ coupled to a boson with frequency $\omega_b$ with a coupling strength $g_q$. (**b**) Spectral intensity map for an electron with parabolic band dispersion $\varepsilon_k = \varepsilon + \hbar^2 k^2 / 2m$. The Dirac $\delta$ functions in Eq. (4) have been replaced by Lorentzian functions with a 20 meV broadening

In Fig. 1a we show the spectral function obtained from Eq. (4) considering $\varepsilon = -40\,\text{meV}$, $\hbar\omega_b = 100\,\text{meV}$, $g_q = 100\,\text{meV}$. A picture in closer agreement with angle-resolved photoemission spectroscopy is obtained when considering the case of dispersive electronic states: Fig. 1b illustrates the spectral intensity map for a parabolic band, obtained by replacing the electronic energy with $\varepsilon_k = \varepsilon + \hbar^2 k^2 / 2m$ in Eq. (4). This simple generalization of the localized electron model illustrates that, in presence of nontrivial energy-wavevector dispersion relations, the energy of the satellite features induced by electron-boson coupling also acquires a dependence on the crystal momentum that follows closely the dispersion of the ordinary quasiparticle states. This phenomenon translates into the formation of plasmonic polaron bands due to electron-plasmon coupling (Caruso et al. 2015; Caruso and Giustino 2015; Lischner et al. 2015; Gumhalter et al. 2016; Caruso et al. 2018) and polaron satellites due to electron-phonon coupling (Moser et al. 2013; Wang et al. 2016; Verdi et al. 2017) in the ARPES spectra of semiconductors and $n$-doped oxides, respectively.

Overall, the solution of the localized electron model reveals that the spectral function of a system of interacting electrons and bosons, whereby the interaction is described by the last term of Eq. (1), may exhibit a series of satellite structures, with binding energy blueshifted with respect to the main quasiparticle peak by multiples of the boson energy. Despite the simplicity of the model, this result provides a first indication that the coupling to plasmons and phonons in real systems, in which the coupling Hamiltonian assumes a similar form, may also induce the formation of satellite features for sufficiently strong coupling.

# 3      First-Principles Description of Satellites in Photoemission

Despite the different nature of plasmon and phonon collective excitations in solids, the many-body theory of electron-boson interaction represents the common playground to describe their coupling to electronic states and to investigate the spectral fingerprints resulting from this interaction. The Hedin-Baym equations (Giustino 2017) based on many-body perturbation theory (MBPT) provide a formally exact framework to investigate the coupling to plasmons and phonons and are the starting point for the theoretical description of satellites in photoemission spectra. The electron self-energy for the coupled electron-phonon system in the Migdal approximation, that is neglecting vertex corrections, is given by Hedin and Lundqvist (1970) and Giustino (2017):

$$\Sigma(\mathbf{k}, \omega) = i \int \frac{d\mathbf{q}}{\tilde{\Omega}} \frac{d\omega}{2\pi} G(\mathbf{k} + \mathbf{q}, \omega + \omega')[W_e(\mathbf{q}, \omega') + W_{ph}(\mathbf{q}, \omega')] \tag{5}$$

where $\tilde{\Omega}$ is the reciprocal-space volume, $G$ is the single-particle Green's function, and $W_e$ ($W_{ph}$) is the screened Coulomb interaction due to the electron-electron (electron-phonon) interaction. It can be shown that the electron-phonon part may be expressed as $W_{ph} = W_e D W_e$ (in symbolic notation), where $D$ is the density-density correlation function for the nuclear fluctuations. Eq. (5) neglects the so-called Debye-Waller contribution to the self-energy; however this contribution is frequency-independent and therefore does not give rise to additional structures in the electron spectral function (Giustino 2017).

If the nuclei are treated in the clamped-ion approximation, that is $W_{ph}(\mathbf{q}, \omega) = 0$, the ordinary $GW$ approximation is recovered. By expanding the Bloch wave functions in a basis set of plane waves, $\psi_{n\mathbf{k}}(\mathbf{r}) = \sum_\mathbf{G} c_{n\mathbf{k}}(\mathbf{G}) e^{i(\mathbf{k}+\mathbf{G}) \cdot \mathbf{r}}$, the $GW$ self-energy $\Sigma^{GW}$ can be expressed in a form more suitable for first-principles calculations of crystalline solids (Aulbur et al. 2000):

$$\Sigma_{n\mathbf{k}}^{GW}(\omega) = \frac{i\hbar}{2\pi} \sum_{m\mathbf{G}\mathbf{G}'} \int \frac{d\mathbf{q}}{\Omega_{BZ}} M_\mathbf{G}^{mn}(\mathbf{k}, \mathbf{q})^* M_{\mathbf{G}'}^{mn}(\mathbf{k}, \mathbf{q}) \int d\omega' \frac{v_\mathbf{G}(\mathbf{q}) \varepsilon_{\mathbf{G},\mathbf{G}'}^{-1}(\mathbf{q}, \omega)}{\hbar\omega + \hbar\omega' - \tilde{\varepsilon}_{m\mathbf{k}+\mathbf{q}}},$$
$$\tag{6}$$

where $M_\mathbf{G}^{mn}(\mathbf{k}, \mathbf{q}) = \langle \psi_{m\mathbf{k}+\mathbf{q}} | e^{i(\mathbf{q}+\mathbf{G}) \cdot \mathbf{r}} | \psi_{n\mathbf{k}} \rangle$ are the optical matrix elements, $\Omega_{BZ}$ is the volume of the Brillouin zone, and $v_\mathbf{G}(\mathbf{q}) = e^2/\varepsilon_0 |\mathbf{q} + \mathbf{G}|^2$ ($\varepsilon 0$ is the vacuum permittivity). We defined $\tilde{\varepsilon}_{m\mathbf{k}+\mathbf{q}} = \varepsilon_{m\mathbf{k}+\mathbf{q}} - i\eta \, \text{sgn}(\varepsilon_{m\mathbf{k}+\mathbf{q}})$, with $\eta$ a positive infinitesimal and $\varepsilon_{m\mathbf{k}+\mathbf{q}}$ the Bloch electron energy relative to the chemical potential $\mu$. The dielectric matrix $\varepsilon_{\mathbf{G},\mathbf{G}'}(\mathbf{q}, \omega)$ is related to the screened Coulomb interaction via $W_{\mathbf{G},\mathbf{G}'}(\mathbf{q}, \omega) = v_\mathbf{G}(\mathbf{q}) \varepsilon_{\mathbf{G},\mathbf{G}'}^{-1}(\mathbf{q}, \omega)$. In $GW$ calculations, the dielectric function is typically expressed as $\varepsilon_{\mathbf{G},\mathbf{G}'}(\mathbf{q}, \omega) = \delta_{\mathbf{G},\mathbf{G}'} - v_\mathbf{G}(\mathbf{q}) \chi_{\mathbf{G},\mathbf{G}'}^0(\mathbf{q}, \omega)$, where $\chi_{\mathbf{G},\mathbf{G}'}^0$ is the independent-particle polarizability (see, e.g., Aulbur et al. 2000).

The second term in Eq. (5) represents the electron-phonon self-energy $\Sigma^{\text{ep}}$ in the Migdal approximation. Its expression in the basis of single-particle Bloch wave functions reads:

$$\Sigma_{n\mathbf{k}}^{\text{ep}}(\omega) = \sum_{m\nu} \int \frac{d\mathbf{q}}{\Omega_{\text{BZ}}} |g_{mn\nu}(\mathbf{k}, \mathbf{q})|^2 \times$$

$$\left[ \frac{n_{\mathbf{q}\nu} + f_{m\mathbf{k}+\mathbf{q}}}{\hbar\omega - \varepsilon_{m\mathbf{k}+\mathbf{q}} + \hbar\omega_{\mathbf{q}\nu} + i\eta} + \frac{n_{\mathbf{q}\nu} + 1 - f_{m\mathbf{k}+\mathbf{q}}}{\hbar\omega - \varepsilon_{m\mathbf{k}+\mathbf{q}} - \hbar\omega_{\mathbf{q}\nu} + i\eta} \right], \qquad (7)$$

where $n_{\mathbf{q}\nu}$ and $f_{m\mathbf{k}+\mathbf{q}}$ are the Bose-Einstein and Fermi-Dirac distributions, respectively. Equation (7) is derived after transforming the frequency integration in Eq. (5) into a Matsubara summation to extend the formalism to finite temperatures, and performing the integration analytically by using the expressions for the unperturbed electron and phonon Green's functions. The self-energy is then analytically continued to the real frequency axis (Mahan 2000), and only the diagonal terms are retained, as in Eq. (6). The electron-phonon matrix element $g$ is defined as:

$$g_{mn\nu}(\mathbf{k}, \mathbf{q}) = \langle \psi_{m\mathbf{k}+\mathbf{q}} | \Delta_{\mathbf{q}\nu} V_{\text{KS}} | \psi_{n\mathbf{k}} \rangle. \qquad (8)$$

and it contains the variation of the self-consistent Kohn-Sham (KS) (Kohn and Sham 1965) potential $V_{\text{KS}}$ with respect to a phonon perturbation. The umklapp processes are included by letting $\mathbf{k} + \mathbf{q}$ fall outside the first Brillouin zone and folding it back with a reciprocal lattice vector $\mathbf{G}$. The definition in Eq. (8) corresponds to taking the bare Coulomb potential between the electrons and the nuclei screened by the electronic dielectric function $\varepsilon_{\mathbf{G},\mathbf{G}'}(\mathbf{q}, \omega)$. In principle the matrix element should be frequency dependent; however in ab initio calculations, it is taken to be static, following the adiabatic approximation of standard density-functional theory (DFT). In Sect. 5 we will discuss how going beyond this approximation is needed when describing polarons in ARPES spectra. In practical calculations Eq. (8) is evaluated using density-functional perturbation theory (DFPT) by determining the linear variation of the self-consistent Kohn-Sham potential. A rigorous discussion of the calculation of the DFPT screening as compared to the many-body random-phase approximation (RPA) can be found, for example, in Marini et al. (2015).

## 3.1   The Electron Spectral Function

The calculation of the self-energies defined by Eqs. (6) and (7) constitutes the first step toward the description of satellites from first principles. Details regarding the numerical evaluation of these expressions have been thoroughly reported, for instance, in Marini et al. (2009) and Poncé et al. (2016) and will not be discussed here. Once the electron self-energy $\Sigma_{n\mathbf{k}}(\omega)$ is known, the spectral function is obtained by combining Eq. (2) with the Dyson's equation $G_{n\mathbf{k}} = [\hbar\omega - \varepsilon_{n\mathbf{k}} - \Sigma_{n\mathbf{k}}(\omega)]^{-1}$, which yields:

$$A(\mathbf{k}, \omega) = -\frac{1}{\pi} \sum_n \frac{\operatorname{Im} \Sigma_{n\mathbf{k}}(\omega)}{[\hbar\omega - \varepsilon_{n\mathbf{k}} - \operatorname{Re} \Sigma_{n\mathbf{k}}(\omega)]^2 + [\operatorname{Im} \Sigma_{n\mathbf{k}}(\omega)]^2} \tag{9}$$

The spectral function exhibits sharp peaks whenever the first term in the denominator of Eq. (9) $[\hbar\omega - \varepsilon_{n\mathbf{k}} - \operatorname{Re} \Sigma_{n\mathbf{k}}(\omega)]$ vanishes or has a minimum. In particular, quasiparticle peaks in the spectral function arise at the energies $\hbar\omega = \varepsilon_{n\mathbf{k}} + Z_{n\mathbf{k}} \operatorname{Re} \Sigma_{n\mathbf{k}}(\varepsilon_{n\mathbf{k}})$, where $Z_{n\mathbf{k}} = [1 - \partial \operatorname{Re} \Sigma_{n\mathbf{k}}(\omega)/\partial\omega|_{\omega=\varepsilon_{n\mathbf{k}}}]^{-1}$ is the quasiparticle weight. If the Bloch single-particle energies $\varepsilon_{n\mathbf{k}}$ are obtained from a DFT calculation, Eq. (9) should be modified to avoid double counting of the exchange-correlation (Aulbur et al. 2000).

A more suitable framework for the evaluation of satellites in photoemission is provided by the cumulant expansion approach. The cumulant expansion is an alternative formulation of the (retarded) single-particle Green's function which is in principle exact. The Green's function is expressed in the form (Gumhalter et al. 2016; Kas et al. 2014):

$$G_{n\mathbf{k}}(t) = i\theta(t)\exp[-i(\varepsilon_{n\mathbf{k}} - i\eta)t/\hbar + C_{n\mathbf{k}}(t)], \tag{10}$$

where we introduced the cumulant function $C_{n\mathbf{k}}(t)$ which is defined by:

$$C_{n\mathbf{k}}(t) = -\frac{1}{\hbar\pi} \int d\omega \operatorname{Im} \Sigma_{n\mathbf{k}}(\varepsilon_{n\mathbf{k}}/\hbar - \omega) \frac{1 - e^{i\omega t} + i\omega t}{\omega^2} \tag{11}$$

In practice, the spectral function obtained from Eqs. (2), (10), and (11) can be recast into a form that is more suitable for numerical calculations (Aryasetiawan et al. 1996; Aryasetiawan and Gunnarson 1998; Verdi et al. 2017):

$$A(\mathbf{k}, \omega) = \sum_n \left[ 1 + A_{n\mathbf{k}}^{S1}(\omega) * + \frac{1}{2} A_{n\mathbf{k}}^{S1}(\omega) * A_{n\mathbf{k}}^{S1}(\omega) * + \cdots \right] A_{n\mathbf{k}}^{QP}(\omega). \tag{12}$$

Here we introduced the following quantities:

$$A^{QP}(\omega) = \frac{e^{\operatorname{Re}\Sigma'(\varepsilon/\hbar)}}{\pi} \frac{|\operatorname{Im}\Sigma(\varepsilon/\hbar)|}{[\hbar\omega - \varepsilon - \operatorname{Re}\Sigma(\varepsilon/\hbar)]^2 + [\operatorname{Im}\Sigma(\varepsilon/\hbar)]^2},$$

$$A^{S1}(\omega) = -\frac{1}{\pi} \frac{\operatorname{Im}\Sigma(\varepsilon/\hbar + \omega) - \operatorname{Im}\Sigma(\varepsilon/\hbar) - \hbar\omega\operatorname{Im}\Sigma'(\varepsilon/\hbar)}{(\hbar\omega)^2},$$

where we omitted the dependence on $n$ and $\mathbf{k}$, and the prime symbol denotes the first derivative. In the limit of a localized electron interacting with a plasmon bath, one may show that Eq. (12) reduces to the exact solution of the localized electron model given by Eq. (4). The application of this formalism to core and valence excitations of crystalline solids, on the other hand, involves several approximations such as neglecting *recoil* effects, that is, the correlations between successive boson

emission and reabsorption events. A detailed discussion of the range of validity of the cumulant expansion has been reported, for instance, in Hedin (1980), Gumhalter et al. (2016), Kas et al. (2014), and Zhou et al. (2015).

As discussed by Holm and Aryasetiawan (1997), the cumulant expansion has the advantage of introducing additional crossing and non-crossing Feynman diagrams that are neglected in the standard $GW$ and Migdal approximation for the self-energy, and it results in an improved description of the electron-plasmon and electron-phonon interactions. The ab initio cumulant expansion approach is based on the evaluation of Eq. (12) employing either the $GW$ or Migdal self-energy. As discussed in Sect. 6, this formalism also lends itself to describe the formation of hybrid modes resulting from the combined effects of plasmons and phonons.

The self-consistent solution of the Dyson's equation could in principle provide an alternative route to include additional diagrams beyond the $GW$/Migdal approximation in the Green's function. However, while self-consistent $GW$ has been shown to systematically improve the description of the quasiparticle energies of molecules and solids (Caruso et al. 2013, 2016; Kutepov et al. 2012), the study of satellites has revealed that self-consistency leads to an unphysical renormalization of the satellite intensity which, ultimately, is expected to deteriorate the agreement with experiment (Holm and von Barth 1998). Additional first-principles investigations would be needed to further explore this aspect.

## 3.2   Plasmon Satellites

The concept of plasmons, collective fluctuations of the electron density, can be introduced based on a simple model of carrier dynamics for a homogeneous system (that is, a system characterized by a homogeneous electron density and a positively charged ionic background) in which the quantum-mechanical character of the electrons is ignored. If an external perturbation as, for example, a homogeneous electric field is present, a displacement $\mathbf{x}$ of the electron density with respect to the positively charged ionic background is induced. The displaced electron density then generates an induced polarization $\mathbf{P} = -ne\mathbf{x}$, where $n$ is the average electron density and $e$ the electron charge and an electric field $\mathbf{E} = -\mathbf{P}/\varepsilon_0$. Using Newton's law $m\ddot{\mathbf{x}} = -e\mathbf{E}$ with $m$ the electron mass, the classical equation of motion for the density displacement vector $\mathbf{x}$ may be rewritten as $\ddot{\mathbf{x}} + ne^2\mathbf{x}/(\varepsilon_0 m) = 0$. This model illustrates that the classical collective dynamics of electrons in solids can be approximately described by a harmonic oscillator with a characteristic frequency $\omega_P = \sqrt{ne^2/(\varepsilon_0 m)}$, the plasma frequency, which is independent of the perturbation and is determined exclusively by the intrinsic properties of the solid.

More generally, plasmons in solids may be excited at momenta $\mathbf{q}$ and frequencies $\omega_P$ which correspond to vanishing real part of the macroscopic dielectric function $\varepsilon_M$ and sufficiently small imaginary part, that is:

$$\varepsilon_M(\mathbf{q}, \omega_P) = i\eta, \tag{13}$$
**Fig. 2** The loss function of the HEG for a Wigner-Seitz radius $r_s = 4$. The plasmonic structures in the loss function follow a characteristic parabolic dispersion which, for momenta smaller than a critical momentum $q_c$, is well separated from the continuum of electron-hole excitations (e-h). For $q > q_c$, the plasmons are damped by the interaction with electron-hole pairs (Landau damping)

The macroscopic dielectric function $\varepsilon_M$ is related to the microscopic dielectric function $\varepsilon$ via $\varepsilon_M^{-1}(\mathbf{q}, \omega) = [\varepsilon_{\mathbf{G},\mathbf{G'}}(\mathbf{q}, \omega)]_{\mathbf{G}=\mathbf{G'}=0}^{-1}$, with $\mathbf{G}$ and $\mathbf{G'}$ reciprocal lattice vectors and $\mathbf{q}$ in the first Brillouin zone. Whenever the condition expressed by Eq. (13) is satisfied, the system may support collective charge fluctuations even in the absence of an external driving field. In practice, the possibility of exciting plasmons is reflected by the emergence of sharp peaks in the loss function $L(\mathbf{q}, \omega) = \text{Im}\,[\varepsilon_M^{-1}(\mathbf{q}, \omega)]$ at the momenta and frequencies at which the macroscopic dielectric function $\varepsilon_M$ vanishes. The plasmon peaks in the loss function exhibit well-defined energy-momentum dispersion relations. These structures are exemplified in Fig. 2 for the loss function of the homogeneous electron gas (HEG). If one neglects local-field effects and thus assumes that the macroscopic and microscopic dielectric functions coincide, the plasmon energy is obtained by seeking the frequencies that satisfy the condition $v(\mathbf{q})^{-1} = \text{Re}\,\chi_0(\mathbf{q}, \omega)$. For the HEG in the long-wavelength limit ($\mathbf{q} \to 0$), this condition yields again the result $\omega_P = \sqrt{e^2 n/(\varepsilon_0 m)}$.

The inspection of Eqs. (13) and (6) reveals that when the condition for the excitation of plasmons is satisfied, the screened Coulomb interaction $W_{\mathbf{G},\mathbf{G'}}(\mathbf{q}, \omega) = v_{\mathbf{G}}(\mathbf{q})[\varepsilon_{\mathbf{G},\mathbf{G'}}(\mathbf{q}, \omega)]^{-1}$ exhibits a pole at the plasmon energy. Correspondingly, one expects the $GW$ self-energy to encode information regarding electron-plasmon interaction.

To examine in more detail the inclusion of electron-plasmon coupling effects in the $GW$ self-energy, we discuss below its connection with the electron-boson coupling model introduced in Sect. 2. Using the condition given in Eq. (13) in combination with Eq. (6), the plasmonic contribution to the screened Coulomb interaction $W$ can be disentangled from the other electronic contributions to the screening, such as electron-hole pairs. This idea, initially introduced for the homogeneous electron gas (Lundqvist 1967) and subsequently generalized to semiconductors (Caruso and Giustino 2016), allows one to define a self-energy

which stems exclusively from the coupling between electrons and plasmons. The resulting electron-plasmon self-energy can be recast into the following form (Caruso and Giustino 2016):

$$
\Sigma_{n\mathbf{k}}^{\mathrm{eP}} = \int \frac{d\mathbf{q}}{\Omega_{\mathrm{BZ}}} \sum_m |g_{mn}^{\mathrm{eP}}(\mathbf{k}, \mathbf{q})|^2
$$

$$
\times \left[ \frac{n_\mathbf{q} + f_{m\mathbf{k}+\mathbf{q}}}{\varepsilon_{n\mathbf{k}} - \varepsilon_{m\mathbf{k}+\mathbf{q}} + \hbar\omega_\mathrm{P}(\mathbf{q}) + i\eta} + \frac{n_\mathbf{q} + 1 - f_{m\mathbf{k}+\mathbf{q}}}{\varepsilon_{n\mathbf{k}} - \varepsilon_{m\mathbf{k}+\mathbf{q}} - \hbar\omega_\mathrm{P}(\mathbf{q}) + i\eta} \right],
\tag{14}
$$

where the coefficients $g_{mn}^{\mathrm{eP}}(\mathbf{k}, \mathbf{q})$ are the electron-plasmon scattering matrix elements between the initial state $\psi_{n\mathbf{k}}$ and the final state $\psi_{m\mathbf{k}+\mathbf{q}}$ and are given by:

$$
g_{mn}^{\mathrm{eP}}(\mathbf{k}, \mathbf{q}) = \left[ \frac{\varepsilon_0 \Omega}{e^2 \hbar} \frac{\partial \varepsilon(\mathbf{q}, \omega)}{\partial \omega} \right]_{\omega_\mathrm{P}(\mathbf{q})}^{-\frac{1}{2}} \frac{1}{|\mathbf{q}|} \langle \psi_{m\mathbf{k}+\mathbf{q}} | e^{i\mathbf{q}\cdot\mathbf{r}} | \psi_{n\mathbf{k}} \rangle,
\tag{15}
$$

with $\Omega$ being the volume of the unit cell. Equation (14) has the form of an electron-boson coupling self-energy in the Migdal approximation (see Eq. (7)), which may alternatively be derived from an electron-boson coupling Hamiltonian of the form:

$$
\hat{H}^{\mathrm{eP}} = \sum_{nm} \sum_{\mathbf{k}, \mathbf{q}} g_{nm}^{\mathrm{eP}}(\mathbf{k}, \mathbf{q}) \hat{c}_{m\mathbf{k}+\mathbf{q}}^\dagger \hat{c}_{n\mathbf{k}} (\hat{b}_\mathbf{q} + \hat{b}_{-\mathbf{q}}^\dagger).
\tag{16}
$$

Here $\hat{b}_{-\mathbf{q}}^\dagger$ ($\hat{b}_\mathbf{q}$) and $\hat{c}_{m\mathbf{k}+\mathbf{q}}^\dagger$ ($\hat{c}_{n\mathbf{k}}$) are the boson and fermion creation (destruction) operators, respectively. The localized electron model of Eq. (1) is recovered from Eq. (16) by (i) replacing the Bloch energies $\varepsilon_{n\mathbf{k}}$ with a single nondispersive energy and (ii) neglecting the $\mathbf{k}$-dependence of the electron-boson coupling matrix elements. This result indicates that the $GW$ self-energy accounts for the coupling between electrons and plasmons. However, at variance with the localized electron model which could be solved exactly, here the electron-plasmon interaction is treated only at first-order in the interaction strength, which corresponds to the Migdal approximation in the ordinary electron-boson coupling theory.

The inclusion of electron-plasmon coupling in the $GW$ theory is reflected by the emergence of plasmon satellites in the spectral function, which are analogous to the satellite features discussed in Sect. 2. In fact, in the presence of plasmons, the frequency dependence of the self-energy typically presents a pole, which may produce additional satellite structures in the spectral function signaling the coupling to plasmons.

Two clear shortcomings emerge when evaluating the spectral function within the $GW$ approximation and limit its predictive power for the description of satellites in PES: (i) the energy difference between the satellite and the quasiparticle peak is typically overestimated by a factor of 1.5 with respect to photoemission experiments, and (ii) the $GW$ approximation may erroneously predict the formation of
**Fig. 3** Spectral function for a model self-energy in the strong (**a**) and weak (**b**) coupling regime. Quasiparticle peaks are marked by vertical dashed lines and correspond to the intersection between $\mathrm{Re}\,\Sigma(\omega)$ and $\hbar\omega - \varepsilon$

spurious *plasmaron* peaks, which stem from additional solutions of the quasiparticle equation and often result in an overestimation of satellite intensities. The concept of plasmaron was initially introduced by Lundqvist (1967) as a new quasiparticle state emerging from the strong coupling between electrons and plasmons. Later studies, however, revealed that plasmaron peaks are an artifact of the $GW$ approximation and, in fact, they disappear when one resorts to a more accurate level of theory (Langreth 1970). These issues can be illustrated by using a simplified model for the $GW$ self-energy: $\Sigma(\omega) = \alpha(\hbar\omega - \varepsilon + \omega_P + i\eta)^{-1}$. This expression is derived from Eq. (6) by (i) assuming nondispersive electron energies, (ii) replacing the oscillator strengths by $\delta$ functions, (iii) using a plasmon-pole model for the dielectric function in the form $\varepsilon^{-1}(\omega) = 1 + \tilde{\omega}/(\omega^2 - \omega_P^2 + i\eta)$, and (iv) carrying out the frequency integration analytically. As shown in Fig. 3, the self-energy exhibits a pole at frequencies around $\omega = \hbar^{-1}(\varepsilon - \hbar\omega_P)$, which may lead to additional unphysical solutions of the quasiparticle equation when $\hbar\omega - \varepsilon = Re\,\Sigma(\omega)$ as shown in panel (a) or to a minimum in $\hbar\omega - \varepsilon - Re\,\Sigma(\omega)$ resulting in a weak satellite, as shown in panel (b). In both cases the spectral function is characterized by the emergence of satellites; however their binding energy is blue-shifted with respect to the energy $\varepsilon - \hbar\omega_P$ at which satellites are typically observed in PES experiment. As we will discuss in Sect. 4, the combination of the $GW$ approximation with the cumulant expansion approach ($GW$+C) allows to successfully address these issues and recover an energy separation between satellite and quasiparticle peaks that agrees well with PES measurements for a broad class of materials.

## 3.3   Polaron Satellites

Similarly to the case of the interaction with plasmons, the coupling between electrons and phonons may give rise to satellite structures in the spectral function of semiconductors and insulators, which are the signature of the dressing of the electronic quasiparticles as *polarons*. The formation of polarons is typically linked

to the polarization of the lattice induced by longitudinal optical (LO) phonons. In other words, in polar semiconductors and insulators, the fluctuations of the ionic positions corresponding to LO phonons at long wavelength generate macroscopic electric fields which can couple strongly to electrons and holes. This long-range interaction is known as Fröhlich coupling. The Fröhlich model strictly describes the interaction of a conduction electron in a parabolic band with LO phonons of constant energy $\hbar\omega_{LO}$, in an isotropic and uniform medium (Fröhlich 1954). Under these assumptions, the electron-phonon matrix element does not depend on the band index and electron momentum, and it takes the form:

$$g_F(\mathbf{q}) = \frac{i}{|\mathbf{q}|} \left[ \frac{e^2}{4\pi\varepsilon_0} \frac{4\pi}{\Omega} \frac{\hbar\omega_{LO}}{2} \left( \frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_s} \right) \right]^{1/2}, \tag{17}$$

where $\varepsilon_s$ is the total static permittivity (or dielectric constant) and $\varepsilon_\infty$ is the optical dielectric constant, that is, $\varepsilon_M(\mathbf{q} = 0, \omega = 0)$. The matrix element in Eq. (17) is often expressed in terms of a dimensionless parameter $\alpha$ which is referred to as the *Fröhlich coupling constant*:

$$\alpha = \frac{e^2}{\hbar} \left( \frac{m_b}{2\hbar\omega_{LO}} \right)^{1/2} \left( \frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0} \right), \tag{18}$$

with $m_b$ the band effective mass of the conduction electron. The Fröhlich Hamiltonian has the form in Eq. (16) after substituting $g_{mn}^{eP}$ with $g_F\delta_{mn}$, and it is thus historically representative of the general problem of a fermionic particle interacting with a boson field. Depending on the value of $\alpha$, i.e., on the strength of the coupling, the Fröhlich self-energy produces a spectral function that usually exhibits satellite replica of the main quasiparticle band.

First-principles calculations of electron-phonon self-energies and ARPES spectra to capture polaronic effects are limited by the almost prohibitive computational cost of sampling the singular behavior of the matrix elements for small phonon wavevectors. A procedure that enables accurate calculations of the electron-phonon coupling in the presence of Fröhlich interaction at a reduced computational cost has been reported by Verdi and Giustino (2015) and Sjakste et al. (2015). This is achieved via the separation of the long-range, singular part of the electron-phonon matrix element and of the short-range part. The long-range part $g^{\mathcal{L}}$ constitutes the generalization of the Fröhlich matrix element to multiple, anisotropic electronic bands and phonon modes and reads:

$$g_{mn\nu}^{\mathcal{L}}(\mathbf{k}, \mathbf{q}) = i \frac{4\pi e^2}{\Omega} \sum_\kappa \left( \frac{\hbar}{2M_\kappa\omega_{\mathbf{q}\nu}} \right)^{1/2}$$
$$\times \sum_{\mathbf{G}, \mathbf{q}+\mathbf{G}\neq 0} \frac{(\mathbf{q}+\mathbf{G}) \cdot \mathbf{Z}_\kappa^* \cdot \mathbf{e}_{\kappa\nu}(\mathbf{q})}{(\mathbf{q}+\mathbf{G}) \cdot \boldsymbol{\varepsilon}_\infty \cdot (\mathbf{q}+\mathbf{G})} \langle \psi_{m\mathbf{k}+\mathbf{q}} | e^{i(\mathbf{q}+\mathbf{G}) \cdot (\mathbf{r}-\tau_\kappa^0)} | \psi_{n\mathbf{k}} \rangle, \tag{19}$$

where $\mathbf{Z}_\kappa^*$ is the Born effective charge tensor of atom $\kappa$ in the unit cell, $M_\kappa$ the atomic mass, and $\mathbf{e}_{\kappa\nu}(\mathbf{q})$ a phonon eigenvector. If combined with the Wannier-Fourier interpolation technique of Giustino et al. (2007), Eq. (19) enables accurate calculations of polaron satellites.

As in the case of the $GW$ method, the calculation of the spectral function including electron-phonon coupling in the Migdal approximation suffers from two main shortcomings. First, it produces only a single polaronic satellite rather than a Lang-Firsov series as shown by the model of Eqs. (1) and (4) and as measured in experiments. Second, its energy separation from the main quasiparticle peak is larger than the characteristic LO phonon energy. As we will illustrate in Sect. 4 and 5, the cumulant expansion method can successfully be employed to improve the description of satellites. While this method has been mostly used in combination with the $GW$ approximation to study plasmon satellites, it can also naturally be applied in the context of polaronic systems, since the theory stems from the exact solution of an electron-boson coupling Hamiltonian of the Fröhlich type (Langreth 1970; Story et al. 2014). The formalism corresponds to the one presented in Sect. 3.1, with the Migdal electron-phonon self-energy used as a seed.

## 4    Plasmon Satellites in Metals and Semiconductors

First-principles calculations of plasmon satellites based on the $GW$+C approach have first been performed by Aryasetiawan et al. (1996) for metallic sodium and aluminum. The integrated photoemission spectroscopy experiment on sodium by Steiner et al. (1979) revealed, besides a quasiparticle peak centered at a binding energy of 1 eV which corresponds to the excitation of photo-holes in the valence band, two broader and less intense satellite peaks blue-shifted with respect to the quasiparticle peak by 6 and 12 eV respectively. These energies are compatible with multiples of the plasma energy of sodium $\hbar\omega_\mathrm{P} \simeq 5.9$ eV, suggesting that the satellites arise from the excitation of one and two plasmons. At variance with the $GW$ results, which overestimate the energy and intensity of the satellites, the spectral function of Na obtained from the $GW$+C approach and shown in Fig. 4a improves significantly the agreement with the experiment. Additionally, the $GW$+C approach lends itself to describe also processes in which more than one plasmon are excited and captures the emergence of a series of satellite peaks spaced by the plasmon energy. On the other hand, only one satellite is obtained within the $GW$ approximation, reflecting the fact that multi-plasmon processes are neglected.

Subsequently, photoemission satellites have been measured in the photoemission spectra of graphene, and the identification of these features has been supported by theoretical calculations of the self-energy and spectral function for linearly dispersive bands (Bostwick et al. 2010). Satellites in semiconductors have first been investigated from first principles by Guzzo et al. (2011) for the case of silicon. In analogy with metals, also photoemission measurements of semiconductors may exhibit a series of satellites (Fig. 4b) with an energy separation that is compatible with the plasma energy. In this case, however, plasmons are generally characterized
**Fig. 4**   (**a**) Cumulant expansion for Na. (**b**) Cumulant expansion for silicon (Reproduced with permission from Aryasetiawan et al. 1996 and Guzzo et al. 2011)

by a smaller oscillator strength, which is reflected by the lower intensity of the satellite peaks. For silicon, the $GW$ approximation yields a single satellite blue-shifted by $\sim$22 eV with respect to the quasiparticle peak, which is incompatible with the plasma energy $\hbar\omega_P = 16.6$ eV and with the experimental observations. On the other hand, when vertex corrections are included via the $GW$+C approach, the energy of the plasmon satellite peak is in good agreement with experiment. Some discrepancies between theory and experiment still remain, namely, (i) the intensity of the satellite peak is underestimated, (ii) the relative intensity between the different substructures of the quasiparticle peak differs from the experimental result, and (iii) experiments present a featureless background signal that increases with the electron binding energy and that is not captured by theory. The points (i)–(iii) are directly related to the interpretation of the spectral function as a photoelectron current, an approximation that is typically referred to as *sudden approximation* (Hüfner 2003; Damascelli et al. 2003). In practice, the sudden approximation assumes that all electrons are equally likely to interact with an incoming photon and that after photoexcitation the electrons do not interact further with the sample. These assumptions neglect the scattering cross-section effects due to the different orbital symmetries and the additional energy losses that photo-electrons may undergo after emission from the initial state. The issues mentioned in (i)–(iii) could be improved by adopting a picture of the photoemission process that goes beyond the sudden approximation, e.g., by explicitly accounting for extrinsic losses, background signal, and cross-section effects. In this way, a quantitatively accurate description of satellites in semiconductors may be achieved (Guzzo et al. 2012).

Inspection of the first satellite peak in Fig. 4b indicates that the plasmon-induced spectral features of silicon are characterized by a substructure – in this case a central peak and two shoulders observed in both theory and experiments – that resembles the density of states (DOS) of the ordinary quasiparticle bands. To understand the origin of these features, it is convenient to recall the concept of Van Hove singularities from the quantum theory of solids. The density of states $J$ for a set of Bloch electrons can be expressed as:

$$J(\omega) = \frac{1}{4\pi^3} \sum_n \int_{S(\hbar\omega)} dS_{\mathbf{k}} \frac{1}{|\nabla_{\mathbf{k}}\varepsilon_{n\mathbf{k}}|} \tag{20}$$

where the integral is performed over the isosurfaces in $\mathbf{k}$-space with energy $\hbar\omega$, denoted by $S(\hbar\omega)$. If for a given energy $\hbar\omega$, the isosurface $S(\hbar\omega)$ contains a crystal momentum for which the electron velocity vanishes ($v_{n\mathbf{k}} = \nabla_{\mathbf{k}}\varepsilon_{n\mathbf{k}}/\hbar = 0$), the divergence of the integrand in Eq. (20) leads to a sharp structure in $J(\omega)$, referred to as a Van Hove singularity. Peaks in the DOS may thus be attributed to regions of the Brillouin zone in which electronic bands are flat ($\nabla_{\mathbf{k}}\varepsilon_{n\mathbf{k}} \simeq 0$). These structures are clearly visible in PES experiments of silicon for binding energies between 0 and $-15$ eV (Fig. 5b) and in the DOS obtained from DFT calculations in the local density approximation (Fig. 5c). The structure of plasmon satellites measured in PES also exhibits a substructure of peaks and shoulders that resembles the Van Hove singularities, as it can be noted when comparing it with the DOS of the ordinary quasiparticle bands red-shifted by the plasmon energy (Fig. 5b–c). This suggests

**Fig. 5** (**a**) Theoretical calculations of the plasmonic polaron band of silicon, based on the $GW$ plus cumulant expansion approach. (Adapted from Gumhalter et al. 2016). (**b**) Integrated X-ray photoemission spectrum (XPS) of silicon from Guzzo et al. (2011). (**c**) Density of states of silicon from a density-functional theory calculation alongside with a replica of the full DOS red-shifted by the plasmon energy $\hbar\omega_P = 16.6$ eV

that the plasmon satellites observed in integrated PES also stem from the average over the Brillouin zone of spectral features that are characterized by well-defined energy-momentum dispersion relations.

This hypothesis has been verified by first-principles calculations of the angle-resolved spectral function of silicon in the $GW$+C approach (Caruso et al. 2015), which revealed that electron-plasmon interaction leads to the emergence of *plasmonic polaron bands*, that is, plasmon-induced replica of the valence band structure of semiconductors red-shifted by the plasmon energies. These features are illustrated for silicon in Fig. 5a. As compared to the quasiparticle bands, plasmonic polaron bands are less intense due to the small oscillator strength of plasmon in semiconductors and broadened out by lifetime effects. The existence of plasmonic polaron bands has been corroborated by further theoretical and experimental investigations of the ARPES spectrum of silicon for binding energies up to 40 eV by Lischner et al. (2015). Overall, the dispersive character of plasmon-induced features in ARPES indicates that plasmon satellites in integrated PES may be interpreted as Van Hove singularities which arise from the flattening of the plasmonic polaron bands at specific regions in the Brillouin zone.

## 5    Polaron Satellites in Doped Semiconductors

Low-energy satellites have recently been observed by ARPES experiments in doped oxides. These systems constitute an ideal playground for the study of polaron physics. In particular, satellite replicas were measured for $n$-doped $TiO_2$ (Moser et al. 2013), $SrTiO_3$ (Chang et al. 2010), and monolayer FeSe on $SrTiO_3$ (Lee et al. 2014). Evidence of Fröhlich polarons was found also from the investigation of two-dimensional (2D) electronic states at the surfaces or interfaces of oxides, with the most studied case being the 2D electron gas (2DEG) formed at the surface of $SrTiO_3$ (King et al. 2014; Chen et al. 2015; Wang et al. 2016). Other notable examples are the 2DEG at the interface between $SrTiO_3$ and $LaAlO_3$ (Cancellieri et al. 2016) and on the surface of ZnO (Yukawa et al. 2016). The experiments also show a remarkable evolution of the carriers with doping concentration, from polarons to a Fermi liquid weakly coupled to phonons (Moser et al. 2013; Wang et al. 2016).

Calculations of the spectral function using model self-energies or the localized electron model of Eq. (4) have been performed for some of these systems, for example, in Moser et al. (2013), Lee et al. (2014), King et al. (2014), and Rademaker et al. (2016). Fully *ab initio* calculations showing satellite band replica were first reported for the insulating compounds MgO and LiF by Antonius et al. (2015), subsequently exploring also the effect of the cumulant expansion method (Nery et al. 2018). First-principles calculations of ARPES spectra in doped materials including polaronic effects were carried out by Verdi et al. (2017) for the prototypical case of anatase $TiO_2$ by using the methods presented in Sect. 3. Given that the crystals are doped, an important element that needs to be taken into account when performing *ab initio* calculations is the presence of additional charges in the conduction band. Since the systems of interest are degenerate and present well-

defined Fermi surfaces, doping can be treated in the rigid-band approximation, that is, by placing the Fermi level inside the conduction or valence band of the pristine system. Moreover, the added carriers provide an additional source of screening of the electron-phonon interactions. This effect is critical especially in the case of polar coupling, where the screening of the macroscopic electric field created by the LO phonons can change dramatically the strength of the Fröhlich interaction (Mahan 2000). This aspect can be understood by considering the simple Thomas-Fermi screening model, which describes the static response of a homogeneous electron gas at small wavevectors: $\varepsilon_{\mathrm{TF}}(\mathbf{q}) = 1 + q_{\mathrm{TF}}^2/|\mathbf{q}|^2$, with $q_{\mathrm{TF}} = \sqrt{2e^2 n/(\varepsilon_0 \varepsilon_\infty E_{\mathrm{F}})}$ ($E_{\mathrm{F}}$ is the Fermi energy). From the wavevector dependence of $\varepsilon_{\mathrm{TF}}(\mathbf{q})$, it follows immediately that the screened matrix element, $g_{\mathrm{F}}(\mathbf{q})/\varepsilon_{\mathrm{TF}}(\mathbf{q})$, no longer exhibits a singularity at long wavelength. This model is valid in the adiabatic limit where the doped carriers instantaneously follow the atomic motion. In a more accurate description, the timescale of the electronic response is dictated by the plasma frequency of the doped carriers, $\omega_{\mathrm{P}} = \sqrt{ne^2/(\varepsilon_0 \varepsilon_\infty m_{\mathrm{b}})}$ in the HEG model (Kittel 1976).

To capture the evolution of the electron-phonon coupling and of the polaronic features with doping, the electron-phonon matrix element needs to be screened by the dynamical dielectric function evaluated at the phonon energies, that is, $g_{mn\nu}^{\mathrm{NA}}(\mathbf{k}, \mathbf{q}) = g_{mn\nu}(\mathbf{k}, \mathbf{q})/\varepsilon_{\mathrm{RPA}}(\mathbf{q}, \omega_{\mathbf{q}\nu} + i/\tau_{n\mathbf{k}})$ (Mahan 2000; Verdi et al. 2017). The superscript NA indicates that retardation effects are taken into account by using this non-adiabatic matrix element, and $\hbar/\tau_{n\mathbf{k}}$ is the electron lifetime near the band edge, which can approximately be taken to be constant. In practical calculations the dynamical screening arising from the doped carriers can be computed analytically using the RPA dielectric function for a homogeneous electron gas with the same density $n$, which is known as the Lindhard function (Hedin 1965).

In Fig. 6 we show the ARPES spectra acquired for $n$-doped anatase $TiO_2$ by Moser et al. (2013), and we compare them with the first-principles calculations performed by Verdi et al. (2017). The spectra for the first two doping levels exhibit a satellite about 0.1 eV below the main parabolic band and a second very dim satellite at another 0.1 eV higher binding energy. Since the energy separation of the band replica is compatible with the high-energy $E_u$ LO phonon of anatase $TiO_2$, these satellites were attributed to polaronic effects. At the highest doping, on the other hand, the satellites disappear and are replaced by band structure kinks near a binding energy of 0.1 eV. All the spectral features and their evolution with doping are reproduced by the calculations, thus confirming the transition from a polaronic to a Fermi liquid picture and demonstrating the success of the first-principles methods used to investigate quasiparticle spectra. From the calculated ARPES spectra, the electron-phonon coupling strength $\lambda$ was extracted, by using the ratio between the Fermi velocities of the bare band and of the dressed band (Mahan 2000). The results are reported in Fig. 7, together with an analysis of the energy scales at play. The study showed that the crossover from polarons to a weakly coupled Fermi liquid and, correspondingly, from satellite replica to band structure kinks occurs when the plasma frequency of the carriers becomes of the order of the LO phonon frequency. In fact, in the polaronic regime, corresponding to $\omega_{\mathrm{P}} < \omega_{\mathrm{LO}}$, the carriers
**Fig. 6** ARPES spectra of *n*-doped anatase $TiO_2$ on samples with doping concentrations $5 \times 10^{18}$ cm$^{-3}$ (**a**), $3 \times 10^{19}$ cm$^{-3}$ (**b**), and $3.5 \times 10^{20}$ cm$^{-3}$. (Taken from Moser et al. 2013). The corresponding first-principles spectra from Verdi et al. (2017) are shown in panels (**d**)–(**f**). The calculated spectral functions were multiplied by the Fermi-Dirac distribution at the experimental temperature ($T = 20$ K) and were convoluted with Gaussian masks of widths 25 meV and 0.015 Å$^{-1}$ in order to account for the experimental resolution in energy and momentum, respectively

are too slow to screen the long-range electric field generated by the $E_u$ phonon vibrations. In this case satellites appear in the spectra, and the electron-phonon coupling strength is approximately independent of doping. When $\omega_P > \omega_{LO}$, in the Fermi liquid regime, the Fröhlich coupling is strongly suppressed, with the polaron satellites gradually replaced by kinks. Correspondingly, the coupling strength decreases. This first-principles analysis indicated that the interplay between lattice vibrations and plasma oscillations can have a strong impact on the polaronic properties of charge carriers in doped oxides.

**Fig. 7** Polaronic and Fermi liquid regimes in $n$-doped anatase $TiO_2$, from Verdi et al. (2017): the red disks indicate the plasma energy at each doping level; the blue disks indicate the electron-phonon coupling strength $\lambda$. The blue line is a guide to the eye, while the red line represents the relation between the plasma energy and the doping density in the homogeneous electron gas. The horizontal line is the energy of the LO $E_u$ phonon of anatase $TiO_2$, 109 meV

## 6      Hybrid Plasmon-Phonon Satellites

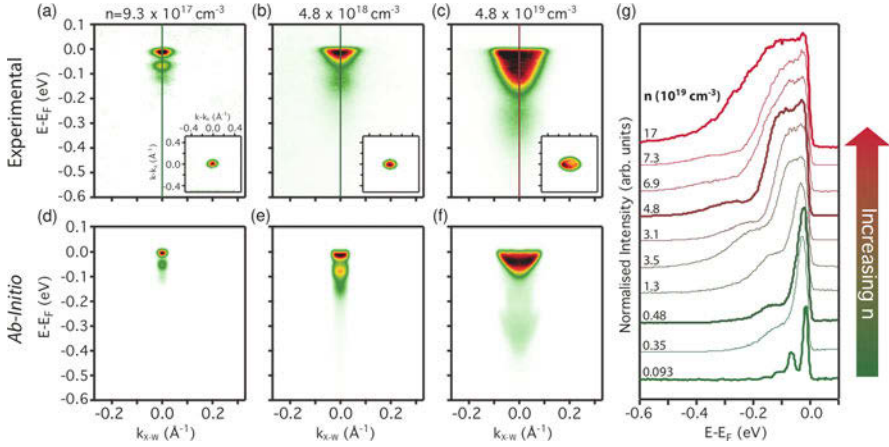
Interestingly, the effects of electron-phonon and electron-plasmon interactions can be readily combined within first-principles calculations if the sum of the relative self-energies (Eqs. (7) and (14)) is included in the calculation of the spectral function, which can thus contain both plasmon and polaron satellite features. This concurrence of plasmon and polaron satellites has been observed experimentally in the case of the ferromagnetic semiconductor EuO and confirmed by first principles calculations (Riley et al. 2018). Experimental ARPES spectra for Gd-doped EuO are reported in Fig. 8a–c for three different doping concentrations, showing the bottom of the conduction band centered at the X point of the Brillouin zone. The energy distribution curves (EDCs) at the conduction band minimum for several dopings are reproduced in Fig. 8g, and they clearly show a shoulder peak whose energy separation with respect to the main quasiparticle band increases with carrier concentration. Such a satellite peak is not resolved above a carrier density $n \approx 10^{20}$ cm$^{-3}$, whereas at low carrier concentration ($n \approx 10^{18}$ cm$^{-3}$) two additional satellites can be distinguished. The spectra calculated with the cumulant expansion method including electron-phonon and electron-plasmon coupling on the same footing are presented in Fig. 8d–f, and they reproduce the features seen in the experiment. In particular, the calculations confirmed that for the lowest doping concentration the series of satellites is mainly due to phonon excitations, with the LO phonon energy of EuO being compatible with the peak separation energy of about 56 meV. Moving to higher dopings, the polar electron-phonon coupling is gradually suppressed by the free-carrier screening, and the satellite peak shifts to higher binding energies. Since the plasma energy increases as the square root of the carrier density, this finding constitutes a fingerprint of the coupling of electrons to plasmonic excitations of the conduction electrons. The first-principles calculations confirmed that the renormalization of the spectral properties at higher dopings is


**Fig. 8** (**a**)–(**c**) Measured ARPES spectra of EuO samples with increasing carrier concentrations as indicated on top of each panel, with the Fermi surface contours shown in the insets. The corresponding first-principles data are shown in (**d**)–(**f**). To directly compare with the experiments, the calculated spectral functions were convoluted with two Gaussian masks of widths 20 meV and 0.015 Å$^{-1}$, and integrated along the out-of-plane direction $k_z$. (**g**) Measured energy distribution curves taken at $k = k_X$ (conduction band minimum) for different doping levels. (Figure adapted from Riley et al. 2018)

due to the interplay between electron-phonon and electron-plasmon coupling, and that in particular the low-energy broad satellite seen in Fig. 8c, f is due to plasmonic excitations (Riley et al. 2018).

We remark that the calculations and methods presented so far neglect the effects of mutual renormalization between plasmon and phonon modes, which can arise when the frequency of plasmon and phonon oscillations are of the same order (Varga 1965; Settnes et al. 2017). The inclusion of these effects entirely from first principles represents one of the challenges still open in the investigation of the spectral properties of doped systems.

## 7    Conclusions

The emergence of satellites in photoemission spectroscopy is a universal manifestation of electron-boson interactions in solids. The origin of satellites can be ascribed to the excitation of different types of bosonic modes such as valence plasmons, extrinsic plasmons, or polar phonons. These spectral features have thus far been observed in metals, semiconductors, and highly-doped oxides. Despite the diversity of the physical processes that underpin the satellite formation, and the broad energy scales (from 50–100 meV up to 15–20 eV), many-body perturbation theory provides a unified framework for their description. In combination with standard approximations for the electron-electron and electron-phonon self-energies, the

cumulant expansion approach is a powerful tool for investigating the emergence of spectral fingerprint of electron-boson coupling in solids.

The study of satellites in solids has thus far provided valuable insight into the many-body interactions between electrons, plasmons, and phonons. Recent work in this area has demonstrated that first-principles techniques have reached an accuracy sufficient to even precede experiments in discovering new hallmarks of the coupling between electrons and bosons. The emergence of satellites in photoemission spectroscopy is just one facet of the many effects that electron-boson interaction may induce. The recent findings discussed in this chapter call for a systematic investigation of the influence of low-energy plasmons on the formation of photoemission kinks, waterfall effects, as well as novel mechanisms of superconductive pairing. Furthermore, other spectroscopic techniques, such as absorption, electron energy loss, or time-resolved spectroscopies, provide less explored tools for investigating the coupling between electrons, plasmons, and phonons. Highly doped oxides constitute a particularly exciting playground for exploring the influence of these phenomena on the optoelectronic properties and possible opportunities for exploiting these new emergent properties. In these compounds, the interplay of carriers, extrinsic plasmons, and polar phonons induces complex spectral features that reflect the simultaneous excitation of plasmon and phonon modes and that are highly tunable via the carrier concentration.

In conclusion, the last few years have witnessed a remarkable increase in the accuracy of theoretical techniques for the description of the excited-state phenomena from first principles. These advances, alongside with a relentless increase in experimental resolution, are contributing to strengthen the synergy between theoretical and experimental research, providing numerous opportunities to unveil and understand unexplored forms of fermion-boson coupling in quantum matter.

# Non-equilibrium Green's Functions for Coupled Fermion-Boson Systems

**17**

Daniel Karlsson  and Robert van Leeuwen

## Contents

### Abstract

In this book section, we give a brief introduction to many-body perturbation theory for coupled fermion-boson systems using non-equilibrium Green's functions. Using the language of modern many-body perturbation theory and the so-called contour-ordered correlators, a single consistent formalism arises which can be applied to a multitude of classes of systems.

# 1    Introduction

The many-body problem is at the heart of the field of condensed matter physics. While the Schrödinger equation is impossible to solve except for the smallest of systems, condensed matter physics deal with the whole spectrum of few-body to many-body physics. This makes it difficult to consider the many-body wave function as a useful object.

Another different route is to try to lower one's ambitions. While the wave function gives access to all measurable observables in a system, including high-order correlation functions, experimentally one is most often interested in low-order correlation functions such as one-particle correlation functions (e.g., particle densities and electric currents) or two-particle correlation functions (e.g., polarizabilities and magnetic susceptibilities). As such, it has been useful to concentrate on obtaining approximate expressions for reduced objects.

Non-equilibrium Green's functions (NEGF) offer one such route. The one-particle Green's function contains all information about one-particle observables, and similarly higher-order Green's functions contain information on higher-order correlators. The complexity of these objects is much lower than for the full wave function, and powerful diagrammatic techniques for calculating the Green's function as a perturbation series are available. Moreover, the NEGF formalism unlocks the door to out-of-equilibrium physics, such as transient effects in quantum transport and pump-probe spectroscopy.

There is plenty of literature concerning different types of electron-boson interactions treated within many-body perturbation theory in (e.g., Fetter and Walecka 2003; Bruus and Flensberg 2004) and out (e.g., Henneberger et al. 2000; Bonitz 2016) of equilibrium. The theoretical structure for different kind of bosons is very similar, as also stressed in Schüler et al. (2016), where quantized photons, phonons, and other excitations can be treated in an almost identical way. They give the example of time-dependent photoemission under the influence of plasmonic excitations. Other electron-boson systems are, for example, electron-magnon systems (Mahfouzi and Nikolić 2014) and electron-phonon systems (Sentef et al. 2016).

We begin with a general introduction to NEGF, and diagrammatic perturbation theory will be systematically built up. The discussion will follow the notation and structure of Stefanucci and van Leeuwen (2013).

# 2    Introduction to NEGF

## 2.1    Time-Dependent Observables

We consider a system containing two different species of particles: fermions and bosons. The system is initially prepared in an ensemble at time $t = t_0$, described by the statistical density matrix $\hat{\rho}(t_0) = \hat{\rho}$. The initial ensemble average $O(t_0)$ of a

general operator $\hat{O}(t)$ is defined as $O(t_0) = \mathrm{Tr}\left[\hat{\rho}\hat{O}(t_0)\right]$, where the trace $\mathrm{Tr}[\cdots]$ is over all states and particle numbers in Fock space. We write the density matrix as $\hat{\rho} = e^{-\beta\hat{H}^M}/Z$, where the Matsubara Hamiltonian $\hat{H}^M = \hat{H} - \mu\hat{N}$ determines the initial state, where $\hat{H} = \hat{H}(t_0)$ is the equilibrium Hamiltonian. $\mu$ is the chemical potential for the fermions, $\hat{N}$ is the corresponding particle number operator, and $\beta$ is the inverse temperature. The partition function $Z = \mathrm{Tr}\left[e^{-\beta\hat{H}^M}\right]$ yields $\mathrm{Tr}\left[\hat{\rho}\right] = 1$.

For times $t > t_0$, we imagine that the system is perturbed to bring it out of equilibrium. This is described by the time-dependent Hamiltonian $\hat{H}(t)$, under which the density matrix changes according to

$$\hat{\rho}(t) = \hat{U}(t, t_0)\hat{\rho}\hat{U}(t_0, t). \tag{1}$$

We introduced the time-evolution operator $U(t, t_0)$, defined as

$$\hat{U}(t_1, t_2) = \begin{cases} \mathscr{T}\left\{e^{-i\int_{t_1}^{t_2} d\bar{t}\,\hat{H}(\bar{t})}\right\} & \text{for } t_2 \text{ later than } t_1 \\ \bar{\mathscr{T}}\left\{e^{+i\int_{t_2}^{t_1} d\bar{t}\,\hat{H}(\bar{t})}\right\} & \text{for } t_1 \text{ later than } t_2 \end{cases} \tag{2}$$

where $\mathscr{T}\{\cdots\}$ ($\bar{\mathscr{T}}\{\cdots\}$) denotes (anti)time-ordering, which orders the latest (earliest) time to the left.

Using the cyclic property of the trace, we can write the time-dependent ensemble average $O(t) = \mathrm{Tr}\left[\hat{\rho}(t)\hat{O}(t)\right]$ as

$$O(t) = \mathrm{Tr}\left[\hat{\rho}\hat{U}(t_0, t)\hat{O}(t)\hat{U}(t, t_0)\right]. \tag{3}$$

Using the definitions, we can write Eq. (3) as

$$O(t) = \mathrm{Tr}\left[\hat{\rho}\bar{\mathscr{T}}\left\{e^{-i\int_t^{t_0} d\bar{t}\hat{H}(\bar{t})}\right\}\hat{O}(t)\mathscr{T}\left\{e^{-i\int_{t_0}^t d\bar{t}\hat{H}(\bar{t})}\right\}\right]. \tag{4}$$

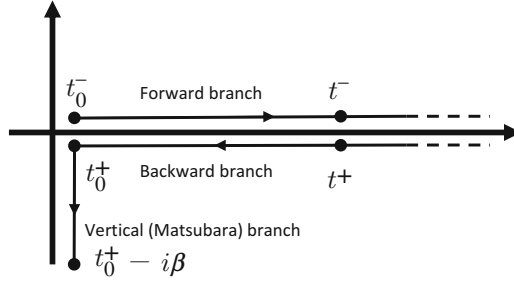
Equation (4) is a bit awkward to handle since it contains two different types of time-ordering operators. The ensemble average can be written in a more convenient way by introducing a vertical track via $e^{-\beta\hat{H}^M} = e^{-i\int_{t_0}^{t_0-i\beta} d\bar{z}\hat{H}^M(\bar{z})}$, where $\hat{H}^M(z) = \hat{H}^M$ is constant. The ensemble average of Eq. (4) can then be viewed as three different time-evolution operators, one going forward in time from $t_0$ to $t$, then going backward in time from $t$ to $t_0$, and then finally going from $t_0$ to $t_0 - i\beta$. All these different time-evolution operators can be written using a single time-ordering by introducing a directed time-ordered contour $\gamma$, depicted in Fig. 1. The contour consists of three branches. Times on the forward and backward branches are denoted $t^-$ and $t^+$, respectively, while times on the vertical (Matsubara) branch are denoted $t^M$. A general contour time is denoted by $z$, and we define $\hat{H}(z = $


**Fig. 1** The contour. The equations of motion are defined on this contour, consisting of a forward branch, backward branch, and an imaginary (Matsubara) branch. The initial point on the contour is $z_i = t_0^-$, and the final point is $z_f = t_0^+ - i\beta$. The contour can be deformed into various other ones used in the literature

$t^\pm) = \hat{H}(t)$, $\hat{H}(z = t^M) = \hat{H}^M$. For all other operators we consider, we define $\hat{O}(z = t^\pm) = \hat{O}(t)$, $\hat{O}(z = t^M) = \hat{O}(t_0)$. The use of the contour allows us to write the ensemble average of Eq. (4) in the elegant form

$$O(z) = \frac{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\,\hat{H}(\bar{z})}\hat{O}(z)\right\}\right]}{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\,\hat{H}(\bar{z})}\right\}\right]}. \tag{5}$$

where $\mathscr{T}_c\{\cdots\}$ denotes contour time-ordering, in the sense of the directed contour. Earlier contour times appear first when following the directed contour starting from $t_0^-$. For an in-depth discussion, see, for example, Stefanucci and van Leeuwen (2013) and Špička et al. (2014).

The time contour allows for elegant expressions of non-equilibrium physics via Eq. (5). Furthermore, the contour yields simple equations of motion for Heisenberg operators. We define an arbitrary Heisenberg operator $\hat{O}_H(z)$ as

$$\hat{O}_H(z) = \hat{U}(z_i, z)\hat{O}(z)\hat{U}(z, z_i) \tag{6}$$

where $z_i$ is the initial time on the contour, and the time-evolution operator on the contour is given by

$$\hat{U}(z_2, z_1) = \begin{cases} \mathscr{T}_c\left\{e^{-i\int_{z_1}^{z_2} d\bar{z}\,\hat{H}(\bar{z})}\right\} & \text{for } z_2 \text{ later than } z_1 \\ \bar{\mathscr{T}}_c\left\{e^{+i\int_{z_2}^{z_1} d\bar{z}\,\hat{H}(\bar{z})}\right\} & \text{for } z_1 \text{ later than } z_2 \end{cases} \tag{7}$$

where $\bar{\mathscr{T}}_c\{\cdots\}$ denotes contour anti-time-ordering. Using the time-evolution operator defined on the contour, we can derive the contour Heisenberg equation of motion:

$$i \frac{\mathrm{d}}{\mathrm{d}z} \hat{O}_H(z) = \left[ \hat{O}_H(z), \hat{H}_H(z) \right]_- + \hat{U}(z_i, z) \left( i \frac{\mathrm{d}}{\mathrm{d}z} \hat{O}(z) \right) \hat{U}(z, z_i) \qquad (8)$$

These are the basic equations necessary to describe systems out of equilibrium. We will now specify the type of systems we will study.

## 2.2   The Structure of the Hamiltonian

We consider a time-dependent fermion-boson Hamiltonian as

$$\hat{H}(z) = \underbrace{\hat{H}_{\mathrm{el}}(z) + \hat{H}_{\mathrm{bos}}(z)}_{\hat{H}_0(z)} + \underbrace{\hat{H}_{\mathrm{el\text{-}el}}(z) + \hat{H}_{\mathrm{el\text{-}bos}}(z)}_{\hat{H}_{\mathrm{int}}(z)}, \qquad (9)$$

where the non-interacting part $\hat{H}_0$ consists of one-body operators and the interaction part $\hat{H}_{\mathrm{int}}$ consists of higher-order operators. To avoid confusion and to increase clarity, we write that the two different kinds of particles are electrons and bosons. We note, however, that the same formalism will be valid if $\hat{H}_{\mathrm{el}}$ and $\hat{H}_{\mathrm{el\text{-}el}}$ would refer to general fermions or bosons. The difference is in the (anti)commutation relations, which we denote $\left[ \hat{O}_1, \hat{O}_2 \right]_{\mp} = \hat{O}_1 \hat{O}_2 \mp \hat{O}_2 \hat{O}_1$, where the upper/lower sign is for bosons/fermions.

The purely electronic part is

$$\hat{H}_{el}(z) = \int \mathrm{d}x \mathrm{d}x' \hat{\psi}^\dagger(x) \left\langle x \left| \hat{h}(z) \right| x' \right\rangle \hat{\psi}(x'), \qquad (10)$$

where $x$ denotes a collective space-spin variable. The field creation operator $\hat{\psi}^\dagger$ and destruction operator $\hat{\psi}$ obey the usual (anti)commutation relations $\left[ \hat{\psi}(x), \hat{\psi}(y) \right]_{\mp} = \left[ \hat{\psi}^\dagger(x), \hat{\psi}^\dagger(y) \right]_{\mp} = 0$, $\left[ \hat{\psi}(x), \hat{\psi}^\dagger(y) \right]_{\mp} = \delta(x - y)$. To simplify the notation, we will assume $\left\langle x_1 \left| \hat{h}(z_1) \right| x_2 \right\rangle = \delta(x_1 - x_2) h(x_1, z_1)$, that is, that the one-body part does not contain spin-flip terms. The one-body term $h(x, z)$ contains the kinetic energy and a general time-dependent external potential.

The electrons interact among each other via a two-body interaction $\hat{H}_{\mathrm{el\text{-}el}}$:

$$\hat{H}_{\mathrm{el\text{-}el}}(z) = \frac{1}{2} \int \mathrm{d}x \mathrm{d}x' \hat{\psi}^\dagger(x) \hat{\psi}^\dagger(x') v(x, x', z) \hat{\psi}(x') \hat{\psi}(x), \qquad (11)$$

where $v(x, x', z)$ is the time-dependent pair interaction. The interaction can be coulombic, but we allow for more freedom by allowing a general two-body interaction; this allows for considering, for example, local interactions where $v(x, x', z) \sim \delta(x - x')$, ubiquitous in model systems and in cold atom gases (Bloch and Zwerger 2008). We also allow for a time-dependence that permits to describe, for example, interaction quenches or an adiabatic switch-on of the interaction.

We now focus on the bosons, which we will treat slightly differently. The fundamental reason for this is that the interaction part of the electron-boson Hamiltonian is not particle conserving. Let us first consider the noninteracting part $\hat{H}_{\text{bos}}$ as

$$\hat{H}_{\text{bos}}(z) = \sum_\mu \omega_\mu(z) \hat{a}_\mu^\dagger \hat{a}_\mu, \tag{12}$$

in the diagonal form where $\omega_\mu(z)$ is the frequency of mode $\mu$ of the bosons and $\hat{a}_\mu^\dagger (\hat{a}_\mu)$ are the corresponding creation (annihilation) operator for mode $\mu$. The operators fulfill the usual commutation relations $[\hat{a}_\mu, \hat{a}_\nu] = [\hat{a}_\mu^\dagger, \hat{a}_\nu^\dagger] = 0$ and $[\hat{a}_\mu, \hat{a}_\nu^\dagger] = \delta_{\mu\nu}$. There are many situations in which it is more convenient to work with the Hermitian displacement $\hat{u}_\mu$ and momentum $\hat{p}_\mu$ operators, defined via the transformation

$$\hat{u}_\mu = \left(\hat{a}_\mu^\dagger + \hat{a}_\mu\right)/\sqrt{2}, \quad \hat{p}_\mu = i\left(\hat{a}_\mu^\dagger - \hat{a}_\mu\right)/\sqrt{2}. \tag{13}$$

The displacement and momentum operators fulfill the usual commutation relations $[\hat{u}_\mu, \hat{u}_\nu] = [\hat{p}_\mu, \hat{p}_\nu] = 0$, and $[\hat{u}_\mu, \hat{p}_\nu] = i\delta_{\mu\nu}$. In order to prepare the discussion for more general situations, it turns out that a convenient description can be obtained if the $\hat{u}_\mu$ and $\hat{p}_\mu$ operators are gathered into a vector $\hat{\phi}_{\mu\xi}$, with $\hat{\phi}_{\mu,1} = \hat{u}_\mu$ and $\hat{\phi}_{\mu,2} = \hat{p}_\mu$. We also introduce the composite index $\bar{\mu} = (\mu, \xi_\mu)$ to simplify the notation. The bosonic Hamiltonian, Eq. (12), can be generalized to

$$\hat{H}_{\text{bos}}(z) = \sum_{\bar{\mu}\bar{\nu}} \Omega_{\bar{\mu}\bar{\nu}}(z) \hat{\phi}_{\bar{\mu}} \hat{\phi}_{\bar{\nu}}. \tag{14}$$

Equation (14) is then written using Hermitian operators, which generalize Eq. (12). More specifically, Eq. (14) can contain terms proportional to $(\hat{a}^\dagger)^2$ and $\hat{a}^2$, thereby violating particle number conservation. The commutation relations between the $\hat{\phi}$-fields can be given compactly as

$$\left[\hat{\phi}_{\bar{\mu}}, \hat{\phi}_{\bar{\nu}}\right]_- = \alpha_{\bar{\mu}\bar{\nu}}, \quad \text{with} \quad \alpha_{\bar{\mu}\bar{\nu}} = \delta_{\mu\nu} \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix}_{\xi_\mu \xi_\nu}. \tag{15}$$

The advantage of the $\hat{\phi}$-field vector formulation will become clear when we later discuss the equations of motion. It implies that instead of using second-order equations for the displacement, we can use a first-order equation for the coupled displacement and momentum operators.

In order to include the multitude of electron-boson interactions in the literature, we take the interaction to be

$$\hat{H}_{\text{el-bos}}(z) = \sum_{\bar{\mu}} \int dx \ \hat{\psi}^{\dagger}(x)\lambda_{\bar{\mu}}(x,z)\hat{\psi}(x)\hat{\phi}_{\bar{\mu}}. \tag{16}$$

As in the case of $v(x, x', z)$, the (real-valued) coupling strength $\lambda_{\bar{\mu}}(x,z)$ can be time-dependent. The electron-boson interaction could be written more generally by letting $\lambda_{\bar{\mu}}(x,z)$ being a differential operator, and this will not change the overall discussion. However, for simplicity, we let $\lambda_{\bar{\mu}}(x,z)$ be a local operator. Equivalent forms of the electron-boson interaction can be obtained by defining $m_{\mu}(x) = (\lambda_{\mu,1}(x) - i\lambda_{\mu,2}(x))/\sqrt{2}$, which yields

$$\hat{H}_{\text{el-bos}} = \sum_{\mu} \int dx \ \hat{\psi}^{\dagger}(x)\hat{\psi}(x)\left(m_{\mu}(x)\hat{a}_{\mu}^{\dagger} + m_{\mu}^{*}(x)\hat{a}_{\mu}\right).$$

Another form can be obtained by choosing a discrete electron basis, $\hat{\psi}(x) = \sum_{l} \varphi_{l}(x)\hat{c}_{l}$, which yields $\hat{H}_{\text{el-bos}} = \sum_{\mu kl} \hat{c}_{k}^{\dagger}\hat{c}_{l}(m_{\mu}^{kl}\hat{a}_{\mu}^{\dagger} + m_{\mu}^{lk,*}\hat{a}_{\mu})$, where the elements $m_{\mu}^{kl} = \int dx \ \varphi_{k}^{*}(x)m_{\mu}(x)\varphi_{l}(x)$. Written in the above way, the general interaction Hamiltonian, Eq. (16), includes the commonly used electron-phonon interaction, electron-plasmon, electron-magnon, electron-photon in cavity quantum electrodynamics, and others.

We finally note that we have not included the so-called half-body terms in the bosonic Hamiltonian, terms proportional to a single $\hat{\phi}$ operator. These terms are important in several contexts, such as in the description of forced oscillators and superfluid systems, but the half-body interactions can change the diagrammatic structure, for example, in a Bose-Einstein condensate. For a thorough diagrammatic treatment of half-body interactions, see De Dominicis (1963). Keeping this in mind, we will limit ourselves to the Hamiltonian of Eq. (9).

## 2.3 Operator Correlators

To calculate time-dependent ensemble averages, like in Eq. (5), we need to deal with time-ordered products of arbitrary operators – operator correlators. In this section, we derive general equations of motion for such objects. The time-ordering operator for the same particle species acts in the following way:

$$\mathcal{T}_{c}\left\{\hat{O}_{1}(z_{1})\hat{O}_{2}(z_{2})\right\} = \theta(z_{1}, z_{2})\hat{O}_{1}(z_{1})\hat{O}_{2}(z_{2}) \pm \theta(z_{2}, z_{1})\hat{O}_{2}(z_{2})\hat{O}_{1}(z_{1}), \tag{17}$$

that is, the time-ordering orders the later contour time to the left. Here, as in the rest of the chapter, the upper/lower sign refers to bosonic/fermionic operators. The functions $\theta(z_{1}, z_{2})$ are step functions on the contour, with $\theta(z_{1}, z_{2}) = 1$ if $z_{1}$ is later than $z_{2}$ on the contour and 0 otherwise. We define the Dirac delta function on the contour as $\delta(z_{1}, z_{2}) = \partial_{z_{1}}\theta(z_{1}, z_{2}) = -\partial_{z_{2}}\theta(z_{1}, z_{2})$. For a string of operators

that contain operators pertaining to different species of particles, we define them to commute under the time-ordering operator.

The equations of motion for the time-ordered product is given by

$$\frac{\partial}{dz_1} \mathcal{T}_c \left\{ \hat{O}_1(z_1) \hat{O}_2(z_2) \right\} = \delta(z_1, z_2) \left[ \hat{O}_1, \hat{O}_2 \right]_{\mp} + \mathcal{T}_c \left\{ \frac{\partial}{\partial z_1} \hat{O}_1(z_1) \hat{O}_2(z_2) \right\}. \tag{18}$$

The generalization of Eq. (18) to an arbitrary correlator is

$$\frac{\partial}{\partial z_k} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{O}_n \right\} = \partial^{\theta}_{z_k} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{O}_n \right\}$$
$$+ \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{O}_{k-1} \left( \frac{\partial}{\partial z_k} \hat{O}_k \right) \hat{O}_{k+1} \dots \hat{O}_n \right\} \tag{19}$$

where we have defined the contribution from differentiating the step functions in the first term on the right-hand side. Most often, one is interested in the equations of motion when the operators $\hat{O}_1, \cdots, \hat{O}_n$ fulfill the extra condition that their equal-time (anti)commutators commute with other operators:

$$\left[ \hat{O}_k(z), \hat{O}_l(z) \right]_{\mp} = c_{kl} \hat{\mathbb{1}}, \tag{20}$$

where $c_{kl}$ is a number. We will consider such cases here; the creation and destruction operators, as well as the $\hat{\phi}$-fields, fulfill the relation of Eq. (20). In that case, the explicit form of $\partial^{\theta}_{z_k} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{O}_n \right\}$ is given by

$$\partial^{\theta}_{z_k} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{O}_n \right\} = \sum_{l=1}^{k-1} (\pm)^{k-l} \delta(z_k, z_l) \left[ \hat{O}_k, \hat{O}_l \right]_{\mp} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{\hat{O}}_l \dots \hat{\hat{O}}_k \dots \hat{O}_n \right\}$$
$$+ \sum_{l=k+1}^{n} (\pm)^{l-k-1} \delta(z_k, z_l) \left[ \hat{O}_k, \hat{O}_l \right]_{\mp} \mathcal{T}_c \left\{ \hat{O}_1 \dots \hat{\hat{O}}_k \dots \hat{\hat{O}}_l \dots \hat{O}_n \right\}, \tag{21}$$

where $\hat{\hat{O}}_l$ denotes that the operator $\hat{O}_l$ is missing from the string.

The equation of motion for operator correlators, Eq. (19), is very general, and is the equation that will give rise to the equations of motion for different kinds of Green's functions with different types of particles. To proceed, we need to specialize our discussion to which types of correlators we want to consider.

### 2.3.1  $n$-Particle Correlators on the Contour

In systems that conserve the number of electrons, all observables can be expressed as linear combinations of field operators that contain an equal number of creation and destruction operators. We thus define the $n$-particle correlator $\hat{G}_n$ as

$$\hat{G}_n(1, \ldots, n; 1', \ldots, n') = (-i)^n \mathscr{T}_c \left\{ \hat{\psi}_H(1) \cdots \hat{\psi}_H(n) \hat{\psi}_H^\dagger(n') \cdots \hat{\psi}_H^\dagger(1') \right\}$$

(22)

where unprimed variables $k = (x_k, z_k)$ pertain to destruction operators $\hat{\psi}_H(k)$, while primed variables $k' = (x_k', z_k')$ pertain to creation operators $\hat{\psi}_H^\dagger(k')$. The $2n$-point correlators $\hat{G}_n(1, \ldots, n; 1', \ldots, n')$ fulfill the following equations of motion, which follow from Eqs. (19) and (21) and the Heisenberg equation of motion, Eq. (8):

$$\left[ i \frac{\partial}{\partial z_k} - h(k) \right] \hat{G}_n(1, \ldots, n; 1', \ldots, n')$$

$$= (-i)^n \mathscr{T}_c \left\{ \hat{\psi}_H(1) \ldots \left[ \hat{\psi}_H(k), \hat{H}_{\text{int}}(z_k) \right]_- \ldots \hat{\psi}_H(n) \hat{\psi}_H^\dagger(n') \ldots \hat{\psi}_H^\dagger(1') \right\}$$

$$+ \sum_{j=1}^n (\pm)^{k+j} \delta(k; j') \hat{G}_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, n; 1', \ldots, \overset{\sqcap}{j'}, \ldots, n'),$$

(23)

and likewise for the primed coordinates. We define $\hat{G}_0 = \hat{\mathbb{1}}$.

We now consider the situation where the operators in the correlator are taken to be $\hat{\phi}$-fields. Similarly to the electronic case, we define the $n$-body bosonic correlator:

$$\hat{\mathbb{D}}_n(1, 2, \ldots, 2n) = (-i)^n \mathscr{T}_c \left\{ \hat{\phi}_H(1) \hat{\phi}_H(2) \ldots \hat{\phi}_H(2n) \right\},$$

(24)

where $1 = (\bar{\mu}_1, z_1)$ is a collective index. Here, $n$ can also be a half-integer, because, as we will see, the ensemble average of an odd number of $\hat{\phi}$-fields is nonvanishing when the electron-boson interaction is present.

The equations of motion for $\hat{\mathbb{D}}_n$ can be found in the same way as for $\hat{G}_n$, yielding

$$i \frac{\partial}{\partial z_k} \hat{\mathbb{D}}_n(1, \ldots \bar{\sigma} z_k \ldots, 2n) - \sum_{\bar{\mu}\bar{\nu}} \alpha_{\bar{\sigma}\bar{\mu}} \bar{\Omega}_{\bar{\mu}\bar{\nu}}(z_k) \hat{\mathbb{D}}_n(1, \ldots, \nu z_k, \ldots, 2n)$$

$$= (-i)^n \mathscr{T}_c \left\{ \hat{\phi}_H(1) \ldots \left[ \hat{\phi}_H(k), \hat{H}_{\text{int}}(z_k) \right]_- \ldots \hat{\phi}_H(2n) \right\}$$

$$+ \sum_{j=1, j\neq k}^{2n} \delta(z_k, z_j) \alpha_{\bar{\sigma}, \bar{\mu}_j} \hat{\mathbb{D}}_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, \overset{\sqcap}{j}, \ldots, 2n).$$

(25)

We define $\hat{\mathbb{D}}_0 = \hat{\mathbb{1}}$ and $\hat{\mathbb{D}}_{-1/2} = \hat{0}$. Equation (25) is somewhat different than the one for $\hat{G}_n$, Eq. (23), owing to the presence of the $\alpha$ matrix from the commutation relations. However, the main structure is identical.

As an illustration of Eq. (25), we consider the case of $n = 1/2$. In this case the correlator is the $\hat{\phi}$-field itself, $\hat{\mathbb{D}}_{1/2}(1) = (-i)^{1/2}\hat{\phi}(1)$. Using the commutators $\left[\hat{\phi}_{\bar{\sigma}}, \hat{H}_{\text{el-bos}}\right]_- = \sum_{\bar{\mu}} \int dx \lambda_{\bar{\mu}}(x, z) \alpha_{\bar{\sigma}\bar{\mu}} \hat{\psi}^\dagger(x) \hat{\psi}(x)$ and $\left[\hat{\phi}_{\bar{\sigma}}, \hat{H}_{\text{bos}}\right]_- = \sum_{\bar{\mu}\bar{\nu}} \bar{\Omega}_{\bar{\mu}\bar{\nu}} \alpha_{\bar{\sigma}\bar{\mu}} \hat{\phi}_{\bar{\nu}}$ where $\bar{\Omega}_{\bar{\mu}\bar{\nu}} = \Omega_{\bar{\mu}\bar{\nu}} + \Omega_{\bar{\nu}\bar{\mu}}$, we obtain

$$i\frac{d}{dz}\hat{\phi}_H(\bar{\sigma}z) = \sum_{\bar{\mu}\bar{\nu}} \bar{\Omega}_{\bar{\mu}\bar{\nu}}(z) \alpha_{\bar{\sigma}\bar{\mu}} \hat{\phi}_H(\bar{\nu}z) + \sum_{\bar{\mu}} \int dx \lambda_{\bar{\mu}}(xz) \alpha_{\bar{\sigma}\bar{\mu}} \hat{\psi}_H^\dagger(xz) \hat{\psi}_H(xz).$$

(26)

Another equivalent form that will be used later can be obtained from Eq. (26) by using the idempotency relation $\delta_{\bar{\sigma}\bar{\sigma}'} = \sum_{\bar{\mu}} \alpha_{\bar{\sigma}\bar{\mu}} \alpha_{\bar{\mu}\bar{\sigma}'}$:

$$\sum_{\bar{\mu}} \left(i\alpha_{\bar{\sigma}\bar{\mu}}\frac{d}{dz} - \bar{\Omega}_{\bar{\sigma}\bar{\mu}}(z)\right) \hat{\phi}(\bar{\mu}z) = \int dx \lambda_{\bar{\sigma}}(xz) \hat{\psi}_H^\dagger(xz) \hat{\psi}_H(xz).$$

(27)

Equations (25) and (23) are independent on the initial state and play an important role in the development of the theory. As we explain in the subsequent sections, the whole structure of diagrammatic perturbation theory is encoded in them.

## 2.4    Many-Body Green's Functions

The ensemble averages of the correlators $\hat{G}_n$ and $\hat{\mathbb{D}}_n$ define corresponding $n$-particle Green's functions as

$$G_n(1, \ldots, n; 1', \ldots, n') \equiv \text{Tr}\left[\hat{\rho}\hat{G}_n(1, \ldots, n; 1', \ldots, n')\right]$$

(28)

$$\mathbb{D}_n(1, \ldots, 2n) \equiv \text{Tr}\left[\hat{\rho}\hat{\mathbb{D}}_n(1, \ldots, 2n)\right].$$

(29)

$n$-particle Green's functions directly provide ensemble averages of $n$-particle objects. With the time contour, as in Eq. (5), Green's functions can be written as

$$G_n(1, \ldots, n; 1', \ldots, n')$$
$$= (-i)^n \frac{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}(\bar{z})}\hat{\psi}(1)\ldots\hat{\psi}(n)\hat{\psi}^\dagger(n')\ldots\hat{\psi}^\dagger(1')\right\}\right]}{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}(\bar{z})}\right\}\right]}$$

(30)

$$\mathbb{D}_n(1, \ldots, 2n) = (-i)^n \frac{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}(\bar{z})}\hat{\phi}(1)\ldots\hat{\phi}(2n)\right\}\right]}{\text{Tr}\left[\mathscr{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}(\bar{z})}\right\}\right]}. \tag{31}$$

Note that the operators appearing in the time-ordering are Schrödinger operators. For future reference, we also define noninteracting Green's functions $g_n$ and $d_n$ by replacing $\hat{H}$ with $\hat{H}_0$. The form of Eqs. (30) and (31) is well-suited for perturbation expansions, which we will discuss in the next section.

The Green's functions $G_n$, $g_n$, $\mathbb{D}_n$, and $d_n$ fulfill the so-called Kubo-Martin-Schwinger (KMS) boundary conditions, which can be derived from Eqs. (30) and (31). For $G_n$, the conditions are $G(z_i, \ldots) = \pm G(z_f, \ldots)$ where $z_i/z_f$ is the initial/final time on the contour. The same holds for all arguments. Likewise, for $\mathbb{D}_n$: $\mathbb{D}_n(z_i, \ldots) = \mathbb{D}_n(z_f, \ldots)$, and similarly for $g_n$ and $d_n$.

The equations of motion for the Green's functions $G_n$ and $\mathbb{D}_n$ follow from the equations for their corresponding correlators, Eqs. (23) and (25).

$$\left[i\frac{\partial}{\partial z_k} - h(k)\right]G_n(1, \ldots, n; 1', \ldots, n')$$

$$= (-i)^n \text{Tr}\left[\hat{\rho}\mathscr{T}_c\left\{\hat{\psi}_H(1)\ldots\left[\hat{\psi}_H(k), \hat{H}_{\text{int}}(z_k)\right]_- \ldots\hat{\psi}_H(n)\hat{\psi}_H^\dagger(n')\ldots\hat{\psi}_H^\dagger(1')\right\}\right]$$

$$+ \sum_{j=1}^n (\pm)^{k+j}\delta(k; j')G_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, n; 1', \ldots, \overset{\sqcap}{j'}, \ldots, n'), \tag{32}$$

$$i\frac{\partial}{\partial z_k}\mathbb{D}_n(1, \ldots \bar{\sigma}z_k \ldots, 2n) - \sum_{\bar{\mu}\bar{\nu}}\alpha_{\bar{\sigma}\bar{\mu}}\bar{\Omega}_{\bar{\mu}\bar{\nu}}(z_k)\mathbb{D}_n(1, \ldots, \nu z_k, \ldots, 2n)$$

$$= (-i)^n \text{Tr}\left[\rho\mathscr{T}_c\left\{\hat{\phi}_H(1)\ldots\left[\hat{\phi}_H(k), \hat{H}_{\text{int}}(z_k)\right]_- \ldots\hat{\phi}_H(2n)\right\}\right] \tag{33}$$

$$+ \sum_{j=1, j\neq k}^{2n}\delta(z_k, z_j)\alpha_{\bar{\sigma}\bar{\mu}_j}\mathbb{D}_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, \overset{\sqcap}{j}, \ldots, 2n).$$

To further discuss these equations, we work out the commutators:

$$\left[\hat{\psi}_H(xz), \hat{H}_{\text{el-el}}(z)\right]_- = \int dx' v(x, x', z)\hat{\psi}_H^\dagger(x'z)\hat{\psi}_H(x'z)\hat{\psi}_H(xz)$$

$$\left[\hat{\psi}_H(xz), \hat{H}_{\text{el-bos}}(z)\right]_- = \sum_{\bar{\mu}}\lambda_{\bar{\mu}}(xz)\hat{\psi}_H(xz)\hat{\phi}_H(\bar{\mu}z)$$

$$\left[\hat{\phi}_H(\bar{\sigma}z), \hat{H}_{\text{el-bos}}\right]_- = \sum_{\bar{\mu}}\int dx \lambda_{\bar{\mu}}(xz)\alpha_{\bar{\sigma}\bar{\mu}}\hat{\psi}_H^\dagger(xz)\hat{\psi}_H(xz).$$

Let us start by considering only $\hat{H}_{\text{el-el}}$, that is, imagining that $\lambda = 0$. In this case, $\mathbb{D}_n = d_n$ and would only couple to $\mathbb{D}_{n-1} = d_{n-1}$. The electronic case is different; $G_n$ couples to $G_{n-1}$ but also to $G_{n+1}$.

In the case of a non-zero electron-electron and electron-boson interaction, $G_n$ would couple to $G_{n-1}$, and $G_{n+1}$, but also to mixed Green's functions consisting of a mix of $\hat{\psi}$, $\hat{\psi}^\dagger$, and $\hat{\phi}$. Likewise, $\mathbb{D}_n$ couples to $\mathbb{D}_{n-1}$ but also to mixed Green's functions. The equations of motion for these objects can also be derived in precisely the same way, but it will turn out that we will not need them for our purposes. For the derivation of mixed Green's functions, see Säkkinen (2016).

The full set of equations are referred to as the Martin-Schwinger hierarchy (Martin and Schwinger 1959). Together with the Kubo-Martin-Schwinger boundary conditions, we can uniquely obtain any $n$th-order correlation function. The exact solution is, of course, out of reach in most physical systems of relevance.

In the noninteracting case, the separate hierarchies of $g_n$ and $d_n$ will close on themselves: $g_n$ ($d_n$) couples only to $g_{n-1}$ ($d_{n-1}$). This allows for writing $g_n$ and $d_n$ in terms of $g_1$ and $d_1$, respectively. This is usually referred to as Wick's theorem and is the cornerstone of perturbation expansions. This will be further discussed below. First we will describe the general structure of perturbation theory for Green's functions.

## 2.5    Perturbation Expansion

Green's functions $G_n$ and $\mathbb{D}_n$ written using the time-contour ordering, Eqs. (30) and (31), permit an expansion in terms of $\hat{H}_{\text{int}}$. We focus on the single-particle $G \equiv G_1$, but the discussion for $\mathbb{D}_1$ or higher-order Green's functions is identical. Under the time-ordering operation $\hat{H}_0$, $\hat{H}_{\text{el-el}}$ and $\hat{H}_{\text{el-bos}}$ commute, and thus the exponentials of the three Hamiltonians can be separated. It then becomes natural to define the noninteracting average as $\text{Tr}\left[ \mathscr{T}_c \left\{ e^{-i \int_\gamma \mathrm{d}\bar{z} \hat{H}_0(\bar{z})} \cdots \right\} \right] = \langle \mathscr{T}_c \{ \cdots \} \rangle_0$ and expand $e^{-i \int_\gamma \mathrm{d}\bar{z} \hat{H}_{\text{el-el}}(\bar{z})} e^{-i \int_\gamma \mathrm{d}\bar{z} \hat{H}_{\text{el-bos}}(\bar{z})}$ in both numerator and denominator, resulting in

$$G(ab') = \frac{-i}{Z} \sum_{k,\tilde{\ell}=0}^{\infty} \frac{(-i)^{k+\tilde{\ell}}}{k!\tilde{\ell}!} \int_\gamma \mathrm{d}\bar{z}_1 \mathrm{d}\bar{z}_{\tilde{1}} \ldots \mathrm{d}\bar{z}_k \mathrm{d}\bar{z}_{\tilde{\ell}} \tag{34}$$

$$\langle \mathscr{T}_c \left\{ \hat{H}_{\text{el-el}}(\bar{z}_1) \ldots \hat{H}_{\text{el-el}}(\bar{z}_k) \hat{H}_{\text{el-bos}}(\bar{z}_{\tilde{1}}) \ldots \hat{H}_{\text{el-bos}}(\bar{z}_{\tilde{\ell}}) \hat{\psi}(a) \hat{\psi}^\dagger(b') \right\} \rangle_0,$$

where the partition function has a similar expansion

$$Z = \sum_{k,\tilde{\ell}=0}^{\infty} \frac{(-i)^{k+\tilde{\ell}}}{k!\tilde{\ell}!} \int_\gamma \langle \mathscr{T}_c \left\{ \hat{H}_{\text{el-el}}(\bar{z}_1) \ldots \hat{H}_{\text{el-el}}(\bar{z}_k) \hat{H}_{\text{el-bos}}(\bar{z}_{\tilde{1}}) \ldots \hat{H}_{\text{el-bos}}(\bar{z}_{\tilde{\ell}}) \right\} \rangle_0. \tag{35}$$

To distinguish between the fermion expansion and the boson one, we denote bosonic coordinates with tildes.

To evaluate Eq. (34), we need to be able to calculate time-ordered strings like $\mathrm{Tr}\left[\mathcal{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}_0(\bar{z})}\psi\ldots\psi\hat{\psi}^\dagger\ldots\hat{\psi}^\dagger\hat{\phi}\ldots\hat{\phi}\right\}\right]$ with an arbitrary number of operators. To make progress, it is crucial to note that the respective operators in $\hat{H}_0 = \hat{H}_{el} + \hat{H}_{bos}$ belong to different Hilbert spaces. As such, the eigenstates for $\hat{H}_0$ factorize into tensor products between the eigenstates of $\hat{H}_{el}$ and $\hat{H}_{bos}$. The noninteracting partition function $Z_0 = \mathrm{Tr}\left[\mathcal{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}_0(\bar{z})}\right\}\right]$ can thus be written as $Z_0 = \mathrm{Tr}_{el}\left[\mathcal{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}_{el}(\bar{z})}\right\}\right]\mathrm{Tr}_{bos}\left[\mathcal{T}_c\left\{e^{-i\int_\gamma d\bar{z}\hat{H}_{bos}(\bar{z})}\right\}\right] = Z_{el}Z_{bos}$. The same type of factorization allows us to simplify the expression above, as

$$\langle\mathcal{T}_c\left\{\psi\ldots\psi\hat{\psi}^\dagger\ldots\hat{\psi}^\dagger\hat{\phi}\ldots\hat{\phi}\right\}\rangle_0 = \langle\mathcal{T}_c\left\{\psi\ldots\psi\hat{\psi}^\dagger\ldots\hat{\psi}^\dagger\right\}\rangle_0\langle\mathcal{T}_c\left\{\hat{\phi}\ldots\hat{\phi}\right\}\rangle_0,$$
(36)

where it will be clear from the context if $\langle\mathcal{T}_c\{\cdots\}\rangle_0$ refers to the electronic or bosonic case.

The right-hand side of Eq. (36) is proportional to noninteracting Green's functions under suitable reorderings of the arguments. $2n$ operators yield $n$-particle Green's functions, $g_n$ for $\hat{\psi}$, $\hat{\psi}^\dagger$, and $d_n$ for $\hat{\phi}$. The expression for $G(ab')$, Eq. (34), with order $k$ for the electrons and $\tilde{\ell}$ for the bosons, yields the following time-ordered averages for the bosonic case (Eq. (31) with $\hat{H} \to \hat{H}_0$):

$$\langle\mathcal{T}_c\{\underbrace{\hat{\phi},\cdots,\hat{\phi}}_{\tilde{\ell}\text{ operators}}\}\rangle_0 = Z_{bos}i^{\tilde{\ell}/2}d_{\tilde{\ell}/2}(\tilde{1},\cdots,\tilde{\ell}).$$

For the fermionic operators, we have (Eq. (30) with $\hat{H} \to \hat{H}_0$)

$$\langle\mathcal{T}_c\{\underbrace{\hat{\psi}^\dagger\hat{\psi}^\dagger\hat{\psi}\hat{\psi},\cdots,}_{4k\text{ operators}}\underbrace{\hat{\psi}^\dagger\hat{\psi},\cdots,}_{2\tilde{\ell}\text{ operators}}\underbrace{\hat{\psi}(a)\hat{\psi}^\dagger(b')}_{2\text{ operators}}\}\rangle_0$$

$$= Z_{el}i^{2k+\tilde{\ell}+1}g_{2k+\tilde{\ell}+1}(a,\tilde{1},\cdots\tilde{\ell},1,1',\cdots;b',\tilde{1}^+,\cdots,\tilde{\ell}^+,1^+,1'^+,\cdots),$$

where we have been careful in reordering the operators, which results in an even number of permutations. To ease notation, we defined $g(\tilde{1},\cdots) = g(x_{\tilde{1}},z_{\tilde{1}},\cdots)$.

From these considerations, we can rewrite Eq. (34) as

$$G(ab') = \frac{Z_0}{Z}\sum_{k,\tilde{\ell}=0}^\infty \frac{i^k}{2^k k!}\frac{i^{\tilde{\ell}/2}}{\tilde{\ell}!}\int v(11')\cdots v(kk')\int \lambda(\tilde{1})\cdots\lambda(\tilde{\ell})$$

$$d_{\tilde{\ell}/2}(\tilde{1},\ldots,\tilde{\ell})g_{2k+\tilde{\ell}+1}(a,\tilde{1},\ldots,\tilde{\ell},1,1',\ldots;b',\tilde{1}^+,\ldots,\tilde{\ell},1^+,1'^+,\ldots),$$
(37)

where we defined $v(11') = \delta(z, z')v(x, x', z)$. The first type of integral is over $1, 1', \ldots, k, k'$, and the second type of integral is over $\tilde{1}, \ldots, \tilde{\ell}$, by which we mean $\int_\gamma d\bar{z}_{\tilde{1}} \cdots d\bar{z}_{\tilde{\ell}} \int dx_{\tilde{1}} \cdots dx_{\tilde{\ell}} \sum_{\bar{\mu}_1, \cdots, \bar{\mu}_{\tilde{\ell}}}$. To ease the notation, we write $\lambda(\tilde{\ell}) = \lambda_{\bar{\mu}_{\tilde{\ell}}}(x_{\tilde{\ell}}, z_{\tilde{\ell}})$ and $d(\tilde{1}, \cdots) = d(\bar{\mu}_{\tilde{1}}, z_{\tilde{1}}, \cdots)$. The factor $1/2^k$ comes from the factor $1/2$ in $\hat{H}_{\text{el-el}}$. The factor $i^1$ conveniently canceled the $(-i)$ factor in the definition of $G$. A similar equation holds for $\mathbb{D} = \mathbb{D}_1$ and all higher-order Green's functions $G_n$ and $\mathbb{D}_n$.

As such, perturbation theory for mixed fermion-boson systems is reduced to finding practical expressions for the separate non-interacting electronic and bosonic $n$-particle Green's functions, $g_n$ and $d_n$. The expressions are provided by Wick's theorem, which is the topic of the next section.

## 2.6    Wick's Theorem

Wick's theorem provides a recipe of how to write $g_n$ as products of $g_1$:s and $d_n$ as products of $d_1$. The original theorem (Wick 1950) was an operator identity which related time-ordered products to normal-ordered ones and contractions. Although being the cornerstone of zero-temperature formalism, where normal-ordered products vanish, the theorem is not immediately applicable for finite temperature or systems out of equilibrium. Also, Wick's discussion was focused on creation and destruction operators.

Here we will show how a Wick-like decoupling works for the general case for $g_n$ and $d_n$. All cases (zero temperature, finite temperature in equilibrium, non-equilibrium) follow from using the general time contour and then deforming it (Stefanucci and van Leeuwen 2013). The decoupling follows from the Martin-Schwinger hierarchy, Eqs. (32) and (33), with $\hat{H}_{\text{int}} = 0$. The decoupling is different for $g_n$ and $d_n$, essentially since $g_n$ contains two types of non-Hermitian operators ($\hat{\psi}$ and $\hat{\psi}^\dagger$), while $d_n$ contains only one type of Hermitian operator ($\hat{\phi}$). As such, we discuss them separately, starting with the more familiar case of $g_n$.

### 2.6.1    Wick's Theorem for $g_n$

The determining relation for $g_n$ is the Martin-Schwinger hierarchy for $G_n$, Eq. (32), with $\hat{H}_{\text{int}} = 0$, and the KMS boundary conditions:

$$\left[ i\frac{\partial}{\partial z_k} - h(1) \right] g_n = \sum_{j=1}^{n} (\pm)^{k+j} \delta(k; j') g_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, n; 1', \ldots, \overset{\sqcap}{j'}, \ldots, n').$$

(38)

The Martin-Schwinger hierarchy for $g_n$ couples only to $g_{n-1}$, and thus by iteration, we can find the solution to Eq. (38) in terms of single-particle Green's functions $g(1; 1') \equiv g_1(1; 1')$. The explicit solution is given by a permanent/determinant for bosons/fermions of $g(1; 1')$ (Martin and Schwinger 1959; Bruus and Flensberg 2004; Stefanucci and van Leeuwen 2013):

$$g_n(1, \ldots, n; 1', \ldots, n') = \begin{vmatrix} g(1; 1') & \ldots & g(1; n') \\ \vdots & & \ldots \\ g(n; 1') & \ldots & g(n; n') \end{vmatrix}_{\pm}, \tag{39}$$

where $g(1; 1')$ satisfies (Eq. (38) with $n = 1$)

$$\left( i \frac{\partial}{\partial z_1} - h(1) \right) g(1; 1') = \delta(1; 1'). \tag{40}$$

The permanent/determinant Eq. (39) satisfies the Martin-Schwinger equations for $g_n$, Eq. (38), as can be checked by applying the differential operator $\left[ i \frac{\partial}{\partial z_k} - h(1) \right]$. Furthermore, the KMS boundary conditions are satisfied since $g$ satisfies them.

As an example, we consider the decoupling for $g_2$:

$$g_2(1, 2; 1', 2') = g(1; 1')g(2; 2') \pm g(1; 2')g(2; 1') \tag{41}$$

which is depicted in Fig. 2. The correct sign is taken into account by simply counting the number of times lines cross each other.

We can also write the decoupling recursively. For $g_3$, expanded along 1

$$g_3(1, 2, 3; 1', 2', 3') = g(1; 1')g_2(2, 3; 2', 3') \pm g(1; 2')g_2(2, 3; 1', 3')$$
$$+ g(1; 3')g_2(2, 3; 1', 2'), \tag{42}$$

which is depicted in Fig. 3. In the recursive form along $k$, it is immediately clear that $g_3$ satisfies the Martin-Schwinger hierarchy by applying $\left[ i \frac{\partial}{\partial z_k} - h(1) \right]$.

**Fig. 2** Wick's theorem for noninteracting two-particle Green's function $g_2$, Eq. (41)

**Fig. 3** Wick's theorem for noninteracting three-particle Green's function $g_3$, Eq. (42). The second diagram on the right-hand side gives a contribution $(\pm 1)$, having one crossing, while the right diagram gives $(\pm 1)^2 = 1$. We have prolonged the edges of the $g_2$:s with a thin dashed line to the correct vertices since we can then easily see which sign the diagram has by counting the number of crossings

### 2.6.2 Wick's Theorem for $d_n$

The determining relation for $d_n$ is the Martin-Schwinger hierarchy for $\mathbb{D}_n$, Eq. (33), with $\hat{H}_{\text{int}} = 0$, and the KMS boundary conditions:

$$\sum_{\bar{\mu}} \left[ i\alpha_{\bar{\sigma}\bar{\mu}} \frac{\partial}{\partial z_k} - \bar{\Omega}_{\bar{\sigma}\bar{\mu}}(z_k) \right] d_n(1, \ldots, \bar{\mu}z_k, \ldots, 2n)$$

$$= \sum_{j=1, j\neq k}^{2n} \delta(z_k, z_j)\delta_{\bar{\sigma}\bar{\mu}_j} d_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, \overset{\sqcap}{j}, \ldots, 2n). \tag{43}$$

The hierarchy for $d_n$, Eq. (43), clearly resembles the hierarchy for the electronic case, $g_n$, Eq. (38). The structure becomes more clear by defining the operator in front of $d_n$ on the first line as an (discrete) integral operator $L_k$, leading to

$$L_k d_n(1, \ldots, k, \ldots, 2n) = \sum_{j=1, j\neq k}^{2n} \delta(k, j) d_{n-1}(1, \ldots, \overset{\sqcap}{k}, \ldots, \overset{\sqcap}{j}, \ldots, 2n). \tag{44}$$

This is the formal analogue to Eq. (38), and as such it is not surprising that Wick's theorem for $g_n$ and $d_n$ is very similar. The difference is that for $d_n$, all operators need to be contracted with each other, as there is no separation into cases as it was for creation and destruction operators.

Another feature that is different from the electronic case is the appearance of an odd number of fields, when $n$ is a half-integer. From Eq. (44), we see that integer $n$ connects with integer $n - 1$ and half-integer $n$ connects with half-integers $n - 1$. As such, we have two separate hierarchies of equations. Furthermore, we have that $d_n = 0$ when $n$ is a half-integer. This can be seen by considering the ensemble average of the equation of motion for $\hat{\phi}_H$, Eq. (27), in the interacting case:

$$\sum_{\bar{\mu}} \left( i\alpha_{\bar{\sigma}\bar{\mu}} \frac{\mathrm{d}}{\mathrm{d}z} - \bar{\Omega}_{\bar{\sigma}\bar{\mu}}(z) \right) \phi(\bar{\mu}z) = \int dx \lambda_{\bar{\sigma}}(xz)G(x, z, x, z^+). \tag{45}$$

This equation can be solved, and the solution is given by

$$\phi(\bar{\sigma}, z) = -i \sum_{\bar{\mu}} \int dx \int_{\gamma} d\bar{z} \, d(\bar{\sigma}z; \bar{\mu}\bar{z})\lambda_{\bar{\mu}}(x, \bar{z})G(x, \bar{z}, x, \bar{z}^+), \tag{46}$$

where $d = d_1$ is the bosonic Green's function of Eq. (44) with $n = 1$ that fulfills

$$\sum_{\bar{\mu}} \left[ i\alpha_{\bar{\sigma}\bar{\mu}} \frac{\partial}{\partial z_1} - \bar{\Omega}_{\bar{\sigma}\bar{\mu}}(z_1) \right] d(\bar{\mu}z_1, 2) = \delta(z_1, z_2)\delta_{\bar{\sigma}\bar{\mu}_2}. \tag{47}$$

In the non-interacting state, we have immediately that $\langle \phi(\bar{\sigma}, z) \rangle_0 = 0$, that is, we have $d_{1/2} = 0$. Moreover, the Martin-Schwinger hierarchy couples half-integers to half-integers. Consider $n = 3/2$:

$$L_1 d_{3/2}(1, 2, 3) = \delta(1, 2)d_{1/2}(3) + \delta(1, 3)d_{1/2}(2) = 0$$

We have that $d_{3/2} = 0$ is a solution, which fulfill the KMS boundary conditions. As such, this is the only solution. By induction, $d_n = 0$ for half-integers. As such, from now on, we only consider $n$ being an integer in the noninteracting case.

As in the case of $g_n$, the equation of motion for $d_n$ only connects to lower-order Green's functions, making it plausible that we can write the solution to Eq. (43) in terms of single-particle Green's functions $d(1, 2) \equiv d_1(1, 2)$. For $d_n$; the solution to Eq. (43) is given by the so-called Haffnian (Säkkinen 2016):

$$d_n(1 \ldots 2n) = d(12)d(34) \cdots d(2n - 1, 2n) + d(13)d(24) \cdots d(2n - 1, 2n) + \ldots,$$
(48)

where ... denote the rest of the permutations of 1 to the set $\{4, \ldots, 2n\}$.

As examples of the decoupling of $d_n$, $d_2$ is given by

$$d_2(1234) = d(12)d(34) + d(13)d(24) + d(14)d(23).$$
(49)

The solution can also be written in a recursive form, which can be seen as expanding the Haffnian around a point. For $d_3$, expanded around the point 1

$$d_3(123456) = d(12)d_2(3456) + d(13)d_2(2456) + d(14)d_2(2356)$$
$$+ d(15)d_2(2346) + d(16)d_2(2345).$$
(50)

The recursive form of Eq. (50) makes it clear that $d_3$ satisfies Eq. (43) with $k = 1$. The expansion for $d_3$ is shown in Fig. 4, which exemplifies that the Haffnian can be visualized in terms of the so-called chord diagrams. We also note that the Haffnian is commonly written in a more symmetric form, due to the symmetry $d(12) = d(21)$:

$$d_n(1 \ldots 2n) = \frac{1}{2^n n!} \sum_P \prod_{i=1}^{n} d(P(2i - 1), P(2i)),$$
(51)

where $P$ denotes permutations of $\{1, \ldots 2n\}$.

We thus again note the crucial difference between Wick's theorem for $g_n$ and $d_n$: For $g_n$ we need to connect unprimed coordinates to primed coordinates in all possible ways. However, for $d_n$, there is no distinction between primed and unprimed coordinates, and we need to connect all coordinates in all possible ways. It is thus natural that for $g_n$ we organize the vertices in two columns, while for $d_n$ it is more natural to put the vertices on a circle. It is important to note, however, that the decoupling, Wick's theorem, is in both cases the solution to the corresponding non-interacting Martin-Schwinger hierarchy with the proper Kubo-Martin-Schwinger
**Fig. 4** Pictorial description of Wick's theorem for $d_3$, Eq. (50), when expanding around point 1. Dots connected with a wiggly line denote $d_1$, while non-connected dots denote higher-order Green's function. Note that we do not need to take into account the number of possible crossings, since the particles here are bosons

boundary conditions. As stated before, the time contour construction permits a finite-temperature, non-equilibrium perturbation theory. By specializing to different contours, we obtain the zero-temperature formalism by an adiabatic switch of the interaction or the Matsubara formalism by considering the vertical track only. This shows the elegance of the contour formalism for mixed electron-boson systems.

## 3    Diagrammatic Perturbation Theory

Wick's theorems provided explicit expressions for noninteracting Green's functions $g_n$ and $d_n$, which were the building blocks in the perturbation expansion for many-body Green's functions $G_n$ and $\mathbb{D}_n$, via equations like Eq. (37).

Equipped with Wick's theorem, we can write the expansion for $G(ab')$, Eq. (37), in diagrams. It turns out, however, that many of the resulting diagrams are topologically equivalent and as such we only need to sum over the topologically inequivalent diagrams. This will cancel the combinatorial factors in Eq. (37). Furthermore, we only need to sum over connected diagrams, meaning that the internal vertices need to connect to the outer vertices (those vertices not integrated over). The disconnected diagrams will cancel against the expansion for $Z$ in Eq. (35). For a more in-depth discussion, see, for example, Säkkinen (2016). The resulting formulas for $G$ and $D$ become

$$G(ab') = \sum_{k,\tilde{\ell}=0}^{\infty} i^{k+\tilde{\ell}} \int v(11') \cdots v(kk') \int \lambda(\tilde{1}) \cdots \lambda(2\tilde{\ell})$$

$$d_{\bar{1}}(\tilde{1}, \ldots, 2\tilde{\ell}) g_{2k+2\tilde{\ell}+1}(a, \tilde{1}, \cdots, \tilde{\ell}, 1, 1', \ldots; b', \tilde{1}, \cdots, \tilde{\ell}, 1^+, 1'^+, \ldots)|_{\text{t.in.c}}$$

$$(52)$$
**Fig. 5** Example diagrams of $G(ab')$. Wavy lines denote $d$ propagators, while dashed lines denote the pair interaction $v(x, x', z)$. Solid straight lines denote $g$ propagators

$$
\mathbb{D}(ab) = \sum_{k,\tilde{\ell}=0}^{\infty} i^{k+\tilde{\ell}} \int v(11') \cdots v(kk') \int \lambda(\tilde{1}) \cdots \lambda(2\tilde{\ell})
$$

$$
d_{\tilde{\ell}+1}(ab\tilde{1}\ldots 2\tilde{\ell})g_{2k+2\tilde{\ell}}(\tilde{1}, \cdots, \tilde{\ell}, 1, 1', \ldots; \tilde{1}, \cdots, \tilde{\ell}, 1^+, 1'^+, \ldots)|_{\text{t.in.c}}, \tag{53}
$$

where the abbreviation (t.in.c) denotes that we consider only the topologically inequivalent and connected diagrams when expanding $g_n$ and $d_n$ in permanents/determinants and Haffnians. The same considerations can be applied to higher-order Green's functions without any formal complication. As such, perturbation theory for coupled electron-boson systems is now completely well-defined.

## 3.1    Skeleton Diagrams and the Kadanoff-Baym Equations

The Feynman rules for the fermionic and bosonic $n$-particle Green's functions completely determine these functions in terms of the propagators $g$ and $d$. We can, however, reduce the number of distinct diagrammatic terms considerably by expressing them in terms of the so-called dressed propagators. Let us start by discussing the dressing of the fermion propagator $G$.

We first give some examples of the diagrammatic expansion of $G(ab')$, in Fig. 5. We note that many diagrams will contain repetitions of smaller blocks. This motivates us to define the concept of an irreducible self-energy $\Sigma$, which consists of the set of diagrams contributing to $G$ that, after the removal of the ingoing and outgoing $g$ lines, cannot be cut into two pieces by removal of a $g$ line. With these definitions we can write $G$ as a repetition in series of irreducible pieces:

$$
G = g + g\Sigma g + g\Sigma g\Sigma g + \ldots = g + g\Sigma G \tag{54}
$$

in which the products in these expressions consist of repeated convolutions, i.e., $ab(1, 2) = \int_\gamma d3\, a(1, 3)b(3, 2)$. The self-energy $\Sigma[g, d]$ is itself expressed as an infinite sum of irreducible diagrams in terms of $g$ and $d$. Examples of diagrams for $\Sigma[g, d]$ are shown in Fig. 6.

Within these $\Sigma$ diagrams themselves, we can also distinguish self-energy insertions (e.g., the last diagram in Fig. 6), i.e., pieces of diagrams that can be made
**Fig. 6** Example diagrams of the electronic self-energy $\Sigma[g, d]$. The last diagram contains a self-energy insertion

**Fig. 7** Example diagrams of the skeletonic electronic self-energy $\Sigma_s[G, d]$

disjoint of the rest of the diagram by cutting two $g$ lines. The diagrams obtained by the removal of all self-energy insertions are the so-called skeleton diagrams. The full set of $\Sigma$ diagrams can be obtained by dressing the skeleton graphs with self-energy insertions in all possible ways. This amounts to the replacement of the bare $g$ lines by the full propagators $G$ in every diagram. We can therefore write $\Sigma[g, d] = \Sigma_s[G, d]$ where we used the subscript $s$ to denote that $\Sigma_s$ is the sums of all skeleton diagrams in terms of $G$ and $d$. We can therefore write

$$G = g + g\,\Sigma_s[G, d]G. \tag{55}$$

Examples of diagrams for $\Sigma_s[G, d]$ are shown in Fig. 7.

Let us now proceed with the discussion of the bosonic Green's function $\mathbb{D}(ab)$. The diagrammatic structure comes from expanding $g_n$ and $d_n$ in Eq. (53), and example diagrams are shown in Fig. 8.

New types of diagrams, the double "tadpole" diagrams (top middle in Fig. 8), occur for $\mathbb{D}(ab)$ that were not present for $G(ab)$, and as such we discuss them first. The tadpoles are in fact the diagrammatic expansion of the half-body term $\phi(a)$. All the tadpole diagrams can be conveniently summed up, which is done in Fig. 9. The diagrammatic rules yield

$$\phi(\bar{\sigma}, , z) = -i \sum_{\bar{\mu}} \int dx \int_\gamma d\bar{z}\, d(\bar{\sigma}z; \bar{\mu}\bar{z})\lambda_{\bar{\mu}}(x, \bar{z})G(x, \bar{z}, x, \bar{z}^+), \tag{56}$$
**Fig. 8** Example diagrams of $\mathbb{D}(ab)$. The top middle diagram is referred to as the double tadpole diagram

**Fig. 9** Summation of all tadpole diagrams, which yields $\phi(a)$, Eq. (56)

**Fig. 10** Example diagrams of $\mathbb{D}(ab)$ after resumming the double tadpole diagrams

a result that we already obtained from the equations of motion for $\phi(a)$, Eq. (46). As such, we can write the expansion for $\mathbb{D}$ as

$$\mathbb{D}(1, 2) = \phi(1)\phi(2) + d(1, 2) + (d\Pi d)(1, 2) + (d\Pi d\Pi d)(1, 2) + \dots, \quad (57)$$

where we also introduced a bosonic self-energy $\Pi[g, d]$ as the collection of diagrams which cannot be made disjoint by cutting two $d$ lines. Some example diagrams are shown in Fig. 10.

Differently from the electronic case, $\mathbb{D}(12)$ does NOT fulfill a Dyson equation, due to the presence of $\phi(a)\phi(b)$. As such, we are motivated to define a new type of Green's function $D(ab) = \mathbb{D}(ab) - \phi(a)\phi(b)$ which has these terms subtracted. $D(ab)$ can be defined using the so-called fluctuation operators,

$$\Pi_s[G, d] =$$ 
**Fig. 11** Example diagrams of the bosonic skeletonic self-energy $\Pi_s[G, d]$
$$\Sigma_{ss}[G, D] =$$ 

**Fig. 12** Example diagrams of the double skeletonic electronic self-energy $\Sigma_{ss}[G, D] = \Sigma_H[G] + \Sigma_{xc}[G, D]$, see Eq. (63). The first two diagrams, the tadpole diagrams, make up the time-local $\Sigma_H$

$\Delta\hat{\phi}_H(a) = \hat{\phi}_H(a) - \phi(a)$, with $\langle\Delta\hat{\phi}_H(a)\rangle = 0$. We then have that $D(ab) = -i\text{Tr}\left[\mathcal{T}_c\left\{\hat{\rho}\Delta\hat{\phi}_H(a)\Delta\hat{\phi}_H(b)\right\}\right]$. The Fluctuation Green's function $D(ab)$ fulfills a Dyson equation, obtained by rewriting Eq. (57) as

$$D = d + d\Pi d + d\Pi d\Pi d + \ldots = d + d\Pi[g, d]D. \tag{58}$$

We can now proceed as above and remove all fermionic self-energy insertions inside $\Pi[g, d]$ diagrams and form skeleton diagrams and replace the bare $g$ by the dressed $G$ as $\Pi_s[G, d] = \Pi[g, d]$. This is shown in Fig. 11.

We note now that we can continue this way and also remove all bosonic self-energy insertions inside the $\Pi_s$ diagrams and dress these diagrams with the full $D$ line such that $\Pi_{ss}[G, D] = \Pi_s[G, d]$ where $\Pi_{ss}$ are the self-energy diagrams that are skeletonic with respect to removal of both fermionic and bosonic self-energy insertions. A similar procedure can be carried out for the fermionic self-energy, where we can write $\Sigma_{ss}[G, D] = \Sigma_s[G, d]$, except that we must not dress the time-local diagrams, as shown in Fig. 12. In conclusion, we obtain the following set of equations

$$G = g + g\Sigma_{ss}[G, D]G \tag{59}$$

$$D = d + d\Pi_{ss}[G, D]D. \tag{60}$$

Example diagrams are shown in Fig. 12 for $\Sigma_{ss}[G, D]$ and Fig. 13 for $\Pi_{ss}[G, D]$.

The Dyson equations, Eqs. (59) and (60), can be rewritten in a form often used in time-dependent calculations, by using the equations of motion for bare Green's functions:
$$\Pi_{ss}[G, D] = \text{}$$

**Fig. 13** Example diagrams of the double skeletonic bosonic self-energy $\Pi_{ss}[G, D]$

$$\left[i\partial_{z_1} - h(1)\right] G(1, 2) = \delta(1, 2) + \int_\gamma d3 \, \Sigma_{ss}[G, D](1, 3)G(3, 2) \tag{61}$$

$$\left[i\alpha\partial_{z_1} - \bar{\Omega}(1)\right] D(1, 2) = \delta(1, 2) + \int_\gamma d3 \, \Pi_{ss}[G, D](1, 3)D(3, 2). \tag{62}$$

These are self-consistent equations for the fermion and boson propagator, once an approximation for $\Sigma_{ss}$ and $\Pi_{ss}$ in terms of skeleton graphs has been chosen. Two similar adjoint equations involving the time derivative with respect to $z_2$ can be derived in a similar way. These equation are known as the Kadanoff-Baym equations (KBE), together with the KMS boundary conditions discussed earlier.

The solution of the KBE yields a wealth of information. Apart from non-equilibrium spectral functions and the total energy, the expectation value of any one-body operator can be obtained from the solution. Since external time-dependent fields are treated explicitly, the approach allows, for example, for the calculation of higher response functions. For the case of linear response functions, this provides an alternative for the Bethe-Salpeter equation while at the same time admitting sophisticated memory kernels which are difficult to treat in the standard approach.

The solution of the KBE requires full self-consistency, as the self-energies depend on Green's functions that are themselves solutions of the equations. This feature can be a numerical disadvantage, but it also has two important theoretical advantages. First of all, it removes the dependence of the result on bare Green's functions, allowing for an unambiguous calculation of observables. Secondly, by a proper diagrammatic choice of the self-energies, we can make sure that the observables calculated from the Green's functions satisfy the conservation laws for energy, momentum, and particle number. For this purpose, the self-energies must be chosen in a so-called $\Phi$-derivable manner. To define this properly, it is convenient to split off the spatially and temporally local Hartree part $\Sigma_H$ of the fermionic self-energy and to define the remaining exchange-correlation part $\Sigma_{xc}$ by

$$\Sigma_{ss}(1, 2) = \Sigma_H(1, 2) + \Sigma_{xc}(1, 2). \tag{63}$$

The Hartree part is given by the two tadpole diagrams of Fig. 12. Now we define a functional $\Phi[G, D]$ by closing each skeleton diagram for $\Sigma_{xc}$ with a $G$ line which produces a set of vacuum diagrams. The procedure is explained in more detail in Fig. 14.

$$\Phi[G, D] = \frac{1}{2} \bigcirc + \frac{1}{2} \bigcirc + \frac{1}{4} \bigcirc + \frac{1}{2} \bigcirc + \frac{1}{4} \bigcirc + \frac{1}{4} \bigcirc \bigcirc + \frac{1}{2} \bigcirc \bigcirc$$
**Fig. 14** Example diagrams of $\Phi[G, D]$ yielding $\Sigma_{ss}[G, D]$ and $\Pi_{ss}[G, D]$. As examples, the operation $\delta/\delta G$, i.e., removing a $G$ line, applied to the first two diagrams gives the third and fourth diagram for $\Sigma_{ss}[G, D]$ in Fig. 12 (Fock-like, or exchange-like, diagrams). The operation $-2\delta/\delta D|_S$ applied to the second diagram yields the first diagram for $\Pi_{ss}[G, D]$ in Fig. 13

Each of the topologically different vacuum diagrams will also be multiplied with a symmetry factor $1/N_S$ where $N_S$ is the number of equivalent $G$ lines that yield the same self-energy diagram by their respective removal (the relevant fact that the different classes of equivalent lines in a vacuum diagram are equal in size can be proven as in Stefanucci and van Leeuwen 2013). We furthermore introduce an additional minus sign since the removal of a $G$ line from a vacuum diagram changes the number of fermion loops by one. By construction the $\Phi$-functional has the property that $\Sigma_{xc}(1, 2) = \delta\Phi/\delta G(2, 1)$. Along the lines of Stefanucci and van Leeuwen (2013), we can further prove that $\Pi_{ss}(1, 2) = -2\delta\Phi/\delta D(1, 2)|_S$ where the subscript $S$ refers to the symmetrized derivative $[\delta/\delta D(12) + \delta/\delta D(21)]/2$.

So far we dealt with the exact self-energies, but in practice we have to consider approximate self-energies. We say that such self-energies $\Sigma_{xc}$ and $\Pi_{ss}$ are $\Phi$-derivable, whenever there exists a functional $\Phi[G, D]$ such that

$$\Sigma_{xc}(1, 2) = \frac{\delta\Phi}{\delta G(2, 1)} \tag{64}$$

$$\Pi_{ss}(1, 2) = -2\frac{\delta\Phi}{\delta D(1, 2)}|_S. \tag{65}$$

In practice the corresponding $\Phi$-functional is obtained by selection of an appropriate set of sub-diagrams of the exact $\Phi$-functional.

The significance of this procedure lies in the fact that the $\Phi$-functional has invariance properties with regard to certain space-time and gauge transformations that imply the satisfaction of corresponding conservation laws for Green's functions obtained from the KBE in which the $\Phi$-derivable self-energies are used (Baym and Kadanoff 1961; Baym 1962). We therefore have a way to automatically guarantee the satisfaction of conservation laws for approximate self-energies. We finally mention that it is also possible to develop partially self-consistent approaches in which, for example, only number conservation is guaranteed (Karlsson and van Leeuwen 2016). Such approaches are of interest when full self-consistency is hard to achieve, for example, due to computational limitations.

We finally note that for the purely electronic case, it is very common to dress also the two-body interaction $v(x, y, z)$, to obtain expansions in terms of the so-called screened interaction $W$. This construction, to lowest order, constitutes the often-used $GW$ approximation (Hedin 1965). The redressed $\Phi$-diagrams are referred to as the $\Psi[G, W]$-functional (Almbladh et al. 1999). In the presence of phonons, similar types of resummations can be done (Hedin and Lundqvist 1970).

We should mention that the KBE for practical applications are typically, by selecting time variables on various branches of the contour, rewritten in terms of real-time, imaginary time, and mixed real-imaginary time components using the so-called Langreth rules. This is more a technical issue, and we refer to the literature (Dahlen and van Leeuwen 2007; Stefanucci and van Leeuwen 2013) for details. In practice these equations are first solved on the vertical imaginary track of the contour, after which a time propagation in the double real-time and real-imaginary time variables can be performed. In practice the KBE are typically converted, using a suitable basis, into time-dependent matrix equations which can be solved by employing suitable time-stepping techniques in the double-time plane (Stan et al. 2009).

## 4    Conclusions

The use of non-equilibrium Green's function methods has seen an explosive rise in the last two decades, mainly due to developments in nano-science and nonlinear pump-probe laser technologies that allow for in-depth studies of non-equilibrium systems.

One of the large research fields that has been developed over the last years is the study of molecular transport which studies charge transport through single molecules and nano-junctions (Stefanucci and Almbladh 2004; Datta 2005; Cuevas and Scheer 2010) attached to metallic leads. The small size of the system makes it necessary to have a detailed description of the electronic structure in which a correct description of the Coulomb interactions between the electrons in the system is crucial. The Kadanoff-Baym approach is well-suited to study time-dependent quantum transport systems. If the macroscopic leads are treated as effectively non-interacting, the leads can be incorporated non-perturbatively into the KBE using the so-called embedding self-energy, which is simply added to the many-body self-energy. The first applications of KBE to transient phenomena in correlated charge transport of electrons are by now a decade old (Myöhänen et al. 2008, 2009; Puig von Friesen et al. 2010; Uimonen et al. 2011) with later developments of numerically efficient but simplified approaches (Latini et al. 2014) based on the so-called generalized Kadanoff-Baym ansatz (Lipavský et al. 1986). These approaches have given new insights into various non-equilibrium phenomena such as transients and memory effects (Myöhänen et al. 2008), as well as bistability (Uimonen et al. 2010; Khosravi et al. 2012), image charge effects (Myöhänen et al. 2012), bias-induced gap closings (Myöhänen et al. 2009), and other correlation effects in the non-equilibrium regime.

Another research field that developed quickly is that of strong-field pump-probe laser spectroscopy of single molecules in strong laser fields. In these systems, there is a considerable ionization yield, and the use of non-equilibrium Green's functions is very well-suited to describe these systems using similar embedding techniques as in the quantum transport case, in which the embedding is now done for the ionization continuum rather than the macroscopic leads. This allows for treating strong external fields non-perturbatively (Perfetto et al. 2015). The formalism has been applied to the first-principle study of ultrafast phenomena in large organic

molecules such as the early-stage density oscillation of the electronic charge in the photoexcited phenylalanine amino acid (Perfetto et al. 2018) as well as the electronic charge separation in photoexcited donor-$C_{60}$ complexes (Boström et al. 2018).

All these systems were purely electronic. However, recent years have seen the development of the KBE for coupled electron-boson systems (Säkkinen et al. 2015a, b) as well as the study of the KBE (Tuovinen et al. 2016) for heat transport (Arrachea et al. 2012; Wang et al. 2014). In these systems we not only deal with electrons but also with various bosonic systems. The KBE for electron-boson systems have been used to study polaron formation in coupled electron-phonon systems (Säkkinen et al. 2015a, b), spin transport for electron-magnon systems (Mahfouzi and Nikolić 2014), and pump-probe spectroscopies in electron-plasmon systems (Schüler et al. 2016), and there is a considerable activity toward the study of electron-photon systems in cavity quantum electrodynamics (Ruggenthaler et al. 2014; Flick et al. 2017) with various connections to time-dependent density functional theory. This research field is growing rapidly, and the KBE method and its simplifications are becoming standard tools; there is a transition of applications from model systems to realistic systems (Perfetto et al. 2015; de Melo and Marini 2016; Schlünzen et al. 2016).

Pump-probe and nonlinear spectroscopy on molecules and solids is also experimentally a growing research field, and therefore there is an increasing need for theoretical methods to interpret and describe new experiments. In this work, we outlined a suitable formalism to achieve this goal. The formalism has already been used successfully in the lowest orders, and many promising new applications and further developments of the theory are within reach.

### Abstract

Intense and ultrashort light pulses allow to investigate new states of matter in complex materials under non-equilibrium conditions. The formulation of dynamical mean-field theory (DMFT) using Keldysh Green's functions provides a framework to calculate the electronic structure of correlated materials out of equilibrium. The approach has contributed insight into a wide range of topics, including photo-induced processes in Mott insulators, non-equilibrium steady

states in driven materials, and the fundamental question how isolated quantum systems thermalize. In this chapter we outline the theoretical foundations of non-equilibrium DMFT, present some of the major results so far, and briefly discuss future directions, which are needed in order to develop a framework in which material properties out of equilibrium can be obtained from first principles.

# 1    Introduction

Traditionally, computational material research is concerned with the equilibrium properties of matter. This is challenged by the new possibilities offered by ultrafast laser techniques (Giannetti et al. 2016). Intense femtosecond light pulses can stimulate new quantum states of matter which exist only out of equilibrium. Examples include possible light-induced superconductivity (Fausti et al. 2011) and the transient control of lattice constants and electronic properties through the excitation of an-harmonically coupled phonons (Rini et al. 2007). Photo-induced changes of material properties can even be long-lived, as evidenced by the switching to hidden phases (Ichikawa et al. 2011; Stojchevska et al. 2014) with new types of spin and orbital order. This new research direction poses great challenges to theory, as many fundamental concepts of condensed matter physics rely on the notion of thermal equilibrium or a projection to low-energy states. Even the single-particle band structure is in part an equilibrium concept: in complex materials, electronic quasiparticles are only well-defined close to the ground state, and the screened potential is determined by the collective response of the electronic system itself. To identify the theoretical challenges, let us discuss some questions in more detail.

**Transient nonthermal dynamics** For many situations one can assume rapid thermalization of electrons, so that photo-excited states in solids can be described in terms of an electronic quasi-equilibrium state. However, nontrivial transient phenomena such as the enhancement of electronic orders cannot be explained by a photo-induced hot electron temperature and must occur prior to thermalization. There is no generic answer to the question how fast a system of interacting particles would thermalize after a perturbation, although this concerns the basic foundations of statistical physics. Isolated model systems can behave strictly non-ergodic, in particular at integrability (Polkovnikov et al. 2011). Condensed matter systems are never ideal in that sense, but their short-time behavior may reflect the non-ergodic behavior of a related integrable system, leading to a two-stage relaxation with an earlier pre-thermal state (Moeckel and Kehrein 2008; Kollar et al. 2011), which can show long-range order even if the corresponding thermal state does not (Sciolla and Biroli 2013; Tsuji et al. 2013). Even far from integrable points, fast electronic thermalization is not obvious, e.g., close to the Mott transition (Sayyad and Eckstein 2016). The validity of Boltzmann kinetic equations, which can describe the dynamics in semiconductors (Haug and Jauho 2008), relies on the existence of well-defined quasiparticles and is not

clear for the ultrafast dynamics in strongly correlated systems. Nonthermal states are also important when non-perturbative electric fields act on a material. Short laser pulses can have peak fields that would break a material in the steady state, but not as long as the dynamics remains quantum coherent (Higuchi et al. 2017), when instead phenomena like Bloch oscillations and high-harmonic generation can occur.

**Non-equilibrium steady states** When a system is subject to a rapidly oscillating time-periodic perturbation, averaging over the fast driving can yield a new effective Hamiltonian, in analogy to dynamical stabilization of new equilibria in mechanical systems (Bukov et al. 2015). This so-called Floquet engineering is used to design tight-binding Hamiltonians in cold-gas experiments (Goldman and Dalibard 2014), including topologically nontrivial band structures (Jotzu et al. 2014). Floquet engineering can be used to manipulate emergent many-body interactions such as spin exchange interactions (Mentink et al. 2015) or superconducting pairing (Knap et al. 2016), which suggests many routes for material design out of equilibrium. The fundamental question in this context is whether a non-equilibrium system can be directed into the ground state or a thermal state of such engineered Hamiltonians or whether the process is dominated by heating effects. To answer this question, one needs to understand the non-equilibrium steady states in strongly correlated open quantum system, in which energy input and dissipation to the environment are balanced.

A viable approach to describe both the ultrafast transient evolution and non-equilibrium steady states of many-body systems is the Keldysh formalism. It is based on non-equilibrium Green's functions, which describe the propagation of particles and holes between different space-time points. Green's functions contain both the information on the spectrum (electronic structure, quasiparticle energies) and the occupation of states, which mutually depend on each other out of equilibrium. In equilibrium, dynamical mean-field theory (DMFT) nowadays provides a standard approach to describe correlated systems (Georges et al. 1996). DMFT maps a lattice model with local interactions to an effective impurity model, which can be solved numerically. This approximation accurately treats local temporal fluctuations and can therefore capture many phenomena that originate from the competition of atomic correlations and the itinerant behavior of electrons. DMFT can be applied to generic models obtained from density-functional theory and thus quantitatively predict the electronic structure of complex materials (Pavarini et al. 2014). When reformulated within the Keldysh formalism, DMFT can describe non-equilibrium phenomena in correlated materials (Aoki et al. 2014; Schmidt and Monien 2002; Freericks et al. 2006). The solution of the DMFT equations in real time still poses many numerical challenges. The purpose of this chapter is to explain the foundations of non-equilibrium DMFT within the Keldysh framework (Sect. 2), to discuss DMFT and the impurity problem out of equilibrium (Sect. 3), and to give examples for the application of non-equilibrium DMFT (Sect. 4). Current developments of non-equilibrium DMFT are briefly sketched in the outlook (Sect. 5).

## 2        Theoretical Foundations

This section summarizes theoretical aspects needed for the development of non-equilibrium DMFT, in particular the Keldysh formalism. Only the main concepts are presented. For more details we refer to the literature, e.g., books by Haug and Jauho (2008) and Kamenev (2011).

### 2.1        Models

We first define typical models which are addressed within non-equilibrium DMFT. The basic model for correlated electrons is the one-band Hubbard model,

$$H = \sum_{i,j,\sigma} v_{ij}\, c_{i\sigma}^{\dagger} c_{j\sigma} + U \sum_j n_{j\uparrow} n_{j\downarrow}. \tag{1}$$

Here $n_{j\sigma} = c_{j\sigma}^{\dagger} c_{j\sigma}$, $c_{j\sigma}^{\dagger}$ ($c_{j\sigma}$) create (annihilate) an electron with spin $\sigma$ at site $j$ of a crystal lattice, $v_{ij}$ is the hopping matrix element, and electrons interact via a local Coulomb interaction $U$. DMFT can also be formulated for models with more than one orbital per site and different *local* interactions, such as a coupling to localized spins (Kondo lattice model) or Einstein phonons (Holstein model). For equilibrium simulations, such lattice Hamiltonians can be downfolded from an ab initio band structure. Regarding non-equilibrium DMFT, the development of analogous downfolding schemes is still subject to current research.

To incorporate electric fields, a tight-binding model such as (1) is modified to

$$H_0 = \sum_{i,j,\sigma} v_{ij} e^{ieA_{ij}} c_{i\sigma}^{\dagger} c_{j\sigma} + \sum_{i\sigma} e\phi_i c_{i\sigma}^{\dagger} c_{i\sigma}, \tag{2}$$

where $e$ is the charge, $\phi_i = \phi(\boldsymbol{R}_i)$ is the scalar potential, and $A_{ij} = \int_{\boldsymbol{R}_i}^{\boldsymbol{R}_j} d\boldsymbol{r} \cdot \boldsymbol{A}(\boldsymbol{r})$ is a vector potential along a link of the lattice. This so-called Peierls substitution, which can be derived assuming localized Wannier orbitals, is the minimal extension of the lattice model that ensures a local gauge symmetry. It does not include terms such as Zeeman fields, Stark-shifts of orbitals, etc. Such terms may be described by additional free parameters in the noninteracting part of the Hamiltonian and do not change the general DMFT framework.

### 2.2        Green's Functions and Electronic Structure

In equilibrium, the electronic structure is fully characterized by the spectral function, which defines the electronic bands in an interacting system. A suitable generalization to non-equilibrium is given in terms of two-time Green's functions. One can start from the electron and hole propagators,

$$G^<_{a,a'}(t, t') = +i \langle c^\dagger_{a'}(t') c_a(t) \rangle, \quad G^>_{a,a'}(t, t') = -i \langle c_{a'}(t) c^\dagger_a(t') \rangle. \tag{3}$$

Here $c^\dagger_a$ and $c_a$ denote the creation and annihilation operators for an electron in a single-particle orbital $|a\rangle$, i.e., momentum or position and spin and orbital degrees of freedom. The time-dependence of the operators is understood in the Heisenberg picture, and $\langle \cdots \rangle = \mathrm{tr}[\rho_0 \cdots]$ averages over the density matrix of the initial equilibrium state at some early time $t_0$. To keep the notation concise, we will only indicate a diagonal momentum index $\boldsymbol{k}$ in the following, $G_{\boldsymbol{k}} \equiv G_{\boldsymbol{k},\boldsymbol{k}}$. The functions $G^<_{\boldsymbol{k}}(t, t')$ and $G^>_{\boldsymbol{k}}(t, t')$ give the amplitude for the propagation of a hole or an additional electron in the (possibly non-equilibrium) many-body state and therefore fully characterize the single-electron dynamics in the solid. In equilibrium, $G^<_{\boldsymbol{k}}(t, t')$ and $G^>_{\boldsymbol{k}}(t, t')$ depend only on time-difference $t - t'$. Using an expansion in many-body eigenstates (Lehmann representation), one can show that the Fourier transform $G_{\boldsymbol{k}}(\omega) = \int dt \, e^{i\omega t} G_{\boldsymbol{k}}(t, 0)$ satisfies the relations

$$G^<_{\boldsymbol{k}}(\omega) = 2\pi i \, A_{\boldsymbol{k}}(\omega) f(\omega), \quad G^>_{\boldsymbol{k}}(\omega) = -2\pi i \, A_{\boldsymbol{k}}(\omega)[1 - f(\omega)], \tag{4}$$

where $f(\omega)$ is the Fermi function and $A_{\boldsymbol{k}}(\omega)$ is the spectral function, which contains the information about the quasiparticle energies and their lifetimes.

### 2.2.1   Wigner Representation and Photoemission Spectrum

Equation (4) is an example of the fluctuation dissipation theorem and allows to rigorously separate spectrum and occupations in equilibrium. Out of equilibrium, such a separation is not possible in general. When time-translational invariance is lost, a suitable representation for two-time functions $F(t, t')$ is the Wigner transform, where one introduces average time $t_{\mathrm{av}} = (t + t')/2$ and relative time $t_{\mathrm{rel}} = t - t'$ and Fourier-transforms with respect to $t_{\mathrm{rel}}$,

$$F(t_{\mathrm{av}}, \omega) = \int dt_{\mathrm{rel}} \, e^{i\omega t_{\mathrm{rel}}} \, F(t_{\mathrm{av}} + t_{\mathrm{rel}}/2, t_{\mathrm{av}} - t_{\mathrm{rel}}/2). \tag{5}$$

The Wigner transform $G^<(t, \omega)$ has an intuitive interpretation: the factorization of $-i G^<_{\boldsymbol{k}}(\omega)$ as product of a density of states and an occupation function (cf. Eq. (4)) suggests that the Wigner transform $G^<_{\boldsymbol{k}}(t, \omega)$ gives the probability distribution to remove a particle with energy $\hbar\omega$ and momentum $\boldsymbol{k}$ from the system at time $t$, e.g., in a time- and angle-resolved photoemission experiments. This interpretation is true, when $G^<_{\boldsymbol{k}}(t, \omega)$ is averaged over a time and frequency window which satisfies the uncertainty relation $\Delta t \Delta \omega \gtrsim 1$, in analogy to the Wigner phase-space density in semiclassical physics, which becomes of positive phase-space density positive after a suitable average of position and momentum over a phase-space volume $\hbar$.

More precisely, time-resolved photoemission measures the probability that an electron with energy $E_{\mathrm{out}}$ is emitted under the action of a probe pulse with finite duration and given delay $t_p$ with respect to some excitation ("time zero"). The

signal can be obtained using time-dependent perturbation theory in the light-matter coupling (Freericks et al. 2009; Eckstein and Kollar 2008),

$$I(E, t_p) \propto \int dt\, dt'\; e^{iE(t-t')}(-i)G^<(t, t')\; S(t - t_p)S(t' - t_p)^*. \tag{6}$$

Here the probe pulse has a frequency $\Omega$ and an envelope $S(t)$, and $E = (E_{\text{out}} - \Omega)$ is the energy extracted from the solid. Matrix elements, which would select out certain orbital and momentum components of $G$, are not shown in Eq. (6). In addition, the sudden approximation was employed in the derivation, which assumes that there is no interaction between the outgoing electrons and the solid. Using a Gaussian profile $S(t) = \exp\!\left(-t^2/2\Delta t^2\right)$ with duration $\Delta t$, Eq. (6) transforms to the convolution of $G^<(\omega, t)$ with the kernel $e^{-\frac{(t-t-p)^2}{\Delta t^2}} e^{-(\omega-E)^2\Delta t^2}$, which implies the abovementioned probabilistic interpretation of non-equilibrium Green's functions.

## 2.3 Keldysh Formalism: Real-Time Evolution

In order to describe the time evolution of a quantum system, we aim to compute observables of the general form

$$\langle \mathcal{O}(t_1)\rangle = \text{tr}\!\left[\rho_0\, \mathcal{U}(t_1, t_0)^\dagger\, \mathcal{O}\, \mathcal{U}(t_1, t_0)\right]. \tag{7}$$

Here $\rho_0$ is the density matrix which defines the state at some initial time $t_0$, and $\mathcal{U}(t, t_0)$ is the unitary time evolution operator, which is given by the time-ordered exponential $T_t \exp\!\left[-i\int_{t_0}^t d\bar{t}\, H(\bar{t})\right]$. Equation (7) describes the evolution of an isolated quantum system without contact to environment.

As a mathematical trick, the time-ordering in $\mathcal{U}(t, t_0)$ and the corresponding anti-time-ordering in $\mathcal{U}(t, t_0)^\dagger$ can be combined into an ordering along a time contour which extends from $t_0$ forward and then backward in time. Furthermore, the thermal density matrix can be written as a time evolution operator along an imaginary time axis $[0, -i\beta]$. The three branches can be combined into a single $L$-shaped contour $\mathscr{C}$, as depicted in Fig. 1. Together with $\mathscr{C}$ we introduce the contour-ordering operator

**Fig. 1** The $L$-shaped Keldysh contour $\mathscr{C}$. Times on the horizontal branches are purely real and denoted with a book-keeping index $\pm$ to distinguish upper and lower branch, respectively. The arrows denote the time-ordering along $\mathscr{C}$ from earlier to later contour times

$$T_{\mathscr{C}}A(t)B(t') = \begin{cases} A(t)B(t') & \text{if } t \text{ later on } \mathscr{C} \text{ than } t' \\ \xi B(t')A(t) & \text{if } t' \text{ later on } \mathscr{C} \text{ than } t \end{cases}, \tag{8}$$

where the sign $\xi$ is $-1$ $(+1)$ if the permutation of $A$ and $B$ involves an odd (even) number of permutations of fermion creation or annihilation operators. The expectation value (7) can then be written as

$$\langle O(t) \rangle = \frac{1}{Z} \text{tr}[T_{\mathscr{C}} e^{-i \int_{\mathscr{C}} d\bar{t} H(\bar{t})} O(t_+)], \tag{9}$$

where $\int_{\mathscr{C}} dt$ is the integral along the contour. The contour ordering allows to formally extend the Matsubara formalism for many-body systems to real time. Diagrammatic perturbation theory and path integrals can be reformulated by merely replacing integrals over imaginary time by integrals over $\mathscr{C}$: in particular, the path-integral action for a generic Hamiltonian $H$ is given by

$$S = \int_{\mathscr{C}} dt \sum_a c_a^*(t) i \partial_t c_a(t) - H[c^*(t), c(t)], \tag{10}$$

the partition function can be written as a path integral $Z = \int \mathscr{D}[c^*c] e^{iS}$, and the expectation value (9) becomes an average $\langle O(t) \rangle_S$, with $\langle \cdots \rangle_S = Z^{-1} \int \mathscr{D}[c^*c] e^{iS} \cdots$. The electron and hole propagators (3) appear naturally as components of a single contour-ordered Green's function,

$$G_{ab}(t, t') = -i \langle c_a(t) c_b^*(t') \rangle_S, \tag{11}$$

with $G(t_+, t'_-) = G^<(t, t')$ and $G(t_-, t'_+) = G^>(t, t')$ for $t, t' \in \mathbb{R}$.

The analogy to the Matsubara formalism implies that contour-ordered Green's functions satisfy Wick's theorem when the action is quadratic (the latter is merely a consequence of Gaussian integration). Hence the rules for constructing Feynman diagrams are identical to the Matsubara formalism (Mahan 2000). We can introduce the two-time self-energy $\Sigma(t, t')$ as the sum over all irreducible diagrams. The Dyson equation then relates interacting ($G$) and noninteracting ($G_0$) Green's functions,

$$G = G_0 + G_0 * \Sigma * G = G_0 + G * \Sigma * G_0. \tag{12}$$

Here $*$ denotes convolution over $\mathscr{C}$. In contrast to equilibrium, where a solution of the Dyson equation is obtained in Fourier space, the Dyson equation in real time is an integral equation on $\mathscr{C}$. Its solution presents a formidable numerical task, which is discussed in the next section.

## 2.4 Kadanoff-Baym Equations

Given an approximation to the self-energy, the determination of the Green's function requires the solution of the Dyson equation (12). With a suitable time grid of $M$ time slices along $\mathscr{C}$, the linear integral equation (12) may be reduced to a matrix equation of dimension $M$ (Freericks 2008). In practice, however, one mostly proceeds differently, in order to make use of the causality in the time-propagation: on a given time grid, the solution of Eq. (12) can be extended from real times $t, t' \leq n\Delta t$ to the domain $t, t' \leq (n + 1)\Delta t$ without modification of the solution on previous times. The Dyson equation can therefore be formulated as a time-propagation scheme. This is useful because typically $\Sigma[G]$ itself is a (causal) functional of the Green's function, e.g., in the form of a perturbation expression. Mathematically, the causal structure implies that integral equations on $\mathscr{C}$ can be reduced to a set of Volterra equations, which can be solved using high-order accurate algorithms (Brunner and van der Houwen 1986). The representation of the Dyson equation in terms of coupled integral equations for the real-time propagators is referred to as Kadanoff-Baym equations. Various implementations have been presented, which differ in the representation of the Green's function in terms of the lesser, Keldysh, and retarded components (Bonitz 2000; Eckstein et al. 2010a; Aoki et al. 2014).

Applications of two-time Green's functions to condensed matter systems range from the dynamics of screening in semiconductors (Bányai et al. 1998) to electron-phonon coupled superconductors (Kemper et al. 2017). In general, for $M$ time slices, the required computational resources scale like $\mathscr{O}(M^2)$ for memory and $\mathscr{O}(M^3)$ for CPU time. This is a major limiting factor, in particular when Green's functions carry many orbital indices. Simulations based on full Kadanoff-Baym equations have therefore been restricted to few-orbital model systems. An important step toward first-principle simulations of non-equilibrium electronic structure would be a formulation of the GW approximation (Onida et al. 2002) in the time domain. Within GW, the self-energy $\Sigma_{\boldsymbol{k}}$ is expanded to leading order in the screened interaction $W_{\boldsymbol{k}}$, and the polarizability $\chi_{\boldsymbol{k}}$ is in turn computed using the Lindhard function. This captures nonlocal phenomena resulting from charge fluctuations, including screening and plasmonic modes. Even though the Dyson equations for $W_{\boldsymbol{k}}$ and $\Sigma_{\boldsymbol{k}}$ can be computed in parallel, the calculation of the self-energies and polarization functions requires a summation over all $\boldsymbol{k}$-points, which makes the solution of the full lattice GW simulations a formidable task. Results for a four-band system have been discussed in Golež et al. (2016).

The numerical cost of solving the Kadanoff-Baym equations motivates a possible truncation of the integrals. The convolution $\Sigma * G$ in the Dyson equation corresponds to memory effects in the propagation of the single-particle Green's functions. In contrast, kinetic equations provide a differential equation for the propagation of a single-particle density matrix (occupations) without memory integrals. A possible approximation to the Kadanoff-Baym approximation which focuses on the single-particle density matrix is the so-called generalized Kadanoff-Baym ansatz (GKBA) (Lipavský et al. 1986), used in combination with a mean-field approximation to the retarded propagators, i.e., assuming ideal quasiparticles. To what extent the GKBA

is useful in condensed matter systems relies on the validity of the quasiparticle approximation, which needs to be critically accessed for correlated systems.

## 3    The Dynamical Mean-Field Formalism

### 3.1    Self-Consistent Mapping to an Impurity Model

The starting point for the development of DMFT has been the limit of infinite lattice coordination number (Metzner and Vollhardt 1989). For a fermionic tight-binding model, this limit is defined together with a rescaling of the hopping matrix elements $v$, in order to preserve the competition between kinetic and interaction energies which underlies many phenomena in correlated electron systems. For a $d$-dimensional cubic lattice with nearest neighbor hopping, the correct rescaling is $v = v_*/\sqrt{2d}$, where $v_*$ is kept constant for $d \to \infty$. The infinite-dimensional limit implies that the self-energy becomes momentum-independent, i.e., local in real-space (Müller-Hartmann 1989),

$$\Sigma_{ij}(t, t') = \delta_{ij} \, \Sigma_{ii}(t, t'). \tag{13}$$

This fact is proven by counting powers of $d$ in the diagrams and therefore holds equally well in the Keldysh and Matsubara formalism.

The locality of the self-energy can be taken as a non-perturbative approximation for finite-dimensional systems. The summation of local $\Sigma$-diagrams to infinite order is facilitated by the solution of an auxiliary impurity model (Georges and Kotliar 1992), as illustrated in Fig. 2. The mapping to the impurity model can be explained, e.g., in a functional language: in general, the self-energy can be expressed as a functional of the fully interacting Green's function. This so-called skeleton functional $\Sigma^{\text{skel}}[G]$ consists of the sum over all self-energy diagrams in which the lines do not have self-energy insertions and are in turn replaced by the fully

**Fig. 2** Mapping from a lattice model with local self-energy to an impurity model with hybridization function $\Delta(t, t')$

interacting $G$. For an auxiliary impurity problem in which one site of the lattice is embedded in a noninteracting medium, the skeleton functional $\Sigma^{\text{imp}}[G]$ does not depend on the form of the noninteracting part of the Hamiltonian. The solution of the impurity model for the Green's function $G_{\text{imp}}$ and self-energy $\Sigma_{\text{imp}}$ can therefore be seen as a device to approximate the lattice functional $\Sigma^{\text{skel}}_{jj}[G]$ with the contributions from the local Green's function $G_{jj}$ to all orders. This argument was first given for the Falicov-Kimball model by Brandt and Mielsch (1991). An alternative intuitive and elegant way to formulate the mapping to an impurity model is given by the so-called cavity method, as introduced in Georges et al. (1996).

For the single-band Hubbard model, the corresponding impurity model has the form of a general Anderson impurity Hamiltonian (Georges and Kotliar 1992)

$$H_{\text{imp}} = U c^\dagger_\uparrow c_\uparrow c^\dagger_\downarrow c_\downarrow + \epsilon_f \sum_\sigma c^\dagger_\sigma c_\sigma + \sum_{p\sigma}(V_p(t)c^\dagger_\sigma a_{p\sigma} + h.c.) + \sum_{p\sigma} \epsilon_p(t) a^\dagger_{p\sigma} a_{p\sigma},$$
(14)

where one interacting site is coupled to noninteracting bath orbitals $p$. Equivalently, we can write the model as a single site with a general quadratic action, which is defined through the hybridization function $\Delta(t, t')$,

$$S_{\text{imp}} = \int_{\mathscr{C}} dt \Big\{ \sum_\sigma c^*_\sigma(t) i \partial_t c_\sigma(t) - H_{\text{loc}}(t) \Big\} - \sum_\sigma \int_{\mathscr{C}} dt dt' \, c^*_\sigma(t) \Delta(t, t') c_\sigma(t').$$
(15)

The impurity Dyson equation $G_{\text{imp}} = \mathscr{G} + \mathscr{G} * \Sigma_{\text{imp}} * G_{\text{imp}}$ fixes a relation between the impurity Green's function $G_{\text{imp}}(t, t') = -i\langle c(t)c^*(t')\rangle_{S_{\text{imp}}}$ and the impurity self-energy ($\mathscr{G}[\Delta]$ is the noninteracting impurity Green's function). The impurity self-energy is then taken as an approximation for the local lattice self-energy,

$$\Sigma_{\text{imp}}(t, t') = \Sigma_{jj}(t, t'),$$
(16)

and the lattice Green's function $G_{ij}(t, t')$ is obtained from the lattice Dyson equation. (To simplify the notation, the framework is presented for a translationally invariant state, i.e., a possible dependence of local quantities on the site is not shown.) At this stage, the noninteracting lattice Green's function incorporates the effect of external electromagnetic fields. The DMFT equations are closed when the bath $\Delta(t, t')$ (or equivalently the bath parameters $V_p(t)$ and $\epsilon_p(t)$) are determined self-consistently such that the local lattice Green's function and the impurity Green's functions $G_{\text{imp}}(t, t') = G_{jj}(t, t')$ match.

In equilibrium, the self-consistent solution of the DMFT equations is achieved iteratively. One can start from a guess for $\Sigma$, solve the lattice Dyson equation to obtain $G_{jj}$, invert the impurity Dyson equation to get $\Delta$, and solve the impurity model with action (15) to get $\Sigma$. DMFT is in essence a solution of the lattice Dyson equation with a nonlinear functional $\Sigma_{jj}[G]$ defined through the auxiliary

impurity model. Because this functional is causal, the DMFT equations on the Keldysh contour can be solved step by step in time, as explained for the Dyson equation in Sect. 2.4. The main conceptual and computational bottleneck in the DMFT framework is the solution of the impurity model, which we summarize in the following section.

## 3.2    Impurity Solvers

At present there is no general-purpose approach to solve the impurity problem, but a number of techniques which work well in certain parameter regimes, or provide exact results in a short time.

### 3.2.1    Weak-Coupling Expansions

When perturbation theory is applied to the impurity model, i.e., in combination with a self-consistent determination of the bath, it can capture non-perturbative phenomena like the Mott metal-insulator phase transition (Georges et al. 1996). The most important example is iterated perturbation theory (IPT), i.e., a second-order expansion of $\Sigma$ in $\mathscr{G}[\Delta]$. IPT is numerically relatively inexpensive (using IPT, the numerical cost of DMFT is determined by the solution of the lattice Dyson equation). Interesting applications include the study of nonthermal critical points in the quench dynamics of the antiferromagnetic spin-density wave (Tsuji et al. 2013). However, IPT is a non-conserving approximation. Diagrammatic approximations to the self-energy respect conservation laws like energy and particle number when they are based on a truncation of the skeleton expansion in terms of the interacting $G$ (Baym and Kadanoff 1961). In equilibrium, expansions in the *bare* Green's functions are often quantitatively more accurate, but their non-conserving nature can become problematic in the real-time evolution (Eckstein et al. 2010a). The use of IPT has so far remained restricted to the weak-coupling regime, although in equilibrium IPT extrapolates between weak and strong coupling for the half-filled single-band model.

### 3.2.2    Strong-Coupling Expansions

The perturbative expansion in the hybridization function is a flexible approach to study systems in the strongly interacting regime. Starting from the isolated impurity Hamiltonian $H_{\text{loc}}$, it defines propagators $\mathscr{G}_{a,a'}$ in terms of the *many-body* Fock states of the impurity site. Particle creation and annihilation events on the impurity induce transitions between the states $a$, i.e., the hybridization $\Delta$ in the action (15) corresponds to a retarded "two-body" interaction between the many-body states. Although Wick's theorem is not valid when the zeroth order of the expansion corresponds to a non-quadratic Hamiltonian, one can re-sum the expansion of the partition function in terms of $\Delta$ to generate conserving approximations. The adaption of the strong-coupling techniques to the Keldysh contour is described in Eckstein and Werner (2010b). The general starting point of the expansion allows for an extension to arbitrary local Hamiltonians, including electron-phonon coupled

systems (Werner and Eckstein 2013), bosonic DMFT (Strand et al. 2015), or multi-orbital Hubbard models.

The approach has been widely used to study photo-induced dynamics in Mott insulators (Sect. 4.2). However, only the first order (the so-called non-crossing approximation, NCA) and to some extent the second order are numerically feasible. Higher-order expansions require multidimensional integrations over time, which become costly in particular for multi-orbital systems, when the matrix dimension of the propagators $\mathscr{G}_{a,a'}$ is set by the dimension of the local Fock-space. Low-order expansions cannot recover the weakly interacting limit, which has so far excluded studies of correlated metallic phases at low-energy.

### 3.2.3    Quantum Monte Carlo (QMC)

QMC corresponds to a stochastic summation of the perturbation expansion in the hybridization function or the interaction to all orders. This is nowadays the standard approach to solve DMFT in equilibrium at finite temperature (Gull et al. 2011). In real time, however, the terms of the perturbation expansion become complex-valued (dynamical sign problem), and Monte Carlo is so far limited to times of the order of few inverse hoppings (Mühlbacher and Rabani 2008; Werner et al. 2009). QMC solvers have been used to address fundamental problems related to the short-time dynamics (Sect. 4.1), but for the study of the photo-induced dynamics, few hopping times are usually not yet sufficient. A recent development to possibly overcome the dynamical sign problem has been presented by Cohen et al. (2015), using the causality of the time-propagation within a diagrammatic Monte Carlo approach. It will be interesting to apply this approach in the context of non-equilibrium DMFT.

### 3.2.4    Hamiltonian-Based Impurity Solvers

A different direction to develop numerically exact impurity solvers is based on exact diagonalization. Here one takes a finite system such as the single-impurity Anderson model Eq. (14), to approximately reproduce a given hybridization function $\Delta(t, t')$, and uses the size of the bath as a numerical control parameter. Finite representations of the bath have been derived both for the steady state, using an impurity model in which the bath-sites are coupled to dissipative Lindblad terms (Arrigoni et al. 2013) and for real time (Gramsch et al. 2013). In the latter case, wave-function propagation techniques based on matrix product states (MPS) can be used to compute the Green's function (Wolf et al. 2014). The numerical effort in these Hamiltonian-based techniques increases exponentially with the number of orbitals in the representation, which limits the frequency resolution in the steady state and the accessible times in the real-time formalism.

## 3.3    Non-equilibrium Steady States

The Green's function formalism can easily deal with open quantum systems in a quite general environment. When a system is subject to a steady perturbation and coupled to an environment, it can eventually reach a non-equilibrium steady state

in which energy input is balanced by dissipation. We can distinguish two different settings.

### 3.3.1 Time-Independent Perturbations

This includes in particular the coupling to external leads at a given voltage bias. For time-independent perturbations, we can expect that Green's functions depend only on the time-difference, but the Fermi function in (4) is replaced by a nonthermal distribution function. One can impose the time-translational invariance as an ansatz in the DMFT equations. The impurity model then has to be solved for a bath $\Delta$ representing a non-equilibrium steady state, which has so far been done using either IPT or the auxiliary Master equations (Arrigoni et al. 2013). The steady-state formalism has been used, e.g., to discuss the negative differential resistance in a correlated metal (Amaricci et al. 2012) or resistive switching at the Mott transition (Li et al. 2015).

### 3.3.2 Time-Periodic Perturbations

As discussed in the introduction, time-periodic perturbations offer the possibility to control the Hamiltonian parameters in a so-called Floquet Hamiltonian. Under the effect of steady driving, the system can approach a time-periodic steady state, in which all two-time correlation functions remain invariant if both arguments are shifted by the periodicity $\tau$ of the driving, $G^{>,<}(t + \tau, t' + \tau) = G^{>,<}(t, t')$. Again this can be used as an ansatz in the formalism, and Green's functions can be parametrized using a standard Fourier transform for the difference and a discrete Fourier transform for the average time. Within DMFT, this formalism has been pioneered by Schmidt and Monien (2002) and taken up by Tsuji et al. (2008) and Joura et al. (2008). For the details of the representation, we refer to Aoki et al. (2014). As one of the more recent results, e.g., the steady state of a Holstein model with parametric driving of the phonons was studied to investigate the possibility of light-enhanced superconductivity (Murakami et al. 2017).

## 4 Applications

In this section we present some applications of the non-equilibrium DMFT framework. We discuss results for the interaction quench in the Hubbard model, which have provided an important benchmark for the development of the theory, and results for the photo-doped Mott insulators, which best represent the path toward material modelling. This is not at all intended to be an exhaustive list of references. Among the many topics which are omitted here are in particular results for driven systems (Tsuji et al. 2011; Mentink et al. 2015; Murakami et al. 2017), inhomogeneous systems (Eckstein and Werner 2013a), the dielectric breakdown of Mott insulators (Eckstein et al. 2010b), or long-range interactions in extended DMFT (Golež et al. 2015).

## 4.1    Quenches and Thermalization

A fundamental question of statistical physics is whether and how an isolated many-body system thermalizes after an excitation. Motivated by experiments in artificial quantum systems, where parameters can be controlled to high-precision, this question has been investigated in a large class of models (Polkovnikov et al. 2011). Non-equilibrium DMFT opened the unique possibility for numerically exact studies in systems of dimension $d > 2$. Beyond the relevance for the understanding of thermalization, these studies serve as a useful benchmark results for the development of impurity solvers.

The DMFT equations were solved using an QMC impurity solver for a quench in the single-band Hubbard model, where the interaction is suddenly changed from zero to a finite value $U > 0$ (Eckstein et al. 2009). Corresponding numerically exact results for quenches from the atomic limit have been obtained with an MPS-based impurity solver (Balzer et al. 2015). The results for the quench from $U = 0$ are best understood by the evolution of the momentum occupation $n(\boldsymbol{k}) = \langle c_{\boldsymbol{k}}^{\dagger}(t) c_{\boldsymbol{k}}(t) \rangle$. In the initial state, taken at temperature $T = 0$, $n(\boldsymbol{k})$ shows a step discontinuity of size one at the Fermi energy ($\epsilon_{\boldsymbol{k}_F} = 0$). For quenches to small values of $U$, one observes a rapid relaxation to a nonthermal state in which an exact discontinuity at $\epsilon_{\boldsymbol{k}} = 0$ is retained. For quenches to large $U$, $n_{\boldsymbol{k}}$ shows damped collapse and revival oscillations, which reflect the behavior in the atomic limit, where the dynamics is perfectly $2\pi/U$-periodic. Within a sharp crossover region between large and small $U$, rapid thermalization is observed, i.e., within few hopping times the single-particle properties of the system can be described well by a system in thermal equilibrium with the same energy. The small $U$ behavior corresponds to pre-thermalization (Moeckel and Kehrein 2008), which is representative for the dynamics of near-integrable systems, and can be understood in terms of a perturbative time evolution with approximate constants of motion (Kollar et al. 2011). Apart from DMFT only exact numerics for finite or one-dimensional systems currently allow to address the breakdown of the perturbative evolution.

## 4.2    Photo-Doping in Mott Insulators

The Mott metal-insulator transition, at which electrons get localized by a strong Coulomb interaction, is one of the hallmarks of strong correlations in solids. It happens for a large class of transition metal compounds or molecular crystals with narrow conduction bands (Imada et al. 1998). In the Mott phase, spin and orbital degrees of freedom are still active, which is the origin of a variety of complex magnetic and orbital orders. The interaction of doped electrons or holes with such short-ranged magnetic and orbital correlations may furthermore lead to new phases such as high-temperature superconductivity. DMFT has been instrumental in the understanding of the Mott transition, and it is therefore natural to use non-equilibrium DMFT to study the wide range of phenomena related to photo-doped

Mott insulators. This section will outline some major results for the one-band Hubbard model.

**Thermalization of small-gap Mott insulators** DMFT predicts a first-order phase transition from a Fermi liquid to a Mott insulator around $U \approx W$ in the paramagnetic phase of the one-band Hubbard model, with a critical endpoint at a temperature $T^*$, above which the transition becomes a crossover. In the correlated metallic phase, the spectral function features a quasiparticle band around $\omega = 0$ in addition to Hubbard bands around $\omega = \pm U/2$, which corresponds to strongly renormalized quasiparticles. At the Mott transition, the quasiparticle band disappears, and a gap is opened. A straightforward excitation protocol is an electric field pulse with frequency $\Omega \approx U$, which generates charge excitations in the Mott insulator, i.e., doubly occupied and empty sites. This setting was analyzed in Eckstein and Werner (2011). Without coupling to environment (which is justified for times when lattice and electronic subsystem can be treated as decoupled), the system thermalizes on very short timescales if the interaction is close to the metal-insulator transition, and the final state is in the crossover regime. Thermalization can be verified, e.g., by considering the evolution of the double occupancy or the fluctuation dissipation relation (4). The rapid thermalization of small-gap Mott insulators is in agreement with very recent results for the relaxation of photo-doped $TaS_2$ (Ligges et al. 2018). The agreement of theory and experiment in this case is highly nontrivial, as the final thermalized states lie in the metal-insulator crossover regime where quasiparticles are not well-defined and standard kinetic approaches for the description electronic thermalization fail.

The thermalization of small-gap Mott insulators can be interpreted in terms of ultrafast impact ionization processes (Werner et al. 2014), where the kinetic energy of charge excitations is used to generate additional doublon-hole pairs, similar to an Auger process in atomic physics. Impact ionization is a carrier multiplication process which can potentially enhance the efficiency of light-harvesting devices. DMFT show that impact ionization processes in Mott insulators can be much faster than typical electron-phonon relaxation times, which would mostly dominate intra-band relaxation in semiconductors.

**Doublon-hole recombination** Deep in the Mott phase, the thermalization time increases exponentially with $U/W$. For $U \gg W$, this result has an intuitive interpretation: a single charge excitation can only take an energy comparable to the single-particle bandwidth $W$, while the conversion of a high-energy excitation into multiple excitations is generally expected to give exponentially long lifetimes. The decay of doublons has been discussed and measured with ultra-cold atoms (Strohmaier et al. 2010), and the DMFT results are in agreement with the observed exponential scaling (Eckstein and Werner 2011). In condensed matter systems, the decay of photo-excited carriers in Mott insulators can indeed range to picoseconds, i.e., thousands of hopping times (Okamoto et al. 2010). For a quantitative understanding, one must account for additional processes which involve spins (Lenarčič and Prelovšek 2014) or high energy phonons (Mitrano et al. 2014).

**The buildup of the Fermi liquid** The high temperature state after the thermalization of a correlated metal is a so-called bad-metal (Deng et al. 2013), in which coherent quasiparticles are absent and the scattering length becomes comparable to the lattice constant. A fundamental question is on which timescale the Fermi liquid can be reformed by cooling the electronic system, e.g., by coupling to phonons. Assuming rapid electronic thermalization, the corresponding timescale would be set by the rate of energy transfer to the bath. Surprisingly, there appears to be a much slower relaxation bottleneck of electronic origin at the onset of the Fermi liquid (Sayyad and Eckstein 2016). The finding implies that ultrashort quasiparticle lifetimes, i.e., rapid quasiparticle scattering, do not at all imply rapid thermalization, which clearly demonstrates the failure of naive kinetic descriptions. To date, the precise timescale for the formation of the Fermi liquid must be considered an open question. In practice, the absence of well-defined quasiparticles implies bad metallic properties of photo-doped Mott insulators (Eckstein and Werner 2013b), which could be analyzed using transient THz spectroscopy.

**Coupling of charge dynamics with antiferromagnetic correlations** At low temperatures, the half-filled single-band Hubbard model shows a tendency toward antiferromagnetism. In the Mott phase, antiferromagnetism is a consequence of a super-exchange interaction $4v_*^2/U$. Excitation of long-lived charge carriers, as described previously for the paramagnetic phase, now leads to both melting of the order parameter and a reduction of the kinetic energy of the carriers (Werner et al. 2012). This mutual interaction of the carriers with the spin background happens because a hole or doublon in the antiferromagnetic spin background induces a spin-flip in every hopping process, and each spin-flip transfers an energy $\mathcal{O}(J_{ex}) \sim v_*^2/U$ from the mobile charges to the spin sector (Golež et al. 2014). The rapid energy transfer to spins is also possible in the paramagnetic phase due to short-range spin correlations. Short-range fluctuations cannot be captured in conventional single-site DMFT, but they have been studied using cluster extensions of non-equilibrium DMFT (Eckstein and Werner 2016). The relaxation times $\tau \sim 10 - 20\, fs$ are compatible with the timescales found in the rise-time of the optical response in cuprates after a laser excitation and exact diagonalization results (Dal Conte et al. 2015).

## 5   Future Directions

As the previous examples have shown, non-equilibrium DMFT simulations have led to a number of predictions so far, mainly based on one-band model systems. By adjusting the parameter of these models, first quantitative agreement with experiment could be achieved. The status of non-equilibrium DMFT is thus comparable to equilibrium DMFT 15 years ago (Georges et al. 1996). A long-term goal is certainly to make DMFT as useful for the study of non-equilibrium states as it is nowadays for the prediction of equilibrium properties. This suggests a few developments which are subject to ongoing research:

Many phenomena in correlated materials rely on the existence of several degenerate valence orbitals. The behavior of multi-orbital systems is governed by the interplay of orbital order, spin-order, and the strong coupling to the lattice. The strong-coupling impurity solver (Eckstein and Werner 2010b) can be extended to impurity models with more than one orbital. The multi-orbital nature becomes manifest already at the shortest times, as it opens new relaxation path for photo-excited carriers (Strand et al. 2017). At long times, systems with more than one orbital may be prone to expose thermodynamically hidden states under non-equilibrium conditions when the multi-orbital nature may lead to competing orders. A controlled theoretical description of such hidden orders is an open question. A possible first step may be to measure the interactions between competing order parameters in the photo-doped state, similar to the measurement of spin-exchange interaction in the photo-doped single-band Hubbard model (Mentink and Eckstein 2014).

Furthermore, a wide range of phenomena relies on long-range interactions. Of immediate importance is the long-range Coulomb interaction, which leads to screening of the local interactions and provides a feedback of non-equilibrium distribution on the interaction parameters. In equilibrium simulations, GW+DMFT is used as a parameter-free approach to determine the interactions and the band structure, which does not suffer from the double-counting problem that arises when the ground-state DFT is combined with the finite-temperature diagrammatic DMFT approach (Biermann et al. 2003). GW+DMFT out of equilibrium provides a way to obtain the local interactions in a self-consistent way and may therefore provide the basis to a first-principle approach to correlated systems out of equilibrium (Golez et al. 2017). A full GW simulation out of equilibrium is currently not feasible because of the numerical restriction given by Kadanoff-Baym equations. However, as a first step, one can set up a multi-scale approach, in which DFT is used to obtain a band structure in a wide energy range, from which successively smaller energy windows are selected for more accurate few-band GW and DMFT+GW simulations.

**Abstract**

Quantum Monte Carlo (QMC) comprises a set of techniques that use random numbers to address quantum mechanical problems. They are some of the most accurate techniques that can address large systems. This chapter gives the basics of QMC techniques on first principles models of materials.

# 1    First Principles

Any quantum system is defined by a Hilbert space $\mathscr{H}$ and Hamiltonian $\hat{H}$. Already at this level, there are several choices to be made. In all cases considered here, different choices will lead to the same results within some limit.

## 1.1    The Hilbert Space

The simplest case is for a fixed number of fermions $N$ with open boundary conditions, in which case $\mathscr{H}$ is the space of all $L^2$ normalizable antisymmetric functions from $\mathbb{R}^{3N} \to \mathbb{C}$. This Hilbert space is appropriate for an isolated molecule or other finite system. Table 1 collects a few common choices for the Hilbert space.

## 1.2    First Principles Hamiltonian

The fundamental mathematical problem is the many-particle Schrödinger equation:

$$i \frac{\partial |\Psi(t)\rangle}{\partial t} = \hat{H} |\Psi\rangle. \tag{1}$$

In first principles (ab initio) calculations of condensed matter, materials, and chemical systems, the nonrelativistic Hamiltonian is universal:

**Table 1** Hilbert spaces commonly used in first principles calculations

| | |
|---|---|
| Molecule | $\mathbb{R}^{3N} \to \mathbb{C}$, antisymmetric, $L_2$ normalizable |
| Solid (twisted boundary conditions) | $\Psi_k(r_1, r_2, \ldots, r_k + L, \ldots, r_N) = e^{i\mathbf{k}\cdot\mathbf{L}}\Psi_k(r_1, r_2, \ldots, r_k, \ldots, r_N)$, antisymmetric, normalizable on the unit cell defined by lattice vectors $\mathbf{L}$ |
| Embedding | As above, but the number of particles can vary (Fock space) |
| On a basis | Space spanned by some basis: $|\Psi\rangle = \prod c^\dagger |0\rangle$ |

$$\hat{H} = \sum_i \frac{-\hbar^2}{2m_e} \nabla_i^2 + \sum_\alpha \frac{-\hbar^2}{2m_\alpha} \nabla_\alpha^2 + \sum_{ij} \frac{e^2}{r_{ij}} + \sum_{i\alpha} \frac{-Z_\alpha e^2}{r_{i\alpha}} + \sum_{\alpha\beta} \frac{Z_\alpha Z_\beta e^2}{r_{\alpha\beta}}, \quad (2)$$

where
$i, j$ electron indices
$\alpha, \beta$ nuclear indices
$Z_\alpha$ atomic number of nucleus $\alpha$
$m_\alpha$ mass of nucleus $\alpha$
$m_e$ mass of the electron

Throughout this chapter, we will use atomic units, in which $\hbar$, $m_e$, and $e$ are all set to 1. The unit of energy is the Hartree (27.2114 eV) and the unit of length is the Bohr (0.529 Å). This Hamiltonian is not quite perfect; it is missing relativistic effects. At the current accuracy of quantum Monte Carlo calculations, the relativistic effects are often of similar size to the solution error.

## 1.3   Born-Oppenheimer Approximation

Most electronic structure quantum Monte Carlo calculations are performed within the Born-Oppenheimer approximation, in which the *electronic* Hamiltonian is used. It is not absolutely necessary to do this; QMC techniques can operate with fully quantum nuclei and electrons. However, the approximation is often quite small and improves the efficiency and simplicity of the algorithms by a large amount.

## 1.4   Effective Core Potentials

For nuclei with large $Z$, the core electrons increase the variance of the total energy, which decreases the efficiency of Monte Carlo. However, these electrons do not affect the physics and chemistry of the material very much at the energies of interest. For that reason, it is often a good trade-off in terms of accuracy/efficiency to replace the core electrons with an effective core potential:

$$\frac{Z_\alpha}{r_{\alpha i}} \rightarrow \frac{Z_{eff,\alpha}}{r_{i\alpha}} + V_l(r_{i\alpha}) + \sum_{\ell m} V_\ell(r_{i\alpha}) |lm\rangle \langle lm| . \quad (3)$$

This must be done with high accuracy; if density functional theory (DFT) potentials are used, then the QMC calculation will be limited mainly by the accuracy of the potential. There are now several sets of effective core potentials (Trail and Needs 2013; Burkatzki et al. 2007, 2008) meant for QMC calculations that retain accuracy and are smooth for efficiency purposes. These are chosen so that the ions (nucleus plus the core electrons) emulate accurate calculations of the full system. They also

typically include at least averaged relativistic effects and may include polarization terms and non-scalar relativistic effects like $\mathbf{L} \cdot \mathbf{S}$ coupling.

## 1.5   Useful Mathematical Relationships

Some of these relationships are available in most books on quantum mechanics; we remind the reader of them here and clarify notation.

$\hat{H}$ can be diagonalized. There is a set of states $\{|\Phi_i\rangle\}$ such that

$$\hat{H} = \sum_i |\Phi_i\rangle\, E_i\, \langle\Phi_i| . \tag{4}$$

The state with lowest energy $E_0$ is called the ground state $|\Phi_0\rangle$. If $|\Psi\rangle \in \mathcal{H}$, then it has a spectral expansion $|\Psi\rangle = \sum_i c_i |\Phi_i\rangle$, for some complex numbers $c_i$. If $|\Psi\rangle \in \mathcal{H}$, then by the variational principle:

$$\langle\Psi|\hat{H}|\Psi\rangle \geq E_0. \tag{5}$$

This is provable using the above relationships.

**Projection**  Suppose that $|\Psi(\tau)\rangle = \exp\left(-\tau\hat{H}\right)|\Psi(0)\rangle$. Then $|\Psi(\tau)\rangle = \sum_i c_i \exp(-\tau E_i)|\Phi_i\rangle$ and

$$\frac{|\Psi(\tau)\rangle}{\sqrt{\langle\Psi(\tau)|\Psi(\tau)\rangle}} = \sum_i \frac{c_i \exp(-\tau E_i)}{\sqrt{\sum_j c_j^2 \exp\left(-2\tau E_j\right)}} |\Phi_i\rangle . \tag{6}$$

Define

$$c_i(\tau) = \frac{c_i \exp(-\tau E_i)}{\sqrt{\sum_j c_j^2 \exp\left(-2\tau E_j\right)}}. \tag{7}$$

Suppose that there is a $k$ such that $E_k < E_i$. Then we can divide the numerator and denominator by $\exp(-\tau E_k)$:

$$c_i(\tau) = \frac{c_i \exp(-\tau(E_i - E_k))}{\sqrt{c_k^2 + \sum_{j \neq k} c_j^2 \exp\left(-2\tau(E_j - E_k)\right)}}. \tag{8}$$

So long as $c_k \neq 0$, $c_i(\tau)$ goes to zero exponentially as $\tau \to \infty$. The only remaining nonzero coefficient is the lowest eigenstate with a nonzero component of $|\Psi\rangle$. This is an example of the power method, in which an operator is applied repeatedly to obtain its largest eigenstate.

**Mixed estimator for energy**   As long as $\langle \Phi_i | \Psi \rangle \neq 0$,

$$\frac{\langle \Phi_i | \hat{H} | \Psi \rangle}{\langle \Phi_i | \Psi \rangle} = E_i. \tag{9}$$

This can be derived by using $\hat{H} | \Phi_i \rangle = E_i | \Phi_i \rangle$.

As a result of Eqs. 8 and 9, if $\langle \Psi | \Phi_0 \rangle \neq 0$,

$$\frac{\langle \Psi | \exp\left(-\tau \hat{H}\right) \hat{H} | \Psi \rangle}{\langle \Psi | \exp\left(-\tau \hat{H}\right) | \Psi \rangle} = E_0, \tag{10}$$

the ground state energy.

## 2   Monte Carlo

The main use of Monte Carlo in this chapter will be to evaluate many-dimensional integrals. Suppose that $\mathbf{X}$ is some vector. Then

$$\int f(\mathbf{X}) \rho(\mathbf{X}) d\mathbf{X} = \langle f(\mathbf{X}) \rangle_{\mathbf{X} \sim \rho}. \tag{11}$$

Here, $\mathbf{X} \sim \rho$ means that $\mathbf{X}$ is sampled from the probability density $\rho$, and the angle brackets $\langle \rangle$ denote the average. For this to be true, $\rho(\mathbf{X})$ must be a probability density ($\rho(\mathbf{X}) \geq 0$ and $\int \rho(\mathbf{X}) dX = 1$), but $f(\mathbf{X})$ may be any function.

Monte Carlo evaluation of an integral consists of two parts: sampling and averaging. Sampling means to generate $\mathbf{X}$ with probability proportional to $\rho(\mathbf{X})$. Averaging means evaluation of $f(\mathbf{X})$ and evaluation of statistical uncertainties.

Suppose that we generate some number $N$ of $\mathbf{X}_i \sim \rho$. For the moment, we will assume that the $\mathbf{X}_i$ are independent, although this is not necessary. Then we would like to know the distribution of the average variable $f_N = \frac{1}{N} \sum_i^N f(\mathbf{X}_i)$. Let the variance of $f$ be

$$\mathrm{Var}_f = \left\langle (f(\mathbf{X}) - \langle f(\mathbf{X}) \rangle)^2 \right\rangle_{\mathbf{X} \sim \rho}. \tag{12}$$

If $\mathrm{Var}_f$ is finite and in the limit of large $N$, then the central limit theorem states that $f_N$ has a normal distribution centered around the exact average and with reduced variance:

$$f_N \sim \mathcal{N}\left(\langle f \rangle, \frac{\mathrm{Var}_f}{N}\right). \tag{13}$$

Every Monte Carlo calculation should include an estimate of the variance of the average. On plots, the square root of the variance (the standard deviation) is typically represented as an "error bar."

## 3    Trial Functions

Trial functions are many-particle wave functions. Typically there are some parameters $\mathbf{P}$ in the wave function. $\mathbf{x}$ is the position ($\mathbf{r}$) and spin ($\omega$) coordinate of an electron. $\chi_i$ is a function of $\mathbf{x}$ which produces a complex number. $N$ is the number of electrons. Much of the code in quantum Monte Carlo programs is devoted to evaluating trial wave functions efficiently.

Quantum Monte Carlo brings two major improvements over deterministic methods based on variational wave functions. First, a complex Jastrow factor can be used, which improves the efficiency and accuracy dramatically. While a single Slater determinant is often not a good approximation to an interacting electronic system, a Slater determinant multiplied by a Jastrow factor is much better. Second, projection Monte Carlo techniques can be used which further improve the accuracy beyond an analytic form.

## 3.1    Slater Determinant

Then

$$\Psi_S(\mathbf{x}_1, \mathbf{x}_2, \ldots; \chi_1, \chi_2, \ldots, \chi_N) = \begin{vmatrix} \chi_1(\mathbf{x}_1) & \chi_1(\mathbf{x}_2) & \chi_1(\mathbf{r}_3) & \cdots & \chi_1(\mathbf{x}_N) \\ \chi_2(\mathbf{x}_1) & \chi_1(\mathbf{x}_2) & \chi_2(\mathbf{r}_3) & \cdots & \chi_2(\mathbf{x}_N) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \chi_N(\mathbf{x}_1) & \chi_N(\mathbf{x}_2) & \chi_N(\mathbf{r}_3) & \cdots & \chi_N(\mathbf{x}_N) \end{vmatrix}$$

is antisymmetric on exchange of spin and position. It is a functional of the spin orbitals.

For spin collinear calculations, one typically works in a basis of $S_z$ eigenstates, so there is a constant $N_\uparrow$ and $N_\downarrow$.

$$\chi_i(\mathbf{x}) = \begin{cases} \phi_i(\mathbf{r})\alpha(\omega) & \text{if } i \leq N_\uparrow \\ \phi_i(\mathbf{r})\beta(\omega) & \text{if } i > N_\uparrow \end{cases} \tag{14}$$

Assume $N_\uparrow \geq N_\downarrow$. Then the real-space orbitals $\phi_i$ can be either restricted, which means that $\phi_i = \phi_{i+N_\uparrow}$ for $i = 1 \ldots N_\uparrow$, or they can be unrestricted, which relaxes this condition.

**Table 2** Common basis functions used in quantum Monte Carlo

| Name | Basis type |
|------|-----------|
| Blip | Localized finite support basis |
| Gaussian | Sum of Gaussian basis functions centered around atoms |
| Slater | Sum of exponential basis functions centered around atoms |
| Localized numerical | Numerical basis functions centered around atoms |
| Plane waves | Periodic plane wave functions |

A given real-space orbital $\phi_i$ is parameterized in a basis $\{b_j\}$:

$$\phi_i(\mathbf{r}) = \sum_j c_{ij} b_j(\mathbf{r}). \tag{15}$$

The trial function is thus specified by the basis functions $\{b_j\}$ (see Table 2) and the coefficient matrix $c_{ij}$. These may be optimized directly within the variational Monte Carlo framework (Toulouse and Umrigar 2008) or taken from a density functional theory or quantum chemistry program. Most QMC packages provide conversion tools for this operation. In some cases, a hybrid approach is used (Wagner and Mitas 2003), in which the orbitals are generated using different density functionals.

It is also possible to perform noncollinear calculations using quantum Monte Carlo (Melton et al. 2016). In that case, $\omega$ is parameterized and allowed to dynamically change.

## 3.2 Jastrow Factor

The Jastrow factor (Bijl 1940; Dingle 1949; Jastrow 1955) is an all-positive factor that includes electron-electron correlations:

$$\Psi_J(\mathbf{x}_1, \mathbf{x}_2, \ldots; \mathbf{P}) = \exp\left[\underbrace{\sum_{ij} \chi(\mathbf{x}_i, \mathbf{x}_j; \mathbf{P}_{\text{cusp}})}_{\text{Cusp condition}} + \underbrace{\sum_{ij} f(\mathbf{r}_i, \mathbf{r}_j; \mathbf{P}_{\text{Correlation}})}_{\text{Correlation factor}}\right] \tag{16}$$

For electronic systems, a high-quality Jastrow factor can account for between 50% and 85% of the correlation energy with a few parameters. It is related to the $f_{12}$ and transcorrelated methods used in quantum chemistry.

The cusp part of the Jastrow factor enforces the Kato cusp conditions. The correlation part can be expanded in many ways, which can differ from implementation to implementation. It appears that different parameterizations obtain quite similar results (Doblhoff-Dier et al. 2016).

### 3.3 Multiple Slater Determinants

As in quantum chemistry calculations, the many-body wave function can be expanded as a sum of Slater determinants. When multiplied by a Jastrow factor, the convergence in determinants is much faster than without (Umrigar et al. 2007). Determinants can be selected from a configuration interaction calculation, one of various selected configuration interaction calculations, or directly within quantum Monte Carlo (Holzmann et al. 2003; Williams and Wagner 2016).

### 3.4 Backflow and Iterated Backflow

Construct a dressed coordinate:

$$\mathbf{q}_i = \mathbf{r}_i + \sum_{j \neq i} f(\mathbf{r}_j, \mathbf{r}_i), \tag{17}$$

where $f$ is a vector-valued function. Then instead of $\mathbf{x}_i = (\mathbf{r}_i, \omega)$, use $\mathbf{x}_i = (\mathbf{q}_i, \omega)$ in the Slater determinant (or pairing wave function). There are several ways to achieve this (Kwon et al. 1993; López Ríos et al. 2006; Taddei et al. 2015). As in the original application (Feynman and Cohen 1956), this wave function is particularly effective for metallic systems. If the function $f$ is efficient to evaluate, then the Slater determinant can be evaluated with a moderate increase in computational time (Filippi et al. 2016).

### 3.5 Tensor Networks, Correlator, and Matrix Product States

The broad class of tensor network states (Wouters et al. 2014) and correlator product states (Changlani et al. 2009) have been used in some quantum Monte Carlo studies as trial wave functions. These work essentially and similarly to a determinant expansion, since they are written in a second-quantized notation. These functions have not been used very much in first principles calculations and so this chapter will not focus on them.

### 3.6 Pairing Wave Functions: Geminal and Pfaffians

The most general form of the pairing wave function is the Pfaffian (Bajdich et al. 2006):

$$\mathrm{Pf} \begin{bmatrix} \xi^{\uparrow\uparrow} & \Phi^{\uparrow\downarrow} & \phi^{\uparrow} \\ -\Phi^{\uparrow\downarrow T} & \xi^{\downarrow\downarrow} & \phi^{\uparrow} \\ -\phi^{\uparrow T} & -\phi^{\uparrow T} & 0 \end{bmatrix}, \tag{18}$$

where each of the Greek letters in the matrix is a sub-matrix that correlates electrons of the corresponding spins and the $\phi$ sub-matrices address unpaired electrons. This function is antisymmetric due to the properties of the Pfaffian, which can be computed in a similar amount of time as a determinant.

If the same-spin electrons are not correlated ($\xi = 0$ in Eq. 18), Eq. 18 reduces to the antisymmetrized geminal product, which only correlates the different-spin electrons. This is the same as the number-projected Bardeen-Cooper-Schrieffer wave function. In practice, these wave functions suffer from severe size-consistency issues which require them to be used with a Jastrow factor (Neuscamman 2012).

## 4  Quantum Monte Carlo Methods

### 4.1  Variational Monte Carlo

Parameterize a wave function according to some parameters $\mathbf{P}$. Then the expectation value of the energy is

$$E(\mathbf{P}) = \frac{\langle \Psi(\mathbf{P}) | \hat{H} | \Psi(\mathbf{P}) \rangle}{\langle \Psi(\mathbf{P}) | \Psi(\mathbf{P}) \rangle}. \tag{19}$$

This expectation value can be written as an integral in some basis $|b\rangle$ (suppressing the $\mathbf{P}$ argument from $\Psi$):

$$E(\mathbf{P}) = \frac{\int \langle \Psi | b \rangle \langle b | H | \Psi \rangle db}{\int \langle \Psi | b \rangle \langle b | \Psi \rangle db} \tag{20}$$

$$= \int \underbrace{\frac{\langle \Psi | b \rangle \langle b | \Psi \rangle}{\int \langle \Psi | b \rangle \langle b | \Psi \rangle db}}_{\rho(b)} \underbrace{\frac{\langle b | H | \Psi \rangle}{\langle b | \Psi \rangle}}_{f(b)} db, \tag{21}$$

where $\rho(b)$ and $f(b)$ refer to Eq. 11. It is most common for the basis $b$ to be the position, but other basis sets are possible (Neuscamman 2012).

Using the variational principle (Eq. 5), $E(\mathbf{P}) \geq E_0$. So minimizing $E(\mathbf{P})$ gives an upper bound to the ground state energy. The current state of the art uses the linear method (Umrigar et al. 2007) to accomplish this. In this method, the wave function is approximated using a first-order Taylor expansion:

$$|\Psi(\mathbf{P})\rangle = |\Psi(\mathbf{P}_0)\rangle + \sum_i \delta p_i \left. \frac{\partial |\Psi(\mathbf{P})\rangle}{\partial p_i} \right|_{\mathbf{P}=\mathbf{P}_0}. \tag{22}$$

Minimizing $E(\mathbf{P})$ results in a generalized eigenvalue problem. The reason this method is efficient is that it is possible to evaluate the necessary matrix elements

with very low variance. A major theme of advances in variational Monte Carlo techniques is the reduction of variance while maintaining zero bias.

## 4.2    Projection Monte Carlo

Projection Monte Carlo techniques are stochastic implementations of the power method. Let the projection operator with parameter $\tau$ be $\hat{P}(\tau)$. Typically, as $\tau \to 0$, $\hat{P}$ goes to the identity operator, and often there is an accuracy/efficiency trade-off as $\tau$ is increased. Formally, we wish to stochastically implement the operation:

$$|\Psi(N\tau)\rangle = \left(\hat{P}(\tau)\right)^{N} |\Psi(0)\rangle . \tag{23}$$

As $N \to \infty$, $|\Psi(N\tau)\rangle$ will be the desired state, as shown in Eq. 8 for the $e^{-\tau\hat{H}}$ operator.

The stochastic implementation of projection can be understood as a Monte Carlo integration. Insert identity operators in a many-body basis $b$ in Eq. 23:

$$\langle b_0|\Psi(N\tau)\rangle = \int \left[\prod_{i=1}^{N}\langle b_{i-1}|\hat{P}(\tau)|b_i\rangle\right] \langle b_N|\Psi(0)\rangle db_1 \dots db_N. \tag{24}$$

The set $\{b_i\}$ of $N$ many-body coordinates in the basis space is called the *path*. It must be the case that the matrix element $\langle b_{i-1}|\hat{P}(\tau)|b_i\rangle$ is known. This is often why $\tau$ must be relatively small; for the example of $\hat{P}(\tau) = \exp\left(-\tau\hat{H}\right)$, the Trotter-Suzuki (Trotter 1959; Suzuki 1976) expansion can be used for small enough $\tau$. To simplify the notation, set

$$\langle b_{i-1}|\hat{P}(\tau)|b_i\rangle = P_{i-1,i} \tag{25}$$

and

$$B = \{b_i\} \tag{26}$$

To fully translate Eq. 24 into a Monte Carlo integral, we must identify a probability density $\rho$ to sample and a function $f$ to evaluate. The main constraints are that $\rho$ must be a probability density and that the variance of $f$ must be finite and small enough so that its expectation value can be determined using the central limit theorem efficiently. There are many choices of these functions, which can affect efficiency and biases of the final algorithm. In this chapter, we will focus on the *mixed estimator* (Eq. 10), which allows for efficient evaluation of the ground state energy. This estimator is

$$\frac{\langle \Psi(0)|\hat{H}|\Psi(N\tau)\rangle}{\langle \Psi(0)|\Psi(N\tau)\rangle} = E_0 = \qquad (27)$$

$$\int \underbrace{\frac{\langle \Psi(0)|\hat{H}|b_0\rangle}{\langle \Psi(0)|b_0\rangle}}_{\tilde{f}} \underbrace{\frac{\langle \Psi(0)|b_0\rangle \left[\prod_{i=1}^{N} P_{i-1,i}\right] \langle b_N|\Psi(0)\rangle}{\int \langle \Psi(0)|b_0\rangle \left[\prod_{i=1}^{N} P_{i-1,i}\right] \langle b_N|\Psi(0)\rangle db_1 \ldots db_N}}_{\tilde{\rho}} \, db_1 \ldots db_N$$

$$(28)$$

$\tilde{\rho}(B)$ is not quite a probability density yet, since it may be negative or in some cases it can be complex. In some cases, including bosonic systems and a number of model Hamiltonians, a formulation of $\tilde{\rho}$ and $\tilde{f}$ can be found such that $\tilde{\rho}$ is positive and the variance of $\tilde{f}$ is small enough so that the method can be efficient. In other techniques, such as the released node or transient, the signs of $\tilde{\rho}$ are put into $\tilde{f}$, which increases the variance of $\tilde{f}$ dramatically. This variance increases exponentially with system size, which is called the *sign problem.*

In cases where the sign problem cannot be removed, one is either left with an algorithm that scales exponentially, or an approximation must be made. The simplest approach is to approximate $\tilde{\rho}$ such that it is always positive. For example, one can take the following weight function:

$$w(B) = \begin{cases} \tilde{\rho}(B) & \text{if } \tilde{\rho}(B) \geq 0 \\ 0 & \text{if } \tilde{\rho}(B) < 0 \end{cases}. \qquad (29)$$

Then one can sample a probability density $\rho(B) = \frac{w(B)}{\int w(B)dB}$. This can be done in several ways, as noted in Sect. 5.3.

The differences between projector Monte Carlo methods consist of what approximation (if any) is made for $\rho$ and $f$ and what basis $B$ is used to express the path and matrix elements. Some of the methods write their basis in second-quantized form, while others write them in first-quantized form. For a detailed discussion, see Kolodrubetz et al. (2013) and Umrigar (2015). These choices interact with one another, and there are many variations and trade-offs between them. Table 3 lists several common projector Monte Carlo methods and their choices.

## 5 Simulation Errors

### 5.1 Time Step Errors

Suppose that we use the projector $\exp\left(-\tau \hat{H}\right)$ and are working in the real-space basis. Then we wish to evaluate the matrix elements:

**Table 3** Projection operators and basis used in different Monte Carlo techniques

| Method | Basis | Quantization | Operator | Stabilization |
|---|---|---|---|---|
| DMC | **R** | First | $\exp\left(-\tau\hat{H}\right)$ | Fixed node/phase |
| Reptation Monte Carlo[a] | **R** | First | $\exp\left(-\tau\hat{H}\right)$ | Fixed node/phase |
| Full CI QMC | Finite basis | Second | $(1-\tau\hat{H})$ | Initiator |
| Auxiliary field QMC | Finite basis | Second | $\exp\left(-\tau\hat{H}\right)$ | Phaseless |
| Lattice regularized DMC | Lattice on **R** | First | $(1-\tau\hat{H})$ | Fixed node/phase |
| Green function MC | **R** | First | $(1-\tau\hat{H})^{-1}$ | Fixed node/phase |

[a]Also known as variational path integrals and path integrals for the ground state

$$\langle\mathbf{R}|\exp\left(-\tau\hat{H}\right)|\mathbf{R}'\rangle. \tag{30}$$

This is typically done in the small $\tau$ approximation and is a rather lengthy subject. A detailed discussion for this operator on electronic systems can be found in Umrigar et al. (1993).

## 5.2    Finite Size Effects

Bulk systems are typically approximated using twisted boundary conditions, in which the bulk wave function is approximated as wave function with the following constraint:

$$\Psi_{\mathbf{k}}(\mathbf{r}_1, \mathbf{r}_2 + \mathbf{L}, \ldots, \mathbf{r}_N) = \exp(i\mathbf{k}\cdot\mathbf{L})\Psi_{\mathbf{k}}(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N), \tag{31}$$

where $\mathbf{L}$ is a lattice vector of the simulation cell. The infinite limit is taken by increasing the size of the simulation cell and the number of particles, keeping the density $N/V$ constant.

There are two main sources of finite size errors, corresponding to the kinetic and potential energy of the Hamiltonian. Kinetic energy errors can be corrected by considering many values of $\mathbf{k}$, so-called twist averaging. Errors due to the Coulomb interaction can be removed in several ways, either through embedding (Drummond et al. 2008) or using the electron structure factor (Chiesa et al. 2006).

## 5.3    Fixed Node/Sign Control Errors

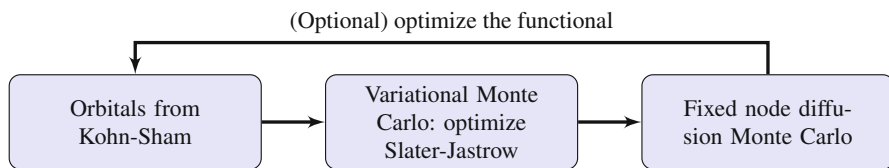
In many cases, projection Monte Carlo methods have a sign problem as discussed in the relevant section. This sign problem makes exact calculations untenable except for quite small systems. Different techniques approach this sign error in different ways, noted in Table 3.


**Fig. 1** Workflow for FN-DMC calculations of materials

## 6 Variational + Fixed Node Diffusion Monte Carlo

This chapter has so far focused on general statements about quantum Monte Carlo techniques for ab initio systems. This section will focus on a standard operating procedure that has emerged in the past decades. It offers a good trade-off between accuracy, efficiency, and complexity of the calculation (Fig. 1).

### 6.1 Hamiltonian

Since core electrons are very expensive to simulate, they are typically replaced with an effective core potential. Potentials based on density functional theory are typically not accurate enough (Saritas et al. 2017), so correlation-consistent potentials must be used (Burkatzki et al. 2007, 2008; Trail and Needs 2013; Bennett et al. 2017). Modern algorithms use the T-move (Casula 2006; Casula et al. 2010) method to handle the nonlocal operator in the projector.

### 6.2 Trial Wave Function

The trial wave function $|\Psi_T\rangle$ is the Slater-Jastrow wave function, which consists of a Slater wave function multiplied by a Jastrow correlation factor. The orbitals in the Slater determinant are typically taken from Kohn-Sham density functional theory calculations. The functional used can affect the quality of the orbitals; often using hybrid DFT orbitals offer good quality without needing to optimize the orbitals within QMC. The Jastrow factor is typically energy optimized (Umrigar et al. 2007), which leads to better wave functions than variance optimizations.

### 6.3 Fixed Node Diffusion Monte Carlo (FN-DMC)

Application of FN-DMC to the trial wave function results in an energy dependent on several factors: $E_{DMC}(\{\phi_i\}, \tau, N)$, where $\{\phi_i\}$ are the orbitals, $\tau$ is the time step, and $N$ is the number of electrons in the simulation. If $\tau$ is small enough and $N$ is large enough, then

$$E_{DMC}(\{\phi_i\}, \tau, N) = E_{DMC}(\{\phi_i\}, 0, N) + \tau \varepsilon_{\text{time step}}(\{\phi_i\}, N). \tag{32}$$

One thus performs the calculation for several values of $\tau$ and extrapolates the result to zero to obtain $E_{DMC}(\{\phi_i\}, 0, N)$. Then

$$E_{DMC}(\{\phi_i\}, 0, N) = E_{DMC}(\{\phi_i\}, 0, \infty) + \varepsilon_{\text{finite size}}(\{\phi_i\})/N. \tag{33}$$

Finally, $E_{DMC}(\{\phi_i\}, 0, \infty)$ is an upper bound to the exact ground state energy. One can vary $\{\phi_i\}$ to obtain the lowest upper bound.

## 7    Effective Interactions and Models from Quantum Monte Carlo

The stabilization method for projector Monte Carlo restricts what wave function can be obtained using the technique. One way to understand this is that the final wave function after projection is now a *functional* of the guiding wave function: $|\Phi_{\text{projected}}[\Psi_G]\rangle$. For brevity, we will just call this $|\Phi[g]\rangle$, where $g$ is the guiding wave function. Because of the projection operation, $|\Phi[g]\rangle$ contains only small components of high-energy wave functions. By varying $g$, one can obtain a sampling of wave functions with relatively low energy compared to the overall spectrum. As noted in Sect. 6, $g$ can be varied to obtain minimum upper bounds, if a variational way of evaluating the energy expectation value can be found. However, these wave functions can also be used to explore effective models. The detailed theory is available in a recent publication by Changlani et al. (2015).

Consider the objective of estimating an electronic gap using quantum Monte Carlo. The effective model of the material is $\sum_{i\sigma} \varepsilon_i \hat{n}_{i\sigma}$, where $\hat{n}_i$ is the orbital occupation operator. Then

$$E[g] = \sum_{i\sigma} \varepsilon_i \langle \Psi[g] | \hat{n}_{i\sigma} | \Psi[g] \rangle, \tag{34}$$

where $\Psi[g]$ is only allowed to vary along the lowest-energy wave functions that change the orbital occupation. From this equation, one can compute $\varepsilon_i - \varepsilon_j$ by varying the occupation. This is typically done in solids by using two trial functions: Slater-Jastrow wave functions with different occupations of KS orbitals. Empirically, this procedure obtains results that are in close agreement to experimental values, with around 0.1 eV errors.

The same procedure can be used to estimate superexchange constants using QMC. In this case the effective model is

$$E[g] = \sum_{ij} J_{ij} \langle \Psi[g] | S_i \cdot S_j | \Psi[g] \rangle, \tag{35}$$

so one should sample projected wave functions that differ in their spin orientations.

An example of how this works for a spin dimer. It is relatively easy to compute the frozen spin states of the dimer, $|\uparrow\uparrow\rangle$ and $|\uparrow\downarrow\rangle$. For a dimer Heisenberg model,

$$H = J S_1 \cdot S_2 = \frac{1}{2} J \left[ (S_1 + S_2)^2 - S_2^2 - S_1^2 \right] = \frac{1}{2} J \left[ s(s+1) - 3/2 \right] . \tag{36}$$

For the two frozen spin states:

$$E(\uparrow\uparrow) = \langle \uparrow\uparrow | J S_1 \cdot S_2 | \uparrow\uparrow \rangle = J/4 \tag{37}$$

and

$$E(\uparrow\downarrow) = \langle \uparrow\downarrow | J S_1 \cdot S_2 | \uparrow\downarrow \rangle = -J/4. \tag{38}$$

The energy difference between these two states is thus $J/2$. The singlet eigenstate $\sqrt{\frac{1}{2}}\left(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle\right)$ (with $s = 0$) has energy $-3J/4$, while the triplet eigenstate $|\uparrow\uparrow\rangle$ (with $s = 1$) has energy $J/4$, so the singlet-triplet excitation energy is $J$.

## 8    Conclusions and outlook

At the time of this writing (2018), quantum Monte Carlo techniques have been applied to many materials systems. A semi-complete list of strongly correlated systems studied using these techniques was compiled in 2016 (Wagner and Ceperley 2016). Excitation energy gaps, equations of state, including bulk moduli and lattice constants, and ground state magnetic orderings are now a matter of routine for these techniques with modern program packages. Nonenergetic ground state properties like electron density, spin density, and static correlation functions are also computed routinely. A very rough limit on the size of systems treatable with modern computational resources is around 1000 valence electrons, although this number can vary dramatically depending on the energy scale and variance of the quantity of interest. Currently, this is very much a moving target and so we will not go very much into detail; we refer readers to ▶ Chap. 46, "Quantum Monte Carlo for Electronic Systems Containing $d$ and $f$ Electrons" in this volume for more details.

## Contents

## Abstract

Within the general framework of skeleton diagrammatic expansions, the fully self-consistent GW approximation (sc-GW) is the simplest scheme based on the lowest-order diagrams. However, this established method for electronic structure calculations is rarely used in its original form when the polarization function is obtained from the product of two fully dressed single-particle Green's functions because its most serious deficiency is known to be an incorrect prediction of the dielectric response. In this contribution, we examine the sc-GW approximation

for the homogeneous electron gas and find that problems with the dielectric response are solved by enforcing the particle number conservation law in the polarization function. Our protocol for restoring physical properties of the sc-GW approximation (and more advanced schemes based on computing higher-order vertex corrections) is physically transparent and easy to implement at no additional computational cost. We further examine the accuracy of the sc-GW approximation and systematic convergence of the bold diagrammatic Monte Carlo scheme to the exact result for the single-orbital hydrogen chain system.

# 1    Introduction and Formalism

Dealing with interacting many-electron systems and accurately predicting properties of real solid-state materials are the major challenges of great technological importance. Among numerous theoretical methods developed for this problem, the diagrammatic many-body perturbation theory (Fetter 1971; Mahan 2000) offers a number of unique advantages. Instead of dealing with finite ensembles of electrons, the field-theoretical approach discussed in this work is based on the standard Feynman diagrammatic technique formulated in terms of single-particle propagators, or Green's functions, and interactions. Even the lowest-order schemes can grasp the essential physics of screening effects and allow one to deal with the long-range Coulomb interaction in the thermodynamic limit. One of the simplest schemes is the random-phase approximation (RPA) that can qualitatively (and even quantitatively) explain such features of metals as screening, plasmon, and Friedel oscillations. In principle, the skeleton diagrammatic expansion discussed below allows one to systematically improve on these results and obtain accurate solutions to the many-electron problem. In practice, however, progress is hindered because more sophisticated than RPA lowest-order diagrammatic approximations are not necessarily leading to better results right away (and in this contribution, we explain why and how this is happening), while evaluation of higher-order vertex corrections within the skeleton approach appears to be too costly computationally (apart from important questions concerning series convergence).

For three-dimensional systems with Coulomb interactions, one cannot use the diagrammatic expansion in terms of the bare interaction potential $V(k) = 4\pi e^2/k^2$ because of divergencies coming from geometric series-based "bubble" diagrams. The way out is to work with a formulation that expresses all diagrams self-consistently in terms of fully dressed propagators and interactions (Hedin 1965). Here we employ the skeleton expansion of the Luttinger-Ward (LW) functional $\Phi[G, W]$ (Luttinger and Ward 1960). The method is thermodynamically consistent and conserving; in particular, the relation between the Fermi momentum $k_F$ and particle density is preserved (Baym and Kadanoff 1961; Baym 1962). As the corresponding diagrams for the electron self-energy, $\Sigma$, and polarization, $\Pi$, are composed of three-point vertices connected pairwise by fully dressed Green's functions, $G$, and screened effective interactions, $W$ (with the exception of the Hartree diagram that is based on $V$), the corresponding diagrammatic technique

is often called the $G^2W$-expansion. Self-consistency is achieved through the Dyson equations written symbolically as

$$G = G_0 + G_0 \Sigma G, \qquad\qquad W = V + V \Pi W, \qquad\qquad (1)$$

where $G_0$ is the bare electronic propagator (depending on the representation, the products on the r.h.s. should be understood as convolutions over the space, time, spin, orbital, etc. indexes not mentioned here for brevity).

The self-consistent GW (sc-GW) approximation truncates the skeleton sequence at the lowest-order graphs (see upper left panel in Fig. 1), and contributions to $\Sigma$ and $\Pi$ are based on pair products of the $G$ and $W$ functions. Within the bold diagrammatic Monte Carlo (BDMC) framework (see, e.g., Van Houcke et al. 2012; Kulagin et al. 2013), the configuration space of leading vertex corrections (upper right panel in Fig. 1) and higher-order diagrams (lower panel in Fig. 1) is sampled stochastically. Since different diagram topologies contribute with a different sign, one might naively expect to be faced with a sign problem in the Monte Carlo simulation. Note, however, that there is no conventional sign problem:

(i) the diagrammatic theory is formulated directly in the thermodynamic limit, and therefore there is no exponential scaling of the computational time with system volume (Prokof'ev and Svistunov 2007; Van Houcke et al. 2012);

(ii) the sign alternation of diagrammatic contributions is essential to be able to sum the full series: in the best-case scenario, it can render the series convergent, and polynomial computational complexity can be achieved (Rossi 2017; Rossi et al. 2017) – in this specific sense, it is rather "sign blessing" than problem;

(iii) there is no vanishing denominator to deal with because normalization is established through the lowest-order terms.

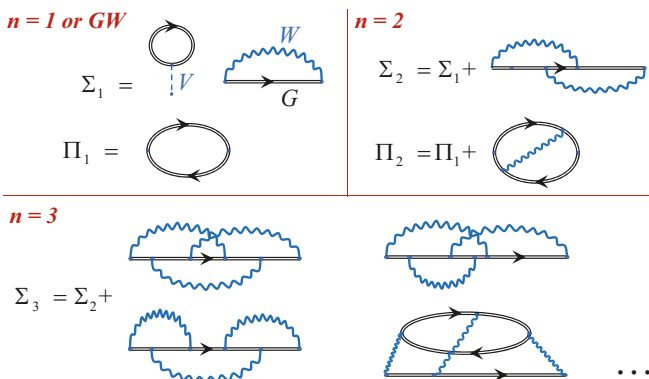

**Fig. 1** Skeleton diagrams for self-energy and polarization function in terms of fully dressed Green's functions (double lines) and screened interactions (wavy lines) at order $n = 1$ (equivalent to the sc-GW approximation) and order $n = 2$, upper left and right panels, respectively. In the lower panel, we show some of the self-energy diagrams at order $n = 3$

Moreover, diagrammatic Monte Carlo can be applied to any system at finite temperature with arbitrary dispersion relation (doped or undoped) and with arbitrary shape of the interaction potential. Both $\Sigma$ and $\Pi$ are computed as sums of skeleton graphs, up to order $n$; we denote these sums as $\Sigma_n$ and $\Pi_n$ and abbreviate the corresponding level of approximation as $BDMC_n$, i.e., $BDMC_1$ is identical to sc-GW. To obtain final answers, one has to perform an extrapolation to the $n \to \infty$ limit; this was demonstrated for several Coulomb systems in Tupitsyn et al. (2016) and Tupitsyn and Prokof'ev (2017).

In this contribution, we discuss two related topics. First we examine properties of the sc-GW approximation for the jellium model – a system of electrons on a homogeneous positive charge background with the same charge density – and present a simple strategy to enforce physical behavior for charge correlations. Our strategy can be applied at every order of the skeleton expansion and does not produce any systematic bias in the infinite-order limit for convergent series. We also provide accurate values for the ground-state energy, the quasiparticle $Z$-factor, and the effective mass renormalization $m_*/m$ (where $m$ is the bare electron mass) at the Fermi level. Second, we discuss merits of the sc-GW approximation for the single-orbital hydrogen chain system and demonstrate that the BDMC method allows one to obtain highly accurate results with full control over systematic errors by evaluating higher-order corrections. Most of the discussion closely follows material presented in Van Houcke et al. (2017) and Motta et al. (2017).

## 2    Jellium Model

Self-consistent GW approximation is the most established "beyond RPA" diagrammatic method for electronic structure calculations (Hedin 1965; Aryasetiawan and Gunnarsson 1998; Onida et al. 2002). However, by evaluating "bubble" diagrams in a self-consistent way [we do not discuss here numerous variations of the method based on partial, or incompletely dressed, propagators and interaction lines], the sc-GW approximation fails to reproduce some key results for the two-particle correlation functions and does not properly describe even the plasmon properties, in contrast to RPA. This drawback has been clearly demonstrated for a homogeneous electron gas (jellium model) by Holm and von Barth in Holm and von Barth (1998). Moreover, incorrect screening properties are expected to have a feedback on single-particle spectra of real materials for which the sc-GW approximation sometimes fails to account for the observed value of the absolute bandgap (Schöne and Eguiluz 1998).

Let us start by briefly reviewing the sc-GW approximation for the unpolarized jellium model. In the position-imaginary time $(r, \tau)$-representation, the lowest-order skeleton diagrams for the self-energy $\Sigma$ and polarization $\Pi$ read as (the Hartree diagram is canceled by the positive background)

$$\Sigma(r, \tau) = -G(r, \tau)W(r, -\tau), \qquad \Pi(r, \tau) = 2G(r, \tau)G(r, -\tau), \qquad (2)$$

where the factor of two comes from the sum over the spin index. These are self-consistently defined through algebraic solutions of the Dyson equations in the momentum-Matsubara frequency $(k, \omega_n)$ representation:

$$G(k, \omega_n)^{-1} = G^0(k, \omega_n)^{-1} - \Sigma(k, \omega_n), \qquad W(k, \omega_n)^{-1} = V(k)^{-1} - \Pi(k, \omega_n).$$
(3)

Here $G^0_\sigma = (i\omega_n + \mu - k^2/2m)^{-1}$. Knowing the one-body Green's function $G$ is sufficient for obtaining the system's energy, as well as quasiparticle properties such as $m_*$ and $Z$ (see Fetter 1971; Mahan 2000).

We performed all calculations at finite temperatures well below the Fermi energy $\varepsilon_F = k_F^2/2m$. Equations (2) and (3) were solved by iterations until the convergence was reached. The chemical potential $\mu$ used in each step was adjusted to preserve the desired electron density with accuracy up to six significant digits. After convergence, the total energy is computed from $\Sigma$ and $G$. For ground-state properties, we extrapolated results to zero temperature using the Fermi-liquid behavior. In Fig. 2, we show a typical plot for energy measured in units of Hartree, $Ha = me^4/\hbar^2$ at $r_s = 1$, with standard definition of $r_s$ as the ratio of the typical interparticle spacing and the Bohr radius $a_B = \hbar^2/me^2$.

## 2.1    Dielectric Response

The work by Holm and von Barth (1998) has established that the sc-GW approximation is not suitable for analysis of two-particle correlation functions. More precisely, the spectral function $S(k, \omega)$ of the polarization $\Pi$ was found to have incorrect

**Fig. 2** Energy per electron (in Ha) as a function of $(T/\varepsilon_F)^2$ revealing the Fermi-liquid behavior. The solid line is a linear fit giving a ground-state energy of $E/N = 0.5783(2)$ Ha
**Fig. 3** Imaginary part of the dielectric function within the sc-GW approximation at $r_s = 1$, $k/k_F = 0.1$, and $T/\varepsilon_F = 0.02$. Red dashed curve is the original sc-GW result, and the solid black line is the corrected sc-GW spectrum. The crucial difference at frequencies $\omega > k v_F$ is clearly seen in the inset

behavior at frequencies $\omega > k v_F$, where $v_F$ is the Fermi velocity; as a consequence, the real part of the dielectric function $\varepsilon(k, \omega) = 1 - (4\pi e^2/k^2)\Pi(k, \omega)$ at small momenta $k \ll k_F$ has its zero shifted away from the plasmon frequency $\omega_p = \sqrt{4\pi n e^2/m}$ to completely unrealistic values (see Fig. 3 in Holm and von Barth (1998)).

Our results confirm this key observation: we also find that at $k \ll k_F$ and $\omega_n \gg k v_F$, the polarization is *orders of magnitude* larger than the values dictated by the hydrodynamic plasmon mode physics, $\Pi(k, \omega_n) \approx -nk^2/m\omega_n^2$ (see thorough discussion in Nozieres (1999)). This unphysical behavior can be traced back to the fact that the sc-GW approximation does not respect the dynamic particle number conservation law, which implies that at zero momentum, $\Pi(k = 0, \omega_n) \propto \delta_{n,0}$ or, identically, $\Pi(k = 0, \tau) = \text{const}$. Indeed, for an arbitrary interaction potential, $\Pi$ is related to the density-density correlation function, $\chi(k, \omega_n) = \langle |\delta \hat{n}(k, \omega_n)|^2 \rangle$, as $\Pi = -\chi/(1 - V\chi)$, while (in imaginary-time representation) $\chi(k = 0, \tau) = \langle \delta \hat{N}(0) \delta \hat{N}(\tau) \rangle \equiv \text{const}$ because the total number of particles $\hat{N}$ commutes with the Hamiltonian. [To prevent divergence of $V(k)$ when substituting $k = 0$, the bare potential may be regularized at small momenta to have the Yukawa form, $V(k) = \frac{4\pi e^2}{k^2 + k_0^2}$, with small but finite Yukawa screening wave vector $k_0$ that is sent to zero at the end of the calculation.] As a result, at $k = 0$ the density response is purely static, $\chi(k = 0, \omega_n \neq 0) \equiv 0$ (see Nozieres 1999), implying that the same is true for the polarization function

$$\Pi(k = 0, \omega_n \neq 0) \equiv 0, \qquad \text{(Particle number conservation law).} \qquad (4)$$

By assuming physical behavior of $\Pi$ at small momenta, one would conclude that $W/V - 1 \to -\omega_p^2/(\omega_p^2 + \omega_n^2)$ and frequencies larger than $100\omega_p$ are not required for highly accurate calculations.

Instead, within the sc-GW approximation, one finds that $\Pi(k = 0, \omega_n)$ has significant amplitudes at finite frequencies, and correspondingly, $\Pi(k, \omega_n \neq 0)$ is not approaching zero when $k \to 0$. This also causes significant problems for the proper technical implementation of the sc-GW approach in Coulomb systems because $(4\pi e^2/k^2)\Pi(k, \omega_n \neq 0)$ tends to diverge as small momenta and forces one to consider extremely large frequencies (exceeding $10^6 \omega_p$) in the calculation of the screened interaction $W$. We believe that this frequency range was not covered in the sc-GW implementations reported in Holm and von Barth (1998), Holm (1999), and García-González and Godby (2001) leading to the discrepancy in the final results outside of reported error bars (see Table 1).

Since all problems originate from the violation of the dynamic particle conservation law, we propose a simple strategy to enforce the physical behavior of $\Pi(k, \omega_n)$. All one has to do is to perform a transformation:

$$\Pi(k, \omega_n \neq 0) \to \Pi(k, \omega_n) - \Pi(0, \omega_n \neq 0), \qquad (5)$$

before calculating the dielectric response from the sc-GW solution. In other words, one has to subtract the spurious frequency dependence at $k = 0$. Note that this transformation is compatible with the higher-order skeleton expansion and the suggestion is that it should be implemented *within* the fully self-consistent skeleton scheme whenever one has to iterate properties of the $W$-function. Indeed, in the large-order expansion limit, the correction term is supposed to vanish as $\Pi(k = 0, \omega_n)$ converges to the correct physical behavior $\propto \delta_{n,0}$.

In Figs. 3 and 4, we show how our protocol works by considering the case of $r_s = 1$ at low temperature $T/\varepsilon_F = 0.02$ and small momentum $k/k_F = 0.1$. After performing numeric analytic continuation of the imaginary frequency data for $\varepsilon(k, \omega_n)$ to get the imaginary part $\varepsilon''(k, \omega)$ (using protocols described in Goulko et al. 2017; Mishchenko 2012), we obtain the real part $\varepsilon'(k, \omega)$ from the Kramers-Kronig relation. The improvement in terms of eliminating the unphysical behavior is dramatic. After the transformation, the high-frequency tail of $\varepsilon''(k, \omega)$ gets suppressed by nearly two orders of magnitude. As a result, the real part of the dielectric function now has its zero at $\omega_p^{(GW)} \approx 0.89(1)\omega_p$ and is approaching unity from below at $\omega \gg \varepsilon_F$. [In order to have $\omega_p^{(GW)}$ to coincide with $\omega_p$ within the sc-GW approximation, one would need to divide $\Pi$ by $Z^2$ by hand, mimicking the effect of vertex corrections that can be obtained properly only by implementing the BDMC$_n$ scheme.] Everything about the original sc-GW data at frequencies $\omega > k v_F$ is completely unsatisfactory.

**Table 1** Minus the ground-state exchange-correlation energy per particle $-E_{XC}$ (in Hartree). We compare results for $-E_{XC}$ obtained within the sc-GW approximation discussed in this chapter with quantum Monte Carlo data from Ceperley and Alder (1980) (labeled as QMC1) and Ortiz et al. (1999) and Ortiz and Ballone (1994) (labeled as QMC2) and with the earlier implementations of the sc-GW approximation data published in García-González and Godby (2001) (labeled as GW1) and Holm and von Barth (1998) (labeled as GW2)

| $r_s$ | 1 | 2 | 4 | 5 | 10 |
|---|---|---|---|---|---|
| QMC1 | 0.5180 | 0.2742 | 0.1464 | 0.1197 | 0.0644 |
| QMC2 | 0.5127 | 0.2713 | | 0.1201 | |
| GW2 | | 0.2741 | 0.1465 | | |
| GW1 | 0.5160(2) | 0.2727(5) | 0.1450(5) | 0.1185(5) | 0.0620(9) |
| GW (this work) | 0.5267(2) | 0.2789(1) | 0.1488(1) | 0.1216(1) | 0.06498(2) |

**Fig. 4** Real part of the dielectric function within the sc-GW approximation at $r_s = 1$, $k/k_F = 0.1$, and $T/\varepsilon_F = 0.02$. The original sc-GW result (red dashed curve) completely misses the plasmon zero and predicts unrealistically large response at frequencies above $\varepsilon_F$. The corrected result (solid black line) crosses zero within 10% of $\omega_p$ and saturates to unity at $\omega > \varepsilon_F$

## 2.2    Ground-State Properties

Since precise knowledge of $G_\sigma$ is required in order to calculate $\Pi$ via Eq. (2), we extract basic Fermi-liquid properties from the Green's function and compare them against known results. Early implementations of the sc-GW approximation (García-González and Godby 2001; Holm and von Barth 1998; Holm 1999) reported ground-state energy values in very good agreement (often at the sub-percent level, see Table 1) with diffusion Monte Carlo results (Ceperley and Alder 1980). We find that our sc-GW exchange-correlation energies differ from those of García-González and Godby (2001), Holm and von Barth (1998), and Holm (1999) well

**Table 2** The quasiparticle residue $Z$ and the effective mass renormalization $m_*/m$ at the Fermi level for the unpolarized 3D homogeneous electron gas. These quantities were obtained by using the *standard* sc-GW approach, i.e., solving the set of Eqs. (2) and (3) without any correction procedures to cure the unphysical behavior of $\Pi$

| $r_s$ | 1 | 2 | 4 | 5 | 10 |
|---|---|---|---|---|---|
| $Z$ | 0.899(1) | 0.842(1) | 0.769(2) | 0.743(2) | 0.658(2) |
| $m_*/m$ | 0.944(2) | 0.931(2) | 0.913(2) | 0.906(2) | 0.875(2) |

**Table 3** Minus the ground-state exchange-correlation energy per particle $-E_{XC}$ (in Hartree), the quasiparticle residue $Z$, and the effective mass renormalization $m_*/m$ at the Fermi level for the unpolarized 3D homogeneous electron gas. These are obtained by using the *modified* sc-GW, or GW($\Pi$), approach, i.e., by solving the set of Eqs. (2) and (3) self-consistently and at the same time applying the transformation Eq. (5) to $\Pi$ at each iteration of the self-consistent scheme.

| $r_s$ | 1 | 2 | 4 | 5 | 10 |
|---|---|---|---|---|---|
| $-E_{XC}$ | 0.5205(2) | 0.2716(2) | 0.1413(1) | 0.1143(1) | 0.05873(2) |
| $Z$ | 0.880(3) | 0.808(2) | 0.722(2) | 0.692(3) | 0.605(4) |
| $m_*/m$ | 0.934(3) | 0.900(2) | 0.834(2) | 0.803(2) | 0.673(4) |

outside the error bounds by an amount bigger than the difference between the sc-GW and various other approximations, for instance GW$^{(0)}$. While the exact origin of discrepancy is not settled yet, it is most likely linked to the violations of the particle conservation law (4) discussed above. To ensure correctness of our sc-GW results, we developed two absolutely independent codes that did not share a single common idea about grids and cutoffs for storing and processing the data, Fourier transforms, and energy evaluation (see next subsection). It turned out that energy data used for plots in Yan (2011) were also in perfect agreement with our results; ultimately, five independently developed finite-$T$ codes (including codes developed by L. Pollet and S. Schultess) were compared and found to be in agreement with each other within the error bounds reported in Table 2.

For benchmark purposes, we also report the quasiparticle residue at the Fermi surface, or $Z$-factor, and the effective mass renormalization in Table 2. Error bounds were estimated from variations induced by changing momentum-time grids, cutoffs, and extrapolation procedures to the zero-temperature limit. All results in the table were obtained for the *standard* sc-GW formulation; i.e., the transformation procedure (5) was *not* applied when solving Eqs. (2) and (3).

While applying the transformation Eq. (5) to the sc-GW solution vastly improves the two-body spectral properties, it is natural to ask what impact it has on the Fermi-liquid properties when applied at each iteration of the self-consistent scheme; we abbreviate the corresponding scheme that always respects (4) as GW($\Pi$). The exchange-correlation energy, $Z$-factor, and effective mass renormalization obtained in that way are given in Table 3. The relative change in exchange-correlation energy ranges from about 1% for $r_s = 1$ up to almost 10% for $r_s = 10$. Given that the relative difference in exchange-correlation energy calculated within the standard sc-GW approach and the diffusion Monte Carlo method (Ceperley and Alder 1980)
**Fig. 5** Effective mass renormalization (solid curves) and quasiparticle residue (dashed curves) as functions of $r_s$ within the sc-GW approach (black) and its modified GW($\Pi$) version

is at the level of few percent, we conclude that the GW($\Pi$) scheme has the same quality in terms of the ground-state energy while it improves the two-body spectral function by orders of magnitude.

The effect of the transformation (5) on $Z$ and especially on $m_*/m$ is more pronounced (see Fig. 5). If changes for the quasiparticle residue can be considered "quantitative," the same cannot be said about the effective mass renormalization – it is far more dramatic within the GW($\Pi$) approach. Moreover, the dependence of $m_*/m$ on $r_s$ within the sc-GW approximation can hardly be extrapolated to unity for the noninteracting system without assuming an anomalously strong increase in the $dm_*/dr_s$ derivative.

## 2.3    Details on Practical Implementation

To verify the correctness of treating the properties at small momenta in our implementation of the sc-GW scheme (no matter how unphysical they might be), a good strategy is to develop a code for the screened Yukawa potential as well. Let us refer to these implementations as the Coulomb code and the Yukawa code, respectively. To recover the final answer for the Coulomb system with the Yukawa code, one should extrapolate results obtained for a set of small $k_0$ values to zero (see Fig. 6). The expectation is that the function is linear. Let us highlight some technical details of the two implementations. We discuss the Yukawa code first.

**Fig. 6** Energy per electron (in Hartree) as a function of Yukawa screening wavevector for $T/\varepsilon_F = 0.02$ and $r_s = 1$. The result of the Coulomb code is also shown

In the Yukawa code, the high-momentum cutoff was set at $17k_F$ for the Green's function and at $33k_F$ for the screened potential. We verified that by increasing these cutoffs by 50%, energies and other Fermi-liquid parameters remained the same up to six significant digits. The smallest momentum resolution was set at $10^{-4}k_F$. This resolution was used in the vicinity of three special points: $k = 0$, $k_F$, and $2k_F$. Away from the special points, the grids were made more sparse (we used logarithmic grids with 16 equidistant points per scale). Similarly, in imaginary-time domain, the smallest time resolution was set at $5 \times 10^{-5}/\varepsilon_F$ in the vicinity of two special points $\tau = 0$ and $\tau = \beta$, and we used the same law (16 equidistant points per scale) to describe the entire domain. All functions in the momentum-imaginary time representation were obtained by considering parabolic (in both momentum and time) interpolations between the grid points. When solving the Dyson equation, we considered up to $2^{20}$ Matsubara frequencies. Our parameters were such that by decreasing the resolution of the grids (increasing the number of grid points) by a factor of two, or increasing the number of Matsubara frequencies, we were not able to detect changes in the final results within the reported error bounds.

When computing the self-energy and polarization function values (in imaginary-time representation) from the momentum integrals of the $GW$ and $GG$ products, the Yukawa code was relying on the direct numerical integration, i.e., the Fourier transforms to the real-space and back to momentum space were not used.

In the Coulomb code, on the other hand, the high-momentum cutoff was set at $25k_F$, for both the Green's function and the screened potential, and it was also verified that final results did not change upon increasing this cutoff. A logarithmic grid was used for small momenta (the smallest momentum being $10^{-8}k_F$). In the region $[0.1k_F, 2k_F]$, the typical spacing is of the order $10^{-3}k_F$, while for momenta bigger than $2k_F$, it is of the order $10^{-2}k_F$. In imaginary-time domain, the smallest time resolution was set at $10^{-6}/\varepsilon_F$ in the vicinity of $\tau = 0$ and $\tau = \beta$, and we used

the same law (80 equidistant points per scale) to describe the entire domain. For the frequency domain, a logarithmic grid was used, the largest frequency being of the order $10^7 \times \pi/\beta$. No dependence of the final results on this cutoff was observed.

In contrast to the Yukawa code, the convolutions to obtain the self-energy and polarization function values in imaginary-time representation were done by explicitly going to position space and back to momentum space via (slow) numerical Fourier transforms. The grid in position space was logarithmic with cutoff $500/k_F$, and the smallest position grid point corresponded to $10^{-4}/k_F$.

## 3  Hydrogen Chain

As it was already mentioned, the sc-GW approximation is one of the most established methods for electronic structure calculations. It is widely used in material science systems, but in many cases, its systematic bias remains unknown. Below we address this question within the hydrogen chain problem (Hachmann et al. 2006) using the BDMC technique. Despite its simplicity, the hydrogen chain contains all the basic ingredients distinguishing real materials from the jellium model.

### 3.1  Hamiltonian and Diagrammatic Representation

In atomic units, the chain of hydrogen atoms, composed of N fixed equidistant protons and N electrons, is described by the Hamiltonian:

$$H = -\frac{1}{2} \sum_i \nabla_i^2 - \sum_{i,m} \frac{1}{|\mathbf{r}_i - \mathbf{R}_m|} + \frac{1}{2} \sum_{i \neq j} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} + \frac{1}{2} \sum_{m \neq n} \frac{1}{|\mathbf{R}_m - \mathbf{R}_n|}, \quad (6)$$

where the first two terms give the kinetic and potential energy of $i$-th electron in the protons' field while the third and fourth terms represent the electron-electron and proton-proton Coulomb interactions. The positions of electrons and protons are described by $\mathbf{r}_i$ and $\mathbf{R}_m$, respectively. The protons along the chain are separated by the distance $R$.

We start by projecting this Hamiltonian onto the finite orbital space using field operators:

$$\Psi_\sigma(\mathbf{r}) = \sum_{i,\alpha} \phi_{i,\alpha,\sigma}(\mathbf{r}) \, f_{i,\alpha,\sigma}, \quad (7)$$

where $\phi_{i,\alpha,\sigma}(\mathbf{r}) \equiv \phi_{\alpha,\sigma}(\mathbf{r} - \mathbf{R}_i)$ is the $\alpha$-th orbital of the electron with spin $\sigma$ at the $i - th$ proton and $f_{i,\alpha,\sigma}$ is the standard electron annihilation operator. To simplify notations, we will also use a composite index $a = (i, \alpha, \sigma)$, as in Fig. 7. In terms of these operators, the Hamiltonian can be presented as
**Fig. 7** Diagrammatic elements representing screened interaction, $W$, Green's function, $G$, and bare interaction, $V$, in the orbital representation. Each index $\{a, b, c, d\}$ combines all three discrete indices $(i, \alpha, \sigma)$

$$\hat{H} = -\sum_{a,b} t_{a,b}\delta_{\sigma_b,\sigma_a}\, f_a^\dagger\, f_b + \frac{1}{2}\sum_{a,b,c,d} V_{a,b,c,d}\delta_{\sigma_a,\sigma_b}\delta_{\sigma_c,\sigma_d}\, f_a^\dagger\, f_c^\dagger\, f_d\, f_b \qquad (8)$$

with nonzero hopping amplitudes and interactions given by

$$t_{a,b} = -\int d\mathbf{r}\, \phi_{i,\alpha,\sigma}^*(\mathbf{r})\left[-\frac{1}{2}\nabla^2 - \sum_a \frac{1}{|\mathbf{r} - \mathbf{R}_a|}\right]\phi_{j,\beta,\sigma}(\mathbf{r}) \qquad (9)$$

and

$$V_{a,b,c,d} = \int d\mathbf{r}d\mathbf{r}'\, \phi_{i,\alpha,\sigma}^*(\mathbf{r})\, \phi_{k,\gamma,\sigma'}^*(\mathbf{r}')\, \frac{1}{|\mathbf{r} - \mathbf{r}'|}\, \phi_{l,\delta,\sigma'}(\mathbf{r}')\, \phi_{j,\beta,\sigma}(\mathbf{r}). \qquad (10)$$

All integrals are taken over the three-dimensional orbital coordinates. In this representation, electronic coordinates are replaced with discrete orbital indices. This solves the problem of strong coupling between the electrons and ions and leads to the diagrammatic technique that is more or less standard for lattice models. Of course, part of the problem complexity is now in the size of the orbital Hilbert space.

From the set of Eqs. 8, 9, and 10, it is clear that the topology of diagrams within the $G^2W$ skeleton expansion remains unchanged, but their index structure gets more complicated. To be more specific, in Fig. 7, we show the structure of all diagrammatic elements in the orbital representation. Each interaction line depends on four site/atom indices $\{(i, j); (k, l)\}$, four orbital indices $\{(\alpha, \beta); (\gamma, \delta)\}$, and two spin indices $\{\sigma; \sigma'\}$ (note that the Coulomb interaction vertex does not change the spin index).

In what follows, we further simplify the problem and limit ourselves to considering one orbital per atom (the so-called minimal basis set; STO-6G basis). In this case, the Hamiltonian takes the form

$$\hat{H} = -\sum_{i,j}\sum_{\sigma} t_{i,j}(\sigma)\, f_{i,\sigma}^\dagger\, f_{j,\sigma} + \frac{1}{2}\sum_{i,j,k,l}\sum_{\sigma,\sigma'} V_{i,j,k,l}(\sigma, \sigma')\, f_{i,\sigma}^\dagger\, f_{k,\sigma'}^\dagger\, f_{l,\sigma'}\, f_{j,\sigma}$$

$$(11)$$

and the 1st order contributions to the self-energy $\Sigma$ and polarization $\Pi$ become (we employ periodic boundary conditions)

$$\Sigma_H(|j-i|, \sigma) = \sum_{\sigma'} \sum_{k,l} G(|k-l|, \tau = -0, \sigma') \, V_{i,j,k,l}(\sigma, \sigma') \quad (12)$$

$$\Sigma_{GW}(|l-i|, \tau, \sigma) = -\sum_{j,k} G(|k-j|, \tau, \sigma) \, W_{i,j,k,l}(-\tau, \sigma, \sigma) \quad (13)$$

$$\Pi(i, j, k, l, \tau, \sigma, \sigma) = G(|k-j|, \tau, \sigma) \, G(|i-l|, -\tau, \sigma), \quad (14)$$

where $G$ and $W$ are the solutions of the Dyson equations. To avoid double counting, the Hartree diagram with fully dressed Green's function should contain only the bare (time-independent) interaction $V_{i,j,k,l}(\sigma, \sigma')$.

To make use of the translation invariance, we introduce variables $u = i - j$ and $v = k - l$, defining relative distances between the orbital centers. Then $u = v = 0$ corresponds to the "density-density" part of the interaction potential $V_{i,j,k,l}(\sigma, \sigma')$. For the model under consideration, this density-density part dominates the answer, and inclusion of terms with nonzero values of $u$ and $v$ in the Dyson equation for $W$ introduces only minor changes. We find that energies per atom, computed with cutoffs $u^* = v^* = 2$, differ from the full answer just by $\sim 10^{-5}$ in relative units even at the smallest inter-atom separations. The possibility to introduce such cutoffs in a controlled way enormously simplifies the computational effort and memory requirements in high diagrammatic orders.

## 3.2 Pauli Exclusion Principle: Zero Terms

There exist two different standards in the formulation of the projected Hamiltonian. The first approach explicitly respects the Pauli exclusion principle in the interaction terms, while the second approach pays no special attention to it. Physically, the two standards deal with identical Hamiltonians and would lead to the same answer if solved exactly. However, if one truncates self-consistent diagrammatic series at low order (as in the sc-GW approximation), the two standards of formulating the projected Hamiltonian would produce different answers. Given that these two approaches are "inherent" to two different communities (lattice models *vs* material science) and that the sc-GW approximation is a widely used method, we consider both alternative here to quantify the effect of adding/subtracting zero Hamiltonian terms on the sc-GW approximation.

To illustrate the point, consider an ideal spin-polarized lattice Fermi gas with added contact interaction term

$$\hat{H}_0 = -\sum_{ij} t_{ij} \, f_{j\uparrow}^\dagger \, f_{i\uparrow} + U \sum_i f_{i\uparrow}^\dagger \, f_{i\uparrow}^\dagger \, f_{i\uparrow} \, f_{i\uparrow}. \quad (15)$$

**Fig. 8** Effect of zero terms on the sc-GW results for the hydrogen chain: energy per atom (minimal basis set, thermodynamic limit). Black line: the DMRG curve (best variational answer). Blue line: the sc-GW($H$) curve (the material science protocol). Red line: the sc-GW($H'$) curve (the lattice model protocol)

Because of the Pauli principle, this interaction term is zero. Even if we keep it, in the diagrammatic expansion with respect to $U$, all diagrams of the same order will cancel each other, order by order. However, this is true only in the case of exact solution accounting for all the orders in $U$. The sc-GW scheme includes some (but not all) higher-order corrections in $U$; unaccounted terms will thus lead to different answers for Eq. 15 with $U = 0$ and $U \neq 0$.

Similar considerations hold true for any Hamiltonian projected onto the orbital basis. The terms with matrix elements $V_{abad}$ and $V_{bada}$ have no effect on the exact answer because of the Pauli principle – they are "zero terms" and one can either (i) keep them (material science community protocol) or (ii) drop them (lattice model Hamiltonian community protocol). We distinguish these two protocols by introducing notation (i) $\hat{H}$ and (ii) $\hat{H}'$, respectively. In Fig. 8 (energy per atom for different values of the lattice distance $R$), we demonstrate how the same sc-GW scheme for two formally identical Hamiltonians $\hat{H}$ and $\hat{H}'$ produces different answers. As one can see from this figure, the effect of zero terms on the sc-GW results is far from being negligible, especially in the region of large inter-atom distances $R > 1.8 \ a_B$. Also, while the sc-GW($\hat{H}$) is more accurate in the perturbative region ($R < 1.8 \ a_B$), the sc-GW($\hat{H}'$) appears to produce more consistent energies throughout the entire range of $R$. Since the two sc-GW answers surround the DMRG one, the difference between them can be considered as an estimate of the systematic bias within the sc-GW approximation. Indeed, in the next subsection, we show that this difference has similar magnitude as the energy shift produced by considering the leading vertex correction.

## 3.3    Energy per Atom: Convergence of BDMC Results

To go beyond the sc-GW approximation, we employ the BDMC technique and obtain the ground-state energy per atom (using the same $T \rightarrow 0$ extrapolation

**Fig. 9** Ground-state energy in different skeleton orders (minimal basis set, thermodynamic limit). By accounting for higher-order vertex corrections, the BDMC results converge to the best variational answer – DMRG (black curve). Red line: The $BDMC_1(H') = sc\text{-}GW(H')$ curve. Green line: The $BDMC_2(H')$ curve. Blue line: the converged $BDMC(H')$ result (see text)
procedure as presented in Fig. 2) for system (11) in the thermodynamic limit (we work with $\hat{H}'$).

The convergence of the $BDMC_n$ results to the exact (DMRG) answer as the largest accounted for order $n$ is increased and is presented in Fig. 9. $BDMC_2$ data are already extremely accurate at the inter-atom separation $R \leq 1.8$ $a_B$. One has to increase the expansion order and consider $BDMC_3$ to achieve the same accuracy for $R = 2.4$ $a_B$, indicating that we are entering a non-perturbative regime. For $R = 2.8$ $a_B$, convergence is reached only when all diagrams up to the 5th skeleton order are included, while larger values of $R$ require simulation of even higher expansion orders and the development of appropriate resummation methods. From this study, we conclude that the BDMC technique for systems with Coulomb interactions can be used to obtain converged answers for interesting parameter regimes (see also Tupitsyn et al. 2016 and Tupitsyn and Prokof'ev 2017) with full control over systematic and statistical errors. The study of the hydrogen chain is the first application of the many-body diagrammatic technique to a material science system (Motta et al. 2017); usually such calculations are limited to the lowest-order schemes and involve an unknown systematic bias.

# 4    Conclusions

We have proposed a simple strategy to drastically improve key properties of the two-particle correlation functions within the sc-GW approximation and applied it to the jellium model. The strategy is designed to cure unphysical behavior of the polarization function $\Pi$ that originates from the violation of the dynamic particle conservation law. The very same trick can be applied to other models and materials science systems and can be used in the diagrammatic Monte Carlo approach that considers higher-order vertex corrections (which should correct the unphysical behavior of $\Pi$). We also provide benchmark values of key Fermi-liquid parameters

for jellium within the *standard* sc-GW approximation and the *modified* GW($\Pi$) version.

To explore merits of the bold diagrammatic Monte Carlo approach for materials, we applied this technique to a prototype material science system by evaluating diagrams of all relevant orders to obtain the answer with controlled accuracy. We proposed a protocol for estimating the systematic bias of the sc-GW method using an important ambiguity in the formulation of this diagrammatic approximation. It is related to two opposite ways of treating the Pauli exclusion principle and inherent to two different communities – to the lattice model Hamiltonian and material science ones. Being "innocent" at the level of exact solution, in the case of low-order schemes, such as the sc-GW approximation, this ambiguity leads to answers that differ by an amount similar to that coming from vertex corrections. We demonstrated that the BDMC technique for the single-orbital hydrogen chain converges to the exact answer, i.e., higher-order vertex corrections allow one to reach the desired accuracy in a controlled way.

**Abstract**

Quantum chemical wavefunction-based theories approximate the true many-electron wavefunction in a compact fashion and bear the potential to predict materials properties with high accuracy. Their computational complexity is significantly higher than that of the current workhorse method in computational materials science, density functional theory in the framework of approximate exchange, and correlation density functionals. However, the increase in available computer power and methodological and algorithmic improvements during the last decade have made quantum chemical studies of increasing system sizes possible. Coupled cluster theories are among the most widely used quantum chemical wavefunction-based methods. They employ an exponential ansatz of the electronic wavefunction that constitutes a good trade-off between accuracy and computational cost for weakly correlated many-electron systems. Here, we discuss methodological aspects and recent developments of coupled cluster and related quantum chemical theories for ab initio-based materials modeling.

# 1      Introduction

The solution of the many-electron Schrödinger equation is at the heart of ab initio calculations in computational materials science. Owing to the complex interplay of interelectronic interactions as well as the Pauli exclusion principle for fermionic systems, the many-electron Schrödinger equation is a "non-polynomial hard" problem. Density functional theory (DFT) in the framework of approximate exchange and correlation energy functionals has revolutionized computational materials science by mapping the many-electron Schrödinger equation to a computationally tractable Kohn-Sham Hamiltonian for noninteracting electrons in an effective potential, achieving reasonable accuracy for quantum mechanical systems. However, despite the great successes of DFT during the last decades, a number of challenges in the field of electronic structure theory calculations remain unresolved. Some of the most prominent examples where currently available approximate density functionals fail in achieving a qualitatively correct description of materials properties include systems with strong electronic correlation effects, systems where nonlocal van der Waals interactions play an important role, and systems with localized electronic states that are incorrectly described due to self-interaction errors. From the perspective of quantum chemical wavefunction theories, these challenges could be dealt with by employing an appropriate ansatz for the true many-electron wavefunction, albeit increasing the computational complexity substantially.

# 2      Quantum Chemical Wavefunction Theories

In traditional quantum chemistry, the many-electron wavefunction is expanded into a basis of Slater determinants that are constructed from a set of orbitals. By construction, this basis is antisymmetric under exchange of two coordinates, as required for any fermionic wavefunction, solving the problem of self-interaction even on the lowest level of quantum chemical wavefunction-based theory, the Hartree–Fock (HF) approximation. In HF theory the many-electron wavefunction is approximated using a single Slater determinant only such that:

$$|\Phi^{\mathrm{HF}}\rangle = \frac{1}{\sqrt{N!}} \left| \begin{pmatrix} \phi_1(\mathbf{r}_1) & .. & \phi_n(\mathbf{r}_1) \\ .. & .. & .. \\ \phi_1(\mathbf{r}_n) & .. & \phi_n(\mathbf{r}_n) \end{pmatrix} \right| . \tag{1}$$

The HF determinant is constructed from a set of orthonormal one-electron orbitals, $\phi_i(\mathbf{r})$, which are obtained by minimizing the Hartree–Fock energy, whereby all the coupling terms of the Hamiltonian between the Hartree–Fock determinant and the corresponding single-excited Slater determinants vanish, which is also referred to as Brillouin's theorem. In periodic systems the index $i$ is a compound index of the Bloch wave vector $k_i$ used to sample the first Brillouin zone and the band index $n_i$. Hartree–Fock (HF) theory can be regarded as a low-rank tensor

approximation to the many-electron wavefunction, employing an antisymmetrized outer product of one-electron orbitals to approximate the many-body wavefunction. Hence, by construction, HF theory neglects electronic correlation effects that cannot be captured using products of one-electron functions only.

Traditional quantum chemical post-HF methods, such as Møller-Plesset perturbation, coupled cluster, and full configuration interaction (FCI) theories, capture electronic correlation effects by extending the wavefunction basis with additional excited HF determinants (Helgaker et al. 2000). The FCI wavefunction reads:

$$|\Psi\rangle = c_0|\Phi^{\mathrm{HF}}\rangle + \sum_{\substack{i\in\mathrm{occ.}\\ a\in\mathrm{unocc.}}} c_i^a|\Phi_i^a\rangle + \sum_{\substack{i,j\in\mathrm{occ.}\\ a,b\in\mathrm{unocc.}}} c_{ij}^{ab}|\Phi_{ij}^{ab}\rangle$$

$$+\ldots+ \sum_{\substack{i_1,..,i_n\in\mathrm{occ.}\\ a_1,..,a_n\in\mathrm{unocc.}}} c_{i_1..i_n}^{a_1..a_n}|\Phi_{i_1..i_n}^{a_1..a_n}\rangle. \tag{2}$$

$|\Phi_i^a\rangle$ correspond to singly excited determinants that are constructed from the HF determinant by replacing the $i$-th occupied orbital with the $a$-th unoccupied orbital. Higher excited determinants are obtained in an analogue manner. In $n$-electron systems we can construct at most $n$-fold excited determinants. These determinants form a complete and orthonormal basis that can be systematically improved upon toward a formally complete basis set. Computationally, the basis of (excited) Slater determinants is very convenient. All required occupied and unoccupied orbitals are obtained in the underlying HF ground state calculation. Furthermore this choice of the basis introduces a large degree of sparsity to the full many-electron Hamiltonian. Based on the Slater-Condon rules, electronic structure codes need to compute one- and two-electron integrals only that can be kept in storage or rapidly calculated on the fly. Furthermore we note that the Coulomb interaction does not couple determinants with different total momenta, increasing the sparsity of the Hamiltonian for systems with periodic boundary conditions even further. However, the downside of this approach is that the number of wavefunction coefficients in the Slater determinant basis ($c_i^a$, $c_{ij}^{ab}$, .. , $c_{i_1..i_n}^{a_1..a_n}$) grows combinatorially with respect to the number of electrons and the number of unoccupied HF orbitals. In ab initio calculations the number of unoccupied orbitals is finite only because the one-electron basis set is truncated. The latter typically corresponds to plane waves or atom-centered basis functions such as Gaussian-type orbitals that are used to expand the occupied and unoccupied one-electron orbitals. In full configuration interaction theory, no further approximations are made to the wavefunction coefficients, and the exact diagonalization of the many-electron Hamiltonian in the Slater determinant basis yields the corresponding coefficients of ground and excited many-electron states. However, in practice full configuration interaction theory is not feasible for real materials that require the treatment of systems containing more than hundred electrons and significantly larger numbers of unoccupied orbitals. Therefore wavefunction parametrizations are needed to approximate the coefficients in a more compact manner without compromising accuracy. We note that for

weakly correlated systems, these coefficients are reasonably well approximated using independent electron pair approximations such as the second-order Møller-Plesser perturbation (MP2) theory (Møller and Plesset 1934). MP2 theory employs intermediate normalization ($c_0 = 1$) and approximates the singles ($c_i^a$) and doubles ($c_{ij}^{ab}$) coefficients as well as the correlation energy in a perturbative manner. MP2 theory accounts for pair-wise additive van der Waals interactions between atoms. We stress, however, that higher-order effects such as the screening of these interactions caused by polarization of the remaining electrons in the system are neglected. Furthermore MP2 theory is not suitable for small gap and metallic systems, where any order of truncated Møller-Plesset perturbation theory fails and would require the resummation of all electron-pair coupling terms in the so-called ring approximation to account for higher-order polarization effects such that the correlation energy in metals converges. The so-called ring approximation is included in the coupled cluster singles and doubles (CCSD) theory as well as in the widely used random-phase approximation. Coupled cluster theory uses an exponential ansatz of cluster operators for the wavefunction that reads:

$$|\Psi^{\text{CC}-n}\rangle = e^{\hat{T}}|\Phi^{\text{HF}}\rangle, \tag{3}$$

where $\hat{T} = \sum_{m=1}^{n} \hat{T}_m$ and

$$\hat{T}_m|\Phi^{\text{HF}}\rangle = \sum_{\substack{i_1,...,i_m \in \text{occ.} \\ a_1,...,a_m \in \text{unocc.}}} t_{i_1..i_m}^{a_1..a_m}|\Phi_{i_1..i_m}^{a_1..a_m}\rangle. \tag{4}$$

In coupled cluster singles and doubles theory, the cluster operator reads $\hat{T} = \hat{T}_1 + \hat{T}_2$. We stress that due to the exponential ansatz of the CCSD wavefunction, the coefficients of all $i$-fold excited Slater determinants with $i \geq 2$ are being approximated using the amplitudes of the singly and doubly excited determinants; for example, $c_{ijk}^{abc} = t_i^a t_{jk}^{bc}$. Coupled cluster theory can be regarded as a low-rank tensor approximation to the exact configuration interaction wavefunction coefficients in the Slater determinant basis. The exponential ansatz used in coupled cluster theories effectively approximates the coefficients of highly excited determinants by outer products of cluster amplitudes with a lower rank. CCSD theory is exact for two-electron systems, and higher orders of coupled cluster theory become exact for systems with the corresponding number of electrons. The cluster amplitudes $t_i^a$ and $t_{ij}^{ab}$ are obtained by solving the amplitude equations $\langle\Phi_i^a|e^{-\hat{T}}He^{\hat{T}}|\Phi^{\text{HF}}\rangle = 0$ and $\langle\Phi_{ij}^{ab}|e^{-\hat{T}}He^{\hat{T}}|\Phi^{\text{HF}}\rangle = 0$, respectively. In this manner the coupling between different electron pairs is accounted for in an approximate manner including perturbation theory diagrams of a certain type to infinite order. The coupled-cluster method was initially proposed by Fritz Coester and Hermann Kümmel for applications in the field of nuclear physics (Coester 1958; Coester and Kümmel 1960). In 1966, Jiri Cizek reformulated the method for electron correlation in atoms and molecules (Cizek 1966), where it became a standard for quantum chemical

calculations on systems that do not exhibit strong static correlation (Bartlett and Musiał 2007). For most applications a good trade-off between computational cost and high accuracy is achieved by truncating the cluster operator at doubles (CCSD) and accounting for the effect of triples in a perturbative manner. This approach is referred to as CCSD(T) theory (Raghavachari et al. 1989) and achieves chemical accuracy for the prediction of reaction energies and barrier heights for a wide range of chemical reactions (Bartlett and Musiał 2007; Helgaker et al. 2000). As a consequence of the approximations to the many-electron wavefunction employed in CC theory, the treatment of strong correlation problems is extremely limited. However, this is an area of ongoing research, and the discussion of quantum chemical theories that are capable of treating strong correlation problems would be beyond the scope of this article.

One advantage of quantum chemical theories is that they constitute a hierarchy, which, starting from the one-particle Hartree–Fock (HF) approximation, allows for a systematic treatment of the quantum many-body effects that are captured with an increasing level accuracy by employing MP2, CCSD, and CCSD(T) theories. Calculated ground state properties such as cohesive energies, lattice constants, or bulk moduli of solids typically exhibit decreasing errors using higher levels of theory. Some of the most widely used ab initio codes for the study of periodic systems that have implementations of theories mentioned above include CRYSCOR, CP2K, FHI-AIMS, PYSCF, SIESTA, and VASP. We note that these implementations differ in their choice of the employed one-electron basis set and algorithms used to compute the electronic correlation energies. For the study of materials using quantum chemical theories, the calculated properties need to be carefully checked for convergence with respect to the employed computational parameters. This has to be done in a similar manner as for the more widely used density functional theory calculations. However, in practice the convergence with respect to the employed basis sets and cutoff parameters is slower than for their DFT counterparts. This is caused by the fact the wavefunction theories account for all electronic correlation effects explicitly.

## 3 Approaching the Complete Basis Set Limit

The many-electron wavefunctions introduced above are expanded in a basis of Slater determinants constructed from (unoccupied) Hartree–Fock orbitals. The computational complexity of canonical Møller-Plesset perturbation theory, coupled-cluster methods, and full configuration interaction theory scales between quadratically and exponentially with respect to the number of unoccupied orbitals. Therefore the ability to span the relevant parts of the Hilbert space with as few orbitals as possible is crucial for the implementation of efficient periodic correlated methods. In practice all calculated quantities suffer from a basis set incompleteness error that is caused by the truncation of the employed unoccupied orbital manifold. The optimal choice of the unoccupied orbital manifold minimizes the incompleteness error of the calculated quantity in a controllable manner.

Some of the most widely used basis sets for the expansion of unoccupied orbitals include plane waves and GTOs. As an illustration of their respective characteristic properties, we consider two limiting cases, the uniform electron gas and an atom in a box. From the perspective of the uniform electron gas, plane waves are the natural choice of basis to expand one- and many-electron wavefunction quantities. Plane waves are eigenfunctions of the kinetic energy operator and exhibit the same periodicity as the simulation cell. In realistic ab initio calculations, these plane waves also have a number of appealing features. A single cutoff parameter that limits the kinetic energy of the included plane waves is used to systematically expand the plane wave basis to completeness which is free from basis set superposition errors (BSSE) and linear dependencies. However, there are obvious drawbacks to plane wave expansions. They lack reference to the nature of the atomic environment, having equal basis coverage throughout the cell. This can lead to a substantial waste of computational effort when studying an atom or molecule in a box (Grüneis et al. 2011).

For atoms or molecules, GTOs form a very compact orbital basis. Their widespread use in the field of quantum chemistry has led to standardized tabulated basis sets of increasing size and flexibility (Dunning 1989; Balabanov and Peterson 2005). Orbitals beyond the core and valence shells are included to account for appropriate polarization of the atomic wavefunctions in bonding environments and to provide a description of correlation effects. Basis sets are commonly arranged in hierarchies so that they can be systematically expanded to allow for consistent and extrapolatable convergence. Gaussian-type orbitals are used in a range of periodic electronic structure codes (Dovesi et al. 2014; Pisani et al. 2012; Maschio et al. 2010; Hirata et al. 2004; Arnim and Ahlrichs 1998; Lippert et al. 1999; Krack and Parrinello 2000; Kudin and Scuseria 2000; Füsti-Molnár and Pulay 2002; VandeVondele and Hutter 2003; Sun et al. 2018). However, the introduction of such local basis sets also leads to several shortcomings such as basis set superposition errors (BSSE) and linear dependencies of diffuse atom-centered basis functions in densely packed solids. These problems can partly be accounted for by counterpoise BSSE corrections and removing linearly dependent basis functions. The local nature of these functions is often used for reduced scaling techniques in order to approach linear scaling mean-field treatments (Goedecker 1999; Strain et al. 1996; Burant et al. 1996; Goedecker and Scuseria 2003) and can also be extended to local treatment of correlation (Maschio et al. 2010; Pisani et al. 2008).

For the calculation of energy differences such as the adsorption energy of a molecule on a surface, it is beneficial to employ basis sets that can be truncated such that a large fraction of the incompleteness error cancels in a controllable manner. GTOs exhibit this advantageous property, allowing for obtaining accurate estimates of interaction energies between weakly interacting fragments such as binding energies of physisorbed molecules on surfaces, despite suffering from large incompleteness errors in the respective absolute energies. Plane wave basis sets can also be used to expand (pseudized) GTOs, inheriting these advantageous properties (Booth et al. 2016).

Another approach to obtain compact unoccupied orbital manifolds for the expansion of many-electron wavefunctions is provided by natural orbitals (Löwdin 1955).

Natural orbitals are obtained by diagonalizing the unoccupied-unoccupied orbital block of the reduced density matrix and truncating the obtained natural orbital manifold according to their occupation number. This procedure yields for many applications an optimal unoccupied orbital manifold. To reduce the computational cost of this procedure, it is possible to approximate the reduced density matrix at a lower level of theory such as direct MP2 only. Natural orbitals "downfold" the unoccupied orbitals calculated using plane wave basis sets for atoms and molecules in a box to manifolds that are similarly compact as GTOs (Grüneis et al. 2011).

Despite all the considerations outlined above, the convergence of the many-electron wavefunction and that of calculated expectation values such as the correlation energy is frustratingly slow with respect to the number of unoccupied orbitals (Helgaker et al. 2000; Hättig et al. 2012). Therefore extrapolation techniques that remove the remaining basis set incompleteness error are needed on top of these fairly large basis set calculations. In the case of plane wave basis set calculations, analytic and numerical results from MP2 theory suggest a $1/M$ decay of the basis set incompleteness error where $M$ is the number of plane waves used in the calculation, allowing for straightforward extrapolation to the CBS limit (Shepherd et al. 2012; Marsman et al. 2009). Similar scaling laws are employed for the extrapolation of correlation energies to the complete basis set limit using GTOs (Helgaker et al. 2000).

## 3.1   Explicitly Correlated Methods

The slow convergence of properties calculated using wavefunction-based methods with respect to the number of orbitals originates from the difficulty to describe the many-electron wavefunction in the vicinity of the electron cusp. As the electrons coalesce, a derivative discontinuity or "cusp" must arise, so that a divergence in the kinetic energy operator cancels an opposite one in the potential. The shape of the wavefunction at the cusp is exactly defined to first-order in the interelectronic distance by the Kato cusp conditions (Pack and Byers Brown 1966; Kato 1957). The a priori inclusion of the cusp conditions in the wavefunction ansatz is a cornerstone of explicitly correlated or so-called F12 theories (Kutzelnigg and Klopper 1991; Ten-no 2004a, b; Werner et al. 2007; Hättig et al. 2010, 2012; Grüneis et al. 2017). Explicitly correlated methods augment the conventional wavefunction expansions discussed in the previous section with additional terms that account for the cusp conditions explicitly. Since electronic correlation is for the most part a short-ranged phenomenon, the proper description of the wavefunction shape at short interelectronic distances allows for capturing the largest fraction of the correlation energy in solids and molecules.

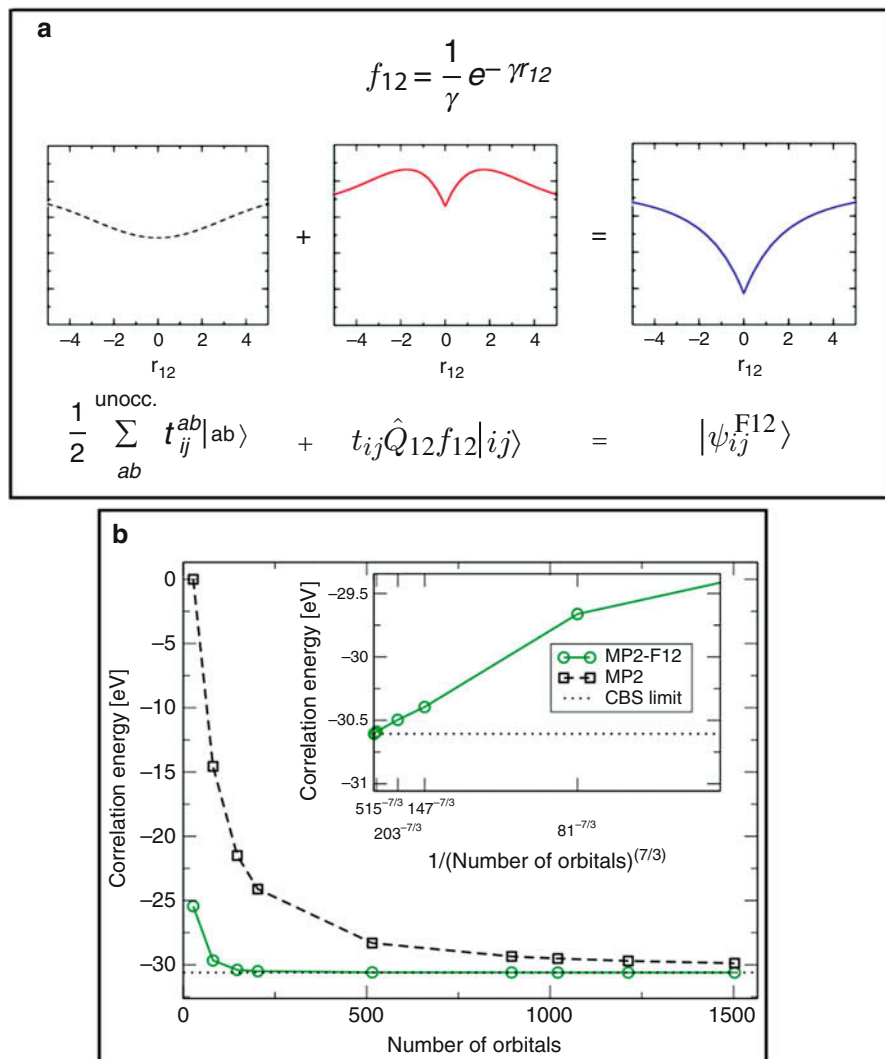
Figure 1a depicts the different contributions to the explicitly correlated first-order wavefunction for two electrons in a box with a homogeneous background. It can be seen that the resultant F12 wavefunction exhibits a cusp at the electron coalescence point. Within an expansion of Slater determinants, the exact cusp is never obtained, and a quantitatively correct linear form at small interelectronic


**Fig. 1** (**a**) Illustration of the different contributions to the explicitly correlated two-electron wavefunction in a box with a homogeneous background. $f_{12}$ is the Slater-type correlation factor with the variational parameter $\gamma$. (**b**) Convergence of the MP2 and MP2-F12 correlation energies for the 54 electron UEG simulation cell ($r_s = 5.0$ bohr) with respect to the employed number of orbitals $M$ (Grüneis et al. 2013)

distances only arises with large basis sets of high momenta. Explicitly correlated methods provide a more compact ansatz for the many-electron wavefunction by augmenting a traditional Slater determinant expansion with geminals that are centered at the electron coalescence points, satisfying the first-order cusp condition

exactly. The first-order pair functions are expanded as:

$$|u_{ij}^{F12}\rangle = \frac{1}{2}\sum_{ab} t_{ij}^{ab}|ab\rangle + t_{ij}\hat{Q}_{12}f_{12}|ij\rangle. \tag{5}$$

The first and second term on the right-hand side of the above equation correspond to the conventional MP1 pair function and the strongly orthogonal geminals, respectively. $t_{ij}$ are geminal amplitudes determined by the universal cusp conditions, and $f_{12}$ is the correlation factor that models the shape of the correlation hole and is typically chosen to be a Slater-type function. This choice ensures that the geminal functions included in the basis are linear with respect to $r_{12}$ in the vicinity of the electron-electron cusp and decay to zero at large $r_{12}$, where the wavefunction is expected to vary smoothly and is generally well-represented by the conventional determinantal basis. The projector $\hat{Q}_{12}$ enforces strong orthogonality between the first-order and the HF wavefunction, and it also enforces orthogonality between the standard and F12 contributions to the first-order wavefunction. Figure 1b shows that the MP2-F12 correlation energy converges much more rapidly than the MP2 correlation energy with respect to the employed basis set ($\approx \frac{1}{M^2}$), reducing the required basis set significantly without compromising accuracy. Even though the findings shown in Fig. 1b were obtained for homogeneous systems, similar basis set reductions can be achieved for ab initio systems. F12 theories introduce the need for three- and sometimes even four-electron integrals. The direct calculation of these integrals is circumvented in practice by the introduction of complementary auxiliary basis sets, significantly increasing the prefactor of the computational complexity for F12 calculations (Klopper and Samson 2002). As a result explicitly correlated methods are only advantageous for more complex parent methods such as CC theories (Knizia et al. 2009; Hättig et al. 2010). In recent years these developments are also being adapted to the field of periodic correlated methods, showing great promise in expanding the scope of quantum chemical wavefunction theories for solids (Usvyat 2013; Grüneis 2015).

## 4 Approaching the Thermodynamic Limit

Quantum chemical wavefunction-based methods are most widely used for the study of atoms and molecules. In contrast to molecular systems, properties of solids and surfaces need to be calculated in the thermodynamic limit (TDL) in order to allow for a direct comparison to experiment. The thermodynamic limit is approached as $N \rightarrow \infty$, where $N$ is the number of particles in the simulation (super-)cell while the density is kept constant. The TDL is usually approached by sampling the first Brillouin zone using increasingly dense $k$-meshes. However, the convergence of calculated properties to the thermodynamic limit is very slow, often exceeding the computational resources of even modern supercomputers due to the steep scaling of the computational complexity of most post-HF methods with respect to system

size. We stress that many properties such as the binding energy of molecules on surfaces converge slower than their counterparts calculated on the level of mean-field theories such as DFT. This originates from the fact that correlated post-HF methods capture long-range electronic correlation effects such as van der Waals interactions explicitly. Even though the corresponding long-ranged contribution to the electronic correlation energy is small compared to short-ranged correlation energy contributions, the accumulation of weak van der Waals interactions can become a non-negligible contribution to the property of interest. Different strategies have been developed to correct for finite size errors that are defined as the difference between the thermodynamic limit and the finite simulation cell results. Local theories that employ correlation energy expressions depending on localized electron pairs can approximate correlation energy contributions of long-distant pairs using computationally more efficient yet less accurate theories. Alternatively local theories can account for electron pairs that are disregarded based on a distance criterion by correcting using an $R^{-6}$-type extrapolation (Usvyat et al. 2012). Canonical implementations of periodic post-HF methods employ scaling laws for extrapolations to the TDL that are based on an analogue rationale (Booth et al. 2013; Ben et al. 2013; McClain et al. 2017). We note in passing that auxiliary field quantum Monte Carlo theory employs finite size corrections that are based on parametrized density functionals obtained from finite uniform electron gas simulation cells (Kwee et al. 2008).

The problem of slow thermodynamic limit convergence and concomitantly large finite size errors is a common feature of quantum Monte Carlo (QMC) and correlated quantum chemical methods. QMC methods employ correction schemes that reduce finite size errors originating from the evaluation of the kinetic and potential energy operators in the many-electron Hamiltonian (Chiesa et al. 2006; Kwee et al. 2008; Holzmann et al. 2016). The most notable corrections include structure factor interpolation techniques and twist averaging. The latter reduces finite size errors originating from the one-electron operators, whereas the structure factor interpolation method allows for reducing finite size errors originating from the two-electron operator. Recently we have introduced finite size correction methods that are inspired by the corresponding techniques used in QMC calculations. These finite size corrections allow for achieving thermodynamic limit results of solids and surfaces using quantum chemical wavefunction theories in a very efficient manner (Gruber et al. 2018; Liao and Grüneis 2016), reducing the computational cost significantly.

## 5    Reduced-Scaling Approximations

In this last section, we briefly mention promising developments from the field of quantum chemical wavefunction-based methods that allow for reducing the scaling of the computational complexity. The steep polynomial scaling of the computational complexity with respect to system size of canonical CCSD ($\mathcal{O}(N^6)$) or CCSD(T) ($\mathcal{O}(N^7)$) theories arises from the use of spatially delocalized canonical

orbitals. Canonical orbitals are conceptually and computationally convenient. They are orthogonal and diagonalize the Fock matrix, greatly simplifying the post-HF correlation schemes. However, these orbitals are spatially delocalized, and their use does not allow one to exploit the fact that electronic correlation is an intrinsically short-ranged phenomenon. The use of spatially localized, instead of canonical, orbitals allows to construct MP2 and CC algorithms that scale more favorably with system size, down to even $\mathcal{O}(N)$, at the price of a significant increase in complexity of the underlying equations with respect to their canonical counterparts. The most notable among them are (based on) the local correlation method of Pulay and Saebø (Pulay and Saebø 1986; Saebø and Pulay 1993; Schütz et al. 1999; Subotnik and Head-Gordon 2005), the so-called local ansatz of Stollhof and Fulde (Stollhoff and Fulde 1978, 1980; Stollhoff 1996), the method of increments of Stoll (Stoll 1992a, b, c; Paulus 2006; Schwerdtfeger et al. 2010; Rościszewski et al. 1999), the atomic orbital basis formulations of Ayala and Scuseria (Ayala and Scuseria 1999; Scuseria and Ayala 1999), or the use of truncated pair natural orbitals (Neese et al. 2009; Kubas et al. 2016; Ma et al. 2017). Other recent developments to reduce the scaling of the computational cost with respect to system size include techniques that calculate the MP2 correlation energy using stochastic methods (Willow et al. 2012; Neuhauser et al. 2013). Furthermore we note that the change of the representation also allows for reducing the scaling of the computational cost without necessarily requiring a local orbital representation (Mardirossian et al. 2018; Schäfer et al. 2017; Friesner 1985).

Finally we note that tensor rank decomposition techniques and so-called tensor hypercontraction methods have also successfully lead to a reduction of the computational cost. The tensor hypercontraction (THC) technique introduced by Hohenstein et al. (Hohenstein et al. 2012a, b; Parrish et al. 2012) performs a low-rank tensor decomposition of the Coulomb integrals. Furthermore, Shenvi et al. (2013) used a similar approach. In the work of Benedikt et al., it was shown that tensor rank decomposition techniques allow for a low-rank decomposition of the coupled cluster amplitudes directly (Benedikt et al. 2013).

The above discussion of reduced scaling approximations is by no means complete but reflects the effort of the electronic structure theory community to reduce the computational cost and expand the scope of quantum chemical methods for the study of materials further.

## 6    Conclusion

In conclusion, we have summarized recent developments in the field of quantum chemical wavefunction-based theories that show great promise of expanding the scope of quantum chemical wavefunction theories for materials modeling. A significant amount of research effort is expended on accelerating the convergence of the many-electron wavefunction approximations and resultant expectation values with respect to the employed orbital basis set, system size, and other computational parameters. Furthermore local approximations allow for the reduction of the scaling

of the computational complexity with respect to system size, making studies of materials containing more than hundred atoms possible. These developments pave the way for a routine use of accurate quantum chemical theories such as coupled cluster methods in the field of surface chemistry and solid-state physics. The ability to predict accurate benchmark results will help the entire electronic structure theory community to improve further upon computationally more efficient yet less accurate ab initio workhorse theories.

# Optimal Control Theory for Electronic Structure Methods

# 22

Alberto Castro

## Contents

### Abstract

Optimal control theory (OCT) is a branch of mathematics that deals with the problem of finding optimal trajectories for dynamical systems. It can be used in combination with time-dependent quantum mechanical methods that describe the evolution of the electronic and/or nuclear wave functions of atoms, molecules, or materials in the presence of external perturbations, such as electromagnetic fields. OCT may then find the optimal shape of those external perturbations: the optimal character is defined in terms of a functional of the behavior of the system. This chapter provides a brief description of the basic elements of the theory and an overview of its applications to quantum dynamics and electronic structure.

# 1 Introduction

*Spectroscopy* studies the interaction of radiation with matter. Its parenthood is attributed to Newton, who explained the famous prism experiments that decomposed light into its colored components. He used for the first time the word *spectrum* (that means *appearance*, *image*, or *apparition*) to refer to the decomposed light image ["Comparing the length of this coloured spectrum with its breadth (. . . )" (Newton 1671)], initiating the field of research and giving it its name at the same time.

The essence of the typical spectroscopic experiment has not changed: take some form of radiation, make it interact with a piece of matter, and observe the radiation reflected or transmitted by it. The resulting data, typically radiation intensities as a function of their wavelength, have continued to be called *spectra* since Newton. By interpreting these spectra, we learn how matter reacts to the perturbation, and, most importantly, we can deduce its microscopic structure. Spectroscopy is the key to understanding how matter looks like at the scale of its constituents.

Moreover, if radiation induces a reaction, it means that the state of matter can be manipulated or *controlled* by tuning the radiation characteristics: expose skin to light, and you can control its tan by adjusting exposition time, modulating its intensity with sunscreen, etc. Initially, only *incoherent control* could be exercised, since all available sources emitted incoherent radiation. One could only manipulate the state of macroscopic portions of matter by tuning time-averaged characteristics of the radiation, since the many photons of an incoherent source impinge stochastically on the microscopic elements of the sample.

This state of affairs changed with the invention of the laser (Maiman 1960): the photons could then be emitted coherently, the frequency could be tuned to the point of almost monochromaticity, and very high intensities could be obtained. The laser is the ideal tool for the manipulation of matter at its microscopic scale. *Coherent control* (Rice and Zhao 2000; Brumer and Shapiro 2003), also known as *quantum control*, was born. In essence, it is some kind of *inverse spectroscopy*: the goal is not to understand how a piece of matter (atom, molecule, nanostructure, solid material, etc.) reacts to an external electromagnetic field but, inversely, to find out what is the precise form of an external field that may induce a given reaction.

The first attempts targeted selective photochemistry, in particular the goal of the cleavage of molecules by some particular bond, with a simple concept: one uses the remarkable monochromaticity that a laser source can achieve to tune the light to the characteristic frequency of that bond. If enough energy can be deposited on it, the bond will break. This can only work if a particular frequency can be associated to the given bond (vibrational molecular modes may not correspond to single-bond vibrations but may represent collective motions). However, the biggest problem is intramolecular vibrational redistribution (IVR) (Bloembergen and Zewail 1984): the energy quickly flows to other degrees of freedom, before the wanted reaction takes place. The final outcome is an increase in the molecular temperature – as it happens when incoherent irradiation is used – and perhaps its fracture at unexpected places.

In the following section, the early proposals of coherent control that overcame this limitation are briefly reviewed. However, the great leap forward was achieved thanks to the improvement of *pulse shapers* – capable of creating almost arbitrary pulses – and the *adaptive feedback control* proposal (AFC) by Judson and Rabitz (1992). This will also be described in the next section. Optimal control theory (OCT) (Kirk 1998) is presented in Sect. 3; its application in combination with electronic structure theories will finally be discussed in Sect. 4.

## 2   Early Coherent Control Proposals and the Adaptive Feedback Control Setup

Given the inability of single monochromatic laser beams to control the complexity of chemical reactions and other quantum processes, the next obvious step is the use of two frequencies. Brumer and Shapiro (1986a, b, 1989) analyzed the problem of unimolecular reactions triggered by light (i.e., photodissociation) and proposed the control through the quantum interference of two pathways: suppose that two reaction channels are accessible from a given initial state and the energy necessary for it can be supplied by two different paths, one single photon of a given frequency and a multiple number of photons of smaller (commensurate) frequency. Furthermore, suppose that the two beams can act *coherently* on the system. Then, the relative phase of the two beams can be adjusted, and the yields of the various channels will depend on the interference between them. The modification of the relative phase (as well as, possibly, the relative intensity) becomes in this way a control mechanism.

A different approach was taken by Tannor and Rice (1985) and Tannor et al. (1986), who proposed the use of femtosecond pulses in a *pump-dump* setup, illustrated in Fig. 1. A compound "ABC" is initially in its ground-state configuration; two dissociative channels, $AB + C$ and $A + BC$, exist in the ground-state potential energy surface but are adiabatically blocked by a barrier. An initial *pump* pulse at $t_0$ can be used to place the system in an electronic excited state surface (or perhaps in a linear combination of those). The system then evolves, and a second *dump* pulse can be used at different times, with different effects: if applied at $t_1$, the system is transferred back to the electronic ground state, but on the dissociative channel $AB + C$; if applied later at $t_2$, the system will dissociate to $A + BC$.

There have been other "early" quantum control scheme proposals – such as the stimulated Raman adiabatic passage (STIRAP) (Gaubatz et al. 1988; Kuklinski et al. 1989), etc. However, all those first schemes were characterized by the use of relatively simple field shapes and few control parameters (the relative phases, the time delay, etc.). It soon became obvious that they could all be regarded as particular forms of a more general concept: the use of arbitrary laser pulse shapes, with durations and frequencies of the order of the mechanism that is to be controlled, and the variation of many control parameters, controlling those shapes.
**Fig. 1** The pump-dump control setup proposed by Tannor, Kosloff, and Rice (Tannor and Rice 1985; Tannor et al. 1986). A compound in its initial "ABC" ground-state configuration is *pumped* at $t_0$ with a femtosecond laser pulse to an electronic excited state. It then evolves freely until a later *dump* pulse transfers it back to the ground state potential energy surface; depending on the delay time, $t_1$ or $t_2$, the system may land on different dissociative channels, $AB + C$ or $A + BC$

The key instrument to realize this ambitious concept is the laser shaper, a device capable of designing the temporal shape of a pulse. This tool quickly evolved during the 1990s (Weiner 2000). Essentially, it works in the following way: A grating decomposes a simply shaped laser pulse into its frequency components, each of which passes through a filter, capable of modifying its intensity, phase, or both. Then, a second grating is used to combine all the components into the output, *shaped* pulse.

Based on the laser shapers, Judson and Rabitz (1992) proposed the adaptive feedback control (AFC) setup. It is illustrated in Fig. 2. Suppose that we wish to find a laser pulse capable of producing some given reaction. This fact can be measured, for example, by using a time-of-flight mass spectrometer. The failure or success of the pulse can be summarized by a *performance function*, defined in terms of the experiment outcome. The idea then is to create a *learning loop*: the value of the performance function is fed to an optimization algorithm, which decides on the value of the parameters that determine the shape of the next laser pulse to be probed. This loop is iterated a number of times, until an optimal pulse is found.

The AFC mechanism has become the most successful control technique for quantum processes (see Brif et al. (2010) for a rather exhaustive list of applications). Its success is based on various facts: (1) the remarkable capacity that laser shapers have acquired to produce almost arbitrary pulses with high intensities, (2) the high repetition rate that the AFC loop normally has, (3) the existence of efficient optimization algorithms for many-variable functions, and (4) the robustness of the solutions found by the AFC technique.

## 3   Optimal Control Theory: Mathematical Framework

In parallel to the experimental advances described above, a complementary theoretical framework was necessary to describe and solve the problem of quantum control, i.e., finding the parameters that define some external action on some model for a quantum system, capable of forcing it to behave in some target manner. This description of the problem falls within the scope of control theory, a branch of engineering and mathematics that was however invented for other problems. Optimal control theory (OCT) (Kirk 1998) is a particularly successful form of control theory. This section is a crash course on OCT. Its application to quantum problems (quantum OCT, i.e., QOCT), with focus on electronic systems, will be the topic of the next section.

The state of a system, within the mathematical framework of dynamical systems, is typically modeled as a point $y$ in some smooth manifold; this state is fully described by a set of coordinates $y_1, \ldots, y_n \equiv y$ (assuming the manifold dimension to be finite). The system evolves according to a *dynamical law*:

$$\dot{y}(t) = f(y(t), u(t), t). \tag{1}$$

$$y(t_0) = y_0. \tag{2}$$

The functions $u(t) = u_1(t), \ldots, u_M(t)$ are the *control inputs* or *control functions*. The idea behind the definition of the *state* of a system is the following: it is a set of numbers (that change in time, as the state changes) such that, given their knowledge at a given time $t_0$, fully determine the behavior of the system at times $t \geq t_0$ (given fixed control inputs). If the evolution of the system is smooth in time, this means that the equation of motion or dynamical law is a first-order differential equation such as Eq. (1).

In a typical formulation of a control problem, the evolution of the system is usually constrained to a set of *admissible* trajectories that we may denote by $Y$. For example, one may require that the starting state is given: $y \in Y \Rightarrow y(t_0) = y_0$. Likewise, the control inputs may be constrained in multiple ways, and therefore we must define a set of admissible controls $U$.

Sometimes, the control inputs are not presented as functions but as real numbers, usually called the *control parameters*. Note that there is no loss of generality in considering one or the other option: in any numerical implementation of the problem, each function is represented by a set of parameters; inversely, any set of parameters can be considered as a set of functions that are constrained to be constant in time.

The previous Eqs. (1) and (2) are not general enough to describe any possible physical model: stochastic terms, for example, are not included, which exclude relevant models such as Langevin's equations. Of course, extensions of the basic framework of OCT exist for more general situations. However, many important processes fall into this category, such as any quantum process described by Schrödinger's equation. In this case, the dynamical law is linear:

$$f(y(t), u(t), t) = -i H[u(t), t] y(t), \tag{3}$$

where $H[u(t), t]$ is the Hamiltonian, a linear Hermitian operator.

In the realm of electronic structure theory, the state $y$ is a many-electron wave function. However, more often than not, one does not solve the full many-electron problem, too large for more than a few electrons, but uses some of the many electronic structure methods that have been developed over the years, for example, multi-configuration time-dependent Hartree-Fock (Nest et al. 2005; Beck et al. 2000) or time-dependent density-functional theory (Marques et al. 2012), which both have been combined with OCT (Mundt and Tannor 2009; Castro et al. 2012).

If the control inputs $u$ are given, the evolution of the system is fully determined by its equations of motion. However, if we can *control* the values of these parameters, then we can manipulate the evolution of the system. This is the gist of control theory; "optimal" control theory, in particular, pursues this control by defining a *performance measure* (also known sometimes as *target functional*), a function dependent on the system trajectory, and searching for the control parameters that maximize it. In some cases, the problem statement obviously and uniquely determines the definition for the performance function, whereas in some other cases, many possible valid options exist, and the practitioner must choose one. A very generic form for this function is:

$$F(y, u) = h(y(T)) + \int_{t_0}^{T} dt \; g(y(t), u(t), t) \,. \tag{4}$$

This definition separates a *terminal* part $h(y(T))$, which depends on the final system state, and a *time-dependent* or *trajectory* part, $\int_{t_0}^{T} dt \; g(y(t), u(t), t)$, which depends on the full evolution of the system. The time $T$ is the final propagation time. This may be fixed or not: an important class of control problems is the minimization of the time that it takes for some process to happen.

We already have all the necessary ingredients to formally formulate the *optimal control problem*: find an admissible control $u^* \in U$, such that it forces the system to follow an admissible trajectory $y^* \in Y$:

$$\dot{y}^*(t) = f(y^*(t), u^*(t), t) \,, \tag{5}$$

$$y^*(t_0) = y_0^* \,, \tag{6}$$

and such that it maximizes the value of the performance measure, i.e.:

$$F(y^*, u^*) = h(y^*(T)) + \int_{t_0}^{T} dt \; g(y^*(t), u^*(t), t) \geq F(y, u) \tag{7}$$

for any other admissible $y$ and $u$. Note that, since the specification of $u$ determines the system evolution, i.e., $u \to y[u]$, one may reformulate this as the maximization of a function of the control inputs alone:

$$G(u) = F(y[u], u) \,. \tag{8}$$

Also note that, one may indistinctly speak of minimization or maximization; the formalism is identical except for a sign in the performance function (that typically changes its name to *cost function* when the goal is its minimization).

One very common example of control problem in the quantum world is the following: suppose that we wish to find the precise shape of the amplitude of an electric field, $u(t)$, such that it has *moderate intensity*, and it maximizes the population of some excited states $y_I$ at the final propagation time $T$. Then, a possible definition for the performance measure is:

$$F(y, u) = |\langle y(T)|y_I\rangle|^2 - \alpha \int_{0}^{T} dt \; u^2(t) \,. \tag{9}$$

The second term somehow codifies the requirement of moderate intensity and is generally called a *penalty* term. Of course, multiple other definitions are possible (given the imprecise character of the *moderate intensity* requirement), and this fact exemplifies the lack of uniqueness in the definition for the performance function that control problems often have.

There are two main mathematical approaches to the control theory problem: the dynamic programming method developed by Bellman (1957) and the method based on Pontryagin's minimum principle (Boltyanskii et al. 1956; Pontryagin et al. 1962). Both are briefly described in the following two subsections.

## 3.1    Dynamic Programming

This approach is based on the *principle of optimality*:

*If a trajectory $y^*(t)$, corresponding to the control inputs $u^*(t)$, is optimal for a given performance measure defined in the interval $[t_0, T]$, then any final piece of that trajectory (i.e., the restriction of $y^*(t)$ to an interval $[t_a, T]$ for any $t_a \in (t_0, T)$), with the same control inputs, is also optimal for the same performance measure.*

This is in fact a rather simple principle, and it can be very easily proved by reductio ad absurdum (Kirk 1998). It can be used to solve the control problem in two different equivalent ways:

- Frequently, the problem is first discretized in time, and the set of admissible states is also fully enumerated (it may happen that the problem is already discrete from the beginning and is posed as a series of decisions). Then, the principle of optimality can be used to create a recurrence relation that fully determines the optimal solution. One starts from the last part of the trajectory, whose optimal solution must be a part of the full solution according to the principle of optimality. Then, a step-by-step backward repetition of this idea is used.
- One may directly derive a partial differential equation that constitutes a necessary and sufficient condition for a set of control inputs and corresponding trajectories to be optimal: the Hamilton-Jacobi-Bellman (HJB) equation. Of course, its solution then requires an a posteriori discretization.

The HJB equation, or the equivalent discretized recurrence algorithms, apparently supplies a complete solution to the optimal control problem. Unfortunately, it is not always useful due to the bad scaling of the computational cost with the problem variables: number of time steps, system state dimensions, and number of control inputs. This drawback was already identified by Bellman, who named it the *curse of dimensionality*, and it is probably the reason behind the fact that dynamic programming has been rarely used for quantum control problems.

## 3.2    Pontryagin's Minimum Principle

Pontryagin et al. (Boltyanskii et al. 1956) established a set of necessary conditions for the optimal control inputs and state trajectory of a control problem, which is known as Pontryagin's minimum principle. This is not the place to present it in detail, or to demonstrate it, but it is worth to outline a simplified version.

Given a control problem defined by the dynamical system, Eqs. (1) and (2), and by the performance function defined in Eq. (4), we define a *Hamiltonian function* (not to be mistaken with the Hamiltonian of the system, if it exists):

$$\mathcal{H}(y(t), u(t), p(t), t) = g(y(t), u(t), t) + p^T(t) \cdot f(a(y(t), u(t), t)). \quad (10)$$

This definition needs a new set of variables, $p(t) = p_1(t), \ldots, p_n(t)$, sometimes called the *costate*, or the momentum variables. The following are necessary conditions for $u^*(t)$ and $y^*(t)$ to minimize the performance functions:

$$\dot{y}^*(t) = \nabla_p \mathcal{H}(y^*(t), u^*(t), p^*(t), t), \quad (11)$$

$$y^*(t_0) = y_0, \quad (12)$$

$$\dot{p}^*(t) = -\nabla_y \mathcal{H}(y^*(t), u^*(t), p^*(t), t), \quad (13)$$

$$p^*(T) = \nabla_y h(y(T)), \quad (14)$$

$$\mathcal{H}(y^*(t), u^*(t), p^*(t), t) \leq \mathcal{H}(y^*(t), u(t), p^*(t), t) \text{ for any } u \in U. \quad (15)$$

Note that this is a simplified version of the principle that assumes that the final time $T$ is fixed, the initial state is also fixed, and, in contrast, the final state at time $T$ is not constrained in any way. However, it is sufficient to display one of its key traits: the use of an auxiliary set of variables, $p(t)$, that verify equations of motion that are similar, but not identical, to the ones verified by the original variables. The boundary conditions specified in Eq. (14), in particular, are given at the final time $T$, which means that the computation of $p$ must be obtained via a backward propagation.

## 4    Application to Electron Dynamics

Pontryagin's minimum principle is in fact at the theoretical base of most applications of OCT to quantum problems. Or, put differently, the equations used in the field of QOCT can be considered re-derivations of Pontryagin's minimum principle for particular cases, even if it is often uncredited. For example, a prototypical QOCT problem may be defined by the target in Eq. (9) and by an evolution governed by Schrödinger's equation – i.e., the linear relation in Eq. (3). Let us assume furthermore that the Hamiltonian has the form:

$$H[u(t), t] = H_0 + u(t)D. \quad (16)$$

$H_0$ may be the field-free Hamiltonian of a molecule, whereas $D$ may be its dipole coupling to the electric field component of a laser pulse whose amplitude is $u(t)$ (assuming the dipole approximation). Then, one can prove that the optimal $u^*$ is given by:

$$u^*(t) = -\frac{1}{\alpha}\text{Im}\langle p^*(t)|D|y^*(t)\rangle\,, \tag{17}$$

where $y^*(t)$ and the auxiliary wave function $p^*(t)$ are fully determined by:

$$\dot{y}^*(t) = -i\,H[u^*(t), t]y^*(t)\,. \tag{18}$$

$$y^*(T) = y_0\,, \tag{19}$$

$$\dot{p}^*(t) = -i\,H[u^*(t), t]p^*(t)\,. \tag{20}$$

$$p^*(T) = \langle y_I|y^*(T)\rangle y_I\,. \tag{21}$$

These equations can be derived by application of Pontryagin's principle or from scratch by making use of variational calculus.

Equation (17) is in fact the zero condition for the variation of the performance function with respect to the control input. Specifically,

$$\frac{\delta G}{\delta u(t)} = 2\text{Im}\langle p[u](t)|D|y[u](t)\rangle - 2\alpha u(t)\,, \tag{22}$$

where, remember, $G(u) = F(y[u], u)$ [Eq. (8)]. Setting the previous functional derivative to zero is obviously a requisite [i.e., Eq. (17)] for the control input (the laser pulse, in our example) to be optimal.

Many algorithms aimed at finding the solution control given in Eq. (17) have been developed over the years. A very successful one was designed by Zhu and Rabitz (1998). We describe it in Fig. 3 as an example, especially since it is the scheme used

---

1. Choose an initial guess solution $u^{(0)}(t)$.
2. Propagate $y_0 \rightarrow y(T)$ using the Hamiltonian $H_0 + u^{(0)}(t)$. The solution is $y^{(0)}$.
3. Let $p^{(0)}(T) = \langle y_I|y^{(0)}(T)\rangle y_I$.
4. Propagate $p^{(0)}(T) \rightarrow p^{(0)}(0)$ using the Hamiltonian $H_0 + u^{(0)}(t)$. The solution is $p^{(0)}$.
5. Let $u^{(1)}(t) = -\frac{1}{\alpha}\text{Im}\langle p^0(t)|D|y^0(t)\rangle$.
6. Let $k = 1$.
7. Propagate $y_0 \rightarrow y(T)$ using the Hamiltonian $H_0 + u^{(k)}(t)$. The solution is $y^{(k)}$.
8. Let $p^{(k)}(T) = \langle y_I|y^{(k)}(T)\rangle y_I$.
9. Propagate $p^{(k)}(T) \rightarrow p^{(k)}(0)$ using the Hamiltonian $H_0 + u^{(k)}(t)$. The solution is $p^{(k)}$.
10. Let $u^{(k+1)}(t) = -\frac{1}{\alpha}\text{Im}\langle p^k(t)|D|y^k(t)\rangle$.
11. If $u^{(k+1)} \approx u^{(k)}$, stop and $u^* = u^{(k+1)}$ is the solution. Otherwise, repeat steps 7–11 until convergence.

**Fig. 3**   The monotonic algorithm of Zhu and Rabitz (1998)

for one of the examples below. Some of the most common features of all quantum control algorithms can be learned from the analysis of this one, namely:

- The algorithm requires backward propagations of the auxiliary state $p$ (since the boundary condition is established at the final propagation time $T$). This is not surprising, as this fact is already implicit in Pontryagin's minimum principle. Note, however, that not all schemes require backward propagations: they are only needed if the scheme makes use of the gradient of the target functional with respect to the control parameters – or the functional derivative with respect to $u(t)$ if a continuous function is used as control. Many algorithms only require function evaluations (e.g., evolutionary algorithms), and therefore the only operation required is the propagation of the equations of motion.
- Convergence to the global optimum is not guaranteed. The algorithm of Zhu and Rabitz is always monotonic, but in general, no algorithm can guarantee that a global optimum will be found. Multiple local solutions may exist.
- The cost of the optimization grows linearly with the cost of propagating the wave functions, as this is the basic operation of the algorithm. The number of propagations needed to reach convergence depends however on the scheme and grows with the number of control parameters or functions.

The previous discussion, based on Eqs. (16), (17), (18), (19), (20), (21), and (22), considers a continuous function of time, $u(t)$. Therefore, the "gradient" of the functional [Eq. (22)] is in fact a functional derivative. It is worth to reconsider the theory assuming that the control inputs are a set of parameters $u_1, \ldots, u_M$ – especially since, upon discretization for their numerical representation, the control input functions are also reduced to a finite set of parameters. Schrödinger's equation would then read:

$$\dot{y}(t) = -iH[u, t]y(t),  \tag{23}$$

$$y(t_0) = y_0.  \tag{24}$$

and the performance function can be, for example:

$$F(y, u) = \langle y(T)|O|y(T)\rangle - P(u),  \tag{25}$$

where $O$ is some operator whose expectation value at the end of the process we wish to maximize (the case $O = |y_I\rangle\langle y_I|$ corresponds with the excited state population described above) and $P(u)$ is a penalty function (which, as in the example above, may be added to avoid unwanted features of the control parameters, such as too high intensities). The previous functional derivative is now a normal gradient, given by:

$$\frac{\partial G}{\partial u_k}(u) = 2\text{Im}\int_{t_0}^{T} dt \ \langle p[u](t)|\frac{\partial H}{\partial u_k}(u, t)|y[u](t)\rangle - \frac{\partial P}{\partial u_k}(u).  \tag{26}$$

where the auxiliary state $p[u]$ is defined by its equations of motion:

$$\dot{p}[u](t) = -iH[u,t]p[u](t)\,, \tag{27}$$

$$p[u](T) = Oy[u](T)\,. \tag{28}$$

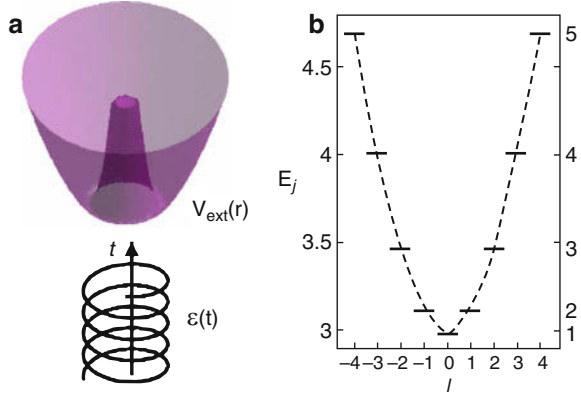
Note the remarkable similarity of these equations to the ones that define the state: $p$ also follows Schrödinger's equation, and the only difference is the initial value condition that changes to a final value one. This similarity is a consequence of (1) the linear character of Schrödinger's equation, (2) the quadratic character of the target functional with respect to the state, and (3) the fact that the target functional only depends on the state at the final time of the propagation, $T$. If any of these conditions is not met, the equations of motion for $p$ become more complex, including nonlinear or inhomogeneous terms.

These QOCT equations, or variations of it, have been applied many times in numerous investigations, since the first attempts in the 1980s (Shi et al. 1988; Peirce et al. 1988; Shi and Rabitz 1989; Kosloff et al. 1989). Most of these, up to recently, have focused on the control, with femtosecond pulses, of the motion of the nuclear wave packet on one or a few potential energy surfaces. That motion typically happens on a time scale of hundreds of femtoseconds or picoseconds. However, laser technology has improved dramatically, reaching the attosecond time scale when the millennium turned (Krausz and Ivanov 2009). This access to the attosecond scale has enabled the possibility of not only observing electron dynamics in their natural time scale but also controlling them.

Therefore, the combination of QOCT with non-equilibrium quantum dynamics methods has become necessary to match the experimental advances. Unfortunately, modeling electron dynamics is notoriously difficult (van Leeuwen and Stefanucci 2013). The main reason is the exponential growth of computational cost and memory requirements with the number of electrons involved in the calculations. For this reason, the simple Schrödinger equation is substituted with more elaborate models that operate on smaller objects, at the cost of losing the structural simplicity of the original linear equation. This problem becomes especially relevant for QOCT calculations: the expression for the gradient of the performance function with respect to the control parameters involves the forward propagation of the system state, and the backward propagation of a fictitious *costate*. This means that performing QOCT calculations is as costly as performing a number of propagations for the system and model employed.

In the following, in order to show a glimpse of the possibilities that the combination of QOCT with electronic dynamics methods offers, three sample cases are briefly presented.

## 4.1    One Electron Case: Control of Motion in Quantum Rings

If there is only one electron (or if the electron-electron interaction can be neglected), electron dynamics is actually easy and manageable, and quantum optimal control


can be performed by making use of the very same equations described above for the case in which the system simply follows Schrödinger's equation.

For example, Räsänen and collaborators (Räsänen et al. 2007) studied single electrons in quantum rings: the rings are in fact two-dimensional traps built in semiconductor heterostructures, where the electrons of the two-dimensional electron gas formed at the interface can be confined. They can be modeled with simple Hamiltonians, i.e.:

$$H_0 = -\frac{\hbar^2}{2m^*}\nabla^2 + \frac{1}{2}m^*\omega_0^2 r^2 + V_0 e^{-r^2/d^2} . \tag{29}$$

This is a 2D Hamiltonian ($r^2 = x^2 + y^2$), whose confinement potential is depicted in Fig. 4a: one may see how the potential well is ring-shaped. Note that to describe these systems, one makes use of the effective mass approximation: the parameter $m^*$ is an effective mass (in this particular example, it was set to 0.067 times the real electron mass, the experimental value measured in GaAs).

The energy levels of this Hamiltonian are also depicted in Fig. 4b. The $x$ axis represents the orbital angular momentum: positive and negative values correspond to clockwise and anticlockwise electron rotation within the ring. The goal of this study was to fully control the rotation of the electron, by placing the electron into any of those excited states, making use of two-component electric fields, i.e., the time-dependent Hamiltonian is given by:

$$H(t) = H_0 - x\varepsilon_x(t) - y\varepsilon_y(t). \tag{30}$$

The fields $\varepsilon_x$ and $\varepsilon_y$ are the control inputs. The optimization was achieved by making use of the rapidly convergent algorithm described above in Fig. 3 (Zhu and Rabitz 1998). The target or performance function was set to be, as above, the population of the excited states, in order to design electric pulses capable of changing the electron rotation.

The use of QOCT in this work led to finding optimal shapes for the controlling fields that are more complex than simple continuous wave pulses tuned to the energy differences of the states. Those optimal pulses could arbitrarily transfer the population between states almost at will in very short times.

## 4.2    QOCT in Combination with Multicomponent Hartree-Fock

In order to go beyond single-electron cases and attempt the control of larger electronic systems, one must make use of one of the many approaches to the time-dependent many-electron problem that have been developed since the dawn of quantum mechanics. Mundt and Tannor were the first to attempt the combination of one of these schemes, multi-configuration time-dependent Hartree-Fock (MCT-DHF) (Nest et al. 2005; Beck et al. 2000), with QOCT (Mundt and Tannor 2009).

In MCTDHF, the very large and unmanageable $N$-electron wave function $\Psi(x_1, \ldots, x_N, t)$ (where $x_i$ represents the position and spin coordinates of one electron) is substituted by the smaller ansatz:

$$\Psi^{MCTDHF}(x_1, \ldots, x_N, t) = \sum_{k_1}^{K} \cdots \sum_{k_N}^{K} c_{k_1, \ldots, k_N}(t) \Pi_{l=1}^{N} \varphi_{k_l}(x_l, t). \tag{31}$$

The single-particle orbitals $\{\varphi_k\}$ define a basis in the single-particle Hilbert space and may change in time along with the coefficients $c_{k_1, \ldots, k_N}(t)$. The number of orbitals $K$ determines the accuracy of the method. The evolution of this new wave function – that means the evolution of the coefficients and of the orbitals – is determined by the Dirac-Frenkel variational principle (Raab 2000), which ensures the minimum possible distance to the true solution. The resulting equations are rather involved, and it is not worth to repeat them here. The key point, however, is that it is no longer a simple set of linear equations such as Schrödinger's. As a consequence, the control equations also become very involved, and, in fact, they were not derived and used in the work of Mundt and Tannor. In contrast, the idea was to use the simple control expressions valid for Schrödinger's equation and use the MCTDHF wave function as an approximation to the true wave function.

This approach can only be valid if the MCTDHF is of very high quality: the number of orbitals of the single-electron basis is very large, in which case the wave function tends to the exact one. Unfortunately, this also means that the computational cost must be very large, too: the cost grows with $\binom{K}{N}$. And, in any case, the obtained optimal control inputs will be sub-optimal, due to the fact that the true control equations for the model are not used. Due to these reasons, this approach has not been widely followed yet.

## 4.3     QOCT in Combination with Time-Dependent Density-Functional Theory

A different approach to the time-dependent many-electron problem is time-dependent density-functional theory (TDDFT) (Marques et al. 2012). Density-based methods substitute the many-electron wave function by the one-electron density as the working variable, an idea that in the case of TDDFT is founded on the one-to-one correspondence between densities and external potentials proved in Runge and Gross (1984). In fact, one can further prove (van Leeuwen 1999) that the time-dependent electron density of a system can be reproduced by a unique external potential in a system with a different electron-electron interaction. If the two systems are identical (i.e., both have the same electron-electron interaction), the uniqueness implies the one-to-one correspondence mentioned above. And, if the first system is the real one but the second one is a noninteracting system, the theorem shows that one can find an external potential for this fictitious system, which reproduces the density of the real one (the *Kohn-Sham (KS) potential*).

This noninteracting system can be modeled with a set of one-particle equations, the time-dependent Kohn-Sham (TDKS) equations:

$$i\frac{\partial}{\partial t}\varphi_i(\mathbf{r}, t) = -\frac{1}{2}\nabla^2\varphi_i(\mathbf{r}, t) + v_{KS}[n](\mathbf{r}, t)\varphi_i(\mathbf{r}, t) \quad (i = 1, \ldots, N/2), \quad (32)$$

$$n(\mathbf{r}, t) = 2\sum_{i=1}^{N/2} |\varphi_i(\mathbf{r}, t)|^2. \quad (33)$$

The orbitals $\varphi_i$ form a single Slater determinant (we assume them here to be doubly occupied, with one pair of spin-up and one spin-down electrons occupying each spatial orbital), which is enough for noninteracting electrons. $n(\mathbf{r}, t)$ is both the real and the fictitious time-dependent electron density. The KS potential $v_{KS}$ is given by:

$$v_{KS}[n](\mathbf{r}, t) = v_{ext}(\mathbf{r}, u, t) + v_{H}[n](\mathbf{r}, t) + v_{xc}[n](\mathbf{r}, t), \quad (34)$$

where $v_{ext}$ is the true external potential, which must be fully determined by the specification of the set of control inputs $u \equiv u_1, \ldots, u_M$. $v_{H}[n](\mathbf{r}, t) = \int d\mathbf{r}' \frac{n(\mathbf{r}', t)}{|\mathbf{r} - \mathbf{r}'|}$ is the electrostatic potential, and $v_{xc}[n](\mathbf{r}, t)$ is the exchange and correlation potential, whose precise form is unknown and must be approximated. In purity, at each time $t$, it depends on all density values at $t' \leq t$. Normally, however, the *adiabatic approximation* is assumed:

$$v_{xc}[n](\mathbf{r}, t) \approx v_{xc}^{GS}[n_t](\mathbf{r}), \quad (35)$$

where $v_{xc}^{GS}[n_t](\mathbf{r})$ is one of the approximations to the exchange and correlation potential functional used in ground-state DFT. The notation of Eq. (32) can be shortened with matrix notation:

$$i\dot{\underline{\varphi}}(t) = \hat{\underline{H}}[n(t), u, t]\underline{\varphi}(t) \,, \tag{36}$$

where we use the underlined symbol $\underline{\varphi}$ to denote a vector containing all KS orbitals and we use the matrix notation $\overline{H}[n(t), u, t] = H_{KS}[n(t), u, t]\underline{I}$ ($\underline{I}$ is the $N/2$-dimensional unit matrix). $H_{KS}[n(t), u, t]$ is the KS Hamiltonian that comprises all the terms in the right-hand side of Eq. (32).

Once the model is fully specified, the control equations can be derived. First, the performance function must be given:

$$F(\underline{\varphi}, u) = F^{\text{td}}(\underline{\varphi}, u) + F^{\text{term}}(\underline{\varphi}(T), u) \,. \tag{37}$$

The first term depends on the full propagation, whereas the second is the *terminal target* that only depends on the state at the end of the propagation. Considering that $u \rightarrow \underline{\varphi}[u]$ (i.e., the specification of the control inputs determines the system trajectory) and defining, once again, $G(u) = F(\underline{\varphi}[u], u)$, one can prove that

$$\nabla_u G(u) = \nabla_u \left. F(\underline{\varphi}, u)\right|_{\underline{\varphi}=\underline{\varphi}[u]} + 2\text{Im}\left[\sum_{j=1}^{N}\int_0^T dt \,\langle \chi_j[u](t)|\nabla_u v_{\text{ext}}(u, t)|\varphi_j[u](t)\rangle\right] \tag{38}$$

where the costate $\underline{\chi}$ is determined by the equations:

$$i\dot{\underline{\chi}}(t) = \left[\hat{\underline{H}}_{KS}[n[u](t), u, t] + \hat{\underline{K}}[\underline{\varphi}[u](t)]\right]\underline{\chi}(t) - i\frac{\delta F^{\text{td}}}{\delta\underline{\varphi}^*} \,, \tag{39}$$

$$\underline{\chi}(T) = \frac{\delta F^{\text{term}}}{\delta\underline{\varphi}^*(T)} \,. \tag{40}$$

The optimal solution is of course found at one of the zeroes of the gradient in Eq. (38). To note:

- The nonlinearity of the TDKS equations causes the appearance of the operator matrix $\hat{\underline{K}}[\underline{\varphi}[u](t)]$. The (operator) matrix elements of this object are given by:

$$\langle\mathbf{r}|\hat{K}_{ij}[\underline{\varphi}[u](t)]|\psi\rangle = -2i\varphi_i[u](\mathbf{r}, t)\times$$

$$\text{Im}\left[\int d^3r' \psi^*(\mathbf{r}') f_{\text{Hxc}}[n[u](t)](\mathbf{r}, \mathbf{r}')\varphi_j[u](\mathbf{r}', t)\right], \tag{41}$$

where $f_{\text{Hxc}}$ is the *kernel* of the Kohn-Sham Hamiltonian, defined as:

$$f_{\text{Hxc}}[n](\mathbf{r}, \mathbf{r}') = \frac{1}{|\mathbf{r} - \mathbf{r}'|} + \frac{\delta v_{\text{xc}}[n](\mathbf{r})}{\delta n(\mathbf{r}')} \,. \tag{42}$$

- Equation (39) is inhomogeneous, due to the presence of the functional derivative of $F^{\text{td}}$ with respect to $\underline{\varphi}$ (the last term in the right-hand side). This term disappears of course if the target functional is only of terminal type.
- The previous scheme permits to control the Kohn-Sham system. However, the goal is to control the *real* system. In principle, one would be tempted to design a target in terms of the real many-electron wave function – an object that however is not provided by TDDFT, which only provides the density. Therefore, the ideal situation would be that in which the performance function can be defined only through the density $n$. In this manner, optimizing for the Kohn-Sham system is strictly equivalent to optimizing for the real one.

This formalism has been implemented in the Octopus code (Marques et al. 2003; Castro et al. 2006). An illustrative simple example was described in Castro et al. (2012): the charge transfer of two electrons between two neighboring asymmetric potential wells, which is defined with the simple model:

$$v_0(x, y) = \frac{1}{64}x^4 - \frac{1}{4}x^2 + \frac{1}{32}x^3 + \frac{1}{2}y^2. \tag{43}$$

This potential landscape is depicted in Fig. 5a. A ground-state DFT calculation performed with the 2D LDA exchange and correlation parameterization provided in Attaccalite et al. (2002) sets the two electrons on the left well [see Fig. 5b].

The control mechanism is an electric field, polarized along the $x$ direction. Its amplitude is parameterized by its Fourier coefficients $u_j$, which constitute the control inputs, i.e.:

$$v_{\text{ext}}(\mathbf{r}, u, t) = v_0(x, y) + \sum_j u_j g_j(t)x, \tag{44}$$

where $g_j(t)$ are the Fourier basis functions (normalized sines and cosines). The coefficients are constrained to enforce $\varepsilon(0) = \varepsilon(T) = 0$. The performance function is defined as:

$$F[\underline{\varphi}, u] = \int_{x>0} d^2r \, n(\mathbf{r}, T) - \alpha \int_0^T dt \, \varepsilon^2[u](t), \tag{45}$$

an expression that encodes the goal: at the final time of the propagation ($T$), there should be as much charge as possible at the right well ($x > 0$). The last term of Eq. (45) is a penalty that prevents the solution field from having too much intensity.

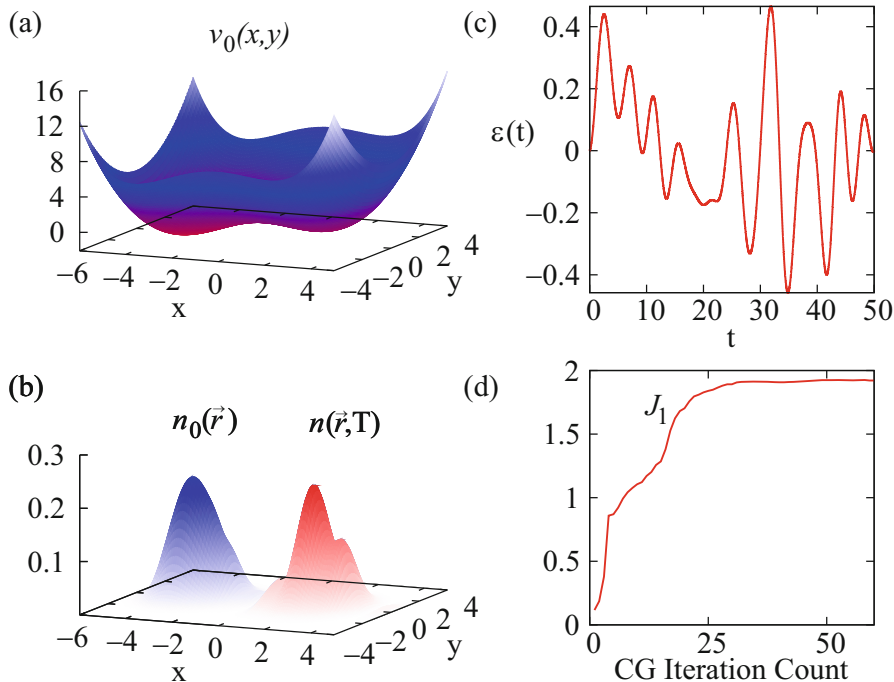
The optimal field is shown in Fig. 5c. In order to find the solution, in this case, a standard conjugate gradient algorithm was used. After around 60 CG iterations (the convergence plot is also shown in Fig. 5), the calculation was converged. The optimal pulse successfully transfers the charge from the left well to the right well. The final charge density is plotted in Fig. 5b.


**Fig. 5** (**a**) External potential defining a model for a double quantum dot. (**b**) Density of the initial ground state [blue, $n_0(\mathbf{r})$] and final propagated density [red, $n(\mathbf{r}, T)$]. Therefore, TDDFT can be combined with QOCT. This combination has been explored a few times, even sometimes in combination with nonadiabatic molecular dynamics to allow for the movement of the nuclei (Castro 2016; Walkenhorst et al. 2016; Gómez Pueyo et al. 2016). The scheme is numerically challenging but tractable. Note, however, that the use of TDDFT always implies an approximation and, in consequence, an error, which may be especially worrisome when employing high-intensity fields. This fact was analyzed, for example, in Raghunathan and Nest (2011).

## 5    Conclusions

The application of OCT to problems in the quantum realm (QOCT) has already some history and can be considered a mature theory, with numerous applications in various fields. QOCT is a generic framework, and its basic formulation makes no assumption on the nature and modeling of the quantum system to be optimized.

It must be *combined* with a given level of theory. In practice, the solution of the QOCT equations requires multiple propagations of the system under study. The cost of applying QOCT is typically therefore multiple times the cost of simulating the system once, and in consequence, it is determined by the cost of the chosen level of theory.

For many-electron systems, the propagations with truly ab initio and precise levels of theory become prohibitively expensive as the number of electrons grows, and usually few-level simplifications and models are used when attempting the combination with QOCT. These simplifications may not be accurate enough: the strong pulses that have nowadays become available imply the occupation of many excited states, and perturbative expansions also fail with increasing intensities. The advances in experimental techniques that permit the access to the attosecond time scale make it necessary to work on the possible combination of QOCT with first-principles methods. TDDFT is one possible choice.

The possibilities that these combinations of QOCT with non-equilibrium time-dependent electron dynamics methods offer are numerous: shaping of the high-harmonic-generation spectrum (i.e., quenching or increasing given harmonic orders), selective excitation of electronic excited states that are otherwise difficult to reach with conventional pulses, control of the electronic current in molecular junctions, etc.

### Abstract

Atomistic simulations are recognized worldwide as an important tool for deepening our understanding of the physics, chemistry, and mechanics of materials. Formidable efforts are being made in the theoretical, modeling, and computational approaches to extend their validity to the complex systems and processes relevant to current technologies as well as to enhance their predictive power. This section reports on recent developments which address the problems of system-size and time scales that are especially critical for ab initio atomistic simulations. In particular, three chapters are devoted to the remarkable advances recently achieved in enhanced sampling methods that are paving the way to the study of the dynamics of complicated transformations and chemical reactions in condensed-matter systems.

# 1 Introduction

During the past two decades, computer simulations at the atomic level have become the dominant tool for the investigation of physical and chemical processes in real materials. Still, many are the challenges one faces in trying to render the simulation "realistic." For example, building a "reliable" model of the system to be simulated is a task of primary importance. On the one hand, the model size should be adequate to represent its composition and the range of the relevant interactions. On the other hand, an approximation must be selected for the system Hamiltonian. Currently, the description of the interatomic interactions mainly relies either on semi-empirical potentials or on "standard" (GGA) schemes derived from density functional theory (DFT). In several cases, these approximations are not sufficiently accurate and more sophisticated methods are required, which are computationally expensive. These include DFT-based molecular dynamics using hybrid exchange-correlation functionals. For advances regarding calculations of the electronic structure of extended systems we refer the reader to the MTM Section "Electronic Structure of Materials by Ab Initio Methods" (Editor: Rubio).

Moreover, there exist fundamental challenges pertaining to the simulation methods themselves, be they Monte Carlo or molecular dynamics. Their ability to represent the thermodynamics as well as the kinetics of activated processes remains the main concern, and in particular their aptness to identify and characterize the so-called rare events. A general discussion of related issues and open problems can be found in a very recent review (Camilloni and Pietrucci 2018).

In this section important method developments of the last decade, including very recent proposals, are discussed which are expected to play an important role for many applications in the near future. A brief overview is reported here with the aim of guiding the reader through a diverse and highly relevant set of chapters.

# 2 A Brief Chapter Overview

The "system-size problem" is especially crucial for nonempirical simulations that involve the calculation of the electronic structure. ▶ Chapter 24, "Extending the Scale with Real-Space Methods for the Electronic Structure Problem" by Chelikowsky shows that a remarkable extension of the size limits can be obtained using a real-space representation of the electronic states, at least within schemes based on density functional theory and reduced to the valence electron subspace via the pseudopotential scheme.

Going beyond "standard" (LDA or GGA) approximations of density functional theory for the description of the electronic structure is important for the atomistic simulations of diverse types of materials. However, currently, this effort is highly computationally demanding. An ingenious and efficient algorithm allowing ab initio molecular dynamics based on correlated wavefunction-based methods is described

in ▶ Chap. 25, "MP2- and RPA-Based Ab Initio Molecular Dynamics and Monte Carlo Sampling" by Hutter et al. A very interesting application to liquid water is then presented including comparison with DFT-based calculations using hybrid exchange-correlation functionals.

In the search for ways to alleviate the "time-scale problem," methods aimed at directly accelerating the simulation are of special interest. For a broad discussion of the latter – including related technical issues – we refer the reader also to the MTM section on "Computational Methods for Long-Timescale Atomistic Simulations" (Editors: Perez and Uberuaga), and to the Chap. 11, "Long Time-Scale Atomistic Modeling and Simulation of Deformation and Flow in Solids" by Fan and Cao in the ACE section "Plenary Topics" (Editors: Andreoni and Yip).

In the present section, Mazzola and Sorella describe in detail a new, very promising, efficient algorithm (▶ Chap. 26, "Accelerated Molecular Dynamics for Ab Initio Electronic Simulations") which is based on Langevin dynamics. A few examples are presented to illustrate its performance, both within classical and ab initio molecular dynamics. We emphasize that in the latter forces can be derived not only from DFT calculations but also from first-principles approaches like the quantum Monte Carlo method.

Enhanced sampling approaches can be considered also as ways to solve the "time-scale problem," when one is interested to investigate systems with multiple metastable states separated by high-energy barriers and capture the mechanisms leading to the related transitions.

In 2002, the seminal paper by Laio and Parrinello (2002) introduced metadynamics as an efficient tool for configurational sampling and the reconstruction of the free-energy surface. In particular, it was readily implemented in DFT-based molecular dynamics. Several ways to extend and improve on the original scheme have been proposed since then. ▶ Chapter 27, "Metadynamics: A Unified Framework for Accelerating Rare Events and Sampling Thermodynamics and Kinetics" by Bussi, Laio, and Tiwari, provides an overview of this progress. In particular, we would like to draw attention to the discussion of a simple algorithm based on metadynamics that was recently introduced by Tiwari and Parrinello (2013) to determine kinetic rates and later successfully applied in several cases. This approach is a welcome addition to the toolbox of methods addressing the kinetics - something that remains one of the major challenges for molecular simulation.

Two additional chapters report on more recent developments and results.

Pietrucci's ▶ Chap. 28, "Novel Enhanced Sampling Strategies for Transitions Between Ordered and Disordered Structures," introduces an effective representation of the physical system, namely the adjacency matrix of interatomic connections. It goes on to demonstrate the ability of this representation to characterize the different states (phases) of the system and to lead to transitions from one to the other. Selected examples illustrate the results of applications of this new conceptual framework coupled to ab initio molecular dynamics and metadynamics or umbrella-sampling. We emphasize that this scheme not only overcomes the bottleneck of having to

choose ad hoc collective variables, but is applicable to a wide variety of physical and chemical processes. Moreover, it describes ordered and disordered systems on the same footing and thus naturally allows for the simulation of order–disorder phase transitions.

▶ Chapter 29, "Variationally Enhanced Sampling" by Valsson and Parrinello, describes a novel theoretical framework aimed at establishing rigorous foundations for enhanced sampling. The problem of exploring and estimating free energy landscapes is recast into that of minimizing a convex functional. In particular, this new scheme allows one to address systems characterized by high-dimensional free energy surfaces or complex processes that cannot be described with a small number of (collective) variables.

Parallel to the many developments in ab initio simulations, progress continues to be made in devising interatomic potentials for a wide variety of materials. This is important because a fully classical scheme permits simulations using larger-size models and for longer duration. On the other hand, other severe fundamental problems continue to limit their application in spite of the increasing development of specific software. Force fields tailored to simulate biological systems have undoubtedly been very successful. For other materials – of interest to this handbook – however, their accuracy and predictive power is often not satisfactory. Typically, in the case of analytic potentials, the functional form is fixed *a priori* and the parameters are adjusted to either empirical data or some DFT calculations or to a mixed set of results, i.e. from both experiment and computations. A general criticism to the use of classical potentials – including the widely employed class of "reactive potentials" (see, e.g., Liang et al. 2013) – regards their transferability, namely their validity in modeling a system in physical and chemical conditions different from those considered in the fitting procedure.

Two examples based on classical schemes are presented in this section.

One is specifically targeted to water. Indeed, building a classical potential that could reproduce a variety of its (anomalous) properties has been the focus of research for decades (for a recent review see, e.g., Demerdash et al. 2018). Not surprisingly, the physical behavior of water continues to be under constant investigation, in diverse conditions and environments, not only experimentally but also via molecular simulations. ▶ Chapter 30, "Water: Many-Body Potential from First Principles (From the Gas to the Liquid Phase)" by Paesani illustrates the performance of a recently developed potential (MB-pol) by means of a critical comparison with ab initio calculations and experiment.

Significant progress in the creation of classical approaches was marked by the introduction of high-dimensional neural network potentials (NNP) for the prediction of the potential energy surface (Behler and Parrinello 2007). ▶ Chapter 31, "Neural Network Potentials in Materials Modeling" by Hellström and Behler provides an exhaustive and critical overview of the state of the art and clarifies the steps needed in the construction of NNP, including their validation. Very recently, the combination of artificial neural networks and advanced machine learning strategies, also employing accurate reference data, has led to a classical scheme of unprecedented performance for the simulation of liquid and solid water (Cheng et al. 2019).

# 3   Conclusions

Over the last 20 years, atomistic simulations have become a "must" for progress to be made in many domains of materials science. Their ability is called for not only for understanding the behavior of given materials under certain conditions, but also for predicting it as well as for designing novel materials and devising or modifying processes relevant to technology. In order to comply with these "tasks," extension of computational power is essential but not sufficient. Currently, advances are primarily required in the simulation methods, in particular along the lines discussed in the various articles of this section. On the one hand, we repeat that the endeavor to improve on the accuracy of the description of the interatomic interactions is crucial, and also to increase the size-scale of the molecular model and its complexity (composition, structure, etc.) and the timescale of the events to be simulated. On the other hand, we recall some of the problems that are still beyond the reach of atomistic simulations: the characterization of the kinetics of nontrivial chemical reactions, the evolution of fundamental processes like that of the nucleation of, say, a crystal phase from a solution, or the dynamics of interfaces between heterogeneous materials as present in typical devices and their structural transformations under device operating conditions. At this stage, not only extensions of current methodologies but also new formulations appear to be necessary.

**Abstract**

In principle, the electronic structure of a material can be determined by a solution of the many-body Schrödinger equation. This was first noted by Dirac shortly after the invention of quantum mechanics in 1929. However, Dirac also noted that the solution of the many-body quantum mechanical equations was much too difficult to be solved. He challenged his colleagues to develop "practical methods of applying quantum mechanics," which can lead to an explanation of the main features of complex atomic systems." In this chapter, we explore concepts and algorithms targeting "Dirac's challenge." Two key physical concepts will be employed: pseudopotential theory and density functional theory. For many weakly correlated systems, this formalism works well for ground-state properties such as phase stability, structural properties, and vibrational modes. However,

e-mail: jrc@utexas.edu

applying this approach to large systems, e.g., systems with thousands of atoms, remains a challenge even with contemporary computational platforms. The goal of this chapter is to show how new algorithms can be used to extend computations to these systems. The approach centers on solving the nonlinear Kohn-Sham equation by a nonlinear form of the subspace iteration technique. This approach results in a significant speedup, often by more than an order of magnitude with no loss of accuracy. Numerical results are presented for nanoscale systems with tens of thousands of atoms and new methods are proposed to extend our work to even larger systems.

## 1    Introduction

Many properties of a material can be determined from a knowledge of its electronic structure, i.e., the energy and spatial distribution of electronic states. For example, optical and structural properties can be predicted by knowing the energetic and spatial distribution of electrons in the material.

This was recognized with the inception of quantum mechanics shortly after the work of Schrödinger, Heisenberg, and Dirac. As Dirac noted: "The underlying physical laws [quantum theory] necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble. It therefore becomes desirable that approximate practical methods of applying quantum mechanics should be developed" (Dirac 1929).

The most popular electronic structure methods are based on pseudopotentials (Phillips 1958; Phillips and Kleinman 1959; Chelikowsky and Cohen 1992) and density functional theory (Hohenberg and Kohn 1964; Kohn and Sham 1965). Pseudopotential theory simplifies the electronic structure problem by replacing the "all electron" atomic potential with an effective "pseudopotential," which only binds the valence states. Density functional reduces the original multi-electron Schrödinger equation into an effective one-electron Kohn-Sham equation, where the nonclassical electronic interactions are replaced by a functional of the charge density, i.e., the spatial distribution of electrons. Combining pseudopotentials with DFT can significantly reduce the number of computed one-electron wave functions. More importantly the energy and length scales are set solely by the valence states. Species such as a silicon and tin can be treated on equal footing in solving the electronic structure problem even though the number of electrons in tin is more than three times that of silicon.

Even with these practical simplifications, solving the Kohn-Sham equation remains computationally challenging when the system of interest contains a large number of atoms, e.g., more than a few thousand atoms. Researchers have advocated different approaches to overcome the computational impediments (Saad et al. 2010). These approaches may be classified as basis-free or basis-dependent approaches, according to whether they use an explicit basis set for electronic orbitals or not.

Among the most popular basis-dependent approaches is the plane wave basis set, which is frequently used in applications of pseudopotential density functional theory to periodic systems where plane waves can easily accommodate the boundary conditions (Kresse and Furthmülle 1996; Giannozzi et al. 2009). Another popular approach uses localized basis sets such as Gaussian orbitals, which are commonly utilized in quantum chemistry calculations (Koch and Holthausen 2000; Martin 2004; Saad et al. 2010).

We focus on a different approach based on *real-space* methods, which are "basis free." These methods are popular owing in great part to their great simplicity and ease of implementation (Chelikowsky et al. 1994a, b; Seitsonen et al. 1995; Beck 2000; Fattebert and Bernholc 2000; Ono and Hirose 2005; Kronik et al. 2006; Enkovaara et al. 2010; Andrade et al. 2013). They can be readily implemented in parallel computing environments as they minimize global communications (Saad et al. 2010). Another advantage of real-space methods is that they do not impose artificial periodicity to handle nonperiodic systems. While plane wave basis techniques can be applied to clusters (or molecules), such applications often proceed by placing the cluster of interest in a large supercell. Provided the supercell is sufficiently large so that the cluster is removed from neighboring replicants, the electronic structure solution will correspond to that of the isolated cluster. However, because the potential from neighboring cells can be significant, in some cases this is not a practical solution, i.e., supercell solutions may converge slowly with the size of the cell (Alemany et al. 2004). A related, and perhaps more significant, issue is that the use of supercells is not easily applied to systems that are electronically charged. Charged systems can be handled within plane wave methods by including a compensating uniform charge or a more complex procedure (Alemany et al. 2004; Teter et al. 1992). Real-space methods need not address such complications. The application of the Hamiltonian to electron wave functions is performed entirely in real space. While the Hamiltonian matrix in real-space methods is typically larger than similar applications with plane waves, the matrices are *extremely sparse* and never stored or computed explicitly. Only matrix-vector products that represent the application of the Hamiltonians on wave functions are calculated.

The prime obstacle to solving the Kohn-Sham equations is obtaining a solution to the nonlinear eigenvalue problem. While one can judiciously choose a well-crafted basis or pseudopotential, the end game is a solution of a difficult eigenvalue problem. For example, suppose one considered a local basis of ten orbitals per atom for a system containing 10,000 atoms. The resulting Hamiltonian matrix is large ($100,000 \times 100,000$) and dense. While we might be interested in obtaining a small fraction of the total number of eigenvalue solutions, this is a difficult problem. Moreover, the scaling of the problem is difficult with a solution often exceeding $\mathcal{O}(N^n)$ where $N$ is the number of eigenvalues and $n$ is formally equal to 3, but owing to a small prefactor in realistic computations the operational value is closer to 2 (Saad et al. 2010). Often workers will focus solely on the scaling, but the prefactor is important too. The prefactor for orthogonalization is often small, so the resulting operation is closer to the square of the eigenvalue number. In general, the key measure is not scalability per se but *time to solution* [TTS].

In this chapter, we center on efficient algorithms for eigensolvers applicable to real-space Hamiltonians. Specifically, we will present examples of nonlinear Chebyshev-filtered subspace iteration algorithms implemented in our solution package called PARSEC (Pseudopotential Algorithm for Real-Space Electronic Calculations) (Chelikowsky et al. 1994a, b).

Although described in the framework of real-space pseudopotentials, subspace filtering can be employed to other approaches. This method takes advantage of the fact that intermediate self-consistent iterations do not require accurate eigenvalues and eigenvectors of the Kohn-Sham equation. Still, the self-consistent solution is the *same* accuracy as other eigensolvers. Unlike some so-called "$\mathcal{O}(N)$" methods (Otsuka et al. 2008; Goedecker 1999), subspace filtering is equally applicable to metals and insulators.

Solutions by filtering do not focus on the intermediate linearized Kohn-Sham eigenvalue problems. Typically, explicit eigenvectors are computed only at the first self-consistent field (SCF) iteration, in order to provide a viable initial subspace. After the first self-consistent step, the explicit computation of eigenvectors at each succeeding iteration is replaced by a subspace filtering step. The method reaches self-consistency within a similar number of iterations, when compared to eigenvalue-based approaches. However, since eigenvalues are not explicitly computed after the first step, a significant gain in execution time results when compared with methods based on explicit diagonalization. When compared with calculations based on efficient eigenvalue packages such as ARPACK (Lehoucq et al. 1998) and TRLan (Wu et al. 1999; Wu and Simon 2000), an order of magnitude speedup is often observed.

Filtering methods enable us to perform a class of challenging electronic structure calculations, including clusters with over tens of thousands atoms, which were not feasible before without invoking additional approximations in the Kohn-Sham problem (Zhou et al. 2006a, b; Zhou and Saad 2007; Schofield et al. 2012b).

## 2    The Kohn-Sham Equation

Density functional theory provides a practical method for solving the electronic structure problem, the Kohn-Sham equation (Kohn and Sham 1965):

$$\left[ -\frac{\hbar^2}{2m}\nabla^2 + V_{total}(\rho(r), r) \right] \Psi_i(r) = E_i \Psi_i(r) \tag{1}$$

where $\Psi_i(r)$ is a wave function or eigenfunction, $E_i$ is a Kohn-Sham eigenvalue, $\hbar$ is the Planck constant, and $m$ is the electron mass. (We use atomic units: $\hbar = m = e = 1$ in the following discussion.)

The *total potential*, $V_{total}$, is the sum of three contributions:

$$V_{total}(\rho(r), r) = V_{ion}(r) + V_H(\rho(r), r) + V_{xc}(\rho(r), r), \qquad (2)$$

where $V_{ion}$ is the external ionic pseudopotential, $V_H$ is the Hartree or Coulomb potential, and $V_{xc}$ is the effective exchange-correlation potential. Within density functional theory, exchange-correlation potentials depend solely on the *charge density* $\rho(r)$, which is defined as

$$\rho(r) = \sum_{i=1}^{n_{occ}} |\Psi_i(r)|^2. \qquad (3)$$

Here $n_{occ}$ is the number of occupied Kohn-Sham levels, which is equal to half the number of valence electrons in the system if the system is nonmagnetic. Equation (3) can be generalized to situations where the highest occupied states have fractional occupancy or when there is an imbalance in the number of electrons for each spin component. The Hartree potential is solved from Poisson's equation using the electronic charge density.

The total potential, $V_{total}$, depends on the charge density $\rho(r)$, which in turn depends on the wave functions $\Psi_i$. The Kohn-Sham equation can be viewed as a *nonlinear eigenvalue problem*.

Such equations are typically solved using an iterative procedure to generate a "self-consistent field." The iteration process begins with an initial guess of the charge density, which is usually constructed from a superposition of free atomic charge densities. Using this approximate density, one obtains the initial $V_{total}$ and solves Eq. (1) for $\Psi_i(r)$'s to update $\rho(r)$ and $V_{total}$. Then the Kohn-Sham (Eq. (1)) is solved again for the new $\Psi_i(r)$'s, and the process is iterated. We terminate the process when the charge density is self-consistent, i.e., the solution of the Kohn-Sham equation yields a charge density consistent with the Hamiltonian used to generate the charge density.

The standard SCF process is described in Algorithm 1 and illustrated in Fig. 1

---

**Algorithm 1** Self-consistent-field iteration

1. Provide initial guess for $\rho(r)$ and get $V_{total}(\rho(r), r)$.
2. Solve for $\Psi_i(r)$, $i = 1, 2, \ldots$, from

$$\left[ -\frac{1}{2} \nabla^2 + V_{total}(\rho(r), r) \right] \Psi_i(r) = E_i \Psi_i(r).$$

3. Compute the new charge density $\rho(r) = \sum_{i=1}^{n_{occ}} |\Psi_i(r)|^2$.
4. Obtain new Hartree potential $V_H$ by solving: $\nabla^2 V_H(r) = -4\pi\rho(r)$.
5. Update $V_{xc}$; get new $\tilde{V}_{total}(\rho, r) = V_{ion}(r) + V_H(\rho, r) + V_{xc}(\rho, r)$ with a potential-mixing step.
6. If $\|\tilde{V}_{total} - V_{total}\| < tol$, stop; Else, $V_{total} \leftarrow \tilde{V}_{total}$, go to step 2.

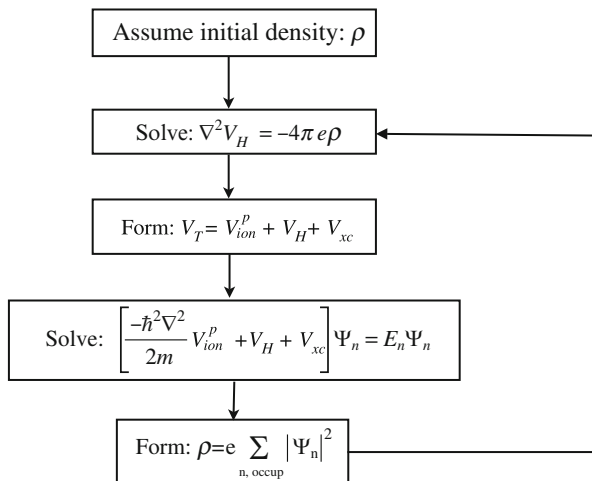
---


**Fig. 1** Flow diagram for obtaining a self-consistent solution of the Kohn-Sham equation

The number of eigenvectors needed in *Step 2* of Algorithm 1 is just the number of occupied states. In practice, a few more eigenvectors are usually computed. For complex systems, i.e., when the number of valence electrons is large, each of the linearized eigenvalue problems can be computationally demanding. This is compounded by the fact that Hamiltonian matrices can be of very large size. For example, a cubic system with 100 grid points on a size results in a matrix of $10^6 \times 10^6$, although the matrix remains very sparse.

For this reason, we wish to reduce the computational load in *Step 2* of Algorithm 1. There are several avenues open to us. One could use some physical arguments to reduce the matrix size or zero some existing elements. One could attempt to avoid diagonalization altogether, as is done in work represented by linear-scaling or order-N methods (see, e.g., Otsuka et al. 2008; Goedecker 1999). This approach, however, has other limitations. In particular, the approximations involved rely heavily on some decay properties of the density matrix in certain function bases. In particular, they can be difficult to implement in real-space discretizations or for systems where the decay properties are not optimal, e.g., in metals. Another option is to use better (faster) eigensolvers.

The approach discussed here avoids *standard* diagonalizations but otherwise makes no new approximations to the Hamiltonian. We take advantage of the fact that accurate eigenvectors are unnecessary at each SCF iteration, since Hamiltonians are only approximate in the intermediate SCF steps, and exploit the nonlinear nature of the problem. The main point of the new algorithm is that once we have a good starting point for the Hamiltonian, it suffices to *filter* each basis vector at each iteration. In the intermediate SCF steps, these vectors are no longer eigenvectors, but together they represent a good basis of the desired invariant subspace.

## 3      Real-Space Approach

A real-space solution of the Kohn-Sham equation is commonly approached using a uniform, Cartesian grid as shown in Fig. 2.

We solve the Kohn-Sham equation, Eq. 1, for the grid-sampled values of wave functions, potentials, and the electron density. The Kohn-Sham wave functions are vectors whose length is the number of grid points. Each of the operators in the Kohn-Sham equation (kinetic, pseudopotential, Hartree, and exchange-correlation) is represented by a square matrix.

We use high-order finite differencing to express the kinetic energy Laplacian term. The discretization of the Laplacian utilizes *several/*neighbors for calculating the derivative around each point of interest, instead of just the immediate neighbors, i.e.:

$$\nabla^2 \varphi(x, y, z)$$

$$= \frac{1}{h^2} \sum_{l,k,m=-M}^{M} [C_k \varphi(x+kh, y, z) + C_l \varphi(x, y+lh, z) + C_m \varphi(x, y, z+mh)]$$

(4)

where $M$ is half the number of neighbors used along each axis or half the *expansion order* and $h$ is the grid spacing. The coefficients $(C_k, C_l, C_m)$ depend only on the choice of the expansion order, $M$. They can be found from a high-order Taylor expansion, although other algorithms for their determination are also available (Fornberg and Sloan 1994). The kinetic energy matrix has only $3M$ elements in each row (in addition to the diagonal), resulting in a very sparse matrix.

**Fig. 2** The finite-difference real-space approach. For open boundary conditions (shown in the figure), wave functions are sampled on a uniform grid within a spherical domain and vanish outside its boundary. Black dots denote grid points, and the blue balls denote atoms (a dimer example is shown)
There are many algorithms for constructing reliable pseudopotentials (Phillips 1958; Phillips and Kleinman 1959; Chelikowsky and Cohen 1992). We employ norm-conserving pseudopotentials. Typically Troullier-Martins pseudopotentials (Troullier and Martins 1991) are used. These potentials have been optimized for convergence with a plane wave basis and can be easily implemented in real-space methods.

The price paid for the simplification afforded by pseudopotentials is that the ionic potential operator is no longer local. Different atomic orbitals experience different pseudopotentials, so that application of the pseudopotential requires nonlocal projectors (Chelikowsky and Cohen 1992):

$$V_{ps}(\mathbf{r}) = \sum_{a=1}^{N} \sum_{l} V_{a,ps}^{l}(|\mathbf{r} - \mathbf{R}_a|) \sum_{m=-l}^{l} |l, m \rangle\langle l, m| \tag{5}$$

where $V_{a,ps}^{l}$ is the pseudopotential of the $l$th angular momentum orbital of the $a$th atom, $\mathbf{R}_a$ is the coordinate of the $a$th atom, and $|l, m\rangle$ is the $lm$th spherical harmonic. An easy way of making the matrix corresponding to the pseudopotential operator sparse is to use the projection scheme suggested by Kleinman and Bylander (1982):

$$V_{ps(\mathbf{r})} = \sum_{a=1}^{N} \left[ V_{a,ps}^{loc}(\mathbf{r}) + \frac{|\Delta V_{a,ps}^{l}(\mathbf{r})\varphi_{lm}^{a}(\mathbf{r})\rangle\langle\Delta V_{a,ps}^{l}(\mathbf{r})\varphi_{lm}^{a}(\mathbf{r})|}{\langle\varphi_{lm}^{a}(\mathbf{r})|\Delta V_{a,ps}^{l}(\mathbf{r})|\varphi_{lm}^{a}(\mathbf{r})\rangle} \right], \tag{6}$$

where $V_{a,ps}^{loc}(\mathbf{r})$ is a pseudopotential corresponding to one specific angular momentum component (of atom a), arbitrarily chosen as the local one, and $\Delta V_{a,ps}^{l}(\mathbf{r}) \equiv V_{a,ps}^{l}(\mathbf{r}) - V_{a,ps}^{loc}(\mathbf{r})$. Finally, $\varphi_{lm}^{a}(\mathbf{r})$ is the atomic pseudo-wave function with $lm$ quantum angular momentum numbers.

This form of the pseudopotential has several advantages: $\Delta V_{a,ps}^{l}$ differs from zero only inside a relatively small region around each atom. (The size of the region corresponds to the pseudopotential cutoff radius). Only the normalization scalars $c_{lm}^{a} = \langle\varphi_{lm}^{a}(\mathbf{r})|\Delta V_{a,ps}^{l}(\mathbf{r})|\varphi_{lm}^{a}(\mathbf{r})\rangle$ and the highly sparse vectors $\mathbf{u}_{lm}^{a} = |\Delta V_{a,ps}^{l}(\mathbf{r})\varphi_{lm}^{a}(\mathbf{r})\rangle$ are stored explicitly instead of holding an entire matrix. The $c_{lm}^{a}$ and $\mathbf{u}_{lm}^{a}$ terms are computed only once in the entire self-consistent solution, because they only depend on the atom coordinates, $\mathbf{R}_a$, and angular momentum numbers, $\{l, m\}$, which do not change during the iterative computation.

The Hartree potential is found by solving the Poisson equation:

$$\nabla^2 V_H(\mathbf{r}) = -4\pi\rho(\mathbf{r}) \tag{7}$$

using the conjugate gradient method. The Hartree potential is local with the associated matrix diagonal. The exchange-correlation potential is defined as the functional derivative of the exchange-correlation energy with respect to the charge density. For a local exchange-correlation, the associated matrix is diagonal.

**Fig. 3** Schematic of the Hamiltonian matrix for $Si_{28}H_{36}$ showing the non-zero matrix elements for the kinetic and nonlocal pseudopotential contributions
The resulting Hamiltonian matrix, being a sum of all matrix operators, each of which is diagonal or highly sparse, is sparse itself. The only quantities computed and stored explicitly are the diagonal elements (diagonal component of kinetic energy, local pseudopotential, Hartree potential, and exchange-correlation potential), the high-order finite-difference expansion coefficients, and the relatively small nonlocal pseudopotential vectors $\mathbf{u}_{lm}$. This results in huge memory savings, which are crucial for the computation of large systems containing thousands of atoms or more.

The structure of the Hamiltonian matrix is illustrated in Fig. 3. Non-zero matrix elements for the kinetic energy operator and for the nonlocal pseudopotential elements are shown for a small nanocrystal ($Si_{28}H_{36}$). The matrix size is $195,112 \times 195,112$ and with $0.0118\%$ of the matrix not sparse. The matrix need not be explicitly stored, nor are there off-diagonal element updates.

## 4    Eigensolvers Using Subspace Filtering

Subspace filtering is an effective operation to extract a subset of eigenvalues. We illustrate some of the essential features of the filtering process. Consider a matrix problem: eigenvalues. Consider a matrix problem:

$$H\Psi = \Lambda\Psi \tag{8}$$

where $H$ is the real-space matrix as defined above. $\Psi$ is a wave function matrix for the eigenfunction solutions for an $N \times N$ matrix:

$$\Psi = \begin{pmatrix} \psi_{1,1} & \psi_{1,2} & \cdots & \psi_{1,N} \\ \psi_{2,1} & \psi_{2,2} & \cdots & \psi_{2,N} \\ \vdots & \vdots & \cdots & \vdots \\ \psi_{N,1} & \psi_{N,2} & \cdots & \psi_{N,N} \end{pmatrix} \tag{9}$$

The eigenvalue matrix is given by

$$
\Lambda = \begin{pmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & \lambda_N \end{pmatrix} \tag{10}
$$

where the Kohn-Sham eigenvalues are given by $\lambda_i$.

Using this notation, we consider the product $\Phi = \Psi \Psi^T$. The diagonal element of $\Phi$ will give the sum of the squares of the wave functions for each grid point. Now consider a different matrix $\Psi U$ where $U$ is an orthonormal matrix such that $UU^T = I$, where $I$ is the identity matrix. We can write $\Phi = \Psi(UU^T)\Psi^T = (\Psi U)(U^T \Psi^T)$, and using the matrix identity, $B^T A^T = (AB)^T$, we get $\Phi = (\Psi U)(\Psi U)^T$.

This matrix manipulation has a clear implication. We can use either $\Psi$ or $\Psi U$ to find $\Phi$. All we care about is the diagonal of $\Phi$. So, we do not need to know each eigenvector to get the charge density as rotation of the space will do.

We can be more explicit. Suppose we consider to define a few more matrices such as $P(H)$ where $P$ is a polynomial. As a simple example, suppose $P = H^2$. Applying $H^2$ to $\Psi$, we find $H^2 \Psi = H(H\Psi) = H\Lambda \Psi = \Lambda^2 \Psi$. In general we can write $P(H)\Psi = P(\Lambda)\Psi$.

Consider the following operations. Suppose we take an approximate eigenfunction, $\tilde{\psi}_j$, for the $j$ eigenvector and apply a polynomial $P(H)$ to $\tilde{\psi}_j$:

$$
P(H)\tilde{\psi}_j = P(H)\left( \sum_i \alpha_{ij} \psi_j \right) = \sum_i \alpha_{ij} P(\lambda_j)\psi_j \tag{11}
$$

where we have assumed that our approximate eigensolution can be expressed as

$$
\tilde{\psi}_j = \sum_i \alpha_{ij} \psi_j \tag{12}
$$

This follows from the completeness of the solution set. Suppose we take our filtered eigenfunction, $\psi_j^f$, as

$$
\psi_j^f = P(H)\tilde{\psi}_j = \sum_i \alpha_{ij} P(\lambda_j)\psi_j \tag{13}
$$

and chose an appropriate polynomial, e.g., suppose we chose $P(\lambda) \approx 0$ for all values of $\lambda$ above the fermi level. In this case, only components of the occupied wave function or eigenfunctions would contribute. This is what we want.

**Fig. 4** Schematic of a filtering polynomial showing regions of "wanted" and "unwanted" eigenvalues

A schematic of a filtering polynomial is shown in Fig. 4. Any polynomial with this shape will do. We want a large amplitude in the desired subspace and a small one otherwise.

## 5 Chebyshev Filters

Often Chebyshev polynomials are useful for our purposes as they have a number of desirable properties. Chebyshev polynomials of the first kind (Parlett 1998; Saad 1992) are defined, for $k = 0, 1, \cdots ,$ :

$$C_k(t) = \begin{cases} \cos\big(k \ \cos^{-1}(t)\big), & -1 \le t \le 1, \\ \cosh\big(k \ \cosh^{-1}(t)\big), & |t| > 1. \end{cases}$$

We can express the polynomials in s convenient recursion relation. We start with the first two polynomials: $C_0(t) = 1$, $C_1(t) = t$. The following recurrence is easy to derive from properties of the cosine function and can be written:

$$C_{k+1}(t) = 2t \ C_k(t) - C_{k-1}(t), \quad t \in \mathbb{R} \tag{14}$$

Within the interval $|t| \le 1$, the polynomials have nodes and possess a magnitude less than unity. In principle, we want the filtering process to magnify the desired components of the wave function. If the process is repeated indefinitely, the filtered wave function should have zero components in the "unwanted" part of the eigenvalue spectrum.

A filtering operation applied to a vector has the effect of enhancing desired eigen-components of the vector relative to undesirable components. If the process is repeated indefinitely, the resulting vector will have zero components in the unwanted part of the spectrum. Suppose our wanted eigenvalues correspond to the occupied states. Our goal is to filter out all components associated with the empty states or, equivalently, to enhance the components associated with occupied states, relative to other components.

We exploit well-known properties of Chebyshev polynomials to accomplish filtering. It is known that among all polynomials of degree $k$, which have value one at a certain point $|\gamma| > 1$, the polynomial $C_k(t)/C_k(\gamma)$ is the one whose maximum absolute value in the interval $[-1, 1]$ is minimal. Thus, $C_k(t)/C_k(\gamma)$ can be viewed

**Fig. 5** Degree six Chebyshev polynomial on the interval [0, 2]. The shaded area corresponds to eigen-components that will be amplified relative to the other eigen-components. The value of $l$ is determined by an affine mapping. See text

as an optimal polynomial if one wishes to dampen values of the polynomial in $[-1, 1]$ among all polynomials $p$ of degree $k$, scaled so that $p(\gamma) = 1$. A 6th degree Chebyshev polynomial so scaled is shown in Fig. 5.

Assume that the full spectrum of $H$ (denoted by $\Lambda(H)$) is contained in $[\gamma, b]$. Then in order to approximate the eigensubspace associated with the lower end of the spectrum, say $[\gamma, a]$ with $\gamma < a < b$, it is necessary to map $[a, b]$ into $[-1, 1]$ before applying the Chebyshev polynomial. This can be easily realized by an affine mapping.

Assume that the full spectrum of $H$ (denoted by $\Lambda(H)$) is contained in $[\gamma, b]$. In order to approximate the eigensubspace associated with the lower end of the spectrum, say $[\gamma, a]$ with $\gamma < a < b$, it is necessary to map $[a, b]$ into $[-1, 1]$ before applying the Chebyshev polynomial. This can be easily realized by an affine mapping defined as

$$l(t) := \frac{t - c}{e}; \quad c = \frac{a + b}{2}, \quad e = \frac{b - a}{2}$$

where $c$ denotes the center and $e$ the half-width of the interval $[a, b]$.

The Chebyshev iteration utilizing the recurrence in Eq. 14 to dampen values on the interval $[a, b]$ is given in Algorithm 2 (see Zhou et al. 2006b). We write the filtered vector as $Y$, with the unfiltered vector as $X$, and perform the operation:

$$Y = p_m(H)X \tag{15}$$

where $p_m(t) = C_m[l(t)]$ is the mapped Chebyshev polynomial.

The recursion operation is given by

$$X_{j+1} = \frac{2}{e}(H - cI)X_j - X_{j-1}, \quad j = 1, 2, \ldots, m - 1.$$

with $X_0$ given and $X_1 = (H - cI)X_0$.

---

**Algorithm 2** $[Y] = \texttt{Chebyshev\_filter}(X, m, a, b, \gamma)$

Filter column vectors of $X$ by an $m$ degree Chebyshev polynomial in $H$ that dampens on the interval $[a, b]$. Output the filtered vectors in $Y$.

1. $e = (b - a)/2; \quad c = (b + a)/2;$
2. $\sigma = e/(\gamma - c); \quad\quad \sigma_1 = \sigma; \quad\quad \gamma = 2/\sigma_1.$
3. $Y = \frac{\sigma_1}{e}(HX - cX);$
4. For $i = 2 : m$
5. $\quad \sigma_2 = 1/(\gamma - \sigma);$
6. $\quad Y_{\text{new}} = \frac{2\sigma_2}{e}(HY - cY) - \sigma\sigma_2 X;$
7. $\quad X = Y;$
8. $\quad Y = Y_{\text{new}};$
9. $\quad \sigma = \sigma_2;$
10. End For

---

The above iteration is without any scaling. In the case of the interval $[-1, 1]$, we scaled the polynomial by $C_k(\gamma)$ in order to ensure that the value of the polynomial at $\gamma$ equals one. For general intervals, this leads to the scaled sequence of polynomials (Saad 1992)

$$\tilde{X}_j = \frac{C_j[\frac{2}{e}(H - cI)]}{C_j[\frac{2}{e}(\gamma - cI)]} X_0.$$

The scaling factor is $\rho_j = C_j[\frac{2}{e}(\gamma - cI)]$.

This algorithm requires an estimate for $\gamma$ which, in our case, is the smallest eigenvalue of the Hamiltonian. However, since this is used for scaling, for the purpose of avoiding overflow, only a rough value is needed.

The eigen-components associated with eigenvalues in $[a, b]$ will be transformed to small values, while those to the left of $[a, b]$ will be around unity owing to the properties of the Chebyshev polynomials. This is the desired filtering property when computing an approximation to the eigensubspace associated with the lower end of $\Lambda(H)$. As seen in Algorithm 2, a desired filter can be easily controlled by adjusting two endpoints that bound the higher portion of $\Lambda(H)$.

The lower bound can be any value that is larger than the Fermi level but smaller than the upper bound. It can also be a value slightly smaller than the Fermi level; thanks to the monotonicity of the shifted and scaled Chebyshev polynomial on the spectrum of $H$ and the fact that we compute $s > n_{\text{occ}}$ number of Ritz values, the desired lowered end of the spectrum will still be magnified properly with this choice of lower bound.

Since the previous SCF iteration performs a Rayleigh-Ritz refinement step, this step provides a natural approximation for the lower bound $a$. Indeed, we can

---

**Algorithm 3** CheFSI for SCF calculation

1. Start from an initial guess of $\rho(r)$, get $V_{total}(\rho(r), r)$.
2. Solve $\left[-\frac{1}{2}\nabla^2 + V_{total}(\rho(r), r)\right]\Psi_i(r) = E_i\Psi_i(r)$ for $\Psi_i(r)$, $i = 1, 2, \ldots, s$.
3. Compute new charge density $\rho(r) = 2\sum_{i=1}^{n_{occ}}|\Psi_i(r)|^2$.
4. Solve for new Hartree potential $V_H$ from $\nabla^2 V_H(r) = -4\pi\rho(r)$.
5. Update $V_{xc}$; get new $\tilde{V}_{total}(\rho, r) = V_{ion}(r) + V_H(\rho, r) + V_{xc}(\rho, r)$ with a potential-mixing step.
6. If $\|\tilde{V}_{total} - V_{total}\| < tol$, stop; Else, $V_{total} \leftarrow \tilde{V}_{total}$ (update $H$ implicitly),
   call the Chebyshev-filtered subspace method (Algorithm 4) to get $s$ approximate wave functions; go to step 3.

---

**Algorithm 4** Chebyshev-filtered Subspace (CheFS) method

1. Get the lower bounds $b_{low}$ and $\gamma$ from previous Ritz values (use the largest one and the smallest one, respectively).
2. Compute the upper bound $b_{up}$ of the spectrum of the current discretized Hamiltonian $H$.
3. Perform Chebyshev filtering (call Algorithm 2 in Sect. 5) on the previous basis $\Psi$, where $\Psi$ contains the discretized wave functions of $\Psi_i(r)$, $i = 1, \ldots, s$:
   $\Psi = \texttt{Chebyshev\_filter}(\Psi, m, b_{low}, b_{up}, \gamma)$.
4. Ortho-normalize the basis $\Psi$ by iterated Gram-Schmidt.
5. Perform the Rayleigh-Ritz step:
   (a) Compute $\hat{H} = \Psi^T H \Psi$;
   (b) Compute the eigendecomposition of $\hat{H}$: $\hat{H}U = UD$,
       where $D$ contains non-increasingly ordered eigenvalues of $\hat{H}$ and $U$ contains the corresponding eigenvectors;
   (c) "Rotate" the basis as $\Psi := \Psi U$; return $\Phi$ and $U$.

---

simply take the largest Rayleigh quotient from the previous SCF iteration step as an approximation to the lower bound for the current Hamiltonian.

The upper bound for the spectrum (denoted by $b$) can be estimated by a $k$-step standard Lanczos method. The higher endpoint $b$ must be a bound for the full spectrum of $H$. This is because the Chebyshev polynomial also grows fast to the right of $[-1, 1]$ (Zhou and Saad 2007). So if $[a, b]$ with $b < \lambda_{max}(H)$ is mapped into $[-1, 1]$, then the $[b, \lambda_{max}(H)]$ portion of the spectrum will also be magnified, which will cause the procedure to fail. Therefore, it is imperative that the bound $b$ be larger than $\lambda_{max}(H)$.

## 6    Subspace Iteration Using Filtering

The main structure of Chebyshev filtering, which is given in Algorithm 3, is quite similar to that of the standard SCF iteration (Algorithm 1). One major difference is that the inner iteration for diagonalization at *Step 2* is now performed only at the first SCF step. Thereafter, diagonalization is replaced by a single Chebyshev subspace filtering step, performed by calling Algorithm 4. The filtering process is illustrated in Fig. 6.

Although the charge density (Eq. (3)) requires only the lowest $n_{occ}$ states, the number of computed states, which is the integer $s$ in Algorithm 3, is typically set to

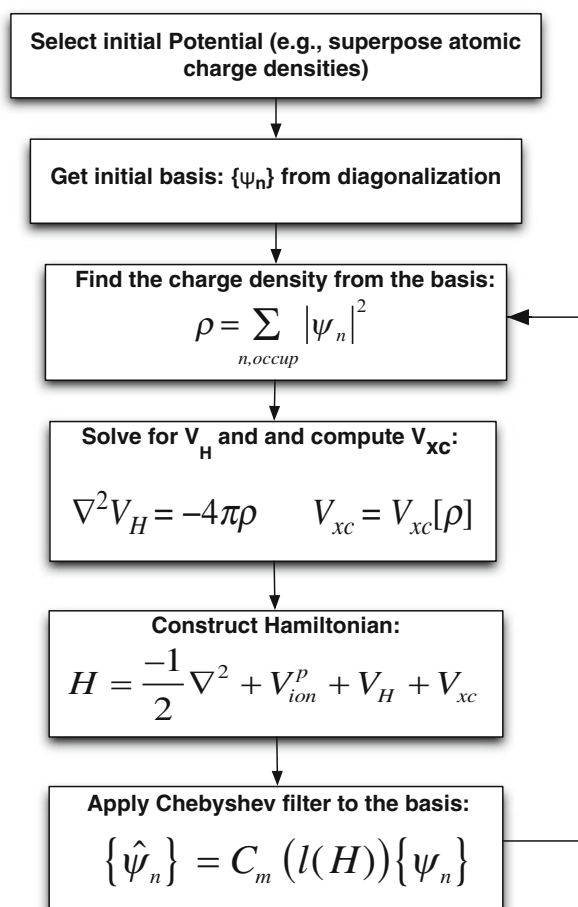

**Fig. 6** Flow diagram for obtaining a self-consistent solution of the Kohn-Shan equation using damped Chebyshev subspace filtering

a value larger than $n_{occ}$, in order to avoid missing any occupied states. In practice we fix an integer $n_{state}$ which is slightly larger than $n_{occ}$.

The parallel implementations of Algorithms 3 and 4 are quite straightforward. The matrix-vector products related to filtering, computing upper bounds, and Rayleigh-Ritz refinement can easily execute in parallel. The re-orthogonalization at *Step 4* of Algorithm 4 uses a parallel version of the iterated Gram-Schmidt DGKS method (Daniel et al. 1976), which scales better than the standard modified Gram-Schmidt algorithm.

If a standard iterative diagonalization method is used to solve the linearized eigenproblem (Eq. 2) at each SCF step, then it also requires (i) the orthonormalization of a (typically larger) basis, (ii) the eigendecomposition of the projected Rayleigh quotient matrix, and (iii) the basis refinement (rotation). These operations need to be performed several times within this single diagonalization. But Algorithm 4 performs each of these operations only once per SCF step. Therefore, although Algorithm 4 scales in a similar way to standard diagonalization-based methods, the scaling constant is much smaller. For large problems, CheFS can achieve a tenfold or more speedup per SCF step, over using the well-known efficient eigenvalue packages such as ARPACK (Lehoucq et al. 1998) and TRLan (Wu et al. 1999; Wu and Simon 2000).

In summary, a standard SCF method has an outer SCF loop – the usual nonlinear SCF loop – and an inner diagonalization loop, which iterates until eigenvectors are within specified accuracy. Algorithm 3 essentially bypasses the second loop, or rather it merges it into a single outer loop, which can be considered as a *nonlinear subspace iteration algorithm*. The inner diagonalization loop is replaced by a single Chebyshev subspace filtering step.

## 7    Applications and Performance

Our real-space package (PARSEC (http://parsec.ices.utexas.edu/)) has been applied to study a wide range of material systems, many of which would not be accessible without a filtering algorithm (Dalpian and Chelikowsky 2006; Tiago et al. 2006; Alemany et al. 2007; Chan et al. 2008, 2009; Chan and Chelikowsky 2010; Chan et al. 2014; Chelikowsky et al. 2011; Sakai et al. 2016).

We focus on large hydrogenated Si nanocrystals, up to systems with over 20,000 atoms. Such a Si nanocrystal is illustrated in Fig. 7. The surface is capped with hydrogen atoms to saturate the surface atoms and remove any dangling bond states from the gap.

Relatively few numerical results exist because of the difficulty of eigenvector-based methods applied to large systems without periodicity. In particular, Zhao et al. (2004) have examined clusters containing up to 1,100 silicon atoms, using the well-known VASP code (Kresse and Furthmülle 1996). They found applications to clusters with more than $\sim$1,200 silicon atoms were "too computationally intensive" with the computation platforms available to them. As a comparison, PARSEC using the Chebyshev filter algorithm (CheFSI), together with the currently developed

**Fig. 7** $Si_{10701}H_{1996}$ nanocrystal the surface is capped with hydrogen atoms shown as a black dots

$Si_{10701}H_{1996}$
**Table 1** $Si_{525}H_{276}$, using 16 processors. The Hamiltonian dimension is 292584, where 1194 states need to be computed at each SCF step. The first step diagonalization by Chebyshev-Davidson costs 79755 #MVp and 221.05 CPU seconds; so the total #MVp spent on CheFS in CheFSI is 110,000. The polynomial degree used is $m = 17$ for Chebyshev-Davidson and $m = 8$ for CheFS. The first step diagonalization by TRLan requires 14909 #MVp and 265.75 CPU seconds

| Method | #MVp | #SCF steps | total_eV/atom | CPU(s) |
|--------|------|------------|---------------|--------|
| CheFSI | 189755 | 11 | −77.316873 | 542.43 |
| TRLan | 149418 | 10 | −77.316873 | 2755.49 |
| Diagla | 493612 | 10 | −77.316873 | 8751.24 |

symmetric operations of real-space pseudopotential methods, can routinely solve silicon clusters with several thousands of atoms.

We used the total energy per atom to assess accuracy of the final results. The number of iteration steps needed to reach self-consistency is given by `#SCF` . The number of matrix-vector products is given by `#MVp`.

In Table 1, we present a relatively small silicon cluster $Si_{525}H_{276}$, which is used to compare the performance of CheFSI with two eigenvector-based methods. The hardware for the computations illustrated here is modest, if not dated: an SGI Altix cluster consisting of 256 Intel Itanium processors at CPU rates of 1.6 GHz, sharing 512 GB of memory (but a single job is allowed to request at most 250 GB memory). Diagla and TRLan are standard eigensolver methods, which are not based on subspace filtering (Stathopoulos et al. 2000; Wu et al. 1999). Computational details such as grid spacings, pseudopotentials, and density functionals can be found in the literature (Zhou et al. 2006a, b).

We considered $Si_{2713}H_{828}$, $Si_{4001}H_{1012}$, and $Si_{9041}H_{1860}$. Results for these nanocrystals are show in Table 2. For these systems, the eigensolver Diagla became too slow to be practical. In the case of $Si_{2713}H_{828}$, we could still apply TRLan for the first step diagonalization for comparison, but we did not iterate until self-consistency was reached without excessive computational resources. Note that with the problem size increasing, Chebyshev-Davidson compares more favorably over TRLan. This is because we employed an additional trick in Chebyshev-Davidson, which corresponds to allowing the last few eigenvectors not to converge to the required accuracy. The number of the nonfully converged eigenvectors is bounded above by $act_{max}$, which is the maximum dimension of the active subspace. Typically $30 \leq act_{max} \leq 300$ for Hamiltonian size over a million where several thousand eigenvectors are to be computed. The implementation of this trick is rather straightforward since it corresponds to applying the CheFS method to the subspace spanned by the last few vectors in the basis that have not converged to required accuracy.

In Fig. 8, we illustrate the density of states for a large nanocrystal: $Si_{20389}H_{3076}$. This system presents a number of challenges. While the nanocrystal possesses some symmetry, the system is not periodic. There are 42,316 occupied states in this system. This requires the diagonalization in the Rayleigh-Ritz step of a large dense matrix.

We can compare the density of states to bulk silicon with the resulting energy distributions of energy levels for the nanocrystal, also shown in Fig. 8. The spectral features of this large nanocrystal have evolved to match the bulk. For this system, we can compute the complete evolution of the electronic structure from small molecular fragments of hydrogenated silicon nanocrystals to the bulk.

Within density functional theory, we can also examine the evolution of adding or removing electrons from a nanocrystal. First, we compute the energy to remove an electron and create a hole. For a semiconductor, this means we remove an electron from the highest occupied state and move it to the vacuum level. This energy is the ionization potential, $I$. The energy to create an electron in the lowest unoccupied state is called the electron affinity, $A$. These energies are defined as follows:

$$I = E(N - 1) - E(N)$$
$$A = E(N) - E(N + 1)$$

(16)

**Table 2** Performance of the CheFSI methods for large hydrogenated silicon nanocrystals. All calculations were done on 16 processors

| System | Dim. of $H$ | $n_{state}$ | #MVp | #SCF | total_eV/atom | 1st CPU | total CPU |
|--------|-------------|-------------|------|------|---------------|---------|-----------|
| $Si_{4001}H_{1012}$ | 1472440 | 8511 | 1652243 | 12 | −89.12338 | 18.63 h | 38.17 h |
| $Si_{6047}H_{1308}$ | 2144432 | 12751 | 2682749 | 14 | −91.34809 | 45.11 h | 101.02 h |
| $Si_{9041}H_{1012}$ | 2992832 | 19015 | 4804488 | 18 | −92.00412 | 102.12 h | 294.36 h |

where $N$ is the total number of electrons in the system and $E$ is the total electronic energy. In principle, the affinity and ionization energies are ground-state properties, and if the correct functional were known, these quantities would be accurately predicted by density functional theory.

We examine the scaling of the ionization potential and the electron affinity by assuming a simple power law behavior and fitting such a form to the calculated values (shown in Fig. 9):

$$I(D) = I_\infty + A/D^\alpha$$
$$A(D) = A_\infty + B/D^\beta$$

(17)

where $D$ is the diameter of the nanocrystal. A fit of these quantities results in $I_\infty = 4.5\,eV$, $A_\infty = 3.9\,eV$, $\alpha = 1.1$, and $\beta = 1.08$. The fit gives a quasiparticle gap of $E_{qp}(D \rightarrow \infty) = I_\infty - A_\infty = 0.6\,eV$ in the limit of an infinitely large dot. This value is in good agreement with the gap found for crystalline silicon using the local density approximation (Sham and Schlüter 1983).

The gap is not in good agreement with experiment owing to the failure of the local density approximation to describe band gaps of bulk semiconductors in general. We learned something interesting here. Even though $I$ and $A$ were computed from

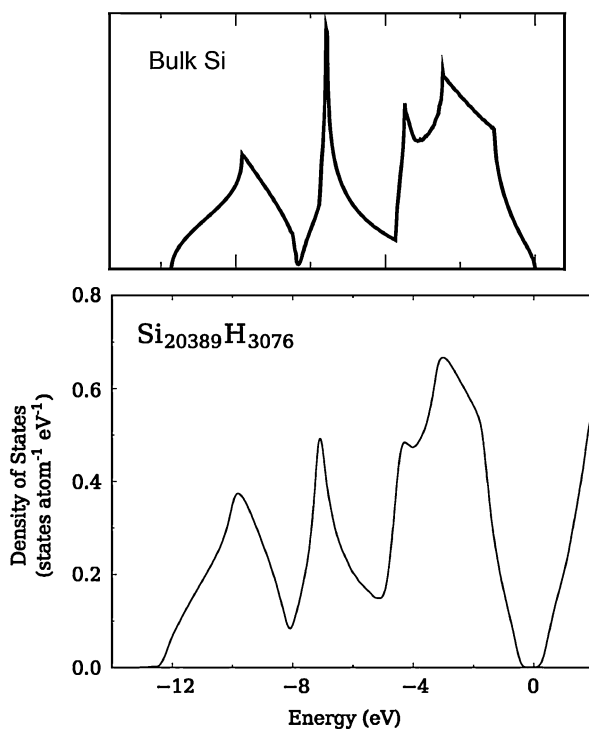
**Fig. 8** Density of states for silicon. Top figure is for bulk silicon. The bottom figure is for a nanocrystal, $Si_{20389}H_{3076}$


**Fig. 9** Evolution of the

the highest occupied
molecular orbital (HOMO)
and the lowest unoccupied
molecular orbital (LUMO)

ground-state properties for large system, they do not yield correct properties for
the ground state. This situation reflects some fundamental flaw in our choice of
functionals and is not surprising as no known functional is "perfect."

A key aspect of this example is to show the scaling of the ionization potential and
electron affinity for nanocrystals ranging from silane ($SiH_4$) to hydrogenated silicon
systems containing thousands of atoms. We not only verify the limiting value of the
quasiparticle gap, but also we can ascertain how this limit is reached, i.e., how the
ionization potential and electron affinity scale with the size of the dot, and what the
relationship is between these quantities and the highest occupied and lowest empty
energy levels. In our example, we effectively have gone from the molecular limit
to the crystalline limit. We have spanned the entire nanocrystal regime, at least for
silicon.

Since values of $I$ and $A$ as calculated from density functional theory are reason-
ably accurate for atoms and molecules, one can ask how the size of the nanocrystal
affects the accuracy of such calculations. Unfortunately, experimental values for the
ionization potentials and electron affinities are not known for hydrogenated silicon
clusters and nanocrystals, a notable exception being silane, where the electron
affinity is negative, which means an electron added to the nanocrystal is unbound.

## 8    Conclusions

A pathway to improving algorithms is to focus on existing "bottlenecks" and remove
them. The resolution of these bottlenecks improves the performance of the code in
a systematic fashion.

A current bottleneck is the Rayleigh-Ritz step in Algorithm 4. This step involves
solving an eigenvalue problem for a dense matrix whose size is equal to the

number of eigenvalues. Suppose we wish to solve for a Si nanocrystal with 100,000 atoms or so. In such a situation, the Rayleigh-Ritz step would involve roughly a $200,000 \times 200,000$ dense matrix. With the algorithms outlined in this chapter coupled to current hardware, this is an insurmountable bottleneck.

A possible solution to this problem is to consider a combination of filters such that the eigenvalue problem is decomposed into a number of such problems each corresponding to a solution within an "energy window." Each window can then be handled separately, introducing an extra level of parallelism.

Implementing such an algorithm is difficult. The windows must be chosen so that each interval has approximately the same number of eigenvalues. This insures some reasonable load balancing. Often the eigenvalue spectrum is known for a similar system of interest, e.g., amorphous silicon or liquid silicon possesses occupied states that have a similar distribution as crystalline silicon. In this case, an approximate windowing is straightforward to implement without knowing the detailed eigenvalue spectrum.

A more challenging problem centers on not missing or duplicating states near the edge of an energy window. To avoid missing states, the energy windows should overlap. However, this overlap can result in double-counting states. Duplicates can be removed by single-value decomposition methods. Ongoing work is focused on this approach (Schofield et al. 2012a). The initial results are promising and should lead to our ability to do systems with thousands or tens of thousands of atoms.

Our focus in this chapter is on scalability and the extension of current methods to very large systems. We have not focused on an important related issue. Namely, can we also improve the accuracy of the computations? Local density functionals as those implemented in the present work are limited to weakly correlated systems, e.g., electronic materials like silicon, carbon, or gallium arsenide. Strongly correlated systems such as rare earths or rare earth oxides require more accurate functionals. These functionals often include nonlocal terms, e.g., the inclusion of Fock exchange. Such functionals can be implemented in real-space methods using the general framework outlined here (Boffi et al. 2016). The implementation of nonlocal functional results in a more complicated Hamiltonian and memory management issues. Typically, the scaling of such methods is notably limited.

Our quest to solve for large-scale systems should be apparent. Many problems require us to consider systems with very large numbers of atoms. For example, suppose we wish to examine a molecular system in an aqueous solution, a nucleation seed in the melt, or a solid-liquid interface. In these case, we might want to include thousands of atoms in a dynamical simulation to address important questions: How do materials dissolve? What is the structural and dynamical nature at a liquid-solid interface? Why do some nucleation sites promote crystal growth in only certain crystallographic directions? These systems are frequently beyond our reach. Numerical methods for these systems offer us the ability to test new models, gain new insights, and picture the microscope world in new ways.

### Abstract

Nonlocal correlation methods based on wave function theory are developed for application to condensed matter systems. These methods include MP2 and direct-RPA theory as well as double-hybrid functionals. Analytic gradients and stress tensors for MP2 theory in the gamma point approximation have been developed.

Sampling complex systems at ambient temperature, for example, liquid water, becomes possible with efficient algorithms for massively parallel computers. Results show a qualitative improvement over standard local density functionals as well as hybrid functionals.

# 1    Introduction

Combining ensemble sampling techniques, like molecular dynamics or Monte Carlo methods, with first-principles electronic structure theory is commonly referred to as ab initio molecular dynamics (AIMD) (Marx and Hutter 2009). AIMD as a modern simulation technique was started by the seminal work of Roberto Car and Michele Parrinello (Car and Parrinello 1985). The Car-Parrinello (CP) method made AIMD simulations possible for a wide range of applications. In the early years, the CP method dominated the field and became a synonym for AIMD. The original CP method was proposed using Kohn-Sham density functional theory within the pseudopotential plane-wave framework. Standard simulation protocols for CP simulations were established and used by many groups. In recent years, new developments were able to overcome limitations of the CP method while keeping all of the benefits of the original method (Hutter 2012).

With the availability of more and more computer power, it became possible to also use Monte Carlo (MC) sampling techniques (McGrath et al. 2005a). In MC sampling the reuse of previous wave function information is much more difficult than in MD sampling. However, when atom-centered basis functions are used, this problem is considerably less severe than, for example, in plane-wave calculations. MC sampling has advantages over MD sampling in specific situations, like the simulation of the vapor-liquid coexistence curve (McGrath et al. 2005a, b), in situations where high barriers make sampling difficult (Schönherr et al. 2014) or if forces are not available (Del Ben et al. 2013b).

In the past, using other electronic structure methods than Kohn-Sham density functional theory was explored but never gained wide popularity. The lack of efficient implementations of correlated wave function methods for periodic systems and, especially, insufficient computational power to perform extensive sampling made such applications very demanding. A first step in the direction of the application of wave function correlation methods in AIMD was the successful incorporation of efficient exact exchange functionals in condensed matter simulations (Todorova et al. 2006; Guidon et al. 2008). Only in recent years, it has been possible to combine extensive sampling approaches with wave function correlation methods (Del Ben et al. 2013b, 2015b). In this article we will summarize developments of electronic structure methods that made the application of wave function correlation methods in AIMD possible. We will also investigate the results from pioneering applications.

## 2 MP2 and RPA Correlation Energy Methods

The generalized gradient model (GGA) within Kohn-Sham DFT had tremendous success in numerous applications. Yet, the model has significant shortcomings that also influence, e.g., the quality of simulations for aqueous chemistry. Most notable are the absence of van der Waals interactions and a significant self-interaction error. The former leads, e.g., to an underestimation of the water density (Schmidt et al. 2009; Wang et al. 2011), while the latter leads to an underestimated bandgap, with implications for redox chemistry (Adriaanse et al. 2012) and the static dielectric constant (Schönherr et al. 2014). It is possible to go beyond GGA in various ways, and improvements have been made by including various descriptors of the electronic system to yield models with improved accuracy. In an attempt to classify this progress, Perdew et al. (2005) employed the metaphor of a "Jacob's ladder" for which each rung of the ladder introduces more descriptors of the electronic system and yields models with improved accuracy. This ladder has currently five rungs which include as descriptors (1) the electronic density; (2) its gradient; (3) the kinetic energy density; (4) the occupied molecular orbitals (MO), usually in the form of Hartree-Fock exchange; and (5) the unoccupied or virtual MOs. GGA belongs to the second rung, while hybrid functionals belong to the fourth rung. At the fifth rung, the inclusion of the virtual orbitals allows for taking into account nonlocal, dynamical, electron correlation effects that contribute to the long-range van der Waals (vdW) dispersion interactions. Many of the various functionals on the fifth rung are based on either the random phase approximation (RPA) (Eshuis et al. 2012; Paier et al. 2012; Grimme and Steinmetz 2016) or second-order Møller-Plesset perturbation theory (MP2) (Grimme 2006; Goerigk and Grimme 2011), in the form of double hybrids (DH). Direct use of RPA and MP2 energies and variations thereof is also of interest for many applications. As a basic building block, the calculation of the RPA and MP2 energies has to be provided. We will in the subsequent sections concentrate on the theory and implementation of these methods.

### 2.1 Theory

We present briefly the theoretical framework of the methods and refer to the original works for more details. First, the resolution of the identity approximation for two-electron repulsion integrals (ERIs) is introduced, and then its application to the different correlation methods is formulated. The following index notation has been adopted: $i, j, k, \ldots$ refer to canonical occupied molecular orbitals (MOs); $a, b, c, \ldots$ to canonical virtual MOs; $\mu, v, \lambda, \ldots$ to atomic orbital basis set functions (AO); and $P, Q, R, \ldots$ to auxiliary basis set functions (AUX). The one-electron MO and AO functions are symbolized with $\psi$ and $\phi$, respectively. The number of occupied and virtual orbitals is denoted by $o$ and $v$ while the total number of primary and auxiliary basis functions as $n$ and $N_a$. In order to express, in general, the system size, the symbol $N$ is used.

### 2.1.1 Periodic Boundary Conditions

In order to minimize boundary effects, simulations of condensed matter systems are performed using periodic boundary conditions. In periodic systems the infinite number of particles to be treated is reduced to the unique particles in the simulation cell, and the calculation of the electronic energy involves an integration over the first Brillouin zone. For disordered systems, as, for example, liquids, this integration can be replaced by a single point in the center of the integration volume, the $\Gamma$-point. In the following chapters, we will always assume that this $\Gamma$-point approximation is invoked, and we can further assume that the single-particle wave functions at this point are real.

### 2.1.2 The Resolution of the Identity (RI) Approximation

The two-electron repulsion integrals (ERI), in Mulliken notation, of the type $(ia|jb)$ are of central importance for all the methods presented. Within the RI approximation (Whitten 1973; Dunlap et al. 1979), based on the Coulomb metric (Vahtras et al. 1993), these integrals are factorized according to:

$$(ia|jb)_{RI} = \sum_{PQ} (ia|P)(P|Q)^{-1}(Q|jb) \tag{1}$$

where $(P|Q)^{-1}$ is the inverse matrix of the Coulomb metric,

$$(P|Q) = \iint \phi_P(\mathbf{r}_1) \frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} \phi_Q(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2. \tag{2}$$

The auxiliary basis set size $N_a$ grows only linearly with the system size (Feyereisen et al. 1993). The main advantage of the RI approximation is that four-center integrals of the type $(ia|jb)$ are computed from three- and two-center ERIs. This allows to strongly reduce the effort for the integral computation without significant loss of accuracy (Weigend and Häser 1997). Since the $(P|Q)$ matrix is positive definite, its inverse can be efficiently obtained from a Cholesky decomposition

$$(P|Q) = \sum_R L_{PR} L_{RQ}^T \tag{3}$$

followed by inversion of the triangular matrix $\mathbf{L}$. In this way the factorization of the $(ia|jb)$ integrals can be expressed in a compact form as:

$$(ia|jb)_{RI} = \sum_P B_P^{ia} B_P^{jb}. \tag{4}$$

$\mathbf{B}$ is a matrix with $ov$ rows and $N_a$ columns, given by:

$$B_P^{ia} = \sum_R (ia|R) L_{PR}^{-1}. \tag{5}$$

Since the three-center integrals $(ia|R)$ are computed starting from integrals over AOs $(\mu\nu|R)$, the final expression for the $B_P^{ia}$ elements reads:

$$(ia|P) = \sum_v C_{va} \sum_\mu C_{\mu i} \sum_R (\mu\nu|R) L_{PR}^{-1} \tag{6}$$

where $\mathbf{C}$ is the MO coefficient matrix.

Computation of the $\mathbf{B}$ matrix thus includes, first, calculation of $(P|Q)$ and via Cholesky decomposition and triangular inversion, $\mathbf{L}^{-1}$. Second, three-center integrals $(\mu\nu|R)$ are computed and transformed using the $\mathbf{C}$ and $\mathbf{L}^{-1}$ matrices (Eq. 6). The first two steps formally scale $O(N^2)$ and $O(N^3)$, respectively, while three-center integral computation requires formally $O(N^3)$ operations and integral transformations scale $O(N^4)$. Within the RI approximation, the asymptotically dominating step in computing $\mathbf{B}$ is thus the index transformation.

### 2.1.3 RI-MP2 Method

In second-order Møller-Plesset perturbation theory (Møller and Plesset 1934), the correlation energy $E^{(2)}$ for a closed-shell system is given by:

$$E^{(2)} = -\sum_{i \leq j}^o (2 - \delta_{ij}) \sum_{ab}^v \frac{(ia|jb)[2(ia|jb) - (ib|ja)]}{\varepsilon_a + \varepsilon_b - \varepsilon_i - \varepsilon_j}. \tag{7}$$

where $\varepsilon_a$ and $\varepsilon_i$ are orbital energies. In a canonical MP2 energy algorithm, the time-limiting step is the computation of the $(ia|jb)$ integrals obtained from the ERIs over AO $(\mu\nu|\lambda\sigma)$ via four consecutive integral transformations. The computational effort for the first quarter transformation (no sparsity considered) is $O(on^4)$, making the MP2 energy calculation a method scaling as $O(N^5)$. The application of the RI approximation to MP2 is straightforward (Feyereisen et al. 1993) and consists in replacing $(ia|jb)$ integrals with the approximate $(ia|jb)_{RI}$ given in Eq. 4. The computation of $(ia|jb)_{RI}$ requires $O(o^2v^2N_a)$ operations implying that the RI-MP2 method is also scaling $O(N^5)$. The main reason for the speedup observed in RI-MP2 lies in the strongly reduced integral computation part.

### 2.1.4 RI Direct Random Phase Approximation Correlation Energy Method

The RPA correlation energy is given as the difference between the zero-point energy of two harmonic oscillator excitation problems for which the first includes a correlated ground state (RPA) and the second does not (configuration interaction singles) (Furche 2008; Scuseria et al. 2008). Within the direct-RPA (dRPA) approach, which is RPA without exchange contributions (Eshuis et al. 2010), $E_c^{\text{dRPA}}$ can be expressed in terms of a frequency integral

$$E_c^{\text{dRPA}} = \frac{1}{2} \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} \text{Tr}(\ln(\mathbf{1} + \mathbf{Q}(\omega)) - \mathbf{Q}(\omega)), \tag{8}$$

with the frequency-dependent matrix $\mathbf{Q}(\omega)$ in the RI basis which is determined by

$$Q_{PQ}(\omega) = 2 \sum_i^o \sum_a^v B_P^{ia} \frac{\varepsilon_a - \varepsilon_i}{\omega^2 + (\varepsilon_a - \varepsilon_i)^2} B_Q^{ia}. \tag{9}$$

For a given $\omega$, the computation of the integrand function in Eq. 8 using Eq. 9 requires $O(N^4)$ operations. The integral of Eq. 8 can be efficiently calculated by Clenshaw-Curtis numerical quadrature, and usually $30-40$ quadrature points are enough to achieve micro-Hartree accuracy. Thus, the introduction of the resolution of the identity approximation and the frequency integration techniques for computing $E_c^{\mathrm{dRPA}}$ lead to a reduction of the computational cost to $O(N^4 N_q)$ and $O(N^3)$ storage, where $N_q$ is the number of quadrature points.

## 2.2    Nuclear Gradients and Stress Tensor

Calculation of analytic derivatives is of central importance for applications in electronic structure theory. The specific derivatives needed for nuclear gradients and stress tensor have received most attention as they are connected to basic structural properties of molecules and materials. In almost all applications, the availability of analytic derivatives is of advantage for reasons of accuracy and efficiency. The quantum chemistry community has a long tradition in developing algorithms for analytic derivatives, especially also for non-variational methods as the ones considered here (Handy and Schaefer 1984). These techniques have been used to derive derivatives for double-hybrid functionals (Neese et al. 2007) and RPA methods (Burow et al. 2014). For periodic systems, derivatives for MP2 in the restricted (Del Ben et al. 2015a) and unrestricted (Rybkin and VandeVondele 2016), as well as RPA (Ramberger et al. 2017) methods, have been reported.

### 2.2.1    Analytic Derivatives for RI-MP2

The analytic derivative of the RI-MP2 energy $E_{\mathrm{RI}}^{(2)}$ with respect to a perturbation parameter $x$, for a closed-shell restricted Hartree-Fock wave function, is given by Weigend and Häser (1997):

$$E_{\mathrm{RI}}^{(2)x} = \frac{dE_{\mathrm{RI}}^{(2)}}{dx} = 4 \sum_Q^{\mathrm{AUX}} \sum_{\mu\nu}^{\mathrm{AO}} \Gamma_{\mu\nu}^Q (\mu\nu|Q)^x - 2 \sum_{PQ}^{\mathrm{AUX}} \Gamma^{PQ} (P|Q)^x$$

$$+ 2 \sum_{pq}^{\mathrm{MO}} \left[ P_{pq}^{(2)} F_{pq}^{(x)} - W_{pq}^{(2)} S_{pq}^{(x)} \right]. \tag{10}$$

In the above expression, for each summation, a common structure can be recognized, that is, the contraction of terms involving AO derivatives $(\mu\nu|Q)^x$, $(P|Q)^x$, $F_{pq}^{(x)}$, $S_{pq}^{(x)}$, with elements of the intermediates $\Gamma_{\mu\nu}^Q$, $\Gamma^{PQ}$, $P_{pq}^{(2)}$, $W_{pq}^{(2)}$. The

first two summations involve the contraction of three- and two-center RI integral derivatives $(\mu\nu|Q)^x$, $(P|Q)^x$ with corrections to the two-particle density matrix (2-PDM), $\Gamma^Q_{\mu\nu}$ and $\Gamma^{PQ}$. These quantities are available from the energy calculation (Del Ben et al. 2015a). The last summation in Eq. 10 consists in the contraction of $P^{(2)}_{pq}$, the MP2 correction to the 1-PDM, and $W^{(2)}_{pq}$, the MP2 correction to the energy-weighted density matrix, with the skeleton derivatives of the Fock and overlap matrix elements

$$F^{(x)}_{pq} = \sum_{\mu\nu}^{\text{AO}} C_{\mu p} \left[ h^x_{\mu\nu} + \sum_{\lambda\sigma} P^{\text{HF}}_{\lambda\sigma}(\mu\nu|\lambda\sigma)^x - \frac{1}{2}\sum_{\lambda\sigma} P^{\text{HF}}_{\lambda\sigma}(\mu\lambda|\nu\sigma)^x \right] C_{vq} \qquad (11)$$

$$S^{(x)}_{pq} = \sum_{\mu\nu}^{\text{AO}} C_{\mu p} S^x_{\mu\nu} C_{vq}. \qquad (12)$$

In Eq. 11, $h^x_{\mu\nu}$ and $(\mu\nu|\lambda\sigma)^x$ are the derivatives of the one-electron Hamiltonian integrals and the ERIs, while $P^{\text{HF}}_{\mu\nu} = 2\sum_i^o C_{\mu i} C_{vi}$ is the Hartree-Fock density matrix. In order to take advantage from sparsity, the update of the $E^{(2)}_{\text{RI}}$ derivative is performed in the AO basis, after back transformation of $P^{(2)}_{pq}$ and $W^{(2)}_{pq}$ from the MO basis.

The diagonal blocks of the 1-PDM $P^{(2)}_{pq}$ can be calculated again using quantities from the energy calculation. The virtual occupied block of $P^{(2)}$ contains information related to the orbital relaxation caused by the perturbation $x$, i.e., first-order response of the MO coefficients. It is computed as the solution of the Z-vector equations (Handy and Schaefer 1984)

$$\sum_a^v \sum_i^o \left[ \delta_{ij}\delta_{ab}(\varepsilon_a - \varepsilon_i) + A_{aibj} \right] P^{(2)}_{ai} = -L_{bj} \qquad (13)$$

where $A_{aibj}$ is an element of the orbital Hessian matrix

$$A_{aibj} = 4(ai|bj) - (ab|ij) - (aj|bi), \qquad (14)$$

and $L$ is a specific RI-MP2 Lagrangian matrix given by:

$$L_{bj} = 2\sum_a^v \sum_Q^{\text{AUX}} (ba|Q)\Gamma^Q_{ja} - 2\sum_i^o \sum_Q^{\text{AUX}} (ij|Q)\Gamma^Q_{ib}$$

$$+ \sum_{ac}^v P^{(2)}_{ac} A_{acbj} + \sum_{ik}^o P^{(2)}_{ik} A_{ikbj}. \qquad (15)$$

Due to the large size of the orbital Hessian matrix $\mathbf{A}$ ($ov \times ov$), the linear system of Eq. 13 is commonly solved by iterative techniques. Rather than calculating and storing the full $\mathbf{A}$, at each iteration, the matrix-vector product $\sum_{ia} X_{ai} A_{aibj}$ is computed, with $\mathbf{X}$ being a trial solution. Finally, the MP2 correction to the energy-weighted density matrix $W_{pq}^{(2)}$ can be calculated from the relaxed 1-PDM $P_{pq}^{(2)}$. The methodology presented is of general validity for any perturbation parameter $x$. In particular, for the calculation of the forces acting on the ions, the gradients of $E_{\mathrm{RI}}^{(2)}$ with respect to the atomic positions have to be computed.

The RI-MP2 contribution to the total stress tensor is calculated according to Nielsen and Martin (1985) and Del Ben et al. (2015a):

$$\Pi_{\alpha\beta}^{(2)} = -\frac{1}{3V} \sum_{\gamma=1}^{3} \frac{\partial E_{\mathrm{RI}}^{(2)}}{\partial h_{\alpha\gamma}} h_{\gamma\beta}^{T} \tag{16}$$

where $h_{\alpha\gamma}$ are elements of the matrix of the cell vectors (Bravais lattice vectors) given by $a_1$, $a_2$, and $a_3$, that is, $\mathbf{h} = [a_1, a_2, a_3]$.

## 2.3 Implementation and Performance

### 2.3.1 RI Gaussian and Plane-Wave Method

The Gaussian and plane-wave (GPW) method has been shown to be an efficient approach for computing ERIs especially when periodic boundary conditions are considered (Del Ben et al. 2012). The basis of the GPW approach for the computation of the ERIs is the direct formulation of the half-transformed integrals of the type $(ia|\lambda\sigma)$ in terms of the electrostatic potential $v^{ia}$ of the pair density $\rho^{ia}$

$$
\begin{aligned}
(ia|\lambda\sigma) &= \iint \psi_i(\mathbf{r}_1)\psi_a(\mathbf{r}_1)\frac{1}{\mathbf{r}_{12}}\phi_\lambda(\mathbf{r}_2)\phi_\sigma(\mathbf{r}_2)d\mathbf{r}_1 d\mathbf{r}_2 \\
&= \int \left[ \int \frac{\rho^{ia}(\mathbf{r}_1)}{\mathbf{r}_{12}}d\mathbf{r}_1 \right] \phi_\lambda(\mathbf{r}_2)\phi_\sigma(\mathbf{r}_2)d\mathbf{r}_2 \\
&= \int v^{ia}(\mathbf{r}_2)\phi_\lambda(\mathbf{r}_2)\phi_\sigma(\mathbf{r}_2)d\mathbf{r}_2.
\end{aligned}
\tag{17}
$$

The form of the last equation is essentially identical to the one used in the GPW method (Lippert et al. 1997) to compute matrix elements of the Hartree potential. Thus, the highly efficient implementation of that operation in the CP2K code can be directly used, and we refer to VandeVondele et al. (2005a) for a detailed discussion.

Within the RI approximation, two types of ERIs have to be computed, the two-center $(P|Q)$ and three-center $(ia|P)$ integrals. Three-center integrals are computed starting from the integrals over AOs that are subsequently transformed with $\mathbf{C}$ and $\mathbf{L}^{-1}$. The index transformation over the auxiliary basis can be avoided,

since it is possible to directly compute half-transformed integrals for an associated density $\rho$ as

$$
\begin{aligned}
(\mu v|P) &= \sum_R (\mu v|R)L_{PR}^{-1} = \iint \phi_\mu(\mathbf{r}_1)\phi_v(\mathbf{r}_1)\frac{1}{\mathbf{r}_{12}}\left[\sum_R \phi_R(\mathbf{r}_2)L_{PR}^{-1}\right]d\mathbf{r}_1 d\mathbf{r}_2 \\
&= \int \phi_\mu(\mathbf{r}_1)\phi_v(\mathbf{r}_1)\left[\int \frac{\rho^P(\mathbf{r}_2)}{\mathbf{r}_{12}}d\mathbf{r}_2\right]d\mathbf{r}_1 = \int \phi_\mu(\mathbf{r}_1)\phi_v(\mathbf{r}_1)v^P(\mathbf{r}_1)d\mathbf{r}_1.
\end{aligned}
\tag{18}
$$

The same approach holds for the $(P|Q)$ integrals. An alternative way to calculate these integrals over Gaussian basis functions using analytic Ewald techniques is also available (Wilhelm et al. 2016).

Of central importance in GPW is the representation of the density on a regular grid, which is equivalent to an expansion of the density in an auxiliary basis of plane waves (PW). The expansion is given by

$$
\rho^P(\mathbf{r}) \approx \frac{1}{\Omega}\sum_{|\mathbf{G}|\leq G_c}\rho^P(\mathbf{G})e^{i\mathbf{G}\cdot\mathbf{r}}
\tag{19}
$$

where the sum over the reciprocal lattice vectors $\mathbf{G}$ is determined by the resolution of the grid. $\rho^P(\mathbf{G})$ are the Fourier coefficients of the density, and $\Omega$ is the volume of the simulation cell. Fast Fourier transforms (FFTs) efficiently change between real-space and reciprocal-space representations. In reciprocal space, it becomes straightforward to solve the Poisson equation for the potential $v^P$

$$
v^P(\mathbf{G}) = \frac{4\pi}{G^2}\rho^P(\mathbf{G})
\tag{20}
$$

and an additional back FFT will yield the potential in real space. For $\mathbf{G} = 0$ the value of the potential is set to zero, corresponding to a constant shift of the potential, enforcing zero average. Due to the orthogonality of the occupied-virtual orbitals, this shift has no influence on the final value of the $(ia|P)$ integrals. Within the GPW method, pseudopotentials have to be employed in order to have sufficiently smooth densities. Once the potential $v^P$ is available, the numerical integration over the basis functions is performed by summing over the grid points. For a given $|P)$, all matrix elements that are non-zero within a given threshold can be obtained in linear scaling time. A further gain in efficiency is obtained by employing a multigrid technique that represents the potential $v^P$ on grids with increasingly coarser grid spacing. Finally, $(\mu v|P)$ integrals are transformed into MO ERIs using (sparse) matrix multiplication as implemented in the DBCSR library (Borštnik et al. 2014).

The accuracy of the RI approximation is directly related to the completeness of the auxiliary basis set. It has been shown that it is possible to generate compact auxiliary basis sets with a size of approximately three times the size of the orbital

**Table 1** Counterpoise-corrected PWPB95-D3 interaction energies (kcal/mol) of the S22 set obtained employing the cc-TZ, cc-QZ, and aug-cc-TZ basis sets (Del Ben et al. 2013a). Mean absolute deviation (MAD), root mean square deviation (RMSD), maximum deviation (Max), and mean absolute percentage deviation (MA%D) of each basis set with respect to the reference values (Goerigk and Grimme 2011) are reported

|        | cc-TZ | cc-QZ | aug-cc-TZ |
|--------|-------|-------|-----------|
| MAD    | 0.43  | 0.27  | 0.15      |
| RMSD   | 0.52  | 0.31  | 0.21      |
| Max    | 1.24  | 0.71  | 0.59      |
| MA%D   | 7.45  | 5.42  | 3.48      |

basis set with a transferable overall accuracy of $\approx 1$mHartree/atom (Weigend et al. 1998). Specific RI basis sets for the application in condensed systems have been generated and tested (Del Ben et al. 2013a).

The setup used in the applications presented later has been tested with respect to the basis set error for correlated calculations. The slow convergence of correlated methods with basis set size is a well-studied problem in quantum chemistry. In Table 1 results for three basis sets are presented for calculations of the S22 reference sets using a double-hybrid functional. An improvement of results with the increase of the basis set can be observed. However, it should be noted that the reference used is itself not fully converged and that there are other parameters, e.g., the pseudopotential used, that result in differences. It can be seen that the results obtained with the cc-TZ basis, that is used in the liquid water simulations, is of good quality but cannot be considered fully converged.

### 2.3.2 Parallel Implementation of the RI-GPW Methods

In this section the parallelization strategies for the methods introduced are presented. The algorithms are split in two steps: the first deals with the computation of the ERIs $(ia|P)$ and is common for all methods, and the second is specific to the type of correlation energy calculated. The parallelization is achieved with a multi-level hybrid OpenMP/MPI scheme using a careful process layout. The first level of parallelization corresponds to distributing the work performed for a single given auxiliary basis function $\phi_P$ or vector $|P) = \sum_R \phi_R L_{PR}^{-1}$. The second level of parallelization corresponds to a distribution of these nearly independent calculations. The $N_p$ processes available in total are split in $N_G$ groups, each group working on a given $\phi_P$ or $|P)$ and each consisting of $N_w$ processes ($N_p = N_G N_w$). The first level of parallelization involves parallel FFTs, halo-exchanges, and sparse matrix multiplications over $N_w$ processes and corresponds to the standard parallelization scheme for DFT calculations in CP2K (VandeVondele et al. 2005a). The second level is straightforward and only requires intergroup redistribution of two-center ERIs $(Q|P)$ in order to calculate $\mathbf{L}^{-1}$.

The total workload for the integral computation is distributed by splitting the auxiliary basis functions into $N_G$ ranges. Additionally, each of the $N_w$ processes within a group is assigned a range of virtual orbital indices, while the occupied

orbital index is fully replicated. Once the integrals $(ia|P)$ are available, we can proceed to calculate the RI-MP2 energy. Since $N_w$ is usually small compared to the total number of processes, the virtual index $a$ is distributed over a small number of MPI tasks within the group $G$, while the auxiliary index $P$ is distributed over a large number of $N_G$ groups. First, the independent $ij$ pairs ($i \leq j$) are distributed over the $N_G$ groups. For each $ij$ pair, the full range of the auxiliary index $P$ is collected on a local buffer from all other groups while keeping the virtual index distribution within the group. The $(ia|jb)$ integrals are generated for the actual $ij$ pair in a matrix-multiplication fashion (Eq. 4) requiring only a small amount of communication within the group. Once the $(ia|jb)$ are available, they are accumulated into the MP2 energy according to Eq. 7, requiring an additional negligible amount of communication within the group. With this choice, the main source of intergroup communication in the parallel algorithm is related to the redistribution of the $B_{ia}^P$ integrals, required for each $ij$ pair. The time-determining step is the $(ia|jb)$ integral generation that is essentially a local matrix multiplication. This allows to fully exploit the performance of highly optimized routines and can be further accelerated by employing a hybrid implementation that utilizes graphics processing units (GPUs).

The dRPA correlation energy implementation is based on the method developed by Del Ben et al. (2013a). The parallel algorithm has a two-level workload distribution. The first level corresponds to the distribution of the work necessary for a given quadrature point of the integral in Eq. 8. The second level distributes the calculation of the independent quadrature points over subgroups of processes. The **B** matrix has to be replicated within the groups in order for the algorithm to proceed independently for each integration point. As a first task, the matrix **B**′ is calculated as $\mathbf{G}(\omega)\mathbf{B}$. Since $\mathbf{G}(\omega)$ is a $ov \times ov$ diagonal matrix with elements $G_{ia,ia}(\omega) = (\varepsilon_a - \varepsilon_i)((\varepsilon_a - \varepsilon_i)^2 + \omega^2)^{-1}$, the calculation of **B**′ proceeds without communication. The time-determining step of the algorithm is the calculation of the matrix $\mathbf{Q}(\omega)$ computed as $2\mathbf{B}^\mathbf{T}\mathbf{B}'(\omega)$. This task is performed as a standard parallel matrix multiplication. The calculation of $\mathrm{Tr}[\ln(\mathbf{Q}(\omega) + \mathbf{1})]$ can be efficiently carried out by considering the identity $\mathrm{Tr}[\ln \mathbf{A}] = \ln(\mathrm{Det}[\mathbf{A}])$, that is:

$$\mathrm{Tr}[\ln(\mathbf{Q}(\boldsymbol{\omega}) + \mathbf{1})] = 2\sum_{i=1}^{N_a} \ln(U_{ii}) \qquad (21)$$

where the **U** matrix is the Cholesky decomposition of $\mathbf{Q}(\omega) + \mathbf{1}$.

The excellent performance of the presented implementation can be seen from the results in Fig. 1. Panel (a) shows the achieved scaling for a 64-water-molecule system using a range of 512 to 32,768 processes. Both methods, MP2 and dRPA, show similar overall scalability with $\approx$80% efficiency over the full range tested. In panel (b) timings for the RI integral generation as well as the energy calculation for different methods are shown. In a doubly logarithmic plot, the system size (generated as increasing water systems) is given versus the total CPU time. All measured timings show a linear dependency, resulting in an estimate for the true
**Fig. 1** (**a**) Measured speedup with respect to 512 processes for the calculation of the MP2 and dRPA energy of 64 bulk water molecules. dRPA calculation performed employing 60 quadrature points for the numerical integration. (**b**) CPU time as a function of the number of replicas of the supercell containing 32 $H_2O$ molecules. Twenty quadrature points were used for dRPA. Lines represent a linear two-parameter fit of the form $y = bx^a$

scaling of the method from the observed slope of the linear fit. The observed scaling laws closely reproduce the theoretical scaling from the analysis of the implemented algorithms.

## 3　　Application: Properties of Water

Despite the apparent simplicity of the $H_2O$ molecule, bulk liquid water has a rich chemistry and physics. This is commonly illustrated referring to its many anomalous properties. These macroscopic properties are well characterized experimentally, but resolving the underlying atomistic picture is far more difficult (Errington and Debenedetti 2001), and even the structure of the neat liquid is still debated intensely (Nilsson and Pettersson 2011; Soper 2013). Ultimately, our understanding must go beyond the neat liquid. The properties of water, as a solvent or reactant, in the bulk, near interfaces or in confinement are of central importance in many fields, such as biology, electrochemistry, catalysis, earth, and climate science.

　　Theory and simulations can complement the experimental efforts and have a long tradition. For example, liquid water was among the first systems studied when molecular dynamics (MD) based on empirical potentials became available in the 1970s (Rahman and Stillinger 1971). Recent models are mostly derived based on high-level electronic structure calculations and show excellent agreement with the experiment for a variety of properties at low computational cost. However, empirical methods might fail when applied outside their fitting range, and the effort to parameterize the models and refine the employed functional forms cannot be underestimated. This challenge rises considerably as soon as solutes come into

play or if more complicated chemical phenomena, such as autodissociation and reactivity, must be taken into account. Computing the intermolecular interactions during the entire simulation using electronic structure theory is an alternative to empirical models as complexity increases, since no assumptions on the form of the interactions must be made. The pioneering application of electronic structure theory to bulk liquid water was based on Kohn-Sham density functional theory using a GGA density functional approximation (Laasonen et al. 1993), and the same class of functionals has been employed for most subsequent applications (see, e.g., VandeVondele et al. 2005b; McGrath et al. 2005a). Recently, also hybrid functionals have been used for the simulation of liquid water (Todorova et al. 2006; Guidon et al. 2008; DiStasio et al. 2014). The importance of vdW interactions for the description of liquid water has also become apparent, and current applications rely on different available approaches to augment standard local functionals. The two main approaches, empirical pair potentials (Grimme et al. 2010) and explicit nonlocal correlation functionals (Dion et al. 2004), are outside the Perdew classification. The performance of these approaches has been extensively tested, and results show a systematic improvement upon the uncorrected GGA or hybrid functionals (Schmidt et al. 2009; DiStasio et al. 2014).

We assess the performance of various methods, with a focus on MP2, RPA, and double-hybrid functionals. In particular, the structural and dynamical properties of bulk liquid water have been studied by means of Monte Carlo (MC) and molecular dynamics (MD) simulations (Del Ben et al. 2013b, 2015b). The MC simulations have been performed in the NpT ensemble under ambient pressure and temperature and are focused on the structural properties, while MD has been employed to obtain dynamical observables, namely, the infrared spectrum and the diffusion constant (Del Ben et al. 2015b). A significant advantage of the MC scheme is that the sampling of the phase space is solely determined by a total energy-based criterion and that forces and stresses are not explicitly required, simplifying the implementation. The downside is that dynamical properties are not available and that suitable moves are needed to efficiently explore large portions of the configuration space.

## 3.1   Computational Setup

All calculations presented have been performed with the CP2K program. The CP2K code makes use of a dual representation for the electronic density and MOs in terms of Gaussian and plane-wave (GPW) (Lippert et al. 1997; VandeVondele et al. 2005a). Unless specified otherwise, the Gaussian basis is of correlation-consistent triple-zeta quality (Dunning 1989; Del Ben et al. 2012), while the PW cutoff is set to 800 Ry. To efficiently expand the density and orbitals in plane waves within GPW, core electrons are replaced by pseudopotentials (Goedecker et al. 1996) that have been parametrized for the employed functionals. The exact exchange calculations are performed employing a $\Gamma$-point implementation making use of a truncated Coulomb operator to avoid divergence of the energy (Guidon

et al. 2008, 2009); the truncation radius is set to 6 Å. The RI auxiliary basis is specifically fitted for this purpose (Del Ben et al. 2015b). All dRPA calculations have been performed employing KS Perdew-Burke-Ernzerhof (PBE) (Perdew et al. 1996) orbitals as input. More details on the computational setups are reported in supporting information of Del Ben et al. (2015b). The model system is made of 64 $H_2O$ molecules in a cubic box under periodic boundary conditions (PBC). The Monte Carlo simulations have been performed with thermodynamic constraints set to ambient conditions, that is, $T = 295$ K and $p = 1$ bar. The MC efficiency is improved with the presampling of moves (Iftimie et al. 2000); in the actual case, the approximated potential is calculated at the DFT level employing the PBE1W (García-González et al. 2007) functional, for which the basis and D3 parameters have been specifically refitted in order to closely approximate the energy of the wave function methods and thus to increase acceptance of moves. Molecular dynamics (MD) simulations which started from equilibrated MC configurations and used a multiple time-step scheme are previously proposed in the context of hybrid density functionals (Guidon et al. 2008).

## 3.2    Structural Properties of Liquid Water

In Fig. 2 the density fluctuation over the MC trajectory obtained with the MP2 and RPA methods is reported. At the RPA level, the density quickly equilibrates, giving an average density of 0.994 g/mL in excellent agreement with the experiment. The root mean square deviation of the instantaneous density is 0.015 g/mL similar to that of the MP2 method which has an average density of 1.020 g/mL. As RPA is computationally less demanding than MP2, roughly twice the number of MC cycles has been performed relative to MP2 (26.8 kcycles vs. 14.6 kcycles). Nevertheless, finite sampling times cannot exclude sudden structural rearrangements on longer timescales. This was observed at the PWPB95-D3 level (Del Ben et al. 2015b), where, initially, the fluctuations of the instantaneous density seem to equilibrate to a stable average value of 1.002 g/mL. However, later a sharp transition occurred to a high-density phase, which was not fully stabilized after an additional 10,000 cycles. Fluctuations between high-density (HD) and low-density (LD) phases would be expected near a liquid-liquid phase transition, for small samples, but the high computational cost of these simulations did not allow for exploring this in depth. Overall the results support the view that the MP2 and RPA methods describe the potential energy surface of bulk liquid water accurately and emphasize the value of treating dispersion interactions at the same level as hydrogen-bond interactions.

Figure 3 shows the radial distribution functions (RDF) obtained at the MP2 and RPA level, respectively. The RDFs are in very good agreement with the recent experimental $g_{OO}(r)$ obtained from X-ray diffraction (Skinner et al. 2013). The height of the first peak is overestimated by about 10%, while the features of the long-range part are remarkably well reproduced, being only very slightly more
**Fig. 2** The red portion of the plots denotes MC cycles considered for equilibration, the green part refers to that used for the calculation of the average properties, and the blue line shows the running average density. Estimated errors are reported as yellow dashed lines. Panel (**a**) shows results for MP2, panel (**b**) for RPA

**Fig. 3** Oxygen-oxygen pair radial distribution functions as obtained from the NpT-MC simulations ($T = 295$ K and $p = 1$ bar) at (**a**) MP2 (**b**), RPA level of theory (solid red line). Experimental RDF (solid black line) taken from Skinner et al. (2013)

structured. In order to gain additional information on the local environment around each water molecule in the liquid, the positions of the 4th and 5th neighboring $H_2O$ were analyzed, as they serve as an indicator for the overlap of coordination shells. GGAs and hybrid functionals not corrected for van der Waals interactions give highly structured and significantly less dense (around 10–20%) liquids. The introduction of dispersion improves the liquid description but in general gives too dense water (5–10%) (Del Ben et al. 2015b). In particular the distributions of the 4th and 5th neighboring waters show a clear separation between the first and second coordination shells for GGA functionals, whereas they move closer when vdW interactions are included, and a similar overlapping pattern is found for MP2 and RPA methods.

The accurate prediction of the water density and structure requires thus a balance between vdW and hydrogen-bond interactions. On this basis, it can be argued that the accurate prediction of the water density and structure by RPA and MP2 can be attributed to the fact that these theories provide, for this system, a correct balance between hydrogen-bond and van der Waals interactions. Reaching this balance might be facilitated by the fact that both interactions are obtained from the same level of theory. Note that in general, MP2 and RPA tend to overbind and underbind, respectively, noncovalent complexes as, e.g., found in the S22 set (Jurecka et al. 2006), which covers a broader range of systems, including compounds that are aromatic or have double bonds (Eshuis and Furche 2012; Ren et al. 2012). While these effects are not pronounced for water, it might nevertheless lead to the slightly higher and lower water densities calculated at the MP2 and RPA level, respectively.

To put these results in context, Table 2 summarizes the density and structural features of the RDF of liquid water obtained from NpT-MC simulations at different levels of theory but with consistent choice of simulation parameters (Del Ben et al. 2015b). In addition to functionals including orbital correlation (RPA, MP2), standard GGA and hybrid functionals (PBE, PBE0) with D3 and nonlocal vdW corrections are shown. The reported average values show the slight overestimation

**Table 2** Average density and structural data obtained from the NpT-MC simulations ($T = 295$ K and $p = 1$ bar). The method labeled with optB88-vdW (Klimeš et al. 2010, 2011) represents a functional of the nonlocal van der Waals type. The label D3 stands for a dispersion correction according to Grimme et al. (2010). For the calculated average densities, an error estimation is reported ($\Delta_\rho$)

|            | Density [g/mL] | | 1st Max | | 1st Min | | 2nd Max | |
|------------|------|-------------|-------|----------|-------|----------|-------|----------|
|            | $\rho$ | $\Delta_\rho$ | $r$ [Å] | $g_{OO}(r)$ | $r$ [Å] | $g_{OO}(r)$ | $r$ [Å] | $g_{OO}(r)$ |
| PBE-D3     | 1.055 | 0.006 | 2.73 | 3.07 | 3.25 | 0.69 | 4.43 | 1.21 |
| PBE0-D3    | 1.053 | 0.005 | 2.74 | 2.88 | 3.29 | 0.79 | 4.32 | 1.21 |
| optB88-vdW | 1.081 | 0.003 | 2.74 | 2.94 | 3.34 | 0.80 | 4.31 | 1.21 |
| MP2        | 1.020 | 0.004 | 2.76 | 3.05 | 3.32 | 0.72 | 4.41 | 1.21 |
| RPA        | 0.994 | 0.006 | 2.78 | 2.93 | 3.41 | 0.78 | 4.49 | 1.19 |
| exp.       | 1.00  |       | 2.80 | 2.57 | 3.45 | 0.84 | 4.5  | 1.12 |

when GGA and hybrid functionals with the D3 vdW corrections are used. For the considered nonlocal van der Waals functional, the obtained results show a larger density of ∼8%, and the structure of the liquid is rather well reproduced but with all features shifted to shorter distances, in agreement with previous NVT simulations (Wang et al. 2011). Even though at the limit of statistical accuracy, both the inclusion of the D3 correction and the use of hybrid functionals reduce the height of the first peak of the $g_{OO}(r)$ for PBE. This combined effect of dispersion and exchange has been emphasized recently (DiStasio et al. 2014).

GGA functionals, which underestimate the bandgap, lead to a too polarizable solvent, which in turn should lead to too strong hydrogen bonds. This is similar to the effect of charge transfer from anions to the solvent that has been observed to be too strong for GGAs as compared to hybrids (VandeVondele et al. 2012). The effect of hybrid functionals on the dielectric constant of water ice has been quantified (Schönherr et al. 2014) showing that GGA functionals lead to more polar structures while also overestimating the polarization of these structures. Whereas the effect of bandgap underestimation is already noticeable in neat water, it becomes even more visible in the context of aqueous electrochemistry. Redox levels of various species can be significantly influenced, if water band edges are incorrect; in particular they will be pushed up if these are close to the valence band of the liquid (Adriaanse et al. 2012). Results obtained with RPA and double-hybrid functionals for redox levels near the band edges appear promising (Cheng and VandeVondele 2016). This highlights the importance of going beyond the neat liquid in assessing the performance of electronic structure theory for liquid water.

Finally the equilibrium parameters of ice Ih, calculated at various levels of theory, are reported in Table 3 for comparison (Del Ben et al. 2015b). The results reported are obtained at 0 K neglecting nuclear quantum effects and zero-point energies. Despite being important in many situations, these effects have been shown to have a lesser influence ($\leq$1%) for the equilibrium volume of ice Ih both theoretically (Santra et al. 2013; Pamuk et al. 2012) and experimentally (Röttger et al. 2012). Analogously to the liquid water case, the calculated ice densities are ∼2% larger and ∼1% smaller than experimental results for MP2 and RPA, respectively. At both the MP2 and RPA level, these results show the nontrivial prediction that ice floats on water, with a quantitatively correct ratio of liquid and solid density.

**Table 3** Equilibrium volumes and energies (at 0 K) for ice Ih expressed per molecule without corrections for the quantum nature of the nuclei and zero-point energies. Experimental values are from Hobbs (1974) and Whalley (1984)

|       | $E_{\mathrm{coh}}$ [kJ/mol] | $V_{\mathrm{mol}}$ [Å$^3$] | $\rho$ [g/mL] |
|-------|------------------|------------------|------------|
| PBE   | −62.8            | 30.69            | 0.975      |
| MP2   | −58.7            | 31.34            | 0.955      |
| RPA   | −52.5            | 32.37            | 0.924      |
| Exp.  | −58.9            | 32.05            | 0.933      |

# 4 Outlook

With the methods described here, nonlocal wave function correlation methods can be applied to liquids, solutions, crystals, and simple interfaces. As the available computational resources continue to grow, such applications will become increasingly more routine. At the same time, the algorithms will be further refined and improved. Reduced scaling algorithms (Wilhelm et al. 2016) will make it possible to tackle larger systems. Multiple time-step algorithms are developed that make ab initio molecular dynamics simulations using high-level methods more efficient. These methods are also combined with path integral techniques (Kapil et al. 2016) and bring MP2 and RPA based simulations including nuclear quantum effects within reach.

# Accelerated Molecular Dynamics for Ab Initio Electronic Simulations

# 26

Guglielmo Mazzola and Sandro Sorella

## Contents

**Abstract**

A recently proposed method for accelerating current molecular dynamics algorithms, used for the simulation of classical particles at finite temperatures, is reviewed (Mazzola and Sorella, Phys Rev Lett 118:015703, 2017). This method is based on an efficient implementation of a first-order Langevin dynamics modified in a way to reduce the autocorrelation times and the time step error for the integration of the stochastic equations of motion. This work represents an improvement upon previously known algorithms that, on one hand, are too much simplified to be used in realistic simulations and, on the other hand, are too much complicated and computationally demanding for their practical implementations.

G. Mazzola
Theoretische Physik, ETH Zurich, Zurich, Switzerland
e-mail: gmazzola@phys.ethz.ch

S. Sorella (✉)

e-mail: sorella@sissa.it

The details of the method are presented with few applications to standard test cases on Lennard-Jones models at various temperatures. In particular it is shown that this technique represents an ideal tool for ab initio molecular dynamics, when the Born-Oppenheimer energy surface is estimated by computationally demanding methods, such as, for instance, the quantum Monte Carlo stochastic approach.

# 1    Introduction

One of the simplest, but nevertheless robust, methods for simulating a given number $N$ of classical particles in a finite volume $V$ for a temperature $T$, namely, for computing physical quantities in the so-called $NVT$ ensemble (Allen and Tildesley 1987; Tuckerman 2010) is given by the *first-order* Langevin dynamics, which is defined by the following set of stochastic differential equations:

$$\frac{d\mathbf{R}(t)}{dt} = \mathbf{f}[\mathbf{R}(t)] + \boldsymbol{\eta}(t), \tag{1}$$

where $\mathbf{R}(t)$ is a (time dependent) $p$ dimensional vector with components $R_j$ ($j = 1, \ldots, p$, with $p = N \times d$, $d$ being the spatial dimensionality). The classical potential $V(\mathbf{R})$ defines the deterministic "force" with components $f_j(\mathbf{R})$:

$$f_j(\mathbf{R}) = -\frac{\partial V(\mathbf{R})}{\partial R_j}; \tag{2}$$

whereas $\boldsymbol{\eta}(t)$ is a random vector with components $\eta_j(t)$ ($j = 1, \ldots, p$), with vanishing mean value and no correlations between components $i \neq j$ and times $t \neq t'$:

$$\langle \eta_j(t) \rangle = 0, \tag{3}$$

$$\langle \eta_i(t)\eta_j(t') \rangle = 2T\delta_{i,j}\delta(t - t'), \tag{4}$$

where $\langle \ldots \rangle$ indicates the expectation value. This conventional first-order Langevin dynamics (CFOLD) (1) is substantially different from the Newton equations of motions that are *second-order* (deterministic) differential equations connecting the actual force to the acceleration of the particles. The advantage of using first-order equations will be clear in the following because of their apparent simplicity. On one hand, they are analytically less involved, and, on the other hand, they contain less parameters, namely, the mass of the particles and their damping coefficients. The latter quantities have to be introduced in the Newton-like equations in order to sample correctly the NVT ensemble, because they provide a simple solution to the well-known ergodicity problems of weakly interacting harmonic systems and, in this way, improve the efficiency of the sampling (Ceriotti et al. 2009; Kühne et al. 2009).

Contrary to ordinary differential equations, the stochastic differential equations do not provide a unique solution starting from a given initial condition, but the possible solutions acquire a statistical meaning: starting at $t = t_0$ from $\mathbf{R}_0 \equiv \mathbf{R}(t_0)$, several stochastic trajectories are possible depending on the particular realization of the noise. Thus, we are naturally led to define the probability $P(\mathbf{R}, t)$ to find a given configuration $\mathbf{R}$ at time $t$, with the initial condition:

$$P(\mathbf{R}, t_0) = \delta(\mathbf{R} - \mathbf{R}_0). \tag{5}$$

After an equilibration time, $P(\mathbf{R}, t)$ converges to the equilibrium distribution $P_{\text{eq}}(\mathbf{R})$ that is independent of the initial condition $\mathbf{R}_0$. Then, the solution $\mathbf{R}_n$ at discrete times $t_n$ of the differential equations (1) provides a large number $M$ of samples that can be used to compute statistically any correlation function $O(\mathbf{R})$:

$$\int \mathbf{dR} \, O(\mathbf{R}) \, P_{\text{eq}}(\mathbf{R}) \approx \frac{1}{M} \sum_n O(\mathbf{R}_n) \tag{6}$$

similarly to the ordinary Monte Carlo method.

The main purpose of this chapter is to show that, by using the simpler formalism of the first-order stochastic equation, it is possible to solve exactly, within the harmonic approximation, the problem of long autocorrelation times, usually affecting the implementation of molecular dynamics in complex systems such as water at ambient conditions or complex processes such as protein folding. The latter phenomenon takes place within the time scale of $\mu s$, much larger than the period of the molecular vibrations of the order of the $fs$ (Scheraga et al. 2007). To this end, we have to introduce a more general approach, already known in literature, starting with the covariant version of the first-order Langevin dynamics equations (LDE):

$$\dot{\mathbf{R}} = S^{-1}[\mathbf{R}(t)]\mathbf{f}[\mathbf{R}(t)] + \boldsymbol{\eta}$$
$$\langle \eta_i \eta_j \rangle = 2T\delta(t - t')S_{ij}^{-1}[\mathbf{R}(t)] \tag{7}$$

where $S[\mathbf{R}(t)]$ is, for the time being, an arbitrary positive-definite symmetric matrix – i.e., with all eigenvalues strictly positive – that is used to accelerate the dynamics in the way we will discuss in the following sections. Notice also that this matrix is explicitly dependent on the atomic positions, a peculiar but very important property of this approach; otherwise, this method coincides with the standard accelerated dynamics introduced long time ago by Parisi (1984). Moreover, for $S_{ij} = \delta_{ij}$, Eq. (7) describes the conventional first-order Langevin dynamics discussed at the beginning.

The equilibrium probability implied by these stochastic differential equations, containing a position dependent matrix $S[\mathbf{R}(t)]$, is given by a generalized Boltzmann distribution:

$$P_{\text{eq}}(\mathbf{R}) = \frac{1}{\mathscr{Z}} |S[\mathbf{R}(t)]|^\gamma \exp\left[-\frac{V(\mathbf{R})}{T}\right],\tag{8}$$

where $|S[\mathbf{R}(t)]|$ is the determinant of the matrix $S[\mathbf{R}(t)]$ and $\mathscr{Z}$ is the partition function, needed for the normalization condition of the probability:

$$\mathscr{Z} = \int \mathbf{dR} |S[\mathbf{R}(t)]|^\gamma \exp\left[-\frac{V(\mathbf{R})}{T}\right].\tag{9}$$

In principle the LDE of Eq. (7) does not depend on the parameter $\gamma$, while the equilibrium distribution is explicitly dependent on it. At first sight, this may appear in contradiction, but, as we will see in the following, this dependency may arise due to the arbitrariness of the continuous limit of stochastic differential equations, as there are several consistent ways to integrate Eq. (7). Notice that for $\gamma = 0$, we obtain the conventional canonical Boltzmann distribution that can be used for our purposes. Another important case is when $\gamma = 1/2$, the matrix $S$ representing the metric of the space, and the LDE acquire the covariant property, namely, they are independent of any nonlinear transformation $\mathbf{R} \to \mathbf{R}'$ of the variables in the non-euclidean space defined by the metric $S[\mathbf{R}(t)]$, namely, the infinitesimal distance $ds$ between two points of the space is given by $ds^2 = \sum_{ij} S_{i,j}[\mathbf{R}] dR_i dR_j$. The motivation for introducing an acceleration matrix $S[\mathbf{R}(t)]$ in the equations becomes clear if we consider the limiting $T = 0$ case, where the finite temperature Eq. (7) reduces to a structural relaxation equation. If we first discretize Eq. (7), with a finite time step $\Delta$, and consider an harmonic problem defined by a potential

$$V_H(\mathbf{R}) = \frac{1}{2} \sum_{i,j} H_{i,j} (\mathbf{R} - \mathbf{R}^{eq})_i (\mathbf{R} - \mathbf{R}^{eq})_j \tag{10}$$

where $H$ is the Hessian matrix and $\mathbf{R}^{eq}$ the equilibrium positions, we obtain that

$$\mathbf{R}(t + \Delta) = \mathbf{R}(t) + \Delta S^{-1} \mathbf{f}(t).\tag{11}$$

Thus, if $S[\mathbf{R}] = H$ and $\Delta = 1$, it is possible to reach the minimum $\mathbf{R}_{eq}$, starting from any arbitrary configuration $\mathbf{R}(t)$, in only one step, simply because $\mathbf{S}^{-1}\mathbf{f}(t) = -(\mathbf{R}(t) - \mathbf{R}^{eq})$ in this case. On the contrary, the standard steepest-descent algorithm, with $S[\mathbf{R}]$ being the identity matrix, is affected by a slowing down controlled by the condition number $K_{\text{cond}} = K_{\max}/K_{\min}$ of the matrix $H$, i.e., the ratio between its maximum ($K_{\max}$) and minimum non-zero ($K_{\min}$) eigenvalues.

In the following we generalize this approach from structural optimization to the finite temperature dynamics of our interest. The main difficulty consists in finding an efficient iterative scheme able to produce the unbiased sampling while retaining the property of decreasing the autocorrelation time by means of a suitable position dependent matrix $S[\mathbf{R}]$. In the next section, we develop such scheme in a general way, without specifying the matrix $S[\mathbf{R}]$ but keeping in mind that, for practical

calculations, this matrix could be a positive-definite matrix that at low temperatures is very close to the Hessian for optimal performances. This approach is similar in spirit to the mass tensor scheme (Bennett 1975; Tsuchida 2015) where a mass tensor **M** plays the role of our acceleration matrix $S$. However the method that we present here becomes much simpler when it is necessary to consider acceleration matrices ($M$ or $S$) that are explicitly dependent on **R**, because the algorithm we propose does not contain any cumbersome differentiation of $S$. On the other hand, recent attempts based on damped molecular dynamics (Ceriotti et al. 2010) cannot have optimal efficiency in the harmonic case but can reduce the correlation time only by a factor proportional to $\sqrt{K_{\text{cond}}}$ (Tassone et al. 1994). They should be therefore much less efficient (by a factor proportional to $\sqrt{K_{\text{cond}}}$) than the algorithm we discuss here.

## 2    Fokker-Planck Equation and Approach to the Canonical Distribution

Quite generally, conventional differential equations are integrated approximately at discrete short time intervals $\Delta$, by introducing a so-called time step error that is unavoidable in any realistic simulation. Unfortunately stochastic differential equations like the LDE in Eq. (7) are not well defined because the noise introduces nonanalytic terms proportional to $\sqrt{\Delta}$, yielding discretized equations depending upon arbitrary choices (e.g., Ito or Stratonovich). In our opinion the correct way to deal with stochastic differential equation is to start just from a given, though arbitrarily chosen, discretized version of the equation and show that the associated probability distribution $P(\mathbf{R}, t)$ satisfies a well-defined Fokker-Planck equation, equilibrating to the canonical distribution $P_{\text{eq}}(\mathbf{R})$ in the long time limit.

We start therefore from the integration of Eq. (7), at discrete time $t = n\Delta$, that is conventionally adopted in textbooks (Risken 1996) and is given by the following rather involved expression

$$\mathbf{R}(t + \Delta)_j = \mathbf{R}(t)_j + \Delta \left( S^{-1}(\mathbf{R})\mathbf{f_R} \right)_j + T\Delta \left( \sum_i \partial_i S_{ji}^{-1}(\mathbf{R}) \right) + \sqrt{2T\Delta} z_j(t)$$

$$\langle z_i(t)z_j(t) \rangle = S_{i,j}^{-1}(\mathbf{R}(t)) \tag{12}$$

$$(\mathbf{f_R})_j = -\partial_j V(\mathbf{R}) + \gamma T \partial_j \ln |S(\mathbf{R})| \tag{13}$$

where, as it will be shown in the following, this discretization provides an equilibrium distribution for $\Delta \to 0$ of the form given in Eq. (8). In the following we are interested to the canonical distribution, defined in the standard Euclidean metric, and therefore we have to keep in mind that our interest is for $\gamma = 0$, though all the forthcoming derivation remains valid for any value of $\gamma$.

The above Markov chain univocally defines a discretized master equation for the probability function $P(\mathbf{R}, t)$ that, in the limit $\Delta \to 0$, becomes a Fokker-Planck one of the following form:

$$\partial_t P(\mathbf{R}, t) = \sum_j \partial_j \left\{ -\left[ S^{-1}(\mathbf{R}) f_{\mathbf{R}} \right]_j P(\mathbf{R}, t) + T \sum_i \left[ S_{j,i}^{-1}(\mathbf{R}) \partial_i \right] P(\mathbf{R}, t) \right\}$$

$$(14)$$

In order to find the equilibrium distribution, it is enough to equate to zero the term between braces which immediately gives $P(\mathbf{R}, t)$ up to a constant, in turn determined by the normalization condition of probabilities, yielding:

$$P_{eq}(\mathbf{R}, t) = \frac{|S(\mathbf{R})|^\gamma \exp(-V(\mathbf{R})/T)}{\mathscr{Z}},$$

$$(15)$$

namely, the desired distribution. Unfortunately the Markov chain of Eq. (12) is not practical, because it contains, what in the following will be named the "cumbersome term":

$$\Gamma_j(\mathbf{R}) = \sum_i \partial_i S_{j,i}^{-1}(\mathbf{R})$$

$$(16)$$

Indeed, this term is computationally very demanding, because the calculation of the inverse of a matrix takes the order of $p^3$ operations, as well as each derivative of $S^{-1}$ with respect to any variable $i$, e.g., by using a finite difference method. Thus, in order to make the summation overall $i$ for each $j$ in the above equation, we end up with an algorithm scaling in most cases as the fourth power of $p$, unless for particularly simple cases. Moreover the expressions for the inverse derivatives become so much complicated that they are very difficult to implement in practice (Mazzola et al. 2012), especially within ab initio approaches such as quantum Monte Carlo (Foulkes et al. 2001), DFT (Kohn and Sham 1965), or quantum chemistry wave function methods (Dykstra et al. 2005).

## 3 Avoiding the "Cumbersome Term": A First Simplified Algorithm

Before deriving the final convenient expression for sampling in the most efficient way the canonical distribution by the proposed accelerated Langevin dynamics, we consider the following Markov chain that does not require the evaluation of the "cumbersome term" $\Gamma_j(\mathbf{R})$:

$$\mathbf{y} = \mathbf{R} + \sqrt{2T\Delta}\mathbf{z}(t)$$

$$\mathbf{R}' = \mathbf{y} + \Delta S^{-1}(\mathbf{R})\mathbf{f}_{\mathbf{R}} - \frac{1}{2}S^{-1}(\mathbf{R})\left[ S(\mathbf{y}) - S(\mathbf{R}) \right](\mathbf{y} - \mathbf{R})$$

$$\langle z_i(t) z_j(t) \rangle = S_{i,j}^{-1}(\mathbf{R})$$

$$(17)$$

where here $\mathbf{R} = \mathbf{R}(t)$ and $\mathbf{R}' = \mathbf{R}(t + \Delta)$. We will show in the following that the above Markov chain implies the same Fokker-Planck equation (14) corresponding the much more involved discretization in Eq. (12), and therefore the equilibrium distribution for $\Delta \to 0$ will be the correct one. In this way it is possible to avoid the "cumbersome term," with a minor computational effort, namely, by calculating the matrix $S$ *twice* for each time step.

Let's therefore proceed with the main proof of this section. The Markov chain in Eq. (17) defines in a unique way the conditional probability density of having $\mathbf{R}' = \mathbf{R}(t + \Delta)$ given $\mathbf{R}(t) = \mathbf{R}$:

$$
\begin{aligned}
K(\mathbf{R}'|\mathbf{R}) = \int dz^p \mu_{\mathbf{R}}(\mathbf{z}) \delta \Big\{ &\mathbf{R}' - \mathbf{R} - \Delta S^{-1}(\mathbf{R})\mathbf{f_R} - \sqrt{2T\Delta}\mathbf{z} \\
&+ \frac{1}{2} S^{-1}(\mathbf{R}) \Big[ S(\mathbf{R} + \sqrt{2T\Delta}\mathbf{z}(t)) - S(\mathbf{R}) \Big] \sqrt{2T\Delta}\mathbf{z}(t) \Big\}
\end{aligned}
$$

$$(18)$$

where the normalized Gaussian probability density $\mu_{\mathbf{R}}(z)$ is given, according to Eq. (17), by:

$$
\begin{aligned}
\mu_{\mathbf{R}}(\mathbf{z}) &= \frac{\exp\left[-\frac{1}{2}(z, S(\mathbf{R})z)\right]}{\int\int dz^p \exp\left[-\frac{1}{2}(z, S(\mathbf{R})z)\right]} \\
&= (2\pi)^{-\frac{p}{2}} \exp\left[-\frac{1}{2}(z, S(\mathbf{R})z) + \frac{1}{2}Tr[\ln S(\mathbf{R})]\right]
\end{aligned}
$$

$$(19)$$

where in the latter equation, we have used a well-known property relating the multi-dimensional Gaussian integrals to the determinant $|S(\mathbf{R})|$ written, for convenience, as $\exp Tr[\ln S(\mathbf{R})]$. Here and henceforth we denote by $(a, b)$ the scalar product of two $p-$ dimensional real vectors, and matrix-vector multiplication is understood when a matrix appears before (from left to right) a given vector. We want to obtain a Fokker-Planck equation in the limit of $\Delta \to 0$. To this purpose we write the master equation:

$$
P_{n+1}(\mathbf{R}') = \int dR^p K(\mathbf{R}'|\mathbf{R}) P_n(\mathbf{R}) \tag{20}
$$

and employ the integration in $dR^p$ after substituting the expression of $K(\mathbf{R}'|\mathbf{R})$ given above. In all the forthcoming derivation, all the effort is spent to extract the leading term $O(\Delta)$ of the above master equation that will define in a unique way the Fokker-Planck equation that is in turn necessary to establish the equilibrium distribution. For this purpose we solve the argument of the $\delta$ function, by replacing $\mathbf{R}$ with $\mathbf{R}'$ when it is allowed at the leading order in $\Delta$:

$$\mathbf{R}(\mathbf{R}') = \mathbf{R}' - \sqrt{2T\varDelta}\mathbf{z} - \varDelta S^{-1}(\mathbf{R}')\mathbf{f}_{\mathbf{R}'}$$
$$+ \frac{1}{2}S^{-1}(\mathbf{R}')\left[S(\mathbf{R}' + \sqrt{2T\varDelta}\mathbf{z}) - S(\mathbf{R}')\right]\sqrt{2T\varDelta}\mathbf{z} + o(\varDelta) \qquad (21)$$

we obtain that the master equation for the evolution of the probability is explicitly given:

$$P_{n+1}(\mathbf{R}') = \int dz^p J_\varDelta(\mathbf{R}(\mathbf{R}'))\mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z})P_n\left(\mathbf{R}(\mathbf{R}')\right) \qquad (22)$$

where $J_\varDelta(\mathbf{R}(\mathbf{R}')) = 1 + \varDelta B(\mathbf{R}') + o(\varDelta)$ is the Jacobian of the transformation of Eq. (21) that can be expanded in $\varDelta$ with a well-defined expression for $B(\mathbf{R}')$ that we do not explicitly write in the following, because, as we will see soon, it is not important for the derivation. $\mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z})$ comes from the original probability density $\mu_{\mathbf{R}}(\mathbf{z})$ in Eq. (19) once $\mathbf{R}$ is substituted with the $\mathbf{z}$-dependent expression given in Eq. (21). Indeed, by substituting the transformation of Eq. (21) in Eq. (22), and expanding the latter equation to the leading order in $\varDelta$, we obtain the following expression:

$$P_{n+1}\left(\mathbf{R}'\right) = \left[1 + \varDelta C(\mathbf{R}')\right]P_n(\mathbf{R}') + \int dz^p \mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z})\left\{-\sum_j\left\{\sqrt{2T\varDelta}z_j\right.\right.$$
$$+\varDelta\left[S^{-1}(\mathbf{R}')\left(\mathbf{f}_{\mathbf{R}'} - \frac{S(\mathbf{R}' + \sqrt{2T\varDelta}\mathbf{z}) - S(\mathbf{R}')}{2\varDelta}\sqrt{2T\varDelta}\mathbf{z}\right)\right]_j\right\}\partial_j P_n(\mathbf{R}')$$
$$\left. + \varDelta T\sum_{i,j}z_i z_j \partial_i \partial_j P_n(\mathbf{R}')\right\} + o(\varDelta) \qquad (23)$$

In the above iteration of Eq. (23), there is therefore a term that simply multiplies $P_n(\mathbf{R}')$ by a function:

$$1 + \varDelta C(\mathbf{R}') \qquad (24)$$

where $C(\mathbf{R}')$ is rather involved and comes from the expansion in small $\varDelta$ of all the factors ($J$ and $\mu$) of the integrand in Eq. (22) multiplying $P(\mathbf{R}(\mathbf{R}'))$:

$$C(\mathbf{R}')\varDelta = -1 + \int dz^p J_\varDelta(\mathbf{R}(\mathbf{R}'))\mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z}) = \varDelta B(\mathbf{R}') - 1 + \int dz^p \mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z}) + o(\varDelta) \qquad (25)$$

Notice that $\mathbf{R}(\mathbf{R}')$ depends on the random variable $\mathbf{z}$ via Eq. (21), and therefore the term $\int dz^p \mu_{\mathbf{R}(\mathbf{R}')}(\mathbf{z})$ in the above equation is nontrivial and different from one by $O(\varDelta)$. We will not attempt to calculate this term, as well as $B(\mathbf{R}')$, but derive it from the conservation of the normalization condition of the probability.

As evident in Eq. (23), there are three different contributions depending on the order of the derivatives. The term that couples to the first derivative of $P_n(\mathbf{R}')$ reads:

$$-\Delta \sum_j \int dz^P \mu_{\mathbf{R}'}(\mathbf{z})$$

$$\left[ S^{-1}(\mathbf{R}') \left( \mathbf{f}_{\mathbf{R}'} - \frac{S(\mathbf{R}' + \sqrt{2T\Delta}\mathbf{z}) - S(\mathbf{R}')}{2\Delta} \sqrt{2T\Delta}\mathbf{z} \right) \right]_j \partial_j P_n(\mathbf{R}') \qquad (26)$$

$$-\int dz^P \mu_{\mathbf{R}'}(\mathbf{z}) \sum_{i,j,k,l} (2\Delta T)z_j$$

$$\left[ \frac{1}{2} z_k \left( \partial_i S_{k,l}(\mathbf{R}') \right) z_l z_i - \frac{1}{2} S_{k,l}^{-1}(\mathbf{R}') \left( \partial_i S_{kl}(\mathbf{R}') \right) z_i \right] \partial_j P_n(\mathbf{R}') \qquad (27)$$

where the latter equation comes from the expansion of $\mu(\mathbf{R}(\mathbf{R}'))$ at leading order $O(\sqrt{\Delta})$, where, to this end, we have also used the following relation:

$$Tr[\ln S\left(\mathbf{R}(\mathbf{R}')\right)] = Tr[\ln S(\mathbf{R}')] - \sum_i Tr[S^{-1}(\mathbf{R}')\partial_i S(\mathbf{R}')]\sqrt{2T\Delta}z_i + O(\Delta)$$

$$= Tr[\ln S(\mathbf{R}')] - \sqrt{2T\Delta} \sum_{i,k,l} S_{kl}^{-1}(\mathbf{R}')\partial_i S_{kl}(\mathbf{R}')z_i + O(\Delta) \quad (28)$$

and in the last equation, we have used that $S^{-1}$ is symmetric because $S$ is symmetric. By carrying out the simple integration in $dz^P$, i.e., by replacing $\int dz^P \mu_{\mathbf{R}'}(\mathbf{z})z_j =<z_j> = 0$ and $\int dz^P \mu_{\mathbf{R}'}(\mathbf{z})z_i z_j = <z_i z_j> = S_{i,j}^{-1}(\mathbf{R}')$ and by applying the Wick's theorem for the integration of the higher-order polynomial involved, i.e., $<z_j z_k z_l z_i> = <z_j z_k><z_l z_i> + <z_j z_l><z_k z_i> + <z_j z_i><z_k z_l>$, we obtain that Eq. (27) reads:

$$-\Delta T \sum_{i,j,k,l} \left[ \left( S_{jk}^{-1}S_{li}^{-1} + S_{jl}^{-1}S_{ki}^{-1} + S_{ji}^{-1}S_{kl}^{-1} - S_{kl}^{-1}S_{ji}^{-1} \right) \partial_i S_{kl} \right] (\mathbf{R}')\partial_j P_n(\mathbf{R}')$$

$$= 2\Delta T \sum_{i,j} \left( \partial_i S_{j,i}^{-1}(\mathbf{R}') \right) \partial_j P_n(\mathbf{R}')$$

$$= 2T\Delta \sum_j \Gamma_j(\mathbf{R})\partial_j P(\mathbf{R}') \qquad (29)$$

where, by $S + \delta S = S(I + S^{-1}\delta S) \rightarrow (S + \delta S)^{-1} = S^{-1} - S^{-1}\delta S S^{-1} + o(\delta S) \rightarrow \partial_i S_{ji}^{-1} = -\left[ S^{-1}(\partial_i S)S^{-1} \right]_{ji}$, we easily verify that the LHS and RHS of the above Eq. (29) are consistent, as, for instance, by using that $S$ is a symmetric matrix, we have that:

$$\sum_{kl} S_{jl}^{-1}(\mathbf{R}') S_{ki}^{-1}(\mathbf{R}') \partial_i S_{kl}(\mathbf{R}') = \sum_{kl} S_{jl}^{-1}(\mathbf{R}') S_{ki}^{-1}(\mathbf{R}') \partial_i S_{lk}(\mathbf{R}') = -\partial_i S_{ji}^{-1}(\mathbf{R}') \tag{30}$$

Thus this term partially cancels with the contribution coming from the expansion in small $\Delta$ of the term

$$\left[ S(\mathbf{R}' + \sqrt{2T\Delta}\mathbf{z}) - S(\mathbf{R}') \right]_{k,l} = \sqrt{2T\Delta} \sum_i \partial_i S_{kl}(\mathbf{R}') z_i \tag{31}$$

present in Eq. (26). Indeed, in the Fokker-Planck equation, the term proportional to $\partial_j P$ coming from the Eq. (26) acquires a contribution:

$$T\Delta \int dz^p \mu(\mathbf{z}) \sum_{i,k,l} S_{j,k}^{-1}(\mathbf{R}') \partial_i S_{k,l}(\mathbf{R}') z_i z_l = T\Delta \sum_{i,k,l} S_{j,k}^{-1}(\mathbf{R}') \partial_i S_{k,l}(\mathbf{R}') S_{i,l}^{-1}(\mathbf{R}')$$

$$= -T\Delta \sum_i \partial_i S_{j,i}^{-1}(\mathbf{R}') = -T\Delta \Gamma_j(\mathbf{R}') \tag{32}$$

where in the last equality, we have used the relation given in Eq. (30). In this way the total term proportional to $\partial_j P_n(\mathbf{R}')$ reads:

$$\sum_j \left\{ -\Delta \left[ S^{-1}(\mathbf{R}') \mathbf{f}_{\mathbf{x}'} \right]_j + T\Delta \Gamma_j(\mathbf{R}') \right\} \partial_j P_n(\mathbf{R}') \tag{33}$$

Finally the term proportional to the second derivative leads to:

$$\Delta T \sum_{i,j} S_{ij}^{-1}(\mathbf{R}') \partial_i \partial_j P_n(\mathbf{R}') = T\Delta \sum_i \partial_i \left[ S_{ij}^{-1}(\mathbf{R}') \partial_j P_n(\mathbf{R}') \right]$$

$$- T \sum_j \left[ \sum_i \partial_i S_{i,j}^{-1}(\mathbf{R}') \right] \partial_j P_n(\mathbf{R}')$$

$$= T\Delta \sum_i \partial_i \left[ S_{ij}^{-1}(\mathbf{R}') \partial_j P_n(\mathbf{R}') \right]$$

$$- T\Delta \sum_j \Gamma_j(\mathbf{R}') \partial_j P_n(\mathbf{R}') \tag{34}$$

By collecting all the terms obtained in Eqs. (24), (33), and (34), all the ones proportional to the "cumbersome gradient" $\Gamma_j(\mathbf{R}')$ cancel out, and, by carrying out the limit $\Delta \to 0$, we obtain the following Fokker-Planck equation:

$$\partial_t P(\mathbf{R}, t) = \sum_j \partial_j \left\{ -\left[S^{-1} f_{\mathbf{R}}\right]_j P(\mathbf{R}, t) + T \sum_i S_{i,j}^{-1} \partial_i P(\mathbf{R}, t) \right\} + \bar{C}(\mathbf{R}) P(\mathbf{R})$$

(35)

where all the terms proportional to $P(\mathbf{R})$ include $C(\mathbf{R})$ and the ones that compensate the expression implied by the total divergence, namely, $\bar{C}(\mathbf{R}) = C(\mathbf{R}) + \sum_j \partial_j \left[S^{-1} f_{\mathbf{R}}\right]_j$. In the above equation, $\bar{C}(\mathbf{R})$ has not been computed explicitly as it should simply vanish because it is determined by the standard property of the Fokker-Planck equation, namely, that the RHS should be a total divergence, so that once integrated overall volume, it guarantees that the normalization of the probability is conserved for any initial probability guess, as a simple consequence that the conditional probability satisfies $\int d[R']^p K(\mathbf{R}'|\mathbf{R}) = 1$ for any $\Delta$ and in particular in the limit $\Delta \to 0$. Therefore we finally obtain the following Fokker-Planck equation with $\bar{C}(\mathbf{R}) = 0$:

$$\partial_t P(\mathbf{R}, t) = \sum_j \partial_j \left\{ -\left[S^{-1}[\mathbf{R}] f_{\mathbf{R}}\right]_j P(\mathbf{R}, t) + T \sum_i \left[S_{j,i}^{-1}[\mathbf{R}] \partial_i P(\mathbf{R}, t)\right] \right\}$$

(36)

that concludes the proof of this section.

## 3.1  A More Efficient Algorithm

The previous Markov chain given in Eq. (17) solves the problem of computing the "cumbersome term" $\Gamma_j(\mathbf{R})$ at the expense of evaluating the matrix $S(\mathbf{R})$ twice for each iteration. In the following we describe another way to obtain the same Fokker-Planck equation, with an iterative scheme requiring only one evaluation of the matrix $S(\mathbf{R})$. This is important in our implementation of the Langevin dynamics, whenever the evaluation of the matrix $S(\mathbf{R})$ requires high computational effort as in computationally demanding applications based on DFT or quantum Monte Carlo. To this purpose the following more convenient iteration scheme defines the new coordinates $\mathbf{R}(t + \Delta)$ not only in terms of $\mathbf{R}(t)$ but also of the previous one $\mathbf{R}(t - \Delta)$. This remains formally a Markov chain in an extended space acting on a $2p-$ dimensional vector $\tilde{\mathbf{R}}_n = [\mathbf{R}_n, \mathbf{R}_{n-1}]$, so that all the results of Markov chains used in the previous section can be applied also in this case. We propose therefore the following iteration scheme:

$$\mathbf{R}(t + \Delta) = \mathbf{R}(t) + \Delta S^{-1}[\mathbf{R}(t)] \mathbf{f}_{\mathbf{R}(t)} + \sqrt{2T\Delta} \mathbf{z}(t)$$

$$-\frac{1}{2} S^{-1}[\mathbf{R}(t)] \{S[\mathbf{R}(t - \Delta)] - S[\mathbf{R}(t)]\} [\mathbf{R}(t - \Delta) - \mathbf{R}(t)]$$

$$\langle z_i(t) z_j(t) \rangle = S_{i,j}^{-1}[\mathbf{R}(t)]$$

(37)

In order to verify that also this Markov chain converges, for $\Delta \to 0$ to the equilibrium distribution given in Eq. (8), it is enough to show that, at the leading order in $\Delta$, the previous iteration scheme is equivalent to the Markov chain in Eq. (17). This is evident by considering that, as in the previous case:

$$(\mathbf{R}(t - \Delta) - \mathbf{R}(t)) = -\sqrt{2T\Delta}\mathbf{z}(t - \Delta) + O(\Delta) \tag{38}$$

Therefore the "cumbersome term" in Eq. (37) comes naturally from simple Taylor expansion:

$$\begin{aligned}
&\{[S(\mathbf{R}(t - \Delta)) - S(\mathbf{R})] (\mathbf{R}(t - \Delta) - \mathbf{R}(t))\}_k \\
&= 2T\Delta \sum_{i,l} \left(\partial_i S_{k,l}(\mathbf{R}(t))\right) z_i(t - \Delta) z_l(t - \Delta) \\
&\simeq 2T\Delta \sum_{i,l} \left(\partial_i S_{k,l}(\mathbf{R})\right) z_i(t) z_l(t)
\end{aligned} \tag{39}$$

Thus the iteration scheme in Eq. (37) is equivalent to the following Markov chain:

$$\begin{aligned}
\mathbf{R}(t + \Delta)_j &= \mathbf{R}(t)_j + \Delta \left(S^{-1}[\mathbf{R}]\mathbf{f_R}\right)_j \\
&\quad -T\Delta \sum_{i,k,l} S_{j,k}^{-1}[\mathbf{R}] \left(\partial_i S_{kl}[\mathbf{R}]\right) z_i(t) z_l(t) + \sqrt{2T\Delta} z_j(t) \\
&\langle z_i(t) z_j(t)\rangle = S_{i,j}^{-1}[\mathbf{R}(t)],
\end{aligned} \tag{40}$$

namely, it coincides with the Markov chain we have considered in the previous section up to order $O(\Delta)$ because one can substitute in Eq. (17) $[S(\mathbf{y}) - S(\mathbf{R})]_{kl}$ with its expansion in $\Delta$: $\sqrt{2T\Delta} \sum_i \partial_i S_{kl} z_i + O(\Delta)$.

Strictly speaking the rightmost equality in Eq. (39) is valid for the associated Fokker-Planck equation where one can substitute the correlator $\langle z_i(t - \Delta) z_l(t - \Delta)\rangle$ with the one $\langle z_i(t) z_l(t)\rangle$, clearly allowed because in this way only a negligible error $O(\Delta)$ is introduced.

We have therefore verified that the Markov chain in Eq. (17) is equivalent to the proposed one in Eq. (40) that can be more efficiently implemented while leading to the same Fokker-Planck equation for $\Delta \to 0$ and therefore to the same equilibrium distribution in Eq. (8).

## 3.2    Renormalization of the Target Temperature

In the case of an harmonic potential $V_H$ with equilibrium position $\mathbf{R}^{eq}$, as defined in Eq. (10), it is readily seen that for $\Delta = 1$, with a matrix $S = H$ independent of $\mathbf{R}$, the Markov chain of Eq. (37) simplifies to:

$$\mathbf{R}(t + \Delta) = \mathbf{R}^{eq} + \sqrt{2T}\mathbf{z}$$

$$\langle z_i z_j \rangle = H_{i,j}^{-1} \tag{41}$$

which corresponds to the direct sampling of the canonical distribution $\exp(-V_H/2T)$, namely, correlation time equal to one and temperature renormalized by a factor two. Thus, in the harmonic case, the present scheme provides a simple scaling of the simulated target temperature $T_{target}$, which turns out to be two times the nominal one $T$ for large time steps $\Delta = 1$ and $S = H$. This consideration suggests that it is possible to apply Eq. (37) and determine the target temperature of the simulation a posteriori as it is often done in the case of second-order Langevin dynamics, by measuring the average squared velocities of the particles. Unfortunately a direct estimation of the simulated temperature is rather difficult in the first-order Langevin dynamics, as the virial theorem usually provides a quite noisy estimate of this quantity and it is also difficult to apply in periodic systems.

## 3.3   Efficiency Gain in Controllable Models

In this section we break our discussion to apply and numerically demonstrate the efficiency of the method. We use different definitions for the matrix $S$ to prove the generality of our framework. In the first, low-dimensional example, the matrix $S$ is derived from geometrical considerations, while in the second case, a dense liquid of dimers interacting with a Lennard-Jones potential, we use a regularized version of the Hessian matrix. A third possibility, which can only be implemented in combination with a quantum Monte Carlo calculation of the forces, will be discussed in Sect. 3.5.

### 3.3.1   Rotating Spring on a Plane

We first consider a simple toy model, a rotating spring lying on a plane. The endpoint $(x, y)$ is subject to a radial harmonic potential of the form

$$U(x, y) = \frac{1}{2}k \left( \sqrt{x^2 + y^2} - a \right)^2 , \tag{42}$$

while being free to rotate around the origin. The configuration's space visited during the dynamics is a circular ring, whose radius is $a$ and width given by the (radial) thermal fluctuation. This is perhaps the simplest model where a strong decoupling of time scale, in this case the vibrational and rotational ones, is present.

Let us define the following matrix $G_\lambda$:

$$G_\lambda = \frac{1}{\lambda} \begin{pmatrix} \frac{x^2 + y^2\lambda}{x^2+y^2} & \frac{xy(1-\lambda)}{x^2+y^2} \\ \frac{xy(1-\lambda)}{x^2+y^2} & \frac{x^2\lambda+y^2}{x^2+y^2} \end{pmatrix} \tag{43}$$
**Fig. 1** Average potential energy as a function of the integration time step $\Delta$. Black points refer to the CFOLD (Eq. (1)), while red points to the improved dynamics (Eq. (37)) with nontrivial metric tensor $S = G_{\lambda=0.1}$, from Eq. (43). The red data series is obtained with the integration scheme of Eq. (37). We use the following parameters, $T = 0.01$, $k = 2$, $a = 1.4$. We see that the new approach greatly alleviates the time step error compared to the standard dynamics while maintaining a very similar rotational diffusion coefficient at fixed $\Delta$ (not shown). Solid lines represent linear fit of the respective data series

where $\lambda$ is a control parameter and $G$ reduces to the identity when $\lambda = 1$. It can be shown, following geometrical considerations, that, if $G_{\lambda}^{-1}$ multiplies the forces, it effectively reduces by a factor $\lambda$ the radial component of the associated displacement. Since this matrix is always positive definite, it represents a good candidate for the dynamics preconditioner. We therefore use $S = G_{\lambda}$ in Eq. (12), with $\lambda < 1$.

From Fig. 1 we see that the preconditioned Langevin dynamics, with nontrivial $S$, results in a better time step error, compared to the standard Langevin dynamics. This demonstrates also in a simple toy model that a large computational gain can be achieved by this framework. In particular the iterative scheme of Eq. (37) removes the time step bias almost completely.

### 3.3.2   A Lennard-Jones Molecular Liquid

The second model is much more realistic, where the force field arises from the following potential:

$$
V = V_{\text{mol}} + V_{LJ} = \sum_{[i,j]_{\text{mol}}}^{N} \frac{1}{2}k(r_{ij} - a_0)^2 + \sum_{[i \neq j]_{\text{mol}}}^{N} 4\epsilon_0 \left[ \left( \frac{\sigma_0}{r_{ij}} \right)^{12} - \left( \frac{\sigma_0}{r_{ij}} \right)^6 \right]
$$

(44)

where $N$ is the total number of atoms, $r_{ij}$ is the distance between atoms $i$ and $j$, and the symbols $[i, j]_{\text{mol}}([i \neq j]_{\text{mol}})$ indicate that the sum includes (excludes) atoms which belong to the same dimer. The force field parameters are chosen to mimic

the radial pair distribution of a dense molecular liquid. In the simulations we fixed $a_0 = 1.4$ a.u., to mimic the equilibrium bond length of the hydrogen molecule (which is nevertheless reduced to $\approx 1.38$ due to the intermolecular interactions), $\sigma_0 = 2$ and $k = 10$, $\epsilon_0 = 0.03$. We set the temperature $T = 0.1$ (with $k_B = 1$) and a particle density given by 0.07 a.u.$^{-3}$. We use periodic boundary conditions.

This dense liquid of dimers is strongly nonharmonic; therefore, its Hessian is not positive definite for any particle configuration. We regularize the Hessian in the following way: we first decompose the $H$ matrix into $H = Q \Lambda Q^T$, where $Q$ contains the eigenvectors (in columns) of $H$ and $\Lambda$ is the diagonal matrix containing the eigenvalues $\lambda_i$, with $i = 1, \cdots, 3N$. Then we regularize the eigenvalues $\lambda_i$ of the Hessian using a smooth function, such that $\lambda_{reg} = u(\lambda)$, with

$$u(\lambda) = \frac{1}{\delta} n((\lambda - \varepsilon)/\tau) + \lambda(1 - n((\lambda - \varepsilon)/\tau)), \qquad (45)$$

where $n(x) = 1/(1+e^x)$ is the Fermi function. This works better than simply cutting off the eigenvalues smaller than $\varepsilon$, because in such a case, the finite difference evaluation of the derivative of $S$ in Eq. (37) could be strongly biased. These parameters are system dependent. We choose $\varepsilon = 1$, $\tau = 2/\delta$. After this procedure we can use this matrix in the preconditioned Langevin equation (Eq. (37)). We notice that much better choices may exist for the hessian regularization.

We again test the time step bias of the different dynamics. We plot in Fig. 2 the results as a function of the dimensionless parameter $\Delta/\tau_{corr}$, where $\tau_{corr}$ is the largest correlation time that can be measured for this system. In our case, one

**Fig. 2** Average potential energy of the MD simulations as a function of the integration time step $\Delta$, renormalized with the measured autocorrelation time $\tau_{corr}$. The system consists of 24 particle dimers in a box, interacting via Eq. (44). We compare the CFOLD integrator (black) with the proposed one, by using Eq. (37) (red), using the regularized Hessian matrix. Solid lines represent quadratic fit of the respective data series

of the slowly varying processes is the autocorrelation time of the intermolecular component, $V_{LJ}$, of the total potential. We measure this quantity for the different dynamics, to have an unbiased estimation of the efficiency gain.

## 3.4    Nuclear Quantum Effects

As it is well known, it is possible to simulate nuclear quantum effects at finite temperature by using the classical mapping to a system of $P$ replicas – usually called beads – of the classical system, provided we make two basic assumptions: (i) the temperature is small but not too small that the statistics of nuclei becomes important; (ii) we can use the Born-Oppenheimer approximation in order to decouple the nuclear motion from the electronic one (Ceriotti et al. 2010; Tuckerman et al. 1993). The resulting classical potential, at rescaled temperature $T_P = T \times P$, is defined in terms of the $p = 3NP$ degrees of freedom $\mathbf{R} = \{\mathbf{r}_i^a\}$, for $1 \leq i \leq N$ and $0 \leq a \leq P - 1$, with periodic boundary conditions, i.e., $\mathbf{r}_i^P = \mathbf{r}_i^0$, and can be written as follows:

$$V_P(\mathbf{R}) = \sum_{i=1}^{N} \sum_{a=0}^{P-1} V(\mathbf{r}_i^a) + \frac{m_i T_P^2}{2} \left( \mathbf{r}_i^a - \mathbf{r}_i^{a+1} \right)^2 \tag{46}$$

where $m_i$ is the mass of the $i$th particle in units $k_B = \hbar = 1$. The Hamiltonian (46) describes a classical system of $PN$ particles that are interacting with an Hessian matrix, whose leading large $P$ term do not couple the $3N$ spatial coordinates $\nu, \mu$:

$$K_{a\nu,b\mu} = \delta_{\nu,\mu} \frac{m_i T_P^2}{2} (2\delta_{a,b} - \delta_{a+1,b} - \delta_{b+1,a}) + \frac{1}{2}\delta_{a,b} \left[ \partial_\nu \partial_\mu V(\mathbf{R}^a) \right] \tag{47}$$

Therefore if we neglect the less relevant terms inside the square brackets, coming from the expansion of $V$, this matrix can be readily diagonalized by a Fourier transform, with plane wave eigenvectors $q_{\omega_n}^\nu(a) = C_{\omega_n} \exp(i\omega_n a)$ with $\omega_n = \frac{2\pi}{P}n$, $n = 0, 1, \cdots P - 1$, $C_{\omega_n}$ appropriate constants and eigenvalues $m_i T_P^2(1 - \cos \omega_n)$. The condition number of the above matrix can be readily evaluated and is given by $K_{\text{cond}} = P^2/\pi$ because the maximum eigenvalue is obtained for $\omega_n = \pi$ and the minimum non-zero one for $\omega_n = \frac{2\pi}{P}$. Thus it is clear that it is possible to accelerate the dynamics by a factor $\simeq P^2$ using for $S$ the harmonic matrix given in Eq. (47), with a reasonable approximation for the term depending on $V$ because this term is almost negligible, i.e., finite, for $P \rightarrow \infty$. We remark therefore that, also for the simulation of nuclear quantum effects, it is extremely important to use an appropriate acceleration matrix in order to avoid extremely large correlation times.

## 3.5     Accelerated Molecular Dynamics Within QMC Applications

This section concerns the specific application of this LDE in QMC. While Eq. (37) can be applied already as it is when using exactly computed ionic forces $\mathbf{f}$ (from either force-fields or DFT based calculations), one additional step is required in the case of QMC, where forces are given with a certain statistical error.

In the simplest variational quantum Monte Carlo approach (Attaccalite and Sorella 2008; Mazzola et al. 2014; Zen et al. 2015) (VMC), it is possible to perform finite temperature ab initio simulation of classical particles interacting via the Born-Oppenheimer energy surface, through a quantum mechanical variational optimization of a correlated electronic wave function $\Psi_{\alpha}$, which contains several parameters $\{\alpha\}$:

$$V(\mathbf{R}) = \text{Min}_{\alpha} \frac{\langle \Psi_{\alpha} | H_{\mathbf{R}} | \Psi_{\alpha} \rangle}{\langle \Psi_{\alpha} | \Psi_{\alpha} \rangle} \tag{48}$$

where $H_{\mathbf{R}}$ is the full-many body electronic Hamiltonian with Coulomb interaction, at fixed atomic positions. Being a statistical method, the forces are affected by a finite statistical error in QMC (Attaccalite and Sorella 2008) and a very useful matrix naturally emerges – the covariance matrix – describing the correlations between the force noise components:

$$Cov(\mathbf{f}) = \langle\langle f_i(\mathbf{R}) f_j(\mathbf{R}) \rangle\rangle - \langle\langle f_i(\mathbf{R}) \rangle\rangle\langle\langle f_j(\mathbf{R}) \rangle\rangle \tag{49}$$

where $\langle\langle \ \rangle\rangle$ indicates a statistical average over a given number of samples at fixed atomic positions.

In this QMC approach, we use $S = Cov(f)$, where $Cov(f)$ is the correlation matrix corresponding to the statistical fluctuations – i.e., the error bars – of the nuclear forces. In this case it is also very simple to correct for the extra noise given by the QMC forces (Luo et al. 2014). This is achieved in a very simple way, just by changing the temperature $T$ used in the dynamics for the correct simulation at a given target temperature $T_{\text{target}}$, simply as follows:

$$2T\Delta = 2T_{\text{target}}\Delta - \Delta^2. \tag{50}$$

that is possible for $\Delta < 2T_{\text{target}}$ (notice that for this particular choice of $S$ the time of the dynamics has the unusual dimension of an energy).

In order to show that this technique is extremely convenient, even within a computationally demanding method such as QMC, we present in Fig. 3 a molecular dynamics simulation of a mixture containing 118 hydrogens and 10 helium, at Jupiter interior conditions, with an accurate basis set. It is remarkable that, within the same simulation, different phases can be reached in a short simulation time, clearly showing the efficiency of the method and its capability to identify the metal-insulator transition/crossover which is of paramount importance for the understanding of the structure of giant planets, such as Jupiter and Saturn.
**Fig. 3** Snapshot of an H-He mixture simulation, a NVE molecular dynamics driven by true QMC nuclear forces (Mazzola et al. 2018). The cyan, yellow, and red colors represent the 108 H, 10 He, and H-molecule bonds (H2), respectively. The temperature is 6000 K and the density 0.53 g/cm$^3$ (P = 54 Gpa), i.e., near to the liquid-liquid metal-insulator transition. The occurrence of these fluctuations between qualitatively different phases indicates that a metal-insulator insulator transition or at least a sharp crossover could occur within this pressure range. This has a clear impact for the equation of state of large planets, such as Jupiter, and is important in view of the recent data reported from the NASA JUNO mission

## 4    Conclusions

Within the framework of first-order Langevin dynamics, it is possible to define a method that, for classical dynamics, solves the problem of working with very different time scales, by using an acceleration matrix S, suitably chosen, that generates an efficient dynamics where all the time scales become equal. Roughly speaking in the period when a fast molecular oscillation occurs also a long distance rearrangement of the electronic structure takes place (e.g., weak molecular binding). From the theoretical side, it is shown that, with the present method, if compared with the standard Langevin dynamics without S, a gain in efficiency of the order of the condition number K of the Hessian matrix (or the square of the condition number of the dynamical matrix) is achieved at least at low temperatures where the harmonic approximation holds. Indeed, provided S is chosen to be equal to the Hessian matrix, the proposed algorithm generates essentially an independent configuration for each step of molecular dynamics, as the time step $\Delta$ can be as large as the correlation time, short and common for all energy scales.

This gain in efficiency is remarkable even if compared with state-of-the-art second-order Newtonian dynamics (Ceriotti et al. 2009; Mouhat et al. 2017) because, in the latter cases, only a gain of order K is possible with present algorithms. Considering that $K$ can be as large as 100 in the water dimer and is typically growing with the system size, the potential of this method is easily understood. For a non-molecular solid, the matrix S can be chosen independent from the atomic positions, and in this case the method coincides with the standard method of acceleration (Parisi 1984). The important result of this work is that the dependence of the matrix S from the atomic positions can be taken formally into account at no cost. This is extremely important because, even at very low temperatures, there exist instances of solids where the molecules do not freeze (therefore the elastic constant matrix K depends explicitly on the instantaneous

orientation of the molecules). A simple example is the low-pressure phase I of hydrogen, which consists of freely rotating H2 molecules centered on a hexagonal close-packed lattice (Loubeyre et al. 1996). This is indeed the generic case at finite temperature, as, for instance, in liquid water, it is impossible to speed up the molecular dynamics without considering, in the acceleration matrix S, the orientation of all the water molecules, because their mutual interaction strongly depends on the hydrogen bonds network. It would be extremely interesting to apply our technique within DFT because it is well known that extremely long simulations are necessary to obtain reliable equilibrium properties in water, the autocorrelation time for Newtonian MD with stochastic velocity rescaling thermostat being around 1 ps (Grossman et al. 2004; Dawson and Gygi 2018). In this case the best choice for S has not been determined yet, but it is likely that, by taking for S a simple Hessian corresponding to independent water molecules, a good speed up should be achieved. So far this technique has been implemented within the ab initio molecular dynamics tool provided in the TurboRVB QMC package and significative performances have been achieved in several systems, from nanotubes (Varsano et al. 2017) to hydrogen-helium mixtures (Mazzola et al. 2018) and structural optimization of graphene (Sorella et al. 2018), but several other applications are possible, especially considering that this useful and simple scheme can be applied even within more conventional ab initio simulation methods based on DFT. It would be also extremely important to generalize this technique within the second-order Newton dynamics, because the time has clear physical meaning in this case. Indeed, the generalization of the acceleration within the Newtonian dynamics with friction has not been carried out so far, and this should be worthwhile for the future development of the method. In principle, with this technique, one could carry out ab initio molecular dynamics, where only the longest, more interesting, time scales remain meaningful, all the other being rescaled.

**Abstract**

Metadynamics is an enhanced sampling algorithm in which the normal evolution of the system is biased by a history-dependent potential constructed as a sum of Gaussians centered along the trajectory followed by a suitably chosen set of collective variables. The sum of Gaussians forces the system to escape from local free energy minima and is used to iteratively build an estimator of the free energy. This original idea has been developed and improved over the years in several variants, which nowadays allow addressing in a unified framework some of the most important tasks of molecular simulations: computing the free energy as a function of the collective variables, accelerating rare events, and estimating unbiased kinetic rate constants. This chapter provides a survey of the many formulations of metadynamics with an emphasis on the underlying theoretical concepts and some hints on the appropriate manner of using this approach for solving complicated real-world problems.

## 1    Introduction

The metadynamics method was introduced in 2002 (Laio and Parrinello 2002), and it has rapidly become popular for the study of thermodynamics and kinetics in molecular systems that are hard to sample even with the best available computing resources. This algorithm, like umbrella sampling, requires the preliminary identification of a set of collective variables (CVs) that are assumed to describe the process of interest. A bias depending on these CVs is then constructed iteratively and dynamically as a sum of Gaussians centered along the trajectory followed by the CVs. The longer the dynamics is continued, the more Gaussians are added. Therefore, the bias is time dependent, and it never stops changing. These Gaussians discourage the system from revisiting the same spot in CV space and encourage an efficient exploration of the free energy surface. Indeed, if the dynamics is started in a free energy minimum, the Gaussian potentials accumulate and fill this minimum, until the system moves to a close-by free energy minimum. This allows the system to migrate from well to well. In the original non-tempered form of metadynamics, when all the wells are filled with Gaussians, the dynamics in the CV space becomes diffusive, and the bias potential of metadynamics resembles the ideal bias of umbrella sampling, namely, the negative of the free energy.

Biasing the dynamics with Gaussians is an idea that was introduced well before the 2002 paper. The taboo search method (Cvijovic and Klinowski 1995) and, in the context of molecular dynamics, the local elevation method (Huber et al. 1994) are based on the same idea. Also the idea of using a history-dependent bias to estimate thermodynamic quantities, in particular the density of states, was introduced before, in the Wang and Landau algorithm (Wang and Landau 2001). The main novelty introduced by metadynamics is exploiting these ideas together with dimensionality reduction, in which the dynamics is considered important and biased only in the CV space, in the spirit of the work by Kevrekidis (Theodoropoulos et al. 2000;

Kevrekidis et al. 2004). In practical terms, this allows using the framework of taboo search for biasing efficiently more than one CV at the same time, still obtaining a meaningful free energy estimate. In 2002, the most popular approach for computing the free energy was thermodynamic integration (Carter et al. 1989), which allows using only one CV at a time. The possibility offered by metadynamics of obtaining "on-the-fly" free energy landscapes in two or three dimensions was extremely important in the field and is possibly one of the main reasons of the success of the algorithm.

A second important advantage of metadynamics is that the method can be proficiently used also for accelerating rare events and studying the reaction mechanism of complex processes. Since the history-dependent potential iteratively compensates the underlying free energy, a system evolved with metadynamics tends to escape from any free energy minimum via the lowest free energy saddle point. This makes metadynamics a rather flexible tool that can be used not only to compute efficiently the free energy but also to explore new reaction pathways, accelerate the observation of rare events, and even compute kinetic rate constants in a relatively straightforward manner. If the CVs are chosen sensibly, the system will quickly find its way over the lowest free energy saddle point and evolve over the next minimum as it would eventually do in a very long molecular dynamics simulation. This flexibility is reflected in the numerous contexts in which this method has been applied so far, including solid state and material science, crystal structure prediction, biophysics and chemistry. A final advantage of metadynamics is its inherent self-diagnostic capability. Indeed, the dynamics of the CVs under the action of the bias can provide useful signs to alert user whether the reconstructed free energy/kinetics can be trusted or not.

The key assumption of the method is that the time-dependent potential defined by the sum of Gaussians deposited up to time $t$ provides an unbiased estimate of the free energy in the region explored during the dynamics. This property, which does not follow from any ordinary thermodynamic identity, such as umbrella sampling (Patey and Valleau 1975), was postulated on a heuristic basis in Laio and Parrinello (2002) and afterward verified empirically in several systems of increasing complexity. Successively (Bussi et al. 2006b), it was shown that this property derives from rather general principles and can be demonstrated rigorously for systems in which the dynamics of the CVs is adiabatically separated from the other degrees of freedom. More recently, a modified version of the algorithm was developed in which convergence can be proved explicitly and rigorously for a generic dynamics (Barducci et al. 2008). In this approach, called well-tempered metadynamics, the rate at which the history-dependent potential is modified gradually decreases during the simulation according to a schedule that allows fluctuations in the potential to be damped out. This is done by introducing an extra parameter that controls this damping and that can be used to interpolate between unbiased molecular dynamics and non-tempered metadynamics. Notably, the modified algorithm only samples a low free energy portion of the CV space and in the long limit corresponds to altering the temperature of the biased CVs alone. A rigorous proof of convergence of the algorithm in this formulation is presented in Dama et al. (2014).

## 2    The Basic Algorithm

Consider a system described by a set of coordinates $x$ and a potential $V(x)$ evolving under the action of a dynamics, which could be, for instance, Langevin, Newtonian (under the action of a thermostat), or Monte Carlo, whose equilibrium distribution is canonical at a temperature $T$. The set of coordinates $x$ may include ordinary atomic positions, but also electronic coordinates, as in Car-Parrinello molecular dynamics (Car and Parrinello 1985), or any other auxiliary variables. We aim at exploring the properties of the system as a function of a finite number of CVs $S_\alpha(x)$, $\alpha = 1 \ldots d$ where $d$ is a small number. The CVs can be any explicit function of $x$ such as, for example, a distance, a coordination number, or the gyration radius of a subset of atoms. The free energy $F(s)$ is given by

$$F(s) = -\frac{1}{\beta} \log \left( \int dx \exp\left(-\beta V(x)\right) \delta\left(s - S(x)\right) \right). \tag{1}$$

where $\beta = \frac{1}{k_B T}$ is the inverse temperature. In Eq. 1 (and in the following), capital $S$ is used for denoting the function of the coordinates $S(x)$, while lower case $s$ is used for denoting the value of the CVs.

In the simplest molecular dynamics implementation of metadynamics, the external potential acting on the system at time $t$ is given by

$$V_G(S(x), t) = w \sum_{\substack{t' = \tau_G, 2\tau_G, \cdots \\ t' < t}} \exp\left( -\frac{\left(S(x) - s\left(t'\right)\right)^2}{2\delta s^2} \right) \tag{2}$$

where $s(t) = S(x(t))$ is the value taken by the CV at time $t$. This specific variant of the algorithm is referred to as "direct metadynamics," to distinguish it from previous variants of the algorithm where the CV dynamics was performed separately from that of the rest of the system either using time-dependent restraints (Laio and Parrinello 2002) or an extended Lagrangian formulation (Iannuzzi et al. 2003). Three parameters enter the definition of the $V_G$:

1. The Gaussian height $w$.
2. The Gaussian width $\delta s$.
3. The frequency $\tau_G$ at which the Gaussians are added.

The first two parameters define the shape of the extra bias added at time intervals of $\tau_G$. As it will be discussed in detail in the following, if the Gaussians are large, the free energy surface will be explored at a fast pace, but the reconstructed profile will be characterized by large fluctuations.

As an example, consider the system in Fig. 1. Metadynamics is performed on the one-dimensional potential with three minima represented in the lower panel.

The system evolves through an overdamped Langevin equation (Risken 1989) with time step 1, diffusion coefficient D = 0.005, and at a temperature of 1. The dynamics is started from the central minimum. Without any bias, the system would escape from this minimum with low probability, since the barriers separating it from the other minima are large with respect to the thermal energy. The upper panel shows the trajectory followed by the system under the action of a metadynamics bias. A Gaussian of width $\delta s = 0.4$ and height $w = 0.3$ is added every 300 steps. After ~20 Gaussians, the central minimum is filled, and the system escapes from the well through the lowest saddle point (blue lines in Fig. 1). The second well is filled after ~70 Gaussians (red lines). The second highest saddle point is reached after ~100 Gaussians, and the full free energy surface is filled with a total of ~180 Gaussians (orange lines). After that time, the motion of the system becomes diffusive and unbound in the region of CV space between ~−5 and 5. The metadynamics potential $V_G$ (Eq. 2) is represented at different times in Fig. 1, middle panel. The lower panel of Fig. 1 reports the sum of $V_G$ and of the external potential (thick black line). Clearly, as the simulation proceeds, $V_G$ iteratively compensates the underlying potential.

This provides a hint of the two different manners in which metadynamics can be used:

- It can be used to escape free energy minima (Laio and Parrinello 2002), namely, to find the lowest free energy saddle point out of a free energy minimum. In this case, metadynamics could be stopped as soon as the walker exits from the minimum and starts exploring a new free energy minimum. In Fig. 1, this happens after ~20 Gaussians are placed.
- It can be used to explore a region in the CV space including two or more free energy minima and reconstruct the free energy surface. In this case, the simulation could be stopped when the motion of the walker becomes diffusive in this region. In Fig. 1, this happens after ~180 Gaussians are placed.

The basic assumption of metadynamics is that $V_G(s, t)$ defined in Eq. 2 after a sufficiently long time provides an estimate of the underlying free energy:

$$V_G(s, t) \sim -F(s) + C(t). \tag{3}$$

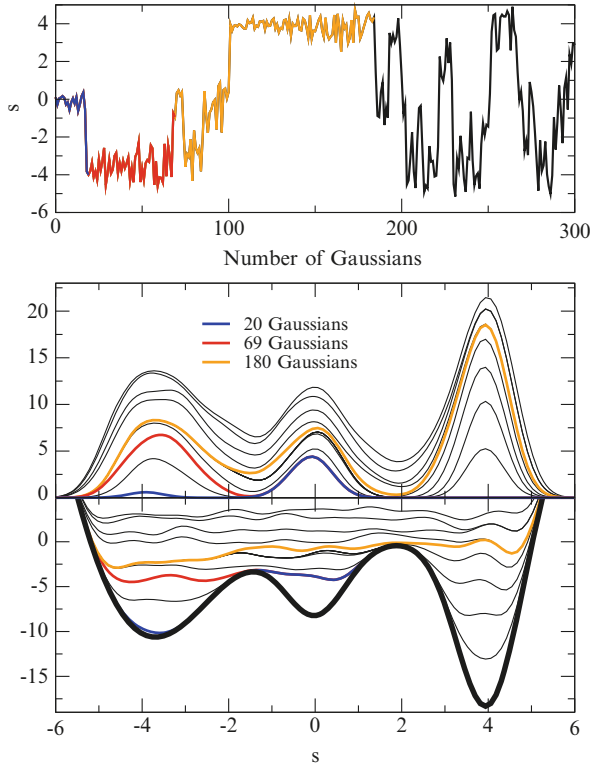
where $C(t)$ depends on time but not on the collective variables $s$. This equation states that an equilibrium quantity, namely, the free energy, can be estimated by a non-equilibrium dynamics in which the bias potential is changed continuously, every time a new Gaussian is added. Equation 3 was postulated heuristically in Laio and Parrinello (2002), based on the behavior observed in model systems. For instance, in the example of Fig. 1, it is clear that the sum of $F$ and $V_G$ after ~180 Gaussians is approximately a constant. For an atomistic system in which the potential depends on several coordinates, the free energy is the result of a complex dimensional reduction; Eq. 3 can be qualitatively understood in the limit of very small $w$. In this limit, $V_G(s, t)$ varies slowly, and the probability to


**Fig. 1** Upper panel: trajectory of a one-dimensional system evolved by a Langevin equation on the three-minima potential represented in the lower panel. The dynamics is biased with a metadynamics potential $V_G$ as defined by Eq. 2. The parameters are $\delta s = 0.4$, $w = 0.3$, and $\tau_G = 300$. Middle panel: time evolution of the metadynamics bias potential $V_G$. Blue line, $V_G$ as when the first minimum is filled and the system escapes to the second minimum; red line, $V_G$ as when also the second minimum is filled; orange line, $V_G$ when the entire profile is filled and the dynamics becomes diffusive. Lower panel: time evolution of the sum of the metadynamics potential $V_G$ and of the external potential, represented as a thick black line. (After Laio and Gervasio 2008)

observe $s$ is always approximately proportional to $\exp\left[-\frac{1}{T}\left(F(s) + V_G(s,t)\right)\right]$. If the function $F(s) + V_G(s,t)$ has some local minimum, $s$ will preferentially be localized in this minimum. It is therefore likely that some Gaussians will be added there until the minimum is filled. Let us consider instead the case in which $F(s) + C(t) \sim -V_G(s,t)$ in a region $\Omega(s)$. The probability will be approximately constant in this region, and the new Gaussians will be placed in a random location. Hence, if $w \to 0$, the only corrugations in the free energy that are not flattened by the dynamics will be of the order of the size of the newly added Gaussians. If the dynamics is continued keeping the value of $w$ fixed, more and more Gaussians will be added, and corrugations of a size of the order of $w$ will appear in different locations.

From this qualitative discussion, we can draw a few important observations, which, as we will show, are at the basis of all the approaches which allow obtaining from metadynamics an estimate of the free energy.

- The bias potential defined in Eq. 2 at finite $w$ provides only an approximate estimate of the free energy, since every new Gaussian adds a corrugation to the profile.
- When the dynamics is diffusive in a region of CV space, the corrugations appear randomly in different positions (see Fig. 1). A more accurate estimate of the free energy can be obtained by taking the time average of the bias potential. This manner of estimating the free energy will be discussed in Sect. 3.
- An alternative manner of obtaining an accurate estimate of the free energy is reducing iteratively the value of $w$, in such a way that the size of the corrugations becomes smaller and smaller. In Sect. 4, we will show that this simple idea can be embedded in a powerful conceptual framework, called well-tempered metadynamics, which allows estimating the free energy *exactly*.

## 3    The Bias Potential as a Dynamic Variable

We first describe a procedure for estimating the free energy based on taking the time average of the bias potential defined in Eq. 2. In order to understand in more detail why this can be done, let us consider the case in which the system evolves following an overdamped Langevin dynamics:

$$dx = -\beta D \nabla V dt + \sqrt{2D} dW(t) \tag{4}$$

where $dW(t)$ is a (possibly multivariate) Wiener process and $D$ is the diffusion coefficient. The evolution of this system under the action of metadynamics is modeled adding a history-dependent term:

$$dx = -\beta D \nabla \left( V(x) + \int_0^t dt' g\left( S(x), s(t') \right) \right) dt + \sqrt{2D} dW(t) \tag{5}$$

where $g(s, s')$ is a kernel that specifies how fast the metadynamics potential changes. In the normal implementation, $g$ is a Gaussian of width $\delta s$ and height $w/\tau_G$ (see Eq. 2):

$$g(s, s') = \frac{w}{\tau_G} \exp\left( -\frac{(s - s')^2}{2\delta s^2} \right)$$

Equation 5 describes a non-Markovian process in coordinate space. In fact, the forces acting on the CVs depend explicitly on their history. Due to this non-Markovian nature, it is not clear if, and in which sense, the system can reach a

stationary state. In Bussi et al. (2006b) a formalism was introduced which allows to map this history-dependent evolution into a Markovian process in which the history-dependent potential itself is considered a dynamic variable. Indeed equation 5 can be written as

$$dV_G\,(s,t) = g\,(s - s\,(t))\,dt \tag{6}$$

$$dx = -\beta D\nabla\left(V(x) + \int ds\delta(s - S(x))V_G(s,t)\right)dt + \sqrt{2D}dW(t) \tag{7}$$

These equations are fully Markovian, i.e., the state of the system at time $t + dt$ depends only on the state of the system at time $t$, *if one assumes that the state of the system is not defined by the coordinates x alone but by the coordinates and the bias potential $V_G\,(s)$.* In other words, the bias potential should be considered a *dynamic variable*, whose evolution is coupled to the evolution of the coordinates as implicit in Eq. 7. Under the action of the dynamics, the configuration of the system $(x, V_G)$ follows a trajectory and samples a probability distribution $P\,(x, [V_G])$ where the $P$ is an ordinary function of the coordinates $x$ and a functional of $V_G\,(s)$.

In Bussi et al. (2006b), it was shown that if the dynamics of the CVs is adiabatically decoupled from the dynamics of the other coordinates, in the limit of long time $P$ converges to a Gaussian in functional space, centered on the negative of the free energy $-F\,(s)$. The expected deviation of $V_G\,(s,t)$ from $-F\,(s) + C(t)$, $\varepsilon = \sqrt{\langle(V_G\,(s) + F\,(s))^2\rangle}$, can be estimated explicitly. The exact expression of the error is rather complex and depends on the dimensionality and on the boundary conditions in CV space. Approximately, for a one-dimensional metadynamics in a region of size $S$ (Laio et al. 2005),

$$\varepsilon \sim C_d\sqrt{\frac{Sw\delta s}{\beta D\tau_G}} \tag{8}$$

where $C_d$ is a constant that depends only on the dimensionality. Thus, $V_G$ deviates from $-F\,(s) + C$ by fluctuations that grow with the square root of the Gaussian height $w$, with the Gaussian width $\delta s$, and with the inverse of the diffusion coefficient $D$.

This is illustrated in Fig. 2 in which the results obtained integrating numerically Eq. 5 for four different profiles $F\,(s)$ are shown. The average value of $V_G\,(s,t) + F\,(s)$ is represented as a continuous line in all the four profiles and is constant in all the explored region. The standard deviation of $V_G$, approximately estimated by Eq. 8, is independent on the free energy profile.

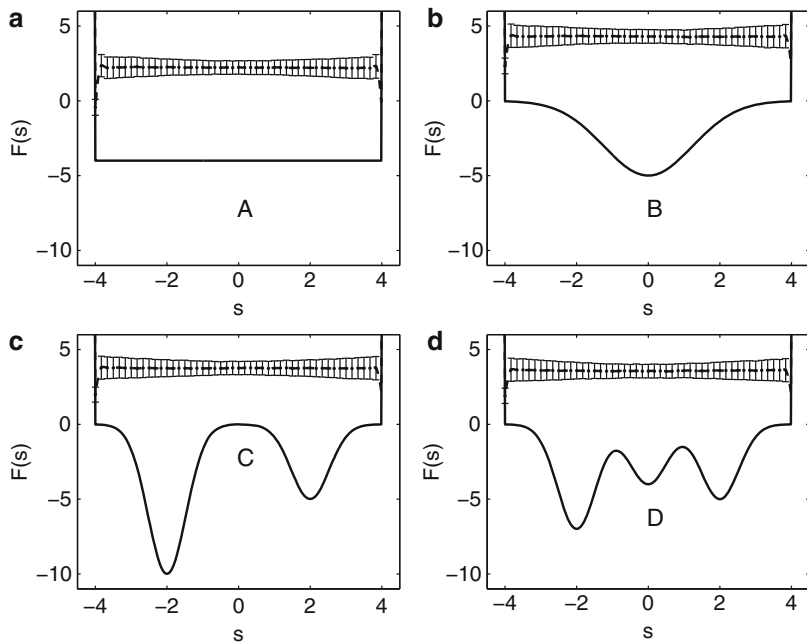
These examples illustrate clearly that, if metadynamics is used to compute the free energy, the history-dependent potential at a single time $V_G\,(s,t)$ *should not be used as a free energy estimator*, even if the dynamics of the CVs is adiabatically decoupled. Indeed, $V_G$ is by construction affected by statistical errors. However, as suggested by Eq. 7, $V_G$ should be considered a dynamics variables, and all the


**Fig. 2** Metadynamics results for four different free energy profiles. A, $F(s) = -4$; B, $F(s) = -5\exp\left(-\left(\frac{s}{1.75}\right)^2\right)$; C, $F(s) = -5\exp\left(-\left(\frac{s-2}{0.75}\right)^2\right) - 10\exp\left(-\left(\frac{s+2}{0.75}\right)^2\right)$; D, $F(s) = -5\exp\left(-\left(\frac{s-2}{0.75}\right)^2\right) - 4\exp\left(-\left(\frac{s}{0.75}\right)^2\right) - 7\exp\left(-\left(\frac{s+2}{0.75}\right)^2\right)$. The average $\langle F(s) + V_G(s, t)\rangle$ computed over 1000 independent trajectories is represented as a dashed line, with the error bar estimated as standard deviations. The metadynamics parameters are $\delta s = 0.1$ and $w/\tau_G = 4 \times 10^{-4}$. We also have $D = 0.0005$ and $T = 1$, and the CVs satisfy reflecting boundary conditions in a region of length 8. (After Laio et al. 2005)

profiles $V_G(s, t)$ are equally reliable estimates of the free energy up to a constant. Thus, as first proposed in Micheletti et al. (2004), after the entire free energy landscape has been filled, the best possible estimate of the free energy is the time average of all the profiles. More precisely, if $t_F$ is the time at which the CV starts diffusing in all the relevant region (possibly fixed by the appropriate boundary conditions, see Sect. 3.1) and $t_{\text{tot}}$ is the total simulation time, the best estimate of the free energy is

$$- \bar{V}_G(s) = -\frac{1}{t_{\text{tot}} - t_F} \int_{t_F}^{t_{\text{tot}}} V_G(s, t)\, dt \qquad (9)$$

Similarly to an average of a standard observable in ordinary molecular dynamics or Monte Carlo, the standard deviation of $-\bar{V}_G$ from the free energy decays to zero with the square root of $t_{\text{tot}} - t_F$. The prefactor is determined by the autocorrelation time $\tau_{\text{corr}}$ of the history-dependent potential:

$$\epsilon^2(s) = \left( \bar{V}_G(s) + F(s) \right)^2 \sim \frac{\tau_{\text{corr}}}{t_{\text{tot}} - t_F} \qquad (10)$$

The error on the free energy estimated by Eq. 9 is conveniently evaluated by block analysis. For example, using $N_B$ blocks, one divides the time interval $[t_F, t_{\text{tot}}]$ in $N_B$ nonoverlapping intervals of the same size. One then computes the average of $V_G(s, t)$ restricted to each block. Since the free energy is always defined modulo an irrelevant constant, one chooses this constant in such a way that the average on the domain in which metadynamics is performed of all the block averages is equal to zero. Denoting by $\bar{V}_G^\alpha$ with $\alpha = 1, \dots, N_B$ the averages on the blocks, the error is then estimated as

$$\epsilon^2(s) = \frac{1}{N_B^2} \sum_{\alpha=1}^{N_B} (\bar{V}_G^\alpha(s) - \bar{V}_G(s))^2 \qquad (11)$$

Like in normal block analysis, one should then repeat this calculation with different $N_B$-s and consider the error estimate meaningful if the result is approximately invariant with respect to this choice.

It is important to remark that Eqs. 9 and 10 have been demonstrated rigorously only if the dynamics is adiabatically decoupled in the CVs (Bussi et al. 2006b). However, these equations have been proved to hold numerically in systems in which this condition is violated, in particular a Ising model in which metadynamics is performed using as a CV the magnetization (Crespo et al. 2010) and a peptide in water solution (Marinelli et al. 2009). We are not aware of a molecular system in which a systematic deviation of the estimator in Eq. 9 from the free energy has been reported.

## 3.1    Boundary Conditions

In order to take the average over different profiles in Eq. 9, it is necessary that the dynamics of the CV is bound in a finite region of CV space, in such a way that the history-dependent potential can reach a stationary state. This can be achieved by restraining the dynamics in the region of choice by a suitable external potential. For example, if one wants to estimate the free energy profile for a distance smaller than 5 Å, one can add a harmonic potential acting on the CV when it becomes larger than 5. However, introducing a potential restraining the dynamics in a finite region is not sufficient for reaching a stationary state for the dynamics of $V_G$. Indeed, metadynamics simulations typically take advantage of a finite Gaussian width to fill the free energy surface quickly. Adding more and more Gaussians can induce systematic errors at the boundaries of CV space (whether natural or artificially imposed): these errors are due to the fact that a sum of finite width Gaussians cannot accurately reproduce the free energy profile where the derivative of the free energy is very high (or infinite, in the case of a sharp boundary). At the beginning of the

simulation, these errors are small and are usually overlooked, but at long times they can become important, preventing the dynamics from reaching a stationary condition. These systematic errors close to the CV boundary can be eliminated in at least three different manners.

The first (and simplest) procedure consists in setting the force deriving from the history-dependent potential equal to zero beyond the boundary (Baftizadeh et al. 2012). If, for example, a restraining potential is active for $s > s_w$, one still updates the history-dependent potential according to Eq. 2, but one then sets to zero the forces coming from $V_G$ if the system is beyond the boundary. In this way, the force on the system for $s < s_w$ comes from metadynamics and molecular interactions. For $s > s_w$, it comes from the restraining potential and the molecular interactions. Using this procedure, the history-dependent potential $V_G$ reaches a stationary state, and its time average in Eq. 9 becomes meaningful. This average value converges to the negative of the free energy everywhere, except in a region close to $s_w$, of size of the order of the Gaussian width $\delta s$. This procedure is simple and efficient, but it works only if the CV is one dimensional.

Another procedure for correcting the systematic errors that is accurate even close to the boundary is described in Crespo et al. (2010). In this procedure, if the system is in $s$, close to a boundary located in $s_w$, one extra Gaussian is added outside the boundary, in a position $2s_w - s$, specular to $s$ with respect to the boundary. The scope of this extra Gaussian is iteratively imposing that, in a suitably interval around $s_w$,

$$V_G(s_w - s, t) \approx 2V_G(s_w, t) - V_G(s_w + s, t) \tag{12}$$

This property ensures that, at stationary conditions, the history-dependent potential is approximately linear close to the boundary, but it does not impose the value of its derivative, which is iteratively determined by the thermodynamic bias. In practice, this condition is implemented as follows. If $|s - s_w| < \chi$, the additional Gaussian has a height $w$. $\chi$ is a free parameter that is normally chosen equal to the Gaussian width. If $|s - s_w| > \chi$, the height of the extra Gaussian is given by

$$(V_G(s_w - s, t) - 2V_G(s_w, t) + V_G(s_w + s, t)) \, y(s_w - s) \tag{13}$$

where the function $y(x) = \left(1 + \left(\frac{s_w - s}{4\chi}\right)^{10}\right)^{-1}$ is approximately one for $x < 4\chi$ and goes to zero for $x > 4\chi$. This ensures that $V_G$ goes smoothly to zero in the unphysical region. The procedure can be straightforwardly generalized to multidimensional CVs, but it leads to small systematic error at points near the joint boundaries of multiple CVs (Michael and de Pablo 2013).

A third approach for correcting the systematic errors at the boundaries was introduced in Michael and de Pablo (2013) and is possibly the most general, since it works in multiple dimensions and in domains of any shape. Consider a metadynamics performed in a finite domain $\Omega$ in arbitrarily many dimensions. The idea is modifying the Gaussian form of the bias potential in such a way

that, when the dynamics is at convergence, adding a new bias potential does not alter on average the free energy estimator. When metadynamics is at convergence in the region $\Omega$, the probability of observing the system in a point $s \in \Omega$ is $P_{\mathrm{conv}}(s) = 1/V_{\Omega} = 1/\int_{\Omega} ds$. One possible form of bias potential satisfying this property is

$$\tilde{g}(s, s') = w \frac{g(s - s')V_{\Omega}}{\int_{\Omega} ds' g(s - s')} \tag{14}$$

where $g(s - s') = \exp\left(-\frac{(s-s')^2}{2\delta s^2}\right)$. Indeed, it is straightforward to prove that $\int_{\Omega} ds' P_{\mathrm{conv}}(s')\tilde{g}(s, s') = w$ for all the possible choices of $s$. This condition automatically ensures that the bias potential becomes asymptotically well behaved as soon as the dynamics becomes diffusive in $\Omega$.

## 4 Well-Tempered Metadynamics

In this section it is described an alternative approach for obtaining a reliable estimator of the free energy, called well-tempered metadynamics. The idea at the basis of this approach is reducing iteratively the height of the Gaussians $w$. We will show that this framework allows deriving an exact estimator of the free energy, valid also at finite simulation time, namely, while $w \neq 0$.

The algorithm discussed in the previous section is a truly non-equilibrium algorithm, where the bias potential acting on the system is modified at a finite rate. For this reason, it is not true that $F(s) + V_G(s, t) = C(t)$. As discussed above, the free energy can be empirically estimated from the time average of $V_G(s, t)$, defined in Eq. 9. An exact relationship between $V_G(s, t)$ and $F(s)$ can be obtained if the rate at which the bias potential is modified is suitable decreased as the simulation progresses. The first algorithm exploiting this idea is well-tempered metadynamics (Barducci et al. 2008). Here, the update rule for the potential is modified as follows:

$$V_G(S(x), t) = w \sum_{\substack{t' = \tau_G, 2\tau_G, \cdots \\ t' < t}} \exp\left(-\frac{V_G(S(x), t')}{k_B \Delta T}\right)$$

$$\exp\left(-\sum_{\alpha=1}^{d} \frac{(S_\alpha(x) - s_\alpha(t'))^2}{2\delta s_\alpha^2}\right) \tag{15}$$

where $\Delta T$ is an additional parameter that has the units of a temperature. Note that often instead of $\Delta T$, one sees the equivalent parameter $\gamma = T + \frac{\Delta T}{T}$ in literature where $T$ is the temperature of the simulation. $\gamma$ is called bias or biasing factor. Clearly, by setting $\Delta T = \infty$, one recovers non-tempered metadynamics. However,

choosing a finite value of $\Delta T$, the rate at which the bias potential grows decreases with time. It has been shown that with this choice the rate decreases proportionally to one over the simulation time and makes the bias converge exactly provided that the simulation is sufficiently long (Barducci et al. 2008; Dama et al. 2014). The choice of including a "tempering factor" $\exp\left(-\frac{V_G(S(x),t')}{k_B \Delta T}\right)$ that depends on the value of $S$ has an interesting consequence. In fact, it can be shown that the potential converges to

$$V_G(s,t) = -\frac{\Delta T}{T + \Delta T} F(s) + C(t) , \qquad (16)$$

that is an a priori tunable fraction of the original free energy profile. In the limit where $\Delta T$ is vanishingly small, plain (unbiased) molecular dynamics is recovered. For a finite $\Delta T$, the residual barriers will make the system sample a probability distribution proportional to $\exp\left(-\frac{F(s)}{k_B T}\right) \exp\left(\frac{\Delta T}{T+\Delta T}\frac{F(s)}{k_B T}\right) = \exp\left(-\frac{F(s)}{k_B(T+\Delta T)}\right)$, which corresponds to increasing the temperature of the sampled CV. Thus, the effect of well-tempered metadynamics is similar to that of other non-equilibrium methods (VandeVondele and Rothlisberger 2002; Rosso et al. 2002; Maragliano and Vanden-Eijnden 2006) but is obtained with a quasi-equilibrium procedure. The influence of the choice of $\Delta T$ on the sampled distribution can be seen in Fig. 3. In short, the consequences of the well-tempered algorithm are twofold:

- The bias potential converges, due to the one-over-time schedule.
- The bias potential does not tend to cancel completely barriers but rather to partially compensate them.

These two factors can also be decoupled, and it is possible to design an algorithm where the potential converges rigorously but also cancels exactly the underlying free energy landscape (see, e.g., the globally tempered algorithm discussed in Dama et al. 2014).

It is interesting to observe that the one-over-time schedule of well-tempered metadynamics is commonly used in stochastic optimization problems, since it allows minimization to converge without remaining stuck. Interestingly, in the stochastic optimization literature, a common recipe is to estimate the parameters from their time average during the optimization procedure. In the case of well-tempered metadynamics, this would amount in using the time average of the bias potential in order to estimate the free energy profile, as it is commonly done in non-tempered metadynamics (see above). Whereas this is not strictly necessary, it can be done in order to decrease the numerical noise of the estimator. We also notice that computing the free energy profiles from the bias potential and comparing results for different simulation lengths might be misleading. Similarly to a cumulative average, such an estimator will converge by construction. In order to estimate errors, reweighting procedures in combination with block analysis are more reliable (see Sect. 4.1).
**Fig. 3** Panels (**a**–**c**): Representative trajectories obtained using well-tempered-metadynamics for different choices of $\Delta T$ (see text for definition) represented in the $(\phi, \psi)$ space for alanine dipeptide in vacuum. Green dots represent the visited conformations. Colors indicate the free energy profile. Panel (**d**): Estimate of the free energy difference between two metastable minima as a function of the simulation time. The estimate, obtained from the bias potential using Eq. 16, converges to the correct value. (After Barducci et al. 2008)

A simple interpretation of the fact that, in a well-tempered metadynamics simulation, the distribution of the CV at long times is not flat is the following. Since the prefactor for the accumulated Gaussians depends on the value of $S$, Gaussians of different heights are placed in different regions of the CV space. In order to reach a stationary distribution, it is thus necessary that the system spends more time in regions where small Gaussians are added and less time in regions where large Gaussians are added. This idea can be pushed further and used to convert metadynamics in an algorithm that is not designed to flatten completely (as in non-tempered metadynamics) or partially (as in well-tempered metadynamics) the histogram of the CVs but rather to enforce a predefined distribution (White et al. 2015; Marinelli and Faraldo-Gómez 2015). This application departs from the usual

scope of metadynamics simulations, which is enhancing sampling, and allows this technique to be used, for instance, to enforce experimental distributions (White et al. 2015; Marinelli and Faraldo-Gómez 2015; Gil-Ley et al. 2016). Notably, it can be shown that this approach is equivalent to a maximum entropy approach (Pitera and Chodera 2012) where the variables of which the average is constrained are the populations of each of the bins in the enforced distribution.

A further comment about the well-tempered formulation of metadynamics is that it is easy to see that the conventional estimator for the free energy Eq. 3 is, in the limit of Gaussians with a small width, completely equivalent to this umbrella sampling relation:

$$F(s) = -k_B T \log N(s) - V_G(s) \tag{17}$$

Here $N(s)$ is the histogram accumulated along the biased trajectory. This latter expression has however a fundamental advantage from the practical standpoint, namely, that it can be used also in the following cases (Branduardi et al. 2012):

- When the width of the Gaussians is too large to represent features of the free energy landscape.
- When one is willing to analyze a variable that is not equivalent to the one biased during the metadynamics simulation (reweighting), as it will be discussed in the next section.

These cases should be treated with some care. In the first case, if the free energy landscape contains significant barriers that can only be compensated by adding narrow Gaussians, clearly those barriers will not be sampled correctly. The second case is even more critical: if the analyzed (and not biased) variable displays significant barriers that were not compensated by a bias potential, its distribution might be very difficult to converge. A detailed analysis of finite width corrections to free energy estimation in well-tempered metadynamics was recently provided in Tiwary et al. (2015a).

## 4.1    Reweighting from Well-Tempered Metadynamics

The reweighting operation in metadynamics is one of its many useful features as it allows projecting probability densities on arbitrary CVs without having to repeat the simulation. As discussed in previous sections, in metadynamics one constructs a time-dependent bias $V(S(x), t)$ as a function of a low-dimensional CV $S(x)$. Here $x$ denotes the configurational coordinates. By assuming that the evolution of $V$ is very slow and that the system is thus at equilibrium, at time $t$ the biased probability distribution for $x$ is given by

$$P(x,t) = \frac{e^{-\beta[U(x)+V(S(x),t)]}}{\int dx \, e^{-\beta[U(x)+V(S(x),t)]}} = P_0(x) \, e^{-\beta[V(S(x),t)-c(t)]} \tag{18}$$

where $U(x)$ is the potential energy of the system (Tiwary and Parrinello 2014), $P_0(x)$ is the unbiased Boltzmann probability density, and the function $c(t)$ is defined as

$$c(t) = \frac{1}{\beta} \log \frac{\int ds e^{-\beta F(s)}}{\int ds e^{-\beta(F(s)+V(s,t))}} \tag{19}$$

As shown in Tiwary and Parrinello (2014) and Valsson et al. (2016), $c(t)$ can be calculated by substituting the running estimate of $F(s)$ (Tiwary and Parrinello 2014) into Eq. 19:

$$c(t) = \frac{1}{\beta} \log \frac{\int ds \, \exp\left\{\left[\frac{\gamma}{\gamma-1}\beta V(s,t)\right]\right\}}{\int ds \, \exp\left\{\left[\frac{1}{\gamma-1}\beta V(s,t)\right]\right\}}. \tag{20}$$

Here $\gamma$ is the bias factor introduced previously. Using Eq. 20 in Eq. 18 , we can then easily calculate the distribution of any generic observable $O(x)$ over the unbiased ensemble from the metadynamics trajectory through

$$\langle O(x)\rangle_0 = \left\langle O(x)e^{\beta[V(S(x),t)-c(t)]} \right\rangle. \tag{21}$$

It is also possible to derive a similar relation that is valid in the case where only the orthogonal variables (not biased) are sampled at equilibrium, provided that an independent estimate of the free energy as a function of the biased CVs $\tilde{P}_0(s)$ is provided. Namely, one can construct an estimator of the unbiased probability $\tilde{P}(x)$ as

$$\tilde{P}(x) = \frac{\tilde{P}_0(S(x))}{\int dx' \, \delta(S(x') - S(x))} P(x) \tag{22}$$

It is interesting that this reweighted distribution is, among all the possible distributions, the one that is closest to the distribution observed during the simulation and at the same time results in a marginal probability as a function of $s$ that is identical to $\tilde{P}_0(s)$, in a maximum entropy spirit (Pitera and Chodera 2012; White et al. 2015; Marinelli and Faraldo-Gómez 2015). By replacing the free energy estimator in Eq. 16, one obtains $\tilde{P}_0(s) \propto e^{-\frac{F(s)}{k_B T}} \propto e^{\frac{V_G(s)}{k_B T}\frac{T+\Delta T}{\Delta T}}$ where $V_G(s)$ is the final bias potential. Similarly, it is possible to notice that the denominator in Eq. 22 is the histogram of the CV as observed during the metadynamics simulations, which, in well-tempered metadynamics, is proportional to $e^{-\frac{V(s)}{k_B \Delta T}}$ (Barducci et al. 2008). By straightforward algebra, one can obtain the following estimator:

$$\tilde{P}(x) \propto e^{\frac{V(S(x))}{k_B T}} P(x) \tag{23}$$

Averages of arbitrary variables can be computed as

$$\langle O(x) \rangle_0 = \frac{\left\langle O(x) e^{\beta[V_G(S(x))]} \right\rangle}{\left\langle e^{\beta[V_G(S(x))]} \right\rangle} \tag{24}$$

where the bias potential at the end of the trajectory should be considered. This scheme has been proposed in Branduardi et al. (2012) to analyze simulations performed with Gaussian potentials larger than the typical features of the simulated landscape but can be used to reweight any CV.

A third option for reweighting has been introduced in an earlier work Bonomi et al. (2009a), although it is less practical than the two methods discussed above since it requires accumulating joint histograms for the biased and non-biased CVs.

It is interesting to compare the two alternative schemes presented in Eqs. 21 and 24. In the latter, the weight of each snapshot only depends on the value of the biased CVs for that specific snapshot, whereas in the former it depends on the specific form of the bias potential at the time when the snapshot was collected. This means that Eq. 24 is practical when analyzing a posteriori a trajectory, since one is not required to synchronize the history-dependent potential with the saved trajectory. However, Eq. 21 is the only option for on-the-fly analysis. The two procedures are expected to provide equivalent results in the long time limits, but performances of the two methods might be different if the simulation is not fully converged. This connects to a powerful yet not very widely used aspect of metadynamics and its self-diagnostic features. There are different schemes to obtain estimates of the converged free energy from a metadynamics run. While agreement in the estimates made using these different schemes is not a sufficient condition to judge the convergence of metadynamics, it clearly is a necessary condition. We thus encourage the user to make use of these different estimators – which are all implemented in a seamless and easy-to-use manner in PLUMED (Tribello et al. 2014) – for judging the quality and reliability of the free energy estimate made in metadynamics.

An important property of reweighting methods is that they basically allow free energies to be computed directly from histograms. These histograms can be compared across as-independent-as-possible fractions of the simulated trajectory (e.g., first half vs second half) or, to rigorously quantify the statistical error, using a block analysis. Clearly, results from different blocks will be consistent only if the same metastable states have been repeatedly visited.

## 4.2    Kinetic Rate Constants from Well-Tempered Metadynamics

One of the recent and very powerful developments in well-tempered metadynamics has been the demonstration of how to obtain unbiased kinetic properties from biased

metadynamics simulations of processes with very high barriers. Here we summarize the key ideas in this approach. We mention its requirements for applicability and how one may ascertain a posteriori whether or not these requirements have been met. We then mention some recent powerful applications of this approach to obtain timescales for difficult rare event problems such as drug unbinding and liquid droplet nucleation.

The method to obtain unbiased timescales from suitably biased metadynamics simulations has been called "infrequent metadynamics" (Tiwary and Parrinello 2013; Salvalaglio et al. 2014; Tiwary and Berne 2016b), as it involves periodic but infrequent biasing of a CV in order to increase the probability of escape from metastable states where the system would ordinarily be trapped for extended periods of time. If the biased CV can demarcate all relevant stable states of interest and if the time interval between biasing events is much longer compared to the transition path time spent in the ephemeral transition state (TS) regions, then one increases the probability of not adding bias in the TS regions and thereby not corrupting the dynamics during barrier crossing. This in turn preserves the sequence of transitions between stable states that the unbiased trajectory would have taken. The acceleration $\alpha$ of transition rates through biasing which directly yields the true unbiased rates can be obtained directly (i.e., without having to converge the free energy) through the use of the following expression which was first proposed by Grubmueller in the context of conformational flooding and independently by Voter in the context of hyperdynamics (Voter 1997; Grubmüller 1995):

$$\alpha = \langle e^{\beta V(s,t)} \rangle_t \tag{25}$$

Here $s$ is the CV being biased, $V(s,t)$ is the bias experienced at time $t$, and the subscript $t$ indicates averaging under the time-dependent potential.

Clearly such an approach will work only if (a) there is a clean timescale separation between the time spent in the TS and in the basins and (b) the chosen CV does actually demarcate between all stable states of interest. One can verify a posteriori if these requirements were met by checking if the cumulative distribution function for the transition times obtained by the use of a time-dependent biasing potential corrected using Eq. 25 indeed conforms to a time-homogeneous Poisson distribution (Salvalaglio et al. 2014). By the use of methods such as SGOOP (Tiwary and Berne 2016c, 2017; Tiwary 2017), it has been shown how one can construct a CV which is likely to meet these requirements on the basis of preliminary metadynamics runs using a sub-optimal CV.

## 5    The Choice of CVs

Similar to other methods that reconstruct the free energy in a set of generalized coordinates, the reliability of metadynamics is strongly influenced by the choice of the CVs. Ideally the CVs should satisfy three properties:

- They should clearly distinguish between the initial state, the final state, and the intermediates.
- They should describe all the slow events that are relevant to the process of interest.
- Their number should not be too large; otherwise it will take a very long time to fill the free energy surface.

Clearly, the second and third condition might be mutually exclusive, and in many cases it can be very difficult to find a "good" set of CVs.

Biasing explicitly all "slow" degrees of freedom is important for (a) the speed at which metadynamics converges to a reliable free energy and (b) the possibility to reconstruct unbiased rate constants from metadynamics. As per the proof of Dama et al. (2014), one may think that in principle metadynamics is agnostic to the precise choice of CVs being used for sampling. That is, even with sub-optimal choices of CVs which have some overlap with all slow degrees of freedom, metadynamics will converge to the right free energy. However in practice it is extremely useful to improve the choice of CVs before attempting to converge a metadynamics simulation. A simple metadynamics run on an idealized model can be enlightening. Consider the Z-shaped two-dimensional free energy depicted in Fig. 4. If a metadynamics simulation is performed biasing only CV1 and neglecting CV2, the simulation, which is started in basin B, is not able to perform in due time a transition toward A, and metadynamics goes on overfilling this minimum. A transition is finally observed only when the height of the accumulated Gaussians will largely exceed the true barrier height. This behavior will continue indefinitely without ever reaching a situation in which the free energy grows evenly like in the example of Fig. 1. A similar behavior is often observed in practical applications of metadynamics to real-world problems and is a strong indication that an important CV is missing. In general, one can check a posteriori if the description provided by the chosen set of CVs is accurate, for instance, by using transition path sampling techniques (Dellago et al. 1998, 2002) or by performing a committor test (see Dellago et al. 1998, 2002) or, when using metadynamics to obtain kinetic properties, by performing a Kolmogorov-Smirnov test as proposed in Salvalaglio et al. (2014). Even without performing a specific check, an hysteretic behavior in the free energy reconstruction always signals the lack of a relevant CV. If, instead, the free energy grows "smoothly," it is likely that the set of variables is adequate.

From the above discussion, it should be clear that it is not easy to a priori identify the correct set of CVs for a given problem at hand, and in many cases, it is necessary to proceed by trial and error, attempting several metadynamics simulations with different combinations of variables. That said, a large number of methods drawing from diverse inspirations have been proposed over the years that aim to systematically identify a good set of CVs for any given problem. Given the wide range of different ideas that have been used to design these methods, it would take another chapter to discuss them in a complete manner. As such, here we just point out some of the references that the interested reader is encouraged to look
**Fig. 4** The effect of neglecting a relevant degree of freedom. Left side: 2D Z-shaped potential. Right side: the projection of the free energy on $s_1$ and a typical metadynamics bias generated using only $s_1$ as CV. Transitions from A to B are not described by $s_1$ causing strong hysteresis in the reconstructed free energy. (After Laio and Gervasio 2008)

up (Tribello et al. 2012; Rohrdanz et al. 2013; Tiwary and Berne 2016c, 2017; Sultan and Pande 2017; McCarty and Parrinello 2017).

# 6   Multi-replica Metadynamics Simulations

In this section, we discuss methods that can be used to combine metadynamics simulations performed simultaneously on separate replicas.

## 6.1   Multiple-Walkers Algorithms

The history-dependent potential used in metadynamics substantially depends on the histogram of the visited conformations in the CV space. The simulation can be straightforwardly parallelized by accumulating this potential *in parallel*. In other words, many simultaneous simulations could be used to update the bias potential that is then felt by all of them. The first application of this principle is the so-called multiple-walkers algorithm (Raiteri et al. 2006). In the non-tempered formulation of metadynamics, it has been shown that the error in the estimator of the free energy profile is independent of the number of walkers (Raiteri et al. 2006; Bussi et al. 2006b). Thus, a large number of walkers can be used to speed up the filling of the potential without affecting the final accuracy of the result. Walkers should only communicate when a new Gaussian is added to the bias potential (i.e., typically every few hundred steps), so that communication does not usually introduce any significant overhead. However, one should make sure that the walkers are initialized as independently as possible from each other. Similar properties are found when using well-tempered metadynamics (Barducci et al. 2008).

Interestingly, this idea has been recently extended to the case where series of similar (though not identical) systems are studied. For instance, if the free energy landscape associated to a protein-ligand binding should be evaluated for a number of different ligands that are similar to each other, then simulations can be performed simultaneously and the bias potential constructed by using also the information obtained with the other ligands. This scheme has been called altruistic metadynamics (Hosek et al. 2016) and requires the definition of an additional parameter, the altruistic factor, which weights the contribution of different simulations to a given bias potential. In its original formulation, the accuracy of the result is slightly deteriorated for large values of this altruistic factor. However, we suggest that by using reweighting schemes where the strict relationship between bias potential and free energy landscape is not required (as, e.g., in Branduardi et al. 2012) systematic errors might be decreased or eliminated.

## 6.2   Parallel Tempering Metadynamics

Parallel tempering metadynamics (PTmetaD) (Bussi et al. 2006a) is another approach based on running several metadynamics in parallel on different replicas. Multiple replicas of metadynamics are run at different temperature. An exchange of the coordinates of two replicas at adjacent temperatures is attempted with a fixed frequency, like in ordinary parallel tempering (Merlitz and Wenzel 2002). The acceptance ratio for an exchange involving replicas $i$ and $j$ is

$$P = \min\left\{1, \exp\left[(\beta_j - \beta_i)(V(x_j) - V(x_i))\right.\right.$$
$$\left.\left. + \beta_i(V_{G_i}(s(x_i)) - V_{G_i}(s(x_j))) + \beta_j(V_{G_j}(s(x_j)) - V_{G_j}(s(x_i)))\right]\right\}$$

where $V$ is the potential energy, $x_i$ are the coordinates of replica $i$, $\beta_i$ is the inverse temperature of replica $i$, and $V_{G_i}$ is the metadynamics potential of replica $i$ before the exchange. If the move is accepted, the coordinates are exchanged.

In this approach, the free energy profile as a function of the same collective variable $s$ is filled in parallel at all temperatures. Combining parallel tempering and metadynamics in this way improves the convergence of the free energy even when the CV is nonoptimal. Indeed, parallel tempering improves the sampling over the degrees of freedom not explicitly included in the CV space. At the same time, the approach converges more quickly than ordinary parallel tempering, since metadynamics enforces the exploration of high free energy configurations, ultimately leading to a more reliable estimate of the height of the free energy barriers.

A similar scheme can be used to combine solute tempering (Camilloni et al. 2008) or other variants of parallel tempering with metadynamics.

## 6.3    Bias Exchange

One of the reasons that make the choice of the CVs in metadynamics delicate is that they cannot be more than two or three in practical applications. Indeed, the time required to escape from a local minimum in the free energy surface is determined by the number of Gaussians that are necessary to fill the well. This number is proportional to $(1/\delta s)^d$, where d is the number of CVs that are biased. Hence, the efficiency of the method decreases exponentially with the number of dimensions involved. This applies both to ordinary metadynamics and to its well-tempered version.

A possible manner of addressing this problem is offered by bias exchange (Piana and Laio 2007) (BE), another technique based on the combined use of replica exchange and metadynamics. In this approach, one runs in parallel, at the same temperature, a large number $NR$ of metadynamics, with a bias potential acting on different CVs. The bias in each replica typically acts only on a single CV. Therefore the free energy wells can be filled efficiently. If all the variables were relevant for describing the process and the replicas were run independently, all the metadynamics would be affected by hysteresis, like in the example in Fig. 4. In bias exchange, at fixed time intervals, one attempts to swap the bias potentials between pairs of replicas. Let us denote by $s_k$, $k = 1, \cdots, NR$ the NR different CVs biased on the NR replicas. For two replicas of coordinates $x_i$ and $x_j$ and bias potentials $V_G(s_k(x_i), t)$ and $V_G(s_l(x_j), t)$, an exchange move consists in swapping $V_G(s_k, t)$ and $V_G(s_l, t)$. The move is accepted with a probability:

$$P = \min \left\{ 1, \exp \left[ \beta(V_G(s_k(x_i), t) + V_G(s_l(x_j), t) \right.\right.$$

$$\left.\left. - V_G(s_k(x_j), t) - V_G(s_l(x_i), t)) \right] \right\}$$

In this way, each replica is sequentially biased by a bias potential acting on one CV at a time. When a swap is accepted, the bias potential acting on two replicas changes direction. Simultaneously, the values of the CVs involved in the swap perform a jump. If, for example, an exchange between replica 1 and 2 is accepted, the CV biased on replica 1 will jump from $s_1(x_1)$ to $s_1(x_2)$, where $x_1$ and $x_2$ are the coordinates of the atoms in replica 1 and 2 before the exchange. These jumps greatly help decorrelating the dynamics and have the effect of improving the accuracy of the free energy estimate, greatly reducing the hysteresis. Of course, hysteresis can be eliminated only if all the relevant variables are included and are biased by at least one replica. Thus bias exchange does not eliminate the necessity of selecting before the simulation an appropriate set of CVs. Still, the approach allows treating simultaneously much more CVs than normal metadynamics. Therefore, it is of great help in setting up a simulation assuming as little as possible on the reaction mechanism.

It should also be remarked that in BE the bias potential grows in order to compensate NR one-dimensional projections of the free energy. In order to obtain multidimensional projections, it is necessary to combine data from all the replicas. This can be done using the WHAM method (Kumar et al. 1995) as explained in detail in Marinelli et al. (2009). A graphic user interface has been developed specifically to perform this task (Biarnés et al. 2012). In a typical BE simulation performed with a few tens of replicas, one might be able to reconstruct the free energy as a function of a few selected CVs. Reconstructing the free energy as a function of all the biased CVs is usually not possible (since it would require accumulating a histogram on a very high-dimensional space). In addition, although it is possible to compute free energies with respect to a posteriori chosen non-biased CVs, one should be aware that some of them might be hindered by non-flattened barriers and, as such, might not be sampled correctly.

The procedure discussed above to combine results from the multiple metadynamics simulations used in BE can be used to combine arbitrarily biased simulations. For instance, a bias-exchange-like procedure was used in Cunha and Bussi (2017) where each replica was running a metadynamics simulations biasing the distance between a ion and a possible binding site. However, in each replica, the coordination of the ion with the other binding sites was hindered by a repulsive potential. This straightforward generalization shows that arbitrary potentials can be added guided by the knowledge of the system and by the results of preliminary calculations and later reweighted using the WHAM method.

## 6.4    Other Ways to Bias a Large Number of CVs

Bias-exchange metadynamics is a commonly used algorithm that allows a large number of CVs to be biased and has been used already in a large number of applications. We here discuss two alternative approaches that emerged more recently.

The first approach is *parallel-bias* metadynamics (Pfaendtner and Bonomi 2015). This approach can be seen as a single-replica variant of the bias-exchange metadynamics protocol. Here, a possibly large number of CVs are defined that are alternatively biased (one at a time) during the simulation. An integer index keeps track of which is the currently biased CV and is evolved using a MC procedure. This procedure resembles the simulated-tempering scheme (Marinari and Parisi 1992), where a single simulation is performed and the temperature of the system is allowed to change in order to enhance sampling. In simulated-tempering simulations, an iterative procedure is required in order to force the simulation to spend the same amount of time at each temperature (see, e.g., Park and Pande 2007). On the contrary, in parallel-bias metadynamics, this effect is an implicit consequence of the self-healing character of the metadynamics bias potential. Indeed, if the simulation spends a large fraction of time biasing one specific CV, the bias potential acting on that CV will grow and will thus favor a transition such that a different CV will be biased. It should be said that in its practical implementation, the extra variable

corresponding to the index of the biased CV is usually marginalized so that it is not necessary to track it. As a consequence, the bias potential acting on the system reads

$$V_{PB}(s, t) = -\frac{1}{\beta} \log \sum_{\alpha} \left( -\beta V_G^{(\alpha)}(s_\alpha, t) \right) \qquad (26)$$

where $V_G^{(\alpha)}$ is the bias potential accumulated based on the history of variable $s_\alpha$. The parallel-bias metadynamics approach can be used in a multiple-walkers fashion (see Sect. 6.1) in order to exploit a parallel machine. The advantage with respect to traditional bias-exchange metadynamics is that the number of required replicas becomes effectively independent of the number of biased CVs.

An alternative procedure has been called *replica exchange with CV tempering* (Gil-Ley and Bussi 2015). Here, multiple CVs are biased concurrently in each simulation. More precisely, bias potentials aimed at compensating barriers on individual CVs are constructed as if these barriers were independent of each other. Since concurrently biasing many variables leads to sampling a conformational space that is very different from the original Boltzmann distribution, unbiased results are recovered by constructing a ladder of replicas with progressively increasing values of the bias factor (see Sect. 4). The resulting bias potential on replica $i$ is thus

$$V_{RECT}^{(i)}(s, t) = \sum_{\alpha} \left( V_G^{(\gamma_i, \alpha)}(s_\alpha, t) \right) \qquad (27)$$

where $V_G^{(\gamma_i, \alpha)}$ is a potential accumulated based on the history of variable $s_\alpha$ and using a bias factor $\gamma_i$. The $\gamma_i$ corresponding to the lowest replica should be set equal to 1 in order to allow unbiased results to be recovered, whereas the one corresponding to the highest replica should be large enough for the important energy barriers to be crossed. Similarly to other replica exchange-based methods, the acceptance rate should take into account the different bias potentials acting on different replicas. Importantly, the accuracy of the final result is independent of the assumption that CVs are independent of each other. We notice that, at variance with parallel-bias metadynamics and bias-exchange metadynamics, replica exchange with CV tempering concurrently accelerates all the chosen CVs. At variance with bias-exchange metadynamics, the number of required replicas scales with the square root of the number of CVs. However, concurrently biasing too many CVs could also be counterproductive since it might enlarge too much the extension of the conformational space that should be sampled in order to converge a simulation. On the other hand, it might be more effective when biasing simple variables that are not well correlated with the overall barriers hindering the free energy landscape.

# 7    Discussion and Outlook

Metadynamics was introduced in 2002 as a method to escape and sample free energy minima in complex molecular systems. Over the years, it has grown significantly in its variants and in range of applications and have been implemented in several software plugins and analysis tools (Bonomi et al. 2009b; Henin et al. 2009; Fiorin et al. 2013; Giorgino et al. 2017; Sidky et al. 2018). In this book chapter, we have attempted to summarize the state of the art concerning the different forms and formulations of metadynamics, with a focus on the theory rather than the applications. We did not discuss all problems in full detail – for example, the methods for automatic construction of the CVs – an important problem at the center of several efforts in the community. In this final section, we conclude with our outlook on some *do*s and *don′t*s concerning metadynamics in its traditional use for estimating free energy profiles, drawing from the experience of the three authors. Our discussion mainly concerns two vital points regarding any metadynamics simulation which we have already discussed in this chapter and would like to emphasize here: (a) the choice of the appropriate variant of metadynamics according to the dimensionality of the CV space and (b) ascertaining when the sampled distribution has converged and the simulation is meaningful. The discussion in this chapter is clearly limited for space reason. Interested readers can refer to the many available reviews dedicated to the metadynamics method (Laio and Gervasio 2008; Barducci et al. 2011; Bussi et al. 2015; Valsson et al. 2016; Tiwary and van de Walle 2016).

- In general, well-tempered metadynamics is an apt choice if the number of CVs is less than or equal to 3. This approach requires choosing one extra parameter with respect to ordinary metadynamics (the CV temperature $\Delta T$) that allows a tuning of the explored region, and its convergence has been proved rigorously (Barducci et al. 2008; Dama et al. 2014). When using more than 3 CVs, bias exchange or other methods based on the idea of reconstructing multiple low-dimensional potentials should be preferred. Indeed, accumulating statistics in a high-dimensional space to construct a bias potential capable to enhance sampling could be virtually impossible. In cases when one-dimensional projections of the free energy are barrierless, non-tempered metadynamics should be preferred, since the quasi-static bias potential obtained at the end of a well-tempered metadynamics simulation would likely not help in enhancing transitions and the simulation could remain stuck. On the contrary, non-tempered metadynamics would effectively increase the diffusion coefficient in the CV space by forcing it to sample equivalently all the points.
- Standard metadynamics should always be used together with the appropriate boundary conditions on the CV, as described in Sect. 3.1. The free energy should be always estimated as a time average of the history-dependent potential, controlling the accuracy by block analysis.

- In metadynamics simulations (as much as in all molecular dynamics simulations), it is very important to check if transitions between "reactants" and "products" are actually observed during the simulation. In case a very small number of such transitions are detected, one should carefully assess the convergence and the reproducibility of the results. Special attention should be paid in analyzing replica exchange simulations, where continuous trajectories should be analyzed (in opposition to the discontinuous trajectories corresponding to each replica).
- When analyzing well-tempered-metadynamics, it is important to recognize that the changes in the bias potential are decreasing by construction since the Gaussian height decreases as one over time. Computing the free energy profile from the bias potential and comparing results for different simulation length might be misleading if there are not multiple transitions observed as discussed above. Performing a block analysis on a reweighting procedure can provide more robust error estimations (see Sect. 4.1).

While in this chapter we did not discuss in detail the various applications of metadynamics to materials modeling problems, here we would like to point out that the metadynamics approach has been extensively used from the very beginning for modeling materials and predicting their properties. For example, the approach was used to characterize the properties of bulk materials, in their crystalline and amorphous phases (Donadio et al. 2005; Donadio and Bernasconi 2005; Di Pietro et al. 2006; Behler et al. 2008; Hu et al. 2012; Pietrucci et al. 2010), and to study nucleation (Trudu et al. 2006; Quigley and Rodger 2008; Piaggi et al. 2017; Salvalaglio et al. 2015, 2016; Fitzner et al. 2017; Mendels et al. 2018), charge diffusion (Laino et al. 2007; Iannuzzi and Parrinello 2004; Vartak et al. 2013), interaction of small molecules with surfaces or porous materials (Palafox-Hernandez et al. 2014; Hasell et al. 2016; Boyer et al. 2016; Munro et al. 2016; Bui et al. 2017), role of solvent in nanoassembly (Tiwary et al. 2015b; Tiwary and Berne 2016a), and hydrogen fuel cells (Cheng et al. 2017), just to name a few. Another field related to material science in which the approach has been applied with great success is crystal structure prediction (Martoňák et al. 2003, 2005, 2006, 2007; Ceriani et al. 2004; Oganov et al. 2005; Karamertzanis et al. 2008). Finally, the method can be used for studying chemical reactions on surfaces and heterogeneous catalysis (Ensing et al. 2006; Zipoli et al. 2004; Fleming et al. 2016; Oliveira et al. 2018; Fu and Pfaendtner 2018).

In conclusion, metadynamics has now become a standard tool in the workbox of a practitioner interested in sampling molecular systems. Many of the original intuitive formulations have now been demonstrated on a sound theoretical footing, and many variants have also come up which have truly extended the applicability of the approach. The role of intuition – especially in the choice of low-dimensional CVs – has not yet been eliminated and possibly will never be completely gone. A very important property of metadynamics is that, if a simulation is analyzed correctly, it is relatively easy to identify errors due to incorrect sampling. In many cases, problematic simulations can be used in order to choose better CVs for a next

round of simulations. This is not true in the case of the standard umbrella sampling protocol performed combining multiple independent restrained simulations, where hysteresis effects are often very difficult to detect. It has also become clear now that the infrequent metadynamics formulation can safely and self-consistently be used to compute unbiased kinetic rate constants in a wide class of rare event systems. We thus end on a note of optimism for the future use of metadynamics in tackling diverse and relevant problems in science and technology.

# Novel Enhanced Sampling Strategies for Transitions Between Ordered and Disordered Structures

# 28

## Fabio Pietrucci

## Contents

**Abstract**

At the atomic scale, condensed matter displays a fascinating variety of structural transformation processes. Examples include phase transitions between ordered and/or disordered structures (crystal to crystal, liquid to crystal, amorphous to crystal, etc.), isomerization of nanoclusters, chemical reactions, protein conformational changes, and many other phenomena. In all these cases, it is necessary to find suitable distance metrics and collective variables in order to analyze atomistic simulations of transformations as well as to accelerate them with enhanced sampling techniques, yielding mechanisms and free-energy landscapes. In this context, the present chapter illustrates approaches stemming from the idea of watching transformations of matter as modifications of the adjacency matrix formed by interatomic connections. The resulting tools have a general formulation and can therefore be applied to a range of different processes in physics, chemistry, and nanoscience.

# 1    Introduction

A major challenge of computational materials science is the accurate prediction of the transition mechanisms connecting together different structures of a same material. These structures, both in extended solids or liquids and in nanostructures, range from perfectly ordered to highly disordered and typically correspond to minima separated by barriers in a free-energy landscape as a function of suitable order parameters. Very often, it is much easier to generate in silico a large number of putative structures than to characterize the transformation pathways between them, and this asymmetry has important practical consequences.

A prominent example is the synthesis of new crystalline structures with desired properties. In recent years, computational structure prediction methods (Glass et al. 2006; Pickard and Needs 2011; Wang et al. 2012) have contributed to the rapid increase of new predicted phases of materials, of high interest for potential applications (see, e.g., Wilmer et al. 2012). However, at present, no general theoretical approach has been developed to guide experiments along the possible pathways connecting stable structures, so that synthesis remains a challenging endeavor, slowed down by expensive trial-and-error cycles and often dominated by kinetics rather than thermodynamics.

In principle, a powerful tool for investigating transformation mechanisms and the corresponding energetics is provided by atomistic molecular dynamics or Monte Carlo simulations combined with enhanced sampling techniques that accelerate barrier-crossing and allow the reconstruction of free-energy landscapes. Unfortunately, available approaches for phase transitions and other structural transformations lack transferability. In other words, the study of each particular system and process typically requires a time-consuming preliminary optimization of the computational setup, often involving trial-and-error and several repetitions of the simulation. In particular, since most enhanced sampling techniques demand to identify system-specific collective variables (CVs) to accelerate the exploration of pathways and reconstruction of free-energy landscapes, finding suitable CVs is often the crucial and most cumbersome step in the computational study (Pietrucci 2017). At the basic level, such CVs must be capable of distinguishing the initial and final states of the transformation, as well as intermediate structures: from this point of view, disordered systems can be more problematic to analyze than ordered ones, due to the lack of evident symmetries.

Both in experiments and in silico, it is unclear, in general, how to find a viable pathway reaching a particular poly(a)morph (or nanostructure) different from the starting one, possibly separated by several intermediate steps. To complicate things, metastable forms are very often involved in phase transitions (Schreiber et al. 2017), and sometimes their kinetic stability is very high. Thus, in order to recover the desired structure, one needs to manipulate the control parameters, e.g., pressure and temperature, often in a complex and delicate way that is not trivial to guess (Radha et al. 2015). A precise understanding of transition mechanisms and the corresponding kinetics is therefore the key to explain and control the behavior of matter. In this chapter, some recent conceptual and practical developments are

presented that aim to bridge the gap between structure prediction and synthetic routes prediction, illustrated by means of different examples ranging from silicon and carbon nanostructures to water poly(a)morphism. As mentioned at the end, this class of methodologies can be very effective also for the study of chemical reactions in solution.

## 2  Representing Matter Through the Adjacency Matrix

Let us consider the possible transformation processes occurring in condensed matter, adopting, for the latter, a broad definition including atomic aggregates like molecules, nanostructures, liquids, and solids. These diverse systems undergo a variety of transformations including, e.g., phase transitions, chemical reactions, or protein conformational changes. From the viewpoint of theory and simulation, an interesting question is whether we can find a unified way to describe in atomic detail the transition pathways of all such different phenomena. One immediately imagines, building upon the basic Cartesian coordinates of atoms, many possible mathematical representations: examples are sets of distances, cell parameters (for periodic systems), coordination numbers, symmetry indicators, dihedral angles, root mean square deviations, etc. However, the preceding examples are typically tailored on specific systems and transformations. Is it possible to find a general representation, able to accurately track the detailed dynamic evolution of a wide range of transformations?

A possible starting point is to consider a generic atomic structure as a network: atoms are the nodes, while links can be defined based on proximity. Likewise, structural transitions become network transformations. The advantages of this view are its generality, encompassing many processes in condensed matter, and the availability of the powerful graph theory toolbox. In particular, a graph of $N$ nodes can be represented by a $N \times N$ adjacency matrix (also called contact matrix): $a_{ij} = 1$ if nodes $i$ and $j$ are connected and zero otherwise. The matrix contains the detailed topology of the network. Clearly, the "connection" between atoms appears as a somehow arbitrary concept: it can be chosen to reflect the existence of a chemical bond (ionic, covalent, hydrogen-bond, etc.), based on energy and electronic structure, or it can be introduced as an arbitrary property of close-enough atoms. Both choices have merits and for its simplicity we will follow the second one (that often is compatible with the first). In practice, it is convenient to introduce a switching function $f(d_{ij})$ of the interatomic distance, decaying smoothly from one to zero in a chosen range of distances (an example is the Fermi-Dirac function). The range can be inferred by inspecting pair distribution functions, e.g., so that $f$ differentiates bonded atomic pairs from second-shell pairs. Note that replacing plain distances with a monotonic function of the distances preserves the same information, except when distances are so large (or so small) that the derivative of $f$ is close to zero.

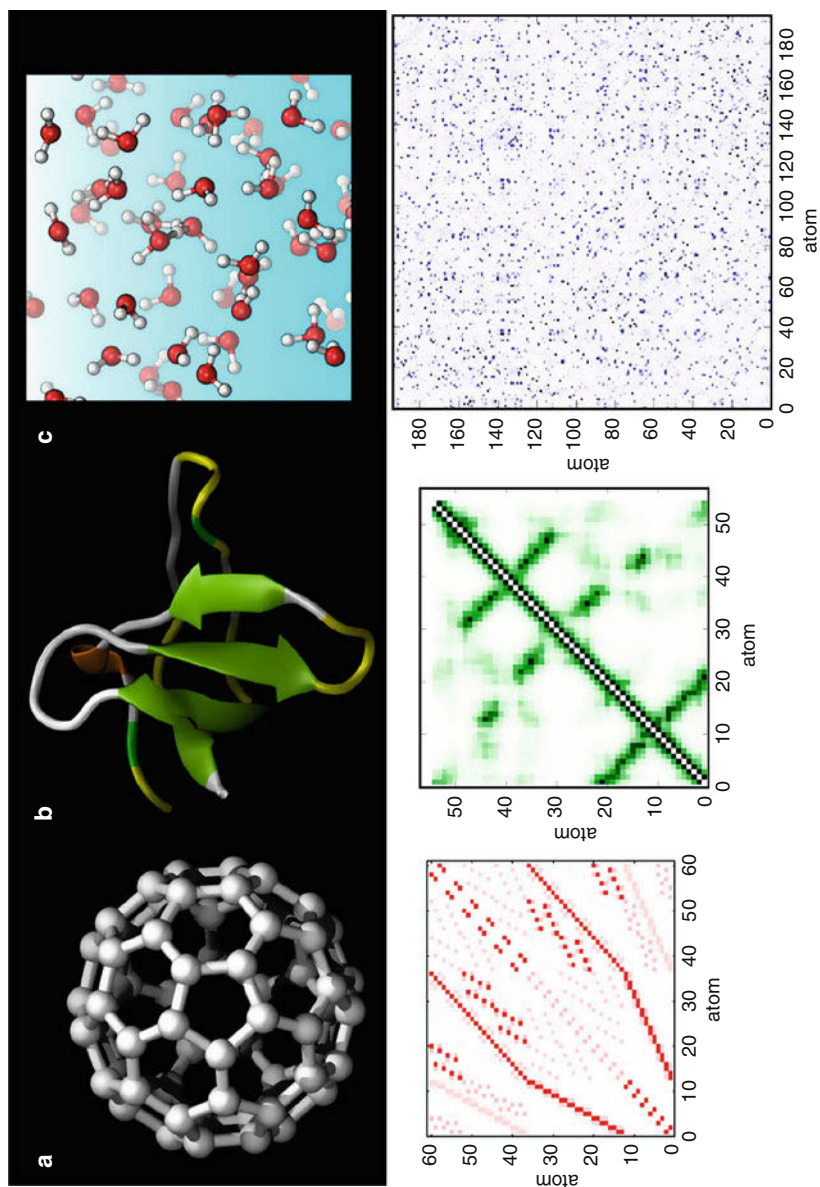
The resulting adjacency matrix is composed by real-valued elements $a_{ij} \equiv f(d_{ij}) \in [0, 1]$: examples for different systems are shown in Fig. 1. In this way,


**Fig. 1** Examples of adjacency matrices of (**a**) a fullerene, (**b**) the SH3 protein (using alpha-carbons only), and (**c**) a model of liquid water

continuous changes of atomic structure are reflected in continuous changes of the matrix, and starting from the latter, one can attempt to construct suitable topology-sensitive coordinates, being able to track the transformations of matter in a rather general way. Besides an analysis tool, such coordinates can be also exploited within enhanced sampling methods to accelerate activated processes.

When adopting the adjacency matrix as a basic representation of matter, we are limited by at least two hypotheses. The first is that we can safely neglect large distances between pairs of atoms (where $f$ tends to zero), hoping that they do not play an important role in distinguishing structures or that they are effectively included in the shorter-range network structure. The second hypothesis is that the invariance of $a_{ij}$ under operations leaving the set of all distances unchanged does not introduce ambiguity. Even if counter-examples violating these hypotheses exist – like enantiomer molecules, where a mirror operation may lead to different interactions with biological systems – the vast majority of structural transformations of matter leaves a clear mark in the adjacency matrix. For this reason, several proposals have been made to employ graph theory in order to classify atomic structures and related physicochemical properties (see, e.g., Manolopoulos and Fowler 1992; Ivanciuc and Balaban 1998; Giuliani et al. 2008; García-Domenech et al. 2008; De Corato et al. 2013). In the following sections, graph theory-inspired coordinates are introduced not only for classification purposes but especially to study dynamical transformation pathways.

Note that, in principle, effective CVs correspond to good approximations of the ideal reaction coordinate: the latter can be defined, for the transition between two metastable states $A$ and $B$, by means of the committor function $p_B(\mathbf{R})$ (or equivalently $p_A(\mathbf{R})$) associating each configuration $\mathbf{R}$ in the full $3N$-dimensional space the probability to reach $B$ before $A$ (or equivalently $A$ before $B$). The committor function varies smoothly between zero and one, assuming a value of 0.5 at the transition state; therefore, it indicates the progress of the reaction, and it can be estimated at selected configurations to test the quality of a CV (Bolhuis et al. 2002; Best and Hummer 2005; Weinan and Vanden-Eijnden 2010; Pietrucci 2017).

## 3    Social PeRmutation INvarianT (SPRINT) Coordinates

This section provides a first example of topology-based coordinates: within the sandbox of nanoclusters isomerization, it illustrates the philosophy behind the invention and exploitation of such tools, and it motivates further developments in the direction of phase transitions and chemical reactions. The reader will hopefully be indulgent if here the adjective "social" is attributed, somehow playfully, to coordinates sensitive to the network of neighbors surrounding a given atom.

The physical properties of nanoscale clusters strongly depend on their precise structure, which unfortunately is often out of reach of experimental techniques (Baletto and Ferrando 2005; Billinge and Levin 2007). Simulations can thus play an important role in exploring the thermodynamically relevant configurations. Numerous computational strategies have been applied to determine low-energy

geometries of atomic clusters (Woodley and Catlow 2008; Rossi and Ferrando 2009), including simulated annealing (Ballone et al. 1988; Roethlisberger et al. 1994; Roethlisberger and Andreoni 1991), genetic algorithms (Deaven and Ho 1995; Ho et al. 1998), random search (Lloyd and Johnston 1998; Saunders 2004), basin hopping (Wales and Doye 1997), and minima hopping (Goedecker 2004; Schoenborn and Oganov 2009) methods. As mentioned in the introduction in the case of crystals, usually in all these techniques, the focus is on the fast generation of candidate low-energy structures rather than on the exploration of physically relevant transition pathways.

An alternative approach based on graph theory and on ab initio (density functional theory (DFT)-based) molecular dynamics was introduced in Pietrucci and Andreoni (2011) and exploits the so-called "Social PeRmutation INvarianT" (SPRINT) coordinates. Consider the adjacency matrix $a_{ij}$ of a nanocluster, where the $ij$ are all pairs of atoms: the matrix is symmetric, nonnegative, and also irreducible when it represents a connected graph, i.e., if any pair of vertices is connected through a path. In this case the Perron-Frobenius theorem holds: the largest modulus eigenvalue $\lambda^{\text{max}}$ is real, positive, and nondegenerate, and the corresponding eigenvector $v_i^{\text{max}}$ has all non-zero components with equal sign (we adopt the positive sign convention). In particular, a few very interesting properties can be shown (considering here binary adjacency matrix for simplicity):

- $\lambda^{\text{max}}$ carries global information on the network: it grows with the number of bonds and lies between the average and the maximum coordination number.
- $v_i^{\text{max}}$ carries information about both the short- and long-range topology of the atomic network surrounding atom $i$: for any positive integer $M$

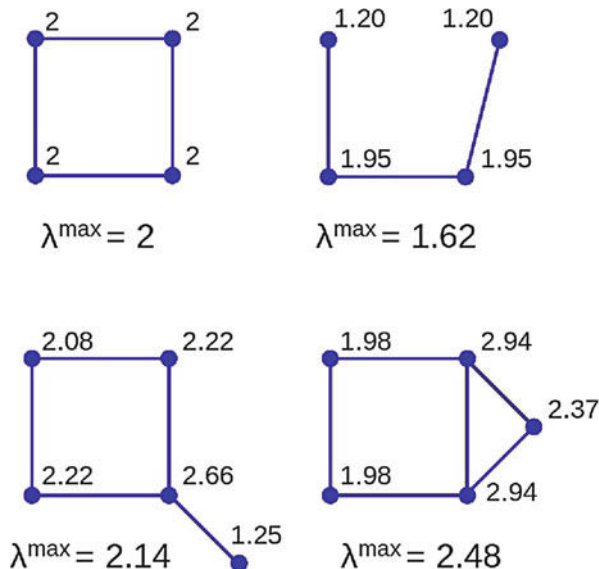
$$v_i^{\text{max}} = \frac{1}{(\lambda^{\text{max}})^M} \sum_j \left(a^M\right)_{ij} v_j^{\text{max}} \tag{1}$$

where $(a^M)_{ij}$ is the number of walks of length $M$ connecting $i$ and $j$. Equation 1 shows the "social character" of $v_i^{\text{max}}$ (Bonacich 1987; Bryan and Leise 2006; Porto et al. 2004).

These observations suggest the possibility to combine the largest eigenvalue and corresponding eigenvector into the following definition of topological SPRINT coordinates:

$$S_i = \sqrt{N} \, \lambda^{\text{max}} \, v_i^{\text{max,sorted}} \, ; \quad i = 1, 2, \ldots, N \tag{2}$$

where $N$ is the number of atoms and the $i$th component must be taken after sorting the eigenvector from its smallest to its largest component. It is this sorting operation that renders the vector **S** invariant with respect to the $N!$ permutations of the labeling of $N$ identical atoms (and thus also with respect to point-group symmetries). Clearly, the constraint $S_1 \leq S_2 \leq \ldots \leq S_N$ strongly reduces the volume of the space to be

**Fig. 2** Examples of simple graphs with each vertex labeled by the SPRINT topological coordinate $S_i$ in Eq. 2. Clearly the coordinate of a vertex is sensitive both to the number of neighbors and to the connectivity of the neighbors themselves


explored: this is a very desirable property in connection with enhanced sampling techniques. On the contrary, a permutation changes the order of rows and columns in $a_{ij}$. An additional advantage is the substantial dimensional reduction from $N(N-1)/2$ elements of the contact matrix to $N$ elements only.

Figure 2 illustrates how the SPRINT coordinates work on a simple example, distinguishing topologically inequivalent atoms and carrying information about both local coordination and the longer-range network topology. In order to track dynamical transitions in a smooth way (as discussed in the previous section), $a_{ij}$ is conveniently generalized from a binary matrix to a real-valued one, by means of a switching function $f(d_{ij})$. Note that the gradual decay of the switching function implies that $S_i$ coordinates contain information not only on the cluster topology but also, to some extent, on the 3D geometry.

It is important to remark that SPRINT coordinates are not a rigorous solution to the problem of resolving isomorphic graphs from truly different ones: in other words, different graphs can share the same SPRINT coordinates. Empirically, however, this degeneracy appears infrequent in small, physically meaningful nanoclusters, where so far these coordinates proved very effective (see below). Instead, different crystal phases sharing a same number of first neighbors for all atoms (e.g., silica) cannot be efficiently resolved by this approach: a solution is presented in next section. It is interesting to note how the principal eigenvector of the adjacency matrix inspired remarkable applications in very different fields, including the compact description of protein structures (Porto et al. 2004), the centrality concept in social networks (Bonacich 1987), and, last but not least, the tremendously successful PageRank algorithm of Google – based on the so-called 25 billion dollars eigenvector (Bryan and Leise 2006).

An interesting application of SPRINT coordinates consists in using them as CVs in combination with metadynamics (Laio and Parrinello 2002; Laio and Gervasio 2008). In the latter technique, a molecular dynamics simulation is supplemented with a history-dependent bias potential constructed as a sum of repulsive Gaussians added in CV space at regular time intervals, with the aim of escaping rapidly from local free-energy minima. SPRINT coordinates are implemented in the plugin PLUMED (Tribello et al. 2014), providing enhanced sampling capabilities to many MD codes. As shown in Pietrucci and Andreoni (2011), in the benchmark case of Lennard-Jones clusters, the simulation, starting from an arbitrary initial structure, is able to quickly explore, among many other isomers, also the global minimum (an icosahedron for 55 atoms and a face-centered truncated octahedron for 38 atoms). An appealing feature of this approach is that the exploration proceeds in a fully blind way, without the need of any educated guess about relevant symmetries or transition mechanisms. Furthermore, the spread of the $S_i$ values easily allows to distinguish high-symmetry from low-symmetry structures: in particular, the passage from a nondegenerate set of SPRINT values to a highly degenerate one marks a disorder-to-order transition. Note that since a large number of CVs are biased at once (one per atom), an unconventional situation in metadynamics applications, the algorithm is somehow in the spirit of local elevation (Huber et al. 1994). The reason is that the aim of this kind of simulations is the quick exploration of a large number of structures with different topologies, not the reconstruction of a low-dimensional free-energy landscape. Alternative CVs for metadynamics simulations of cluster isomerization can be found, e.g., in Tribello et al. (2011) and Rossi and Baletto (2017).

Silicon clusters represent a more realistic system, often taken as benchmark for DFT-based algorithms designed to search for the global minimum. Also for this system, SPRINT-based ab initio metadynamics at room temperature started from arbitrary initial structures lead to the fast and efficient exploration of a multitude of low-energy isomers (Pietrucci and Andreoni 2011). In the case of $Si_{10}$, the consensus lowest-energy structure (tetra-capped trigonal prism) (Ballone et al. 1988; Lyon et al. 2009) is quickly explored, among others. Increasing the cluster size, a richer variety of structures can be observed. For example, in the case of $Si_{16}$, five independent simulations generated hundreds of different geometries over a cumulative time of 400 ps. Geometry optimization identified 16 different isomers within only 45 meV/atom, including a lowest-energy minimum in agreement with previous studies (Goedecker et al. 2005; Yoo and Zeng 2005). Already at this small size, an impressive diversity of structural motifs lie within a narrow energy range, from fused units (e.g., B, C, D, M) to capped (deformed) cores like the tri- or tetra-capped trigonal prism (A, E, F, G, I, K), from symmetric configurations (high SPRINT degeneracy) to quasi-amorphous (low degeneracy), as shown in Fig. 3.

In a study focused on structural transition mechanisms, SPRINT-based ab initio metadynamics was employed to study the spontaneous transformation of small graphene nanoflakes into spheroidal cages (Pietrucci and Andreoni 2014), as observed in transmission electron microscopy experiments (Chuvilin et al. 2010). A set of simulations at different temperatures allowed to identify complex mul-
**Fig. 3** SPRINT coordinates distribution for $Si_{16}$ cluster geometries of increasing energy. Atoms are colored from red to blue for increasing magnitude of the corresponding coordinates. The more a structure is symmetric, the higher the level of degeneracy of the coordinates. (Adapted from Pietrucci and Andreoni 2011)

tistep pathways and discovered without any human bias ingenious transformation processes (Fig. 4). Among them, the zipping of a planar flake into a nanocone, the passage from a "bowl" to a cage with the help of carbon chains, and the formation of a pair of pentagons embedded into hexagons (the pyracylene unit, typical of fullerenes) by expelling a dimer from a four-membered ring. The latter
**Fig. 4** Progressive evolution of a graphene flake toward a three-coordinated carbon cage during an ab initio metadynamics simulation based on SPRINT coordinates. Pyracylene units are highlighted in red and blue. (See Pietrucci and Andreoni 2014 for details)

transformation, in particular, is highly nontrivial, pointing to the exploration power of this technique, and is fully compatible with available experiments, being the inverse process of a well-known synthetic route to $C_{62}$ from the $C_{60}$ fullerene (Qian et al. 2003).

A special case of search of cluster structures and related transition mechanisms consists in exploring the possible isomerization reactions of organic molecules: e.g., in Pietrucci and Andreoni (2011), the possible topologies of a $C_4H_5N$ molecule in gas-phase were explored with metadynamics at room temperature. Remarkably, at times the molecule also splits into smaller fragments that are able to recombine if a wall – i.e., a repulsive potential – prevents very large separations, hence probing dissociation and association reactions. Note that if the fragments remain within the range of the switching function, the adjacency matrix does not break down into separate blocks and the principal eigenvector components remain all positive. Note also that, since different elements are present, sorting of the principal eigenvector in Eq. 2 must be performed only within sets of alike atoms. The simulation could explore a sizable list of linear and ring-like isomers, including pyrrole, and smaller molecules like acetylene and hydrogen cyanide. A similar approach, performed

however in a more systematic way (analyzing an ensemble of trajectories), allowed in Zheng and Pfaendtner (2014) to reconstruct a relatively complex reaction network for methanol oxidation, displaying analogies with the consensus network obtained from literature. Other SPRINT applications include the study of $H_2SO_4 \cdot HSO_4^-$ dimer formation in the atmosphere (Wang et al. 2016) and the kinetics of the $S_N2$ reaction of $CH_3Cl + Cl^-$ (Fu et al. 2017). For comparison, the "ab initio nanoreactor" method of Wang et al. (2014) squeezes together molecular species at extreme pressure to discover reaction channels, albeit obtained under unphysical conditions.

An important class of systems is represented by molecules or clusters embedded into a solid matrix: in these cases, in addition to the internal degrees of freedom of the "guest", its possible manifold interactions with the host have also to be included in the configuration space exploration. In Balan et al. (2016), for instance, DFT-based SPRINT-metadynamics simulations allowed to identify the most probable configurations of $B(OH)_4^-$ (an important proxy of past ocean pH) inside calcite and aragonite crystals. Theoretical $^{11}B$ NMR spectra of the predicted structures were found in agreement with experimental results.

Besides enhanced sampling, a different use of topological coordinates aims at the automatic classification of molecular topologies. The basic idea is that different structural isomers are (usually) characterized by different SPRINT vectors that can be directly compared to detect similarity thanks to their invariance under permutation of identical atoms. Examples are the study of complex combustion reactions of hydrocarbons (Lai et al. 2014; Johansson et al. 2016), of the reaction network of $C_3H_4O$ explored with automated transition state search methods (Martínez-Núñez 2015), and of isomers of pure and hydrogenated silicon nanostructures (Baturin et al. 2014) explored with the USPEX structure prediction method (Glass et al. 2006).

On the other hand, as mentioned above, SPRINT coordinates have a limited resolving power in the case of homogeneous bulk systems with uniform coordination patterns, such as pure silica or water phases, for instance. This is not surprising given the dimensional reduction implied in the passage from the adjacency matrix to a $N$-dimensional vector. The next section introduces a different set of topological coordinates that avoid such dimensional reduction, displaying a remarkable ability to distinguish even very similar structures of bulk materials.

## 4 The Difficult Case of Water Poly(a)morphism: A Simple Metric Resolves Different Topologies

Despite the simplicity of its molecular unit, water is a challenging system, because of its uniquely rich polymorphism (Bartels-Rausch et al. 2012), the existence of different amorphous forms (polyamorphism), as well as predicted but yet unconfirmed features, including an elusive liquid-liquid transition (Palmer et al. 2014) and the possible formation of plastic phases (Himoto et al. 2014). It turns out that it is possible to define a simple metric, capturing changes in the topology of the interatomic network as represented by the adjacency matrix $a_{ij}$, being

able to differentiate water (meta)stable structures. The metric further allows to systematically track transitions among liquid, amorphous, and crystalline forms throughout the whole phase diagram of water: this is a crucial feature, because it naturally leads to CVs for enhanced sampling simulations that open the possibility of studying complex transitions like crystal nucleation from liquid or amorphous forms at a cheap computational cost. As shown below, the formulation of the metric and of the related CVs is very general, not specific to water, indicating applicability to a wide range of materials and transformation processes.

Several experiments disclosed connections between stable and metastable water phases (Mishima and Stanley 1998; Klotz et al. 2005), while simulations highlighted the importance of metastable states in understanding the mechanism of phase transitions and related transformations (Russo et al. 2014). A classic example is the connection between the crystalline ice stable at ambient pressure (ice I) and the low-density amorphous (LDA) and high-density amorphous (HDA) ices: by compressing ice I up to 10 kbar at ≈80 K, one obtains HDA instead of ice VI (Mishima et al. 1984), which may be transformed into LDA by decompression of HDA at 130 K (Klotz et al. 2005) or by heating recovered HDA at ambient pressure to beyond 130 K; (Mishima and Stanley 1998) finally ice I is recovered by heating up LDA. Similar connections between crystalline and amorphous ices are found in the high-pressure region of the water phase diagram, where a very-high-density amorphous (VHDA) ice, plastic ices, and crystalline structures with complex hydrogen-bond network (e.g., ice VII) have been observed or predicted (Amann-Winkel et al. 2016; Himoto et al. 2014). Clearly, the experimental evolution of water structures is a complex matter, and the observed outcomes are often determined by kinetics rather than pure thermodynamics. In other words, the evolution strongly depends on the detailed path followed – a trajectory in pressure, temperature, and time variables. Water appears therefore an ideal playground for simulation techniques able to navigate complex free-energy landscapes.

Molecular dynamics, based on realistic interatomic potentials (or, if affordable, DFT) and accelerated by enhanced sampling techniques, is in principle able to track such transitions. However, the CVs suitable to this task are often designed for specific classes of structural transformations (Lechner and Dellago 2008; Martoňák et al. 2003; Giberti et al. 2015; Haji-Akbari and Debenedetti 2015): no general CV scheme was proved successful for a wide class of different problems, in particular those involving disordered systems. Recently, on the other hand, several distance metrics have been developed with the aim of distinguishing and classifying structures of molecular or extended systems, based on atomic environment and/or interatomic networks (Valle and Oganov 2010; Gallet and Pietrucci 2013; Pietrucci and Martoňák 2015; Pietrucci and Saitta 2015; Zhu et al. 2016; De et al. 2016; Piaggi and Parrinello 2017; Martelli et al. 2018; Barthel et al. 2018). In this context, an important question is whether a given metric is able, besides classifying locally stable structures, to also track dynamical transitions in a continuous and accurate way.

A general and effective metric for the comparison of condensed matter structures results from the permutation invariant vector (PIV) introduced in Gallet and
**Fig. 5** Simple system of two water molecules illustrating the definition of PIV: the upper diagonal part of the 6×6 symmetric adjacency matrix $a_{ij}$ (where values close to one correspond to covalent bonds and 0.25 to hydrogen bonds) is rearranged into a vector **V** of 15 components. The entries from each matrix block corresponding to O–O (in red), O–H (in yellow), and H–H pairs (in gray) are sorted in ascending order

Pietrucci (2013) and Pipolo et al. (2017). Each configuration of the system is associated with a vector **V**, while configurations $A$ and $B$ are compared by simply computing the Euclidean distance between the corresponding vectors $||\mathbf{V}^A - \mathbf{V}^B||$. The vector is built by first organizing the elements of a real-valued adjacency matrix into the following blocks $\mathbf{v}_{kk'}$, where $kk'$ indicates a pair of elements (e.g., in the case of water, O–O, O–H or H–H, see Fig. 5):

$$v_{kk'}^{\beta\beta'} = c_{kk'} \ f \left( \sqrt[3]{\frac{\Omega_0}{\Omega}} \ ||\mathbf{R}_{\beta k} - \mathbf{R}_{\beta'k'}|| \right) . \tag{3}$$

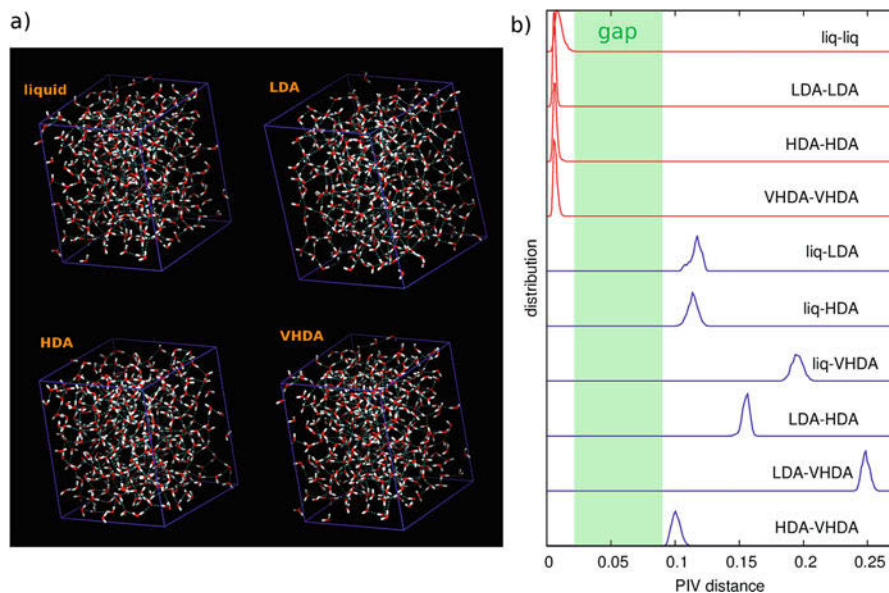
where $\mathbf{R}_{\beta k}$ is the position vector of the $\beta$-th atom of type $k$, with $\beta > \beta'$, $k > k'$; $c_{kk'}$ are coefficients that introduce some flexibility (they can be set to one for simplicity); $\Omega$ and $\Omega_0$ are the volume of the simulation box and a reference volume, respectively; and $f$ is, as usual, a switching function monotonically decreasing from one to zero for increasing distance. The PIV **V** is finally obtained by simply sorting the elements of each $\mathbf{v}_{kk'}$ block in ascending ordered and joining together the blocks into a $N(N-1)/2$ -dimensional vector. The sorting operation within each block introduces invariance upon permutation of identical atoms: with growing system size, this operation becomes computationally demanding, so


**Fig. 6** (**a**) Representative structures of liquid water and low-density, high-density, and very-high-density amorphous ices. (**b**) Distribution of PIV distances between pairs of structures belonging to different disordered water forms. Only oxygen atoms are included in the definition of **V**, and the switching function $f$ is focused in the range 1.0–4.5 Å. The gap between same-type and different-type distances proves the possibility to automatically resolve the four disordered forms, e.g., by means of cluster analysis. (See Pietrucci and Martoňák 2015 for details)

that efficient parallelization is required for high performance. The volume scaling factor was introduced in Pipolo et al. (2017) to avoid excessive fluctuations of the cell parameters during metadynamics simulations (see below). The choice of $c_{kk'}$ coefficients depends on the application: in water, e.g., the computational burden can often be reduced by focusing on oxygen atoms only with $c_{OO} = 1, c_{OH} = c_{HH} = 0$ (Pietrucci and Martoňák 2015; Pipolo et al. 2017) (see Fig. 6).

The decay range of the switching function is the main parameter entering the PIV definition, which is otherwise very general since it does not depend on specific coordination numbers, angles, symmetries, etc. Conceptually, the switching function $f$ is introduced to focus on a specified range of interatomic distances: short- to medium-range distances are usually the most useful ones, as they display differences between structures (for instance, at the level of pair distribution functions). In water, ranges going from about 2–5 to 2–10 Å allow to resolve different phases (Pipolo et al. 2017): since many neighbors beyond the first shell are included, the term "adjacency matrix" is here employed in a broader sense rather than just considering chemical bonds.

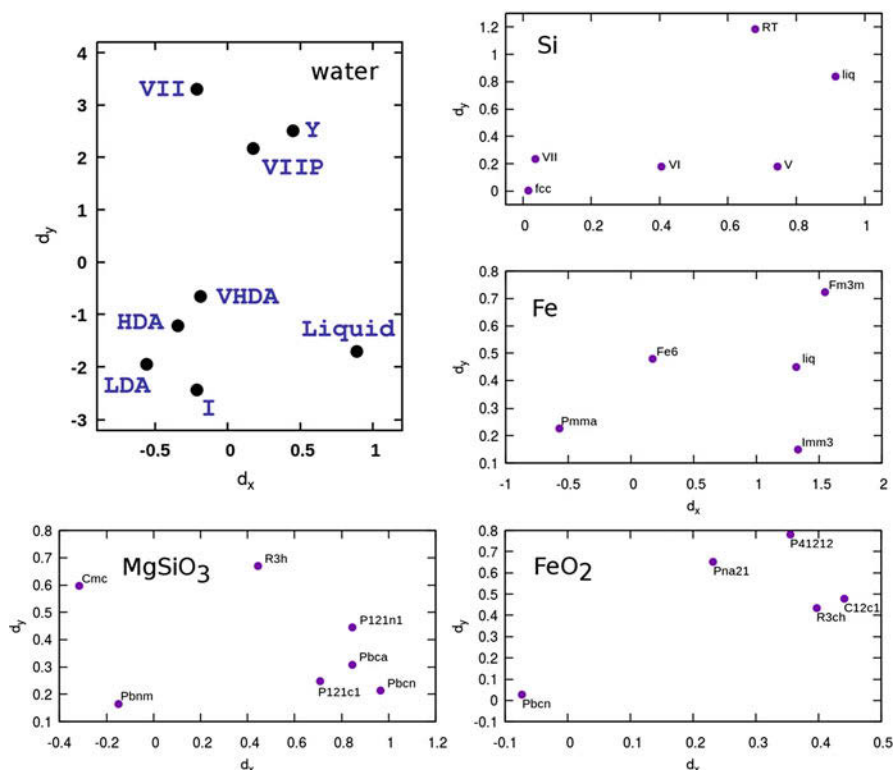
Ideally, the PIV-based metric should display (i) large distances between structures corresponding to different classes like liquid water, crystals, and amorphous forms, (ii) small distances among independent structures within the same class


**Fig. 7** Two-dimensional maps faithfully reproducing PIV distances between structures (deviations <6% for water, correlation coefficient >0.99 in the other systems) for a set of diverse materials. The axes are arbitrary. (See Pipolo et al. 2017 for details)

(differing by thermal fluctuations or by the particular realization of the amorphous network). As shown in Fig. 6, this is indeed the case, with a clear gap between distances corresponding to same-type structures and different-type structures. Based on this result, a convenient graphical representation consists in drawing a two-dimensional diagram, or map, where each structure corresponds to a point and where Euclidean distances between PIVs of the different structures are reproduced with good precision (besides this requirement, the axes of the map are arbitrary). As shown in Fig. 7, it is possible (for reasons that remain to be clarified) to draw such maps in a faithful way for different materials, including water, silicon, iron, and oxides, employing a simple Monte Carlo optimization of the positions starting from random initial ones. This type of illustrations is helpful in visualizing the configuration space of different systems (in the same spirit as alternative approaches of Oganov and Valle 2009; De et al. 2016) and suggests that the PIV-based metric is able to systematically distinguish different forms of a material, both ordered and disordered ones, with ample tolerance for the choice of the switching function

range. Further evidence in this direction comes from the analysis of 50 experimental polymorphs belonging to 13 different materials (covalent, metallic, ionic, and molecular), indicating in all cases the effectiveness of the metric (Pipolo et al. 2017).

## 5    Simulating Transitions Between Ordered and Disordered Water Forms

The maps in Fig. 7 are suggestive of interesting possibilities: in particular, one may wonder whether proximity of structures in the map correlates to kinetic proximity, i.e., the existence of a transformation pathway connecting directly the two forms without passing through the others. In the case of water, comparison with the phase diagram and with the known preparation routes of crystalline and amorphous phases suggests a good correlation (Pietrucci and Martoňák 2015). If confirmed for other materials, this correspondence would allow to organize the vast information available about crystal structures (predicted or observed) in terms of possible transition pathways, helping to guide the experimental synthesis of new materials with desirable properties.

From the point of view of enhanced sampling simulations, the PIV-based metric can be employed to construct CVs able to track complex transformation mechanisms, reconstructing the corresponding free-energy landscapes and barriers. A straightforward recipe makes use of the so-called path CVs (Branduardi et al. 2007): given the structure of the system at a given time $\mathbf{R}(t)$ and a set of $n$ reference structures providing a (discretized) putative pathway between an initial state $\mathbf{R}_1$ and a final state $\mathbf{R}_n$, the variables are defined as

$$s(t) = \frac{\sum_{k=1}^{n} k e^{-\lambda D(\mathbf{R}(t), \mathbf{R}_k)}}{\sum_{k'=1}^{n} e^{-\lambda D(\mathbf{R}(t), \mathbf{R}_{k'})}} \tag{4}$$

$$z(t) = -\frac{1}{\lambda} \log \left( \sum_{k=1}^{n} e^{-\lambda D(\mathbf{R}(t), \mathbf{R}_k)} \right) \tag{5}$$

with $s$ quantifying the progress of the transformation and $z$ the distance from the putative path. Both are important: $s$ allows to direct biasing forces to accomplish the transformation, whereas $z$ discriminates between different pathways and allows tracking transitions to states different from the target. Note that the approach shares similarities with the string method (Weinan et al. 2005; Maragliano et al. 2006). The crucial ingredient is the metric $D$ that in the following is taken simply as the squared Euclidean distance between PIVs: $D(\mathbf{R}(t), \mathbf{R}_k) = ||\mathbf{V}(t) - \mathbf{V}_k||^2$ (see Eq. 3). $\lambda$ is a parameter that can be conveniently set to the order of the inverse distance between neighboring reference configurations, assuming they are equally spaced. A much larger $\lambda$ would produce very irregular and discontinuous pathways, while a much smaller one would hamper the resolution of different phases. In several works, path collective variables have been employed to study conformational

changes of biomolecules (Berteotti et al. 2008; Pfaendtner et al. 2009) and chemical reactions in gas phase (Branduardi et al. 2011; Gallet et al. 2012; Pietrucci and Andreoni 2014), based on simple root mean square deviations between Cartesian positions as a metric. Employing PIV-based distances, these coordinates become an effective tool for the simulation of phase transitions. Clearly, if feasible, using only the initial and final states as references ($n = 2$) amounts to a significant simplification, removing the need for educated guesses about the transformation mechanism: application to water, as described below, demonstrates that this can be done, letting the system discover transition pathways without prejudice (Pipolo et al. 2017) (see also Pietrucci and Saitta (2015) for an analogous scheme applied to chemical reactions in solution, using the distance between coordination patterns of selected atoms as a metric).

Figure 8 overlaps the phase diagram of a realistic model of water (TIP4P/2005 Abascal and Vega 2005) with structural transitions obtained by metadynamics and umbrella sampling simulations (at fixed pressure and temperature) based on PIV path CVs. A particularly interesting result is represented by the crystallization transitions both at low and high pressure, since passing from disordered to ordered water forms (particularly without strong supercooling) is probably one of the most difficult tasks in the general field of molecular simulations. At low pressure, the crystallization of ice I is obtained both from the liquid and from amorphous (LDA) ice, in the temperature range 240–260 K around the melting point ($T_m \simeq 250$ K for the adopted interatomic potential Abascal and Vega 2005). As shown in Fig. 9, nucleation of ice proceeds through the formation of a crystal nucleus of cubic symmetry (Ic), ending up in a final state with either a perfect cubic symmetry or

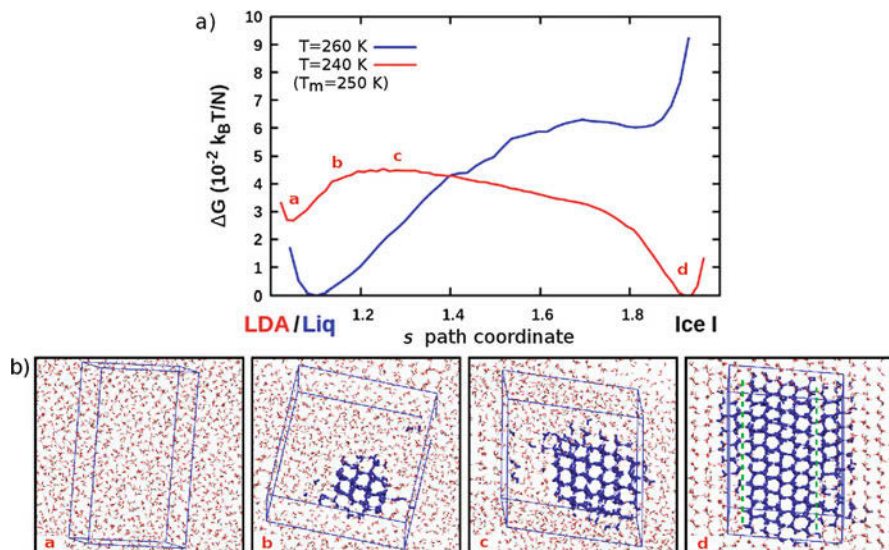
**Fig. 8** The water phase diagram obtained in Abascal and Vega (2005) for the TIP4P/2005 interatomic potential (gray) is superimposed with metadynamics and umbrella sampling simulations of phase transitions (red arrows) between (meta)stable phases (blue). Dashed green lines represent pressure and temperature variations within a phase, obtained with unbiased molecular dynamics simulations. (Adapted from Pipolo et al. 2017)


**Fig. 9** (**a**) Free-energy profiles, projected along the $s$ path coordinate, for the crystallization transitions LDA – ice I at $T = 240$ K and liquid – ice I at $T = 260$ K, both at $P = 1$ bar. The latter transition appears thermodynamically unfavorable, consistently with the temperature being higher than the melting temperature of 250 K (TIP4P/2005 potential). Umbrella sampling simulations with $N = 800$ water molecules were seeded from structures extracted from a metadynamics trajectory. The free-energy minima are arbitrarily set to zero. (**b**) Representative structures along the transition pathway for LDA – ice I crystallization. Ice-like molecules, characterized by an averaged local tetrahedral bond order parameter (Lechner and Dellago 2008) of oxygen >0.7, are marked in blue. Snapshot $c$ shows the ice I nucleus at its critical size. Snapshot $d$ displays stacking-disordered ice I, with cubic regions separated by hexagonal layers (green lines). (See Pipolo et al. 2017 for details)

made up of layers of cubic Ic and hexagonal Ih ice, consistently with experiments finding stacking-disordered ice I (Malkin et al. 2012). At high pressure, simulations of the VHDA–ice VII transformation lead to observe two additional metastable configurations: a plastic phase previously proposed in Himoto et al. (2014) and a new phase characterized by a tetragonal oxygen lattice and stacked layers of hydrogen-bond networks. This result illustrates how the approach does not constrain the system to sample configurations along a simple path connecting the two reference structures but rather allows it to follow complex mechanisms and discover new free-energy basins.

The possibility to study crystallization at (or even above) the melting temperature, in the bulk, without any seeds and with the realistic TIP4P/2005 water model indicates that very challenging transformations can be simulated both in favorable and unfavorable thermodynamic conditions, with a moderate computational cost (of the order of 100 ns for metadynamics and of 1000 ns for umbrella sampling simulations) (Pipolo et al. 2017). The PIV-path-CVs approach helped also providing new insight in the problem of heterogeneous ice nucleation, reconstructing

mechanisms, and free-energy landscapes. In Fitzner et al. (2017), ice nucleation was simulated using the mW model of water (Molinero and Moore 2009) and two different fcc model surfaces: the latter give rise to different precritical nucleation clusters that have an important effect on kinetics by controlling which ice polymorph will form. Since different substrates lead to the formation of different ice crystals, heterogeneous classical nucleation theory turns out to be unsuitable to describe the process.

# 6    Conclusions

In the attempt to find a general description of transformation processes at the atomic scale, the adjacency matrix corresponding to the graph of interatomic connections proves a fruitful starting point for structural comparison metrics as well as enhanced sampling coordinates. A distinct feature of this approach is its simple and universal character, as a broad range of condensed matter systems becomes amenable to study in a unified way, addressing ordered and disordered structures on the same footing. In particular, besides the case studies on nanostructures and bulk materials presented in the preceding sections, another important and rapidly growing field of application of such topology-based techniques corresponds to chemical reactions in solution (Pietrucci and Saitta 2015), traditionally difficult to simulate in a robust way as attested by the lack of systematic studies. Among desirable future developments, an important challenge consists in obtaining a more direct access to the kinetic properties of transformation processes (as of today, most enhanced sampling techniques are focused on time-less free-energy landscapes): eventually, the subtle interplay between thermodynamics and kinetics is the key to understand and control the experimental behavior and synthetic routes of materials. In this context, the possibility to construct in a systematic way good approximations of the ideal reaction coordinates represents a significant step forward.

**Index terms** structural transformations, phase transitions, crystallization, nanostructures, disordered systems, chemical reactions, water phase diagram, enhanced sampling, metadynamics, umbrella sampling, free-energy landscapes, structural comparison, structural fingerprints, distance metrics, collective variables, reaction coordinates, graph theory, adjacency matrix, topology of interatomic bond network.

**Abstract**

Atomistic simulations can give a microscopic understanding of materials. However, their use is generally limited by the time scales that can be accessed as normally this falls short of what is needed to properly sample the complex free energy landscapes that characterize most material systems. Advanced methods are thus needed to enhance the sampling and overcome this time scale problem. Variationally enhanced sampling is one such approach based on identifying the important slow degrees of freedom and enhancing their fluctuations through the introduction of an external bias potential. The method is based on a variational principle that shows how the bias potential can be constructed by minimizing a convex functional, which brings a lot of flexibility. We introduce the theory and methodology of variationally enhanced sampling and discuss various novel and innovative applications and extensions.

## 1    Introduction

Atomistic simulations constitute an important part of material modeling allowing for a microscopic understanding of their behavior. However, it is well known that such simulations generally suffer from severe limitations as the time scales that can be accessed fall short of what is needed. A case in point is nucleation of a crystal, in most cases the nucleation process occurs on much longer time scales than can be simulated in practice. This comes from the fact that free energy landscapes of material systems are characterized by many metastable states that are separated by barriers much larger than the thermal energy, leading to kinetic bottlenecks. This problem is of course quite general and comes up anywhere atomistic simulations are used in chemistry, physics, and biology. It is therefore of great importance to develop advanced methods that lead to an enhanced sampling of phase space.

A large and important class of such enhanced sampling techniques is based on identifying the important slow degrees of freedom and in different manners enhancing their fluctuations, allowing the system more easily to migrate between metastable states (Valsson et al. 2016). In practice this is done by considering so-called collective variables (CVs) which are coarse-grained descriptors that depend on the atomic coordinates and properly distinguish between the metastable states of the system. CV fluctuations are then enhanced by adding a bias potential that acts in the space spanned by the CVs. The origin of this idea can be traced to umbrella sampling introduced by Torrie and Valleau (1977) where they employed a static bias potential obtained by trial and error. Constructing a suitable bias potential that effectively enhances CV fluctuations is far from straightforward as this implies knowledge about the underlying free energy landscape which is nearly always unknown a priori and the very object that one is interested in obtaining. Methods have thus been developed that construct the bias on-the-fly during the simulation. Among such techniques are, for example, local elevation (Huber et al. 1994), adaptive biasing force (Darve and Pohorille 2001), Wang-Landau algorithm

(Wang and Landau 2001), energy landscape paving (Hansmann and Wille 2002), Gaussian-mixture umbrella sampling (Maragakis et al. 2009), and metadynamics (Laio and Parrinello 2002; Barducci et al. 2008), to name a few.

Variationally enhanced sampling (VES) (Valsson and Parrinello 2014) is a method in this spirit that we introduced in 2014. What makes VES interesting is that it is based on a variational principle that shows how an effective bias potential can be constructed by minimizing a convex functional. This brings a lot of flexibility, for example, in the form of the bias potential that can be employed. Furthermore, it is possible to tailor in which way the CV fluctuations are enhanced. We will here introduce the theory and methodology of VES and discuss its various applications and extensions.

## 2 Theory and Methodology of Variationally Enhanced Sampling

### 2.1 Collective Variable-Based Enhanced Sampling

We consider a system described by coordinates $\mathbf{R}$ and potential energy function $U(\mathbf{R})$. The Boltzmann distribution, which one wants to sample with molecular dynamics (MD) or Monte Carlo simulations at a given temperature $T$, is defined as $P(\mathbf{R}) = e^{-\beta U(\mathbf{R})}/\int d\mathbf{R}\, e^{-\beta U(\mathbf{R})}$ where $\beta = (k_\mathrm{B}T)^{-1}$ is the inverse temperature. One can introduce some set of collective variables $\mathbf{s}(\mathbf{R}) = (s_1(\mathbf{R}), s_2(\mathbf{R}), \ldots, s_n(\mathbf{R}))$ that depend on $\mathbf{R}$ and are able to properly distinguish between the relevant metastable states. The equilibrium probability distribution associated with the CVs is defined as

$$P(\mathbf{s}) = \langle \delta\left(\mathbf{s} - \mathbf{s}(\mathbf{R})\right)\rangle = \int d\mathbf{R}\, \delta(\mathbf{s} - \mathbf{s}(\mathbf{R}))\, P(\mathbf{R}). \tag{1}$$

The free energy surface (FES) associated with the CVs is defined as the logarithm of the probability distribution,

$$F(\mathbf{s}) = -\frac{1}{\beta} \log P(\mathbf{s}), \tag{2}$$

where we can ignore immaterial constants. Under the influence of an external bias potential $V(\mathbf{s}(\mathbf{R}))$ that acts in the space spanned by the CVs, the biased probability distribution is

$$P_V(\mathbf{s}) = \langle \delta\left(\mathbf{s} - \mathbf{s}(\mathbf{R})\right)\rangle_V = \int d\mathbf{R}\, \delta(\mathbf{s} - \mathbf{s}(\mathbf{R}))\, P_V(\mathbf{R})$$

$$= \frac{e^{-\beta[F(\mathbf{s})+V(\mathbf{s})]}}{\int d\mathbf{s}\, e^{-\beta[F(\mathbf{s})+V(\mathbf{s})]}} \propto P(\mathbf{s})\, e^{-\beta V(\mathbf{s})} \tag{3}$$

where $P_V(\mathbf{R}) = e^{-\beta[U(\mathbf{R})+V(\mathbf{s}(\mathbf{R}))]} / \int d\mathbf{R}\, e^{-\beta[U(\mathbf{R})+V(\mathbf{s}(\mathbf{R}))]}$ is the biased Boltzmann distribution.

## 2.2 Variational Principle to Enhanced Sampling

Variationally enhanced sampling is based on a variational principle given by a functional $\Omega[V]$ that depends on an external bias potential $V(\mathbf{s})$ (Valsson and Parrinello 2014). The functional is defined as

$$\Omega[V] = \frac{1}{\beta} \log \frac{\int d\mathbf{s}\, e^{-\beta[F(\mathbf{s})+V(\mathbf{s})]}}{\int d\mathbf{s}\, e^{-\beta F(\mathbf{s})}} + \int d\mathbf{s}\, p(\mathbf{s}) V(\mathbf{s}), \tag{4}$$

where $p(\mathbf{s})$ is a predefined probability distribution that is assumed to be normalized. It can be shown that $\Omega[V]$ is invariant under the addition of a constant to $V(\mathbf{s})$, namely, $\Omega[V + k] = \Omega[V]$, and that it is a convex functional, i.e., fulfills

$$\Omega\left[\frac{V_1 + V_2}{2}\right] \leq \frac{1}{2}\Omega[V_1] + \frac{1}{2}\Omega[V_2]. \tag{5}$$

The minimum of $\Omega[V]$ is given up to a constant by

$$V(\mathbf{s}) = -F(\mathbf{s}) - \frac{1}{\beta} \log p(\mathbf{s}). \tag{6}$$

It follows from the convexity of $\Omega[V]$ that this is the global minimum. By inserting this bias potential into Eq. (3), which gives $P_V(\mathbf{s}) = p(\mathbf{s})$, one can see that at the minimum the CVs are sampled according to the distribution $p(\mathbf{s})$. In other words, the distribution $p(\mathbf{s})$ is a so-called target distribution that determines the sampling of CVs that is obtained when minimizing $\Omega[V]$.

The variational principle implies that one can construct an effective bias potential by minimizing $\Omega[V]$ and that the FES $F(\mathbf{s})$ can be directly obtained from the bias potential that minimizes $\Omega[V]$. Furthermore, by appropriately choosing the target distribution, one can tailor the way in which CV fluctuations are enhanced. As discussed below there is considerable freedom in how this can be done.

The functional $\Omega[V]$ has close relation to the concepts of cross entropy, relative entropy, and the Kullback-Leibler (KL) divergence (Rubinstein 1999; Shell 2008; Bilionis and Koutsourelakis 2012; Zhang et al. 2014). This can be seen by rewriting the functional as (Invernizzi et al. 2017)

$$\beta\Omega[V] = D_{\mathrm{KL}}(p||P_V) - D_{\mathrm{KL}}(p||P) = H_{\mathrm{x}}(p||P_V) - H_{\mathrm{x}}(p||P), \tag{7}$$

where $D_{\mathrm{KL}}(P||Q) = \int d\mathbf{s}\, P(\mathbf{s}) \log \frac{P(\mathbf{s})}{Q(\mathbf{s})}$ is the KL divergence (or relative entropy) between two probability distributions $P(\mathbf{s})$ and $Q(\mathbf{s})$ and $H_{\mathrm{x}}(P||Q) =$

$- \int d\mathbf{s}\, P(\mathbf{s}) \log Q(\mathbf{s})$ is the cross entropy. Thus, minimizing $\Omega[V]$ is equivalent to minimizing the KL divergence or the cross entropy between the biased distribution $P_V(\mathbf{s})$ and the target distribution $p(\mathbf{s})$.

## 2.3 Minimization in Practice

In practical applications the variational principle is utilized by assuming some functional form for $V(\mathbf{s}; \boldsymbol{\alpha})$ that depends on a set of variational parameters $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \ldots, \alpha_K)$. In this way, one goes from an abstract functional minimization to that of the multidimensional function $\Omega(\boldsymbol{\alpha}) = \Omega[V(\boldsymbol{\alpha})]$. During the minimization of $\Omega(\boldsymbol{\alpha})$, the variational parameters $\boldsymbol{\alpha}$ are iteratively updated by using some recursion formula that utilizes the gradient $\nabla \Omega(\boldsymbol{\alpha})$. The elements of the gradient $\nabla \Omega(\boldsymbol{\alpha})$ are defined as

$$\frac{\partial \Omega(\boldsymbol{\alpha})}{\partial \alpha_i} = - \left\langle \frac{\partial V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_i} \right\rangle_{V(\boldsymbol{\alpha})} + \left\langle \frac{\partial V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_i} \right\rangle_p, \tag{8}$$

where the expectation values are obtained under the influence of the bias potential $V(\mathbf{s}; \boldsymbol{\alpha})$ or over the target distribution $p(\mathbf{s})$, respectively. If needed, the Hessian matrix $\mathbf{H}(\boldsymbol{\alpha})$ can be defined in similar manner as

$$\frac{\partial^2 \Omega(\boldsymbol{\alpha})}{\partial \alpha_i\, \partial \alpha_j} = - \left\langle \frac{\partial^2 V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_i\, \partial \alpha_j} \right\rangle_{V(\boldsymbol{\alpha})} + \left\langle \frac{\partial^2 V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_i\, \partial \alpha_j} \right\rangle_p$$

$$+ \beta \operatorname{cov} \left[ \frac{\partial V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_i}, \frac{\partial V(\mathbf{s}; \boldsymbol{\alpha})}{\partial \alpha_j} \right]_{V(\boldsymbol{\alpha})}. \tag{9}$$

Since $\nabla \Omega(\boldsymbol{\alpha})$ is intrinsically noisy due to statistical averaging, it is necessary to use stochastic optimization methods. In particular the averaged stochastic gradient descent algorithm introduced by Bach and Moulines (2013) has proven a good choice so far. In this algorithm the variational parameters $\boldsymbol{\alpha}$ are updated according to the following recursion equation

$$\boldsymbol{\alpha}^{(n+1)} = \boldsymbol{\alpha}^{(n)} - \mu \left[ \nabla \Omega(\bar{\boldsymbol{\alpha}}^{(n)}) + \mathbf{H}(\bar{\boldsymbol{\alpha}}^{(n)}) \left[ \boldsymbol{\alpha}^{(n)} - \bar{\boldsymbol{\alpha}}^{(n)} \right] \right], \tag{10}$$

where $\mu$ is a fixed step size and the gradient and Hessian $\mathbf{H}(\bar{\boldsymbol{\alpha}}^{(n)})$ are obtained using the averaged parameters $\bar{\boldsymbol{\alpha}}^{(n)} = \frac{1}{n+1} \sum_{k=0}^{n} \boldsymbol{\alpha}^{(k)}$ (i.e., the bias potential depends on the averaged parameters). The averaging leads to a smooth convergence of the bias and the estimated FES. Furthermore, it allows for the usage of rather short sampling time for each iteration, on the order of few thousand MD steps. It should be noted that this averaged stochastic gradient descent algorithm is not a unique choice and other stochastic optimization methods could be used. In fact, it is an interesting

research question to develop and benchmark new optimization algorithm to perform the minimization of $\Omega(\boldsymbol{\alpha})$.

It has proven quite useful to utilize multiple walkers (Raiteri et al. 2006) within VES. In this scheme multiple copies of the system that share the same bias potential are run in parallel. The averages needed for the gradient and the Hessian are then obtained by combined sampling of the different copies. Furthermore, in the same way as for metadynamics (Bussi et al. 2006), VES can be used together with parallel tempering or other replica exchange techniques that help with sampling missing slow degrees of freedom.

## 2.4    Linear Basis Set Expansion

The most natural way to represent the bias potential is to consider a linear expansion in some set of basis functions $f_k(\mathbf{s})$,

$$V(\mathbf{s}; \boldsymbol{\alpha}) = \sum_k \alpha_k \, f_k(\mathbf{s}). \tag{11}$$

Most applications so far have employed basis functions constructed as tensor product of one-dimensional orthogonal basis functions such as Fourier series (i.e., plane waves) for periodic CVs and Legendre or Chebyshev polynomials for nonperiodic CVs. For example, for two CVs the bias potential is written as

$$V(s_1, s_2; \boldsymbol{\alpha}) = \sum_{i,j} \alpha_{i,j} \, g_i(s_1) \, h_j(s_2), \tag{12}$$

where $g_i(s_1)$ and $h_j(s_2)$ are some one-dimensional orthogonal basis functions. A relatively modest number of basis functions is needed in most cases as FESs are generally smooth functions.

Although the basis function types considered so far have performed quite satisfactory, it is interesting to consider other types and see how they perform. For example, one idea would be using localized basis functions like splines or wavelets. Along this direction, Demuynck et al. (2017) employed VES with one-dimensional bias potential written as a sum of Gaussians, though the performance of this choice was not compared to other basis function types.

## 2.5    Target Distribution

A strength of variationally enhanced sampling is its flexibility in choosing the target distribution $p(\mathbf{s})$, which allows to tailor the sampling of CVs. Generally one wants to employ a target distribution where the sampling is enhanced as compared to the unbiased distribution $P(\mathbf{s})$. The simplest choice is to consider a uniform target distribution, in other words try to completely flatten the sampling in CV space.

However, this is often rather non-optimal as it leads to sampling regions high in free energy that are generally not of interest. Instead, it is usually better to take inspiration from well-tempered metadynamics (Barducci et al. 2008) and consider the so-called well-tempered distribution given by

$$p(\mathbf{s}) = \frac{[P(\mathbf{s})]^{1/\gamma}}{\int d\mathbf{s}\,[P(\mathbf{s})]^{1/\gamma}} = \frac{e^{-(1/\gamma)\beta F(\mathbf{s})}}{\int d\mathbf{s}\,e^{-(1/\gamma)\beta F(\mathbf{s})}},$$

(13)

where $\gamma > 1$ is an adjustable parameter called the bias factor that controls how much the sampling is enhanced as compared to the unbiased distribution $P(\mathbf{s})$. In this way it is possible to enhance CV fluctuations in a controllable manner and focus the sampling toward the lowest free energy regions that are most relevant. This distribution can also be viewed as sampling on an effective free energy landscape where the barriers have been reduced by a factor of $\gamma$. Within VES the dependence on the a priori unknown $F(\mathbf{s})$ is bypassed by using a simple iterative scheme (Valsson and Parrinello 2015).

In general using the well-tempered distribution as target distribution is the most appropriate choice. However, in specific cases it can be useful to use other choices, for example, to localize the sampling on a specific region in CV space or to enforce restraints on the CVs.

## 2.6    Reweighting

From the bias potential it is possible to directly estimate the FES as a function of the biased CV using Eq. 6. However, it should be noted that by reweighting it is also possible to get the FES as a function of any other set of CVs or to get the unbiased expectation values of any observable that depends on the atomic coordinates.

From the relation $P(\mathbf{R}) \propto P_V(\mathbf{R})\,e^{\beta V(\mathbf{s}(\mathbf{R}))}$, one can write the unbiased average of an observable $O(\mathbf{R})$ as

$$\langle O(\mathbf{R}) \rangle = \frac{\left\langle O(\mathbf{R})\,e^{\beta V(\mathbf{s}(\mathbf{R}))} \right\rangle_V}{\left\langle e^{\beta V(\mathbf{s}(\mathbf{R}))} \right\rangle_V},$$

(14)

where the expectation values on the right-hand side are obtained in the biased ensemble. In other words, each configuration obtained in the biased ensemble is weighted by the value of the bias acting on it. It is possible to employ this reweighting even during the VES optimization if the bias potential is changing sufficiently slow that it can be considered as quasi-stationary.

The FES as a function of any set of CVs $\mathbf{s}'$ can be obtained by using the relation

$$F(\mathbf{s}') = -\frac{1}{\beta} \log \left\langle \delta(\mathbf{s}' - \mathbf{s}'(\mathbf{R})) \right\rangle = -\frac{1}{\beta} \log \left\langle \delta(\mathbf{s}' - \mathbf{s}'(\mathbf{R}))\,e^{\beta V(\mathbf{s}(\mathbf{R}))} \right\rangle_V,$$

(15)

which in practice is obtained by computing a reweighted histogram. It can happen that the form of the bias potential employed is efficient enough to enhance the sampling but might not have sufficient variational flexibility to fully represent the FES. In such cases one can use reweighting to obtain the FES for the biased CVs. In any case, it is a good general policy to obtain the FES by reweighting and compare that to the one obtained directly from the bias potential, significant difference between the two might indicate that there are some problems with the simulation, for instance, the CVs are poorly chosen or the basis set size is not sufficient to describe the FES.

## 2.7    Software Implementation

Variationally enhanced sampling is available through the VES code (http://www. ves-code.org) which is a module for the PLUMED 2 molecular dynamics plug-in (Tribello et al. 2014). This makes it possible to use VES with all the MD codes that can be interfaced with PLUMED 2 and make use of its vast library of CVs. The VES code is open-source and is officially integrated into PLUMED since version 2.4. We refer the reader to the manual of PLUMED 2 to see the features available in the VES code.

## 3    Applications and Extensions of Variationally Enhanced Sampling

Variationally enhanced sampling has already been used in various applications (Piccini et al. 2017; Piaggi et al. 2017; Palazzesi et al. 2017; Demuynck et al. 2017; Perego et al. 2018; Yang and Parrinello 2018). However, the most intriguing aspect of VES is that it is based on a variational principle. This can be used in novel and innovative ways by employing clever choices for the bias potential and the target distribution. In some sense VES can be viewed as a framework for developing new ideas and methods within enhanced sampling and free energy calculations. Already there are numerous interesting applications of VES that utilize the variational principle in this direction. We will briefly describe them in the following.

## 3.1    Free-Energy Flooding for Kinetic Rate Calculations

Obtaining kinetic properties of rare events from molecular simulations is of great practical interest, for example, how much time on average the system takes to go from one metastable state to another. Inspired by the success of using metadynamics to obtain kinetics of rare events from biased simulation (Tiwary and Parrinello 2013), an extension of VES has been developed for this purpose.

The main assumption is that the transition state should be free of bias. It can then be shown that following relations holds between the physical transition time $\tau$ and the transition time in the biased simulation $\tau_V$ (Voter 1997; Grubmüller 1995)

$$\tau = \tau_V \left\langle e^{\beta V(\mathbf{s})} \right\rangle_V, \tag{16}$$

where $\langle e^{\beta V(\mathbf{s})} \rangle_V$ is the so-called acceleration factor measured in the biased simulation that tells how much the time is boosted as compared to the unbiased simulation.

The idea that McCarty et al. (2015) followed is to use VES to generate a bias potential that only fills the underlying FES up to some predefined cutoff value $F_c$. Thus, by appropriately choosing the cutoff value, it is possible to significantly accelerate transitions between metastable states while still ensuring that the transition states are free of bias, thus allowing the usage of Eq. 16. This is achieved by considering a bias potential of the form

$$V(\mathbf{s}; \boldsymbol{\alpha}) = v(\mathbf{s}; \boldsymbol{\alpha}) \cdot S(-v(\mathbf{s}; \boldsymbol{\alpha}) - F_c), \tag{17}$$

where $v(\mathbf{s}; \boldsymbol{\alpha})$ is some representation of the FES (e.g., a linear expansion as in Eq. 11) and $S(x)$ is a sigmoidal switching function that continuously goes from 1 to 0 around $x = 0$. This is combined with a target distribution given by

$$p(\mathbf{s}) = \frac{S(F^*(\mathbf{s}) - F_c)}{\int d\mathbf{s}\, S(F^*(\mathbf{s}) - F_c)}, \tag{18}$$

that is iteratively updated using the current best estimate of the FES $F^*(\mathbf{s}) \approx -v(\mathbf{s})$.

In practical applications the bias potential is first optimized with a given cutoff value $F_c$ until a satisfactory convergence has been achieved. The bias potential is then fixed, and many independent simulations are performed to obtain the necessary statistics. It is a good practice to run at least two sets of simulations using different cutoff values in order to check the consistency of the results. The physical time in each simulation is simply obtained by rescaling the MD time step $\Delta t_{\mathrm{MD}}$ by the bias acting at each MD step

$$t_0 = \sum_i^{n_{\mathrm{MD}}} \Delta t_{\mathrm{MD}} \cdot e^{\beta V(\mathbf{s}(t_i))}, \tag{19}$$

where $n_{\mathrm{MD}}$ is the number of MD steps and $\mathbf{s}(t_i)$ is the value of the CVs at time $t_i = i\, \Delta t_{\mathrm{MD}}$.

The method has been used to obtain kinetic rates for chemical reactions (Piccini et al. 2017) and unfolding times of small proteins (Palazzesi et al. 2017).

### 3.2    Approximate Bias Potentials for Exploring High-Dimensional Free Energy Landscapes

It is of great importance to be able to efficiently sample high-dimensional free energy landscapes. Unfortunately, CV-based enhanced sampling methods are generally limited in the number of CVs that can be biased at the same time. Various ideas and methods have thus been introduced that tackle this problem (Piana and Laio 2007; Abrams and Vanden-Eijnden 2010; Pfaendtner and Bonomi 2015).

A rather interesting idea to approach this problem within VES is to employ approximate bias potentials. One of the simplest examples would be to consider a bias potential that is a sum of pairwise terms

$$V (s_1, s_2, \ldots, s_d; \boldsymbol{\alpha}) = \sum_{i,j} V(s_i, s_j; \boldsymbol{\alpha}^{(i,j)}), \tag{20}$$

where for each pairwise term we employ a linear expansion in some basis functions.

This idea was pursued by Shaffer et al. (2016a) which considered the folding of a small protein where the conformational landscape is described by the large number of backbone dihedral angles. They employed a bias potential written as sum of pairwise terms where only nearest-neighbor dihedral angles along the protein backbone were explicitly correlated. The authors then combined this with a clever choice of the target distribution that indirectly accounts for the important long-range correlations that are missing in the approximate bias potential. In this way the authors were able to generate a bias potential that allowed for an efficient sampling of the folding process. In a follow-up paper (Shaffer et al. 2016b), the authors further extended this idea and showed how it can be used to construct simple coarse-grained models for protein dynamics.

### 3.3    Bespoke Bias for Obtaining Free Energy Differences

An intriguing possibility that VES offers is to use purpose-built bias models that depend on a few variational parameters that are optimized. In this spirit, McCarty et al. (2016) considered a bespoke bias potential based on a model for a two-state free energy landscape given by

$$F(\mathbf{s}_A, \mathbf{s}_B) = \frac{F_A(\mathbf{s}_A) + F_B(\mathbf{s}_B)}{2} - \sqrt{\left(\frac{F_A(\mathbf{s}_A) - F_B(\mathbf{s}_B) - \Delta F}{2}\right)^2 + \Delta^2}, \tag{21}$$

where $F_A(\mathbf{s}_A)$ and $F_B(\mathbf{s}_B)$ are free energy models for the two metastable states, $\Delta F$ is a proxy for the free energy difference between the two states, and $\Delta$ is a coupling parameter. The free energy models used in this equation only need to be locally valid descriptions of the two metastable states, thereby bypassing the need to find

CVs that globally describe the full conformational space of interest. By optimizing the two parameters $\Delta F$ and $\Delta$, it is possible to obtain a bias potential that leads to an effective sampling of the two metastable states.

## 3.4    Bespoke Bias from Physical Models

Similar in spirit to the previous example, Piaggi et al. (2016) followed an interesting idea where they designed a bias potential based on a known physical model. In particular, they considered the important subject of nucleation that is rather challenging for molecular simulations due to the long time scale on which the nucleation process occurs. By employing a bias potential based on a free energy model taken from classical nucleation theory, they were able to greatly accelerate the sampling of nucleation events. This example shows clearly the value of employing a bespoke bias potential based on a physically motivated functional form within VES.

## 3.5    Coarse-Graining from Variationally Enhanced Sampling

A common way to tackle complex system is to construct mesoscopic coarse-grained models that are able to describe its main physical behavior. However, such models introduce phenomenological parameters that need to be derived from the microscopic system. In general this is not an easy task. Invernizzi et al. (2017) showed that VES can be turned into a powerful method to systematically obtain these phenomenological parameters from the microscopic simulations. In particular, they considered the Ginzburg-Landau model for a second-order critical point and showed how VES can be used to obtain its phenomenological parameters in the region close to the liquid-vapor critical point of a Lennard-Jones fluid. The procedure introduced by the authors is completely general and can be adapted for other coarse-grained models.

## 3.6    Variational Approach to Monte Carlo Renormalization Group

A rather interesting application of VES to critical phenomena was reported by Wu and Car (2017). They used VES to develop a method for Monte Carlo renormalization group theory where the critical slowing down near a critical point is avoided by using a bias potential. By optimizing the bias potential within VES, it is possible to obtain an accurate estimate of the renormalized coupling constants and the critical exponents. The authors applied their method to the two-dimensional Ising model. The method can be extended to tackle critical phenomena in more complex systems. For instance, the authors mention it should be possible to adapt the method to tackle field theoretical models, such as the Ginzburg-Landau model. Thus, by combining their method with the phenomenological coarse-graining method from the previous Sect. (3.5), it would be possible to investigate critical phenomena starting from the atomistic scale.

# 4    Conclusion and Outlook

Despite the relatively short time since its introduction, variationally enhanced sampling has already been used in numerous innovative and interesting applications, as we have discussed in the previous section. It is our firm belief that many more will come in the future. Furthermore, we believe that the performance of VES can be further improved in many ways. Thus, the future of VES looks bright and there are many new innovations to be expected.

# Water: Many-Body Potential from First Principles (From the Gas to the Liquid Phase)

**30**

Francesco Paesani

## Contents

**Abstract**

Computer simulations have become an integral part of the toolbox of any researcher interested in molecular sciences, often providing new insights that are difficult (if not impossible) to obtain by other means. However, the predictive power of a computer simulation directly depends on the level of realism that can be used to represent the molecular system of interest. Since the early times of computer simulations, the search for a molecular model of water capable of describing its unique properties across different phases has been the focus of intense research. The continued increase in computer power accompanied by advances in the design of efficient algorithms for correlated electronic structure calculations and tremendous progress in the representation of global potential energy surfaces have recently opened the doors to the development of molecular models rigorously derived from many-body expansions of interaction energies. By quantitatively reproducing individual interaction terms between molecules, it has been shown that these many-body potential energy functions

635

can achieve unprecedented accuracy in computer simulations. This chapter provides an overview of the theoretical formalism underlying such many-body representations, with a particular focus on the performance of the MB-pol potential energy function in predicting the energetics as well as structural, thermodynamic, dynamical, and spectroscopic properties of water from the gas to the condensed phase.

# 1 Introduction

The importance of water cannot be overemphasized. This is the case primarily because the combination of unique physical properties and the wide range of conditions in which it exists in the liquid phase make water essential to life as we know it (Maréchal 2007). After decades of research, there is now little question that the unique behavior of water does not simply result from a three-atom, 10-electron molecule, but rather from the delicate interplay of many-body interactions between individual water molecules, which is further modulated by temperature and pressure (Eisenberg and Kauzmann 1969).

Given water's key role as life's matrix (Ball 2008), it is not surprising that many theoretical and computational studies have attempted to derive a molecular-level picture of water from the gas to the condensed phase. Since the first Monte Carlo (MC) and molecular dynamics (MD) simulations of liquid water performed respectively by Barker and Watts (1969), and Rahman and Stillinger (1971), a myriad of models have been developed, based either on molecular mechanics (commonly defined as "force fields") or quantum mechanics (commonly defined as "ab initio" models). Various flavors of force fields, with different degrees of empiricism, have been proposed over the years, ranging from coarse-grained representations with no atomistic details to classical parameterizations in terms of point charges and rigid bonds, and more sophisticated models that account for molecular flexibility, electronic polarization, and charge transfer (Guillot 2002; Vega and Abascal 2011; Cisneros et al. 2016; Shvab and Sadus 2016). Despite much progress, it has been shown that even the most successful and popular water force fields still exhibit limited accuracy and effectively lack predictive power (Cisneros et al. 2016).

On the other hand, ab initio models are based on either wavefunction theory (WFT) or density functional theory (DFT). Although correlated WFT methods, such as coupled cluster with single, double, and perturbative triple excitations, commonly abbreviated as CCSD(T), can enable molecular level studies of water with chemical accuracy, usually defined as a deviation of 1 kcal/mol from the "exact" result (Rezac and Hobza 2013; Simova et al. 2013), the associated computational cost limits their application to systems containing no more than a handful of molecules (Manna et al. 2017). This implies that DFT remains the only viable ab initio approach for simulations of water across different phases. However, existing DFT models are affected by several shortcomings that drastically limit their predictive ability in

describing the properties of water from small clusters in the gas phase to the liquid phase and ice (Gillan et al. 2016).

As an alternative to both force fields and ab initio models, a new class of analytical potential energy functions (PEFs) has recently been introduced. These PEFs are derived from a rigorous representation of the many-body expansion (MBE) of the interaction energy ($V_N$) between N water molecules (Hankins et al. 1970)

$$V_N (r_1, \ldots, r_N) = \sum_{i=1}^{N} V_{1B} (r_i) + \sum_{i<j}^{N} V_{2B} (r_i, r_j)$$
$$+ \sum_{i<j<k}^{N} V_{3B} (r_i, r_j, r_k) + \cdots + V_{NB} (r_1, r_2, r_3, \ldots, r_N) \tag{1}$$

where $r_i$ collectively denotes the coordinates of the oxygen and hydrogen atoms within the $i^{th}$ water molecule. In Eq. (1), $V_{1B}$ is the one-body (1B) potential, representing the energy required to deform an individual water molecule from its equilibrium geometry, while all higher n-body (nB) interaction terms ($V_{nB}$) are defined recursively through

$$V_{nB} (r_1, \ldots, r_n) = V_n (r_1, \ldots, r_n) - \sum_{i=1}^{N} V_{1B} (r_i) - \sum_{i<j}^{N} V_{2B} (r_i, r_j) - \ldots$$
$$- \sum_{i<j<k<\cdots<n-1}^{N} V_{(n-1)B} (r_i, r_j, r_k, \ldots, r_{n-1}). \tag{2}$$

The importance of many-body effects in water was already recognized in the 1950s by Frank and Wen who introduced a molecular picture of liquid water consisting of "flickering clusters of hydrogen-bonded molecules," emphasizing the cooperative nature of hydrogen bonding (Frank and Wen 1957). The first attempts to develop many-body (MB) potential energy functions (PEFs) for water only using ab initio data were made by Clementi and co-workers (Matsuoka et al. 1976; Evans et al. 1987; Niesar et al. 1990). These pioneering studies demonstrated that Eq. (1) converges rapidly for water, showing that 3B effects can contribute as much as 15–20% to the interaction energy of cyclic water structures and 4B effects represent, on average, 1% of the interaction energy.

With the continued development of faster hardware and efficient algorithms for correlated WFT methods, it is nowadays routine to perform calculations of accurate interaction energies for small molecular systems, which can then serve as a reference for deriving analytical representations of the individual terms of Eq. (1). In particular, exploiting the rapid convergence of the MBE for water, the "Stratified Approximation Many-Body Approach" (SAMBA) has been shown

to provide highly accurate interaction energies for water clusters through the application of progressively lower-level electronic structure methods to represent subsequently higher-body terms of the MBE (Gora et al. 2011). In parallel with hardware and algorithmic developments, tremendous progress has been made in constructing multidimensional mathematical functions that can accurately represent global potential energy surfaces with a large number of degrees of freedom (Braams and Bowman 2009; Bartók et al. 2010; Behler 2016). This progress has been accompanied by the development of efficient classical schemes for treating electrostatic interactions in many-body molecular systems (Thole 1981; van Duijnen and Swart 1998; Cisneros et al. 2006; Piquemal et al. 2006; Torheyden and Jansen 2006; Cisneros et al. 2007; Handley et al. 2009; Gao et al. 2014). As a result, several MB PEFs have been proposed in the last years, the most notable of which are CC-pol (Bukowski et al. 2007), WHBB (Wang et al. 2011) HBB2-pol (Babin et al. 2012), and MB-pol (Babin et al. 2013, 2014; Medders et al. 2014).

Among existing many-body PEFs, MB-pol has been shown to correctly predict the properties of water across different phases (Reddy et al. 2016), reproducing the vibration-rotation tunneling spectrum of the water dimer (Babin et al. 2013), the energetics, quantum equilibria, and infrared spectra of small clusters (Babin et al. 2014; Brown et al. 2017), the structural, thermodynamic, and dynamical properties of liquid water (Medders et al. 2014), the energetics of ice phases (Pham et al. 2017), the infrared (IR) and Raman spectra of liquid water (Medders and Paesani 2015; Reddy et al. 2017), the vibrational sum-frequency generation spectrum of the air/water interface (Medders and Paesani 2016), and the IR and Raman spectra of ice $I_h$ (Moberg et al. 2017).

This chapter reviews recent progress in modeling the properties of water across different phases using computer simulations with the MB-pol PEF. After a brief overview of the theoretical formalism underlying MB-pol and associated computational algorithms, a systematic analysis of the MBE for water is presented, with comparisons with both force fields and ab initio models. The accuracy of MB-pol in representing the multidimensional Born-Oppenheimer potential energy surface of water in the liquid phase and ice is then assessed. Finally, the ability of MB-pol to predict structural, thermodynamic, and dynamical properties as well as vibrational spectra of water from small clusters in the gas phase to the liquid phase and ice is discussed. This is followed by a brief outlook on future developments and applications of many-body PEFs in computer simulations of generic molecular systems.

## 2    MB-pol Theoretical Framework and Functional Form

MB-pol was rigorously derived from Eq. (1). It includes explicit 1B, 2B, and 3B terms, while all higher-order contributions are accounted for in a mean field sense through a classical representation of N-body induction (Babin et al. 2013, 2014). Each water molecule is represented by six sites: three sites correspond to the physical atoms (oxygen and two hydrogen atoms), two fictitious sites are located

**Fig. 1** MB-pol model of a water molecule. O, $H_1$, and $H_2$ correspond to the oxygen and hydrogen atoms, respectively, $L_1$ and $L_2$ represent the oxygen lone-pairs, and M is an additional fictitious site
symmetrically along the directions of the oxygen lone-pairs, and an additional M-site is located along the HOH bisector (Fig. 1). The number and location of the six sites were optimized to reproduce both dipole and quadrupole moments of an isolated water molecule as well as to accurately represent the anisotropy of the potential energy surface of the water dimer.

The 1B term of MB-pol corresponds to the monomer PEF developed by Partridge and Schwenke which accurately reproduces the rovibrational spectrum of an isolated water molecule in the gas phase (Partridge and Schwenke 1997). Associated with the 1B energy expression is a nonlinear dipole moment surface represented by geometry dependent (positive) point charges on the two hydrogen atoms, which are balanced by a negative point charge placed on the M-site (Fig. 1). The molecular polarizabity tensor of an isolated water molecule is represented by isotropic atomic polarizabilities located on the three physical atoms.

MB-pol 2B term is expressed by combining classical expressions for permanent and induced electrostatics, and dispersion energy with a multidimensional term that corrects for deficiencies associated with a purely classical representation of intermolecular interactions at short range (Stone 1997). This additional term, which smoothly switches to zero as the separation between the oxygen atoms of the two water molecules within a dimer approaches 6.5 Å, effectively represents quantum-mechanical interactions arising from the overlap of the monomer electron densities (Babin et al. 2013), such as charge transfer and penetration and Pauli repulsion (Khaliullin et al. 2007, 2008). Both 2B permanent electrostatics and induction are represented by a modified Thole-type expression derived from the TTM4-F model (Burnham et al. 2008), while the dispersion energy is expressed through a rigorous fit to the asymptotic ab initio reference energy as originally introduced by the CC-pol PEF (Bukowski et al. 2008). Following the same theoretical scheme,

MB-pol represents 3B interactions by combining a classical 3B induction term with a multidimensional short-range function, which smoothly switches to zero when the oxygen-oxygen separations between all pairs of water molecules within a trimer approach 4.5 Å (Babin et al. 2014). Given its functional form, MB-pol can then be viewed as a many-body PEF built upon a baseline polarizable model supplemented by short-range 2B and 3B contributions that effectively represent quantum-mechanical interactions that cannot be described by purely classical expressions (Medders and Paesani 2015).

The short-range 2B and 3B multidimensional functions are expressed by 4th-degree permutationally invariant polynomials (Braams and Bowman 2009) in variables that are functions of the distances between all six molecular sites (Fig. 1). The invariance is imposed with respect to permutations of whole molecules as well as of the two hydrogen atoms within the same molecule. The coefficients of both 2B and 3B permutationally invariant polynomials were optimized using supervised learning (Abu-Mostafa et al. 2012) to reproduce the interaction energies calculated at the CCSD(T) level of theory in the complete basis set (CBS) limit for approximately 42,000 and 12,000 dimers and trimers, respectively. Specific details about MB-pol 2B and 3B training sets can be found in the original references (Babin et al. 2013, 2014).

As shown in Fig. 2, MB-pol provides an accurate description of the low-order terms (i.e., 2B, 3B, and 4B) of the MBE. Specifically, the 2B term is associated with a root-mean-square-deviation (RMSD) of 0.028 kcal/mol relative to the CCSD(T)/CBS reference values. The latter were obtained via a two-point extrapolation (Halkier et al. 1999a, b) of the energies calculated with aug-cc-pVTZ and aug-cc-pVQZ basis sets (Dunning 1989) supplemented with an additional set of midbond (mb) functions (Tao and Pan 1992) placed at the center of mass of each dimer configuration. The RMSD associated with the MB-pol 3B term is 0.026 kcal/mol relative to CCSD(T)/CBS reference values obtained with the aug-cc-pVTZ basis set supplemented with the same set of midbond functions used for the 2B calculations, which were placed at the center of mass of each trimer configuration. Finally, the RMSD for the 4B interactions is 0.030 kcal/mol relative to MP2 reference values obtained with the aug-cc-pVTZ basis set supplemented with the same set of midbond functions described above, which were placed at the center of mass of each tetramer.

The accuracy of MB-pol in reproducing the individual terms of the MBE (Fig. 2) reflects the ability of the underlying functional form to correctly represent many-body effects at both short and long intermolecular separations. To further demonstrate this aspect, Fig. 3 shows a comparison between the results obtained with MB-pol and the absolutely-localized molecular orbital energy decomposition analysis, ALMO EDA, method (Khaliullin et al. 2007, 2008) for a radial scan along the hydrogen bond coordinate of the minimum energy structure of the water dimer. In this analysis, the O-O distance ($R_{OO}$) is constrained at different values while all other atomic coordinates are optimized. Panel (a) shows the comparison between MB-pol (Thole-damped) permanent and induced electrostatics and the corresponding terms obtained from ALMO EDA calculations carried out at the
**Fig. 2** Correlation plots of 2B (**a**), 3B (**b**), and 4B (**c**) interaction energies. On the x-axes are the reference values calculated at the CCSD(T)/CBS (for 2B and 3B) and MP2/aVTZ (for 4B) levels of theory. On the y-axes are the corresponding MB-pol values. (Adapted from Paesani 2016)

ωB97M-V level of theory (Mardirossian and Head-Gordon 2015) with the def2-TZVPPD basis set (Weigend and Ahlrichs 2005; Rappoport and Furche 2010). In this analysis, ωB97M-V was specifically chosen because it yields interaction energies in close agreement with the CCSD(T) reference data (see Fig. 5), while the def2-TZVPPD basis set is large enough to fully capture charge transfer but still relatively small to avoid inter-monomer-orbital linear-dependence.

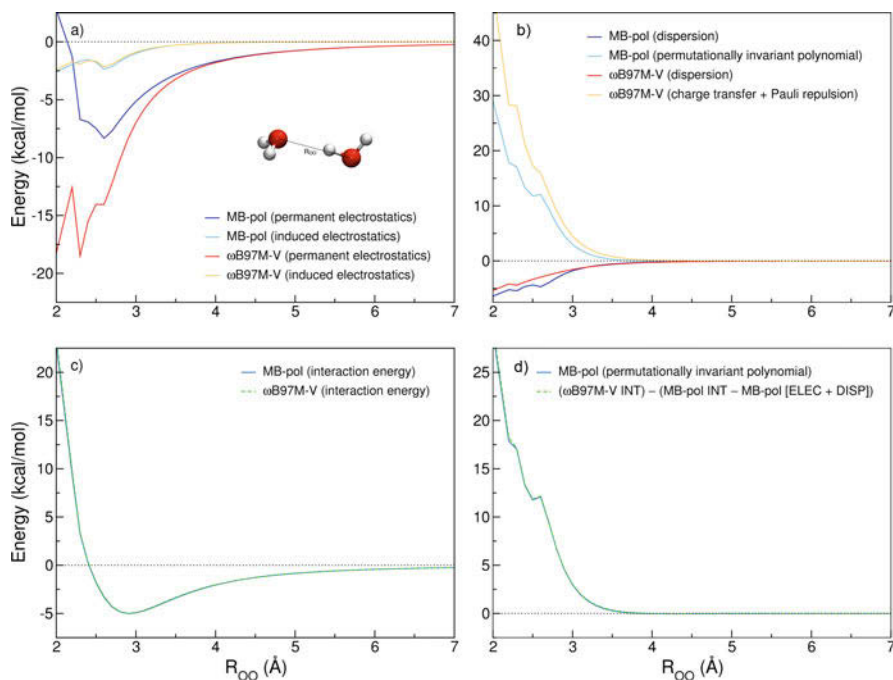
The agreement between MB-pol and ALMO EDA for $R_{OO} > 3.5$ Å demonstrates that the baseline electrostatic model adopted by MB-pol correctly reproduces permanent and induced electrostatic interactions at medium and long range, where there is minimal, if any, overlap between the monomer electron densities. As expected, deviations due to charge penetration, which cannot be represented by classical expressions, are found at short range, particularly, for the contribution associated with permanent electrostatics. Similarly, panel (b) shows that the (damped) dispersion energy term of MB-pol quantitatively reproduces the corresponding


**Fig. 3** Comparison between MB-pol and ALMO EDA energy decomposition for a radial scan along the hydrogen bond coordinate of the minimum energy structure of the water dimer. (**a**) Comparison between permanent and induced electrostatic interactions obtained from MB-pol and ωB97M-V/def2-TZVPPD. (**b**) Comparison of the terms associated with dispersion energy and charge transfer combined with Pauli repulsion obtained from ωB97M-V/def2-TZVPPD calculations with the corresponding MB-pol terms. (**c**) Comparison of MB-pol and ωB97M-V/def2-TZVPPD total interaction energy. (**d**) Comparison between the nonclassical terms obtained with ωB97M-V/def2-TZVPPD and MB-pol permutationally invariant polynomial

ALMO EDA values at medium and long range, with deviations at short distances, where the definition of dispersion energy derived from the asymptotic expansion of the interaction energy breaks down (Stone 1997). The comparisons shown in panel (b) also demonstrate that the energy contribution associated with the MB-pol 2B permutationally invariant polynomial displays the same radial dependence as the combined charge transfer and Pauli repulsion terms calculated from ALMO EDA. However, as expected, there are noticeable differences between these two terms at short range since MB-pol's permutationally invariant polynomial must also recover effects associated with charge penetration that are not taken into account by the baseline classical electrostatic model (panel a).

After adding all MB-pol terms together, the comparison in panel (c) demonstrates that MB-pol quantitatively reproduces the total interaction energy predicted by ωB97M-V. Finally, panel (d) shows that when MB-pol contributions associated with electrostatic interactions and dispersion energy are subtracted from the ωB97M-V

total interaction energy, MB-pol's permutationally invariant polynomial quantitatively recovers all remaining terms (i.e., charge transfer and penetration, and Pauli repulsion) that, by construction, are not included in the classical baseline model adopted by MB-pol. The analysis presented in Fig. 2 thus provides evidence that, within the MB-pol functional form, the 2B and 3B permutationally invariant polynomials quantitatively represent quantum-mechanical effects that cannot be described by purely classical expressions.

As a final note, it should be emphasized that maintaining the same functional form introduced with the original implementation of MB-pol (Babin et al. 2013, 2014), higher accuracy can be achieved by increasing the order of the permutationally invariant polynomials used to represent short-range 2B and 3B interactions. The choice to limit the highest order to the 4th degree was dictated by the necessity of achieving the optimal compromise between accuracy and computational efficiency. It should also be noted that the adoption of permutationally invariant polynomials is simply one among several options that exist to accurately represent multidimensional potential energy surfaces. In this context, it has recently been shown (Thuong et al. 2018) that it is possible to achieve similar accuracy as the original MB-pol implementation by replacing the 2B and 3B permutationally invariant polynomials with analogous neural networks (Behler 2016) and Gaussian approximation potentials (Bartók et al. 2010).

## 3    Energetics of Water Clusters, Liquid Water, and Ice

The accuracy and transferability of MB-pol can be systematically assessed from the analysis of both energetics and many-body effects in small water clusters, liquid water, and ice. To this purpose, MB-pol interaction energies for the low-lying isomers of the tetramer, pentamer, and hexamer clusters are compared in Fig. 4 with the corresponding reference values calculated at the CCSD(T)-F12/VTZ-F12 level of theory (Adler et al. 2007; Peterson et al. 2008; Knizia et al. 2009) for MP2 optimized geometries (Bates and Tschumper 2009; Temelso et al. 2011). Since the interaction energies are defined as the cluster energies minus the energies of the individual molecules in the same geometry as in the cluster, they are not affected by differences in the 1B energies predicted by CCSD(T)-F12/VTZ-F12 and MB-pol. For all isomers of the different clusters, MB-pol provides interaction energies in close agreement with the reference values, with the differences always being within chemical accuracy (Medders and Paesani 2015; Paesani 2016).

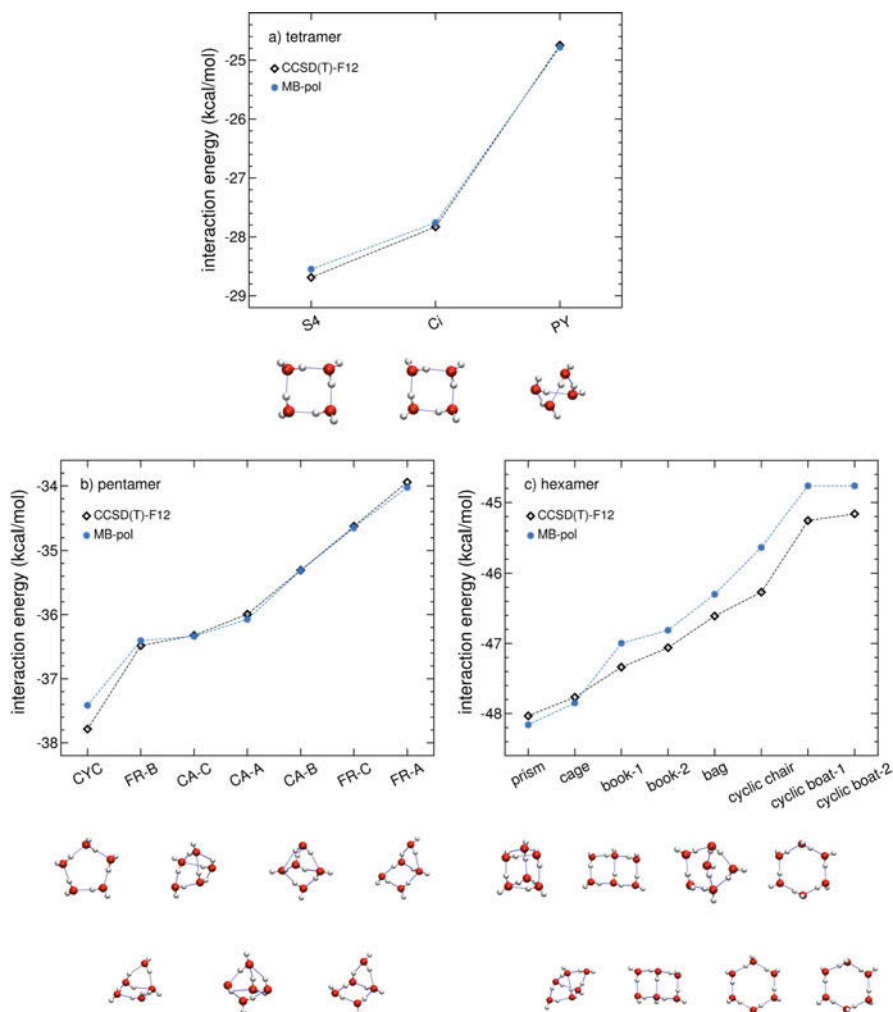
Among small water clusters, the hexamer holds a special place since its low-lying isomers display three-dimensional structures reminiscent of hydrogen-bond arrangements found in liquid water and ice. Furthermore, due to small differences in the interaction energies between different isomers, the hexamer cluster generally serves as a prototypical system to assess the accuracy of force fields and ab initio models of water. Figure 5 shows comparisons between the interaction energies of the low-lying hexamer isomers calculated using several advanced polarizable force fields (Fig. 5a) and common DFT models, without and with dispersion contributions


**Fig. 4** Comparisons between CCSD(T)-F12/VTZ-F12 and MB-pol interaction energies for the low-lying isomers of the tetramer (**a**), pentamer (**b**), and hexamer (**c**) clusters. The clusters geometries, shown at the bottom of the corresponding figures, were optimized at the MP2/avtz level of theory (Bates and Tschumper 2009; Temelso et al. 2011)

(Fig. 5b, c, respectively), and the corresponding CCSD(T)-F12/VTZ-F12 and MB-pol values.

While all polarizable force fields predict interaction energies relatively close to the reference values, only TTM3-F (Fanourgakis and Xantheas 2008) and WHBB (Wang et al. 2011) correctly reproduce the energy order. However, while the difference between TTM3-F and CCSD(T)-F12/VTZ-F12 is approximately of the

**Fig. 5** Interaction energies of the low-lying hexamer isomers calculated with advanced polarizable force fields (**a**), and DFT models without (**b**) and with (**c**) dispersion corrections. Also shown are the reference CCSD(T)-F12 and MB-pol values for comparison. Due to large variations in the interactions energies calculated with polarizable force fields and DFT models, different energy ranges are used in the three panels
same magnitude for all isomers, WHBB, which, as MB-pol, was systematically derived from the MBE in Eq. (1), accurately describes the first two isomers (prism and cage) but predicts interaction energies that progressively deviate (up to 2 kcal/mol) from the reference CCSD(T)-F12/VTZ-F12 values for all other isomers. POLI2VS, which was developed to model vibrational spectra of water (Hasegawa and Tanimura 2011), completely fails to reproduce the energy progression from the prism to the cyclic boat-2 isomers and predicts the cyclic chair isomer, which lies ∼2 kcal/mol above the prism isomer at the CCSD(T)-F12/VTZ-F12 level of theory, to be the most stable isomer. Both versions of the AMOEBA force field, AMOEBA2003 (Ren and Ponder 2003) and AMOEBA2014 (Wang et al. 2013), qualitatively reproduce the overall trend, although the stability of some isomers is inverted. Interestingly, the TTM4-F model (Burnham et al. 2008) fails, by a large margin, to describe the energetics of the first three isomers, predicting prism to be the most unstable structure, while correctly reproduces the energy order of the higher-energy isomers.

Figure 5b, c shows analogous comparisons for several DFT models that are commonly used in computer simulations of water. Specifically, this analysis includes GGA functionals: BLYP (Becke 1988), PBE (Perdew et al. 1996), and revPBE (Zhang and Yang 1998); meta-GGA functionals: TPSS (Tao et al. 2003), and SCAN (Sun et al. 2015); hybrid GGA functionals: B3LYP (Becke 1993), PBE0 (Adamo and Barone 1999), and revPBE0 (Goerigk and Grimme 2011); meta hybrid GGA functionals: M06-2X (Zhao and Truhlar 2008); range-separated hybrid functionals: ωB97X (Chai and Head-Gordon 2008); and range-separated meta hybrid functionals: ωB97M-V (Mardirossian and Head-Gordon 2015). DFT energies were calculated without and with the empirical D3(0) dispersion correction (Grimme et al. 2010) except for ωB97M-V that, by construction, accounts for dispersion energy through the VV10 nonlocal functional (Vydrov and Van Voorhis 2010). All DFT calculations were carried out with the aug-cc-pVQZ basis set using Gaussian 09 (Frisch et al. 2009) except for revPBE, revPBE0, SCAN, and ωB97M-V for which Q-Chem 5.0 was used (Shao et al. 2015).

Without dispersion corrections, only M062X, ωB97X, and SCAN predict the correct energy order of the hexamer isomers, although the differences from the CCSD(T)-F12/VTZ-F12 reference values can be as large as ∼6 kcal/mol. Although the inclusion of dispersion energy contributions significantly improves the agreement with the reference data, none of the functionals examined in this analysis, with the exception of ωB97M-V, achieves the same accuracy as MB-pol.

To further investigate the ability of MB-pol to reproduce many-body effects in water, the interaction energies of the prism, cage, and cyclic chair isomers are decomposed into individual many-body contributions, and the errors relative to the CCSD(T)-F12/VTZ-F12 reference values $\left( \Delta E = \Delta E_{nB}^{model} - \Delta E_{nB}^{CCSD(T)} \right)$ are shown in Fig. 6. To put the MB-pol results in perspective, the same analysis is also carried out with the polarizable force fields and DFT models used in Fig. 5. Independently of the isomer, MB-pol reproduces, nearly quantitatively, the reference values for all terms of the MBE. Importantly, since, within MB-pol all terms higher than 3B are represented entirely by classical many-body induction, the

agreement between MB-pol and the reference values for these terms demonstrates that higher-order interactions in water are primarily electrostatic in nature.

Among functionals without dispersion corrections, PBE and PBE0 provide the closest agreement with the CCSD(T)-F12/VTZ-F12 values. However, both functionals are associated with appreciable errors at the 4B level. Interestingly, the corresponding modified versions (revPBE and revPBE0) largely underestimate 2B contributions, while providing similar accuracy for higher-body terms. The correct energy order predicted by M06-2X in Fig. 5 effectively results from (well-balanced) error cancellation between different interaction terms, which, individually, are associated with errors on the order of 1 kcal/mol even at the 5B level. Large 2B errors are also associated with BLYP, B3LYP, TPSS, SCAN, and ωB97X, with the first three functionals underestimating and the last two functionals overestimating the strength of the interactions in the water dimers, respectively. Explicit inclusion of dispersion contributions significantly improves the accuracy of the 2B terms predicted by BLYP, TPSS, B3LYP, revPBE, and revPBE0, but, at the same time, the 2B terms of PBE-D3, PBE0-D3, and SCAN-D3 become less accurate than those from the bare functionals. Overall, the best performance is provided by ωB97M-V, which effectively exhibits similar accuracy as MB-pol for all interaction terms.

An important aspect that emerges from the analysis reported in Fig. 6 is the inability of some functionals to correctly reproduce high-body interaction terms. As mentioned above, MB-pol is able to correctly reproduce all terms higher than 3B entirely through classical many-body induction. This implies that several functionals that are currently used in water simulations (e.g., PBE-D3, PBE0-D3, revPBE-D3, and revPBE0-D3) effectively provide a less accurate description of many-body interactions than a purely classical electrostatic model. Since, by construction, classical electrostatics relies on a multipole representation of the electron density, functionals that exhibit large errors for high-body interactions are likely unable to correctly describe the electron density (and associated electrostatic properties) of the water molecules.

After investigating water clusters, the final step to assess the ability of MB-pol to accurately describe the multidimensional Born-Oppenheimer surface of water across different phases is represented by the analysis of the energetics of liquid water and different ice phases. As discussed in the Introduction, due to the associated computational cost, CCSD(T) calculations are currently unaffordable for condensed phase systems, and quantum Monte Carlo (QMC) effectively becomes the reference method for molecular systems in periodic boundary conditions. Direct comparison with QMC relative energies calculated for molecular configurations extracted from simulations carried out with the vdW-DF and vdW-DF2 functionals (Morales et al. 2014) determined that MB-pol predicts the energetics of liquid water in close agreement with the reference values, resulting in a mean absolute deviation of 0.048 kcal/mol per molecule, which is more than two times smaller than the most accurate value obtained with popular DFT models commonly used in computer simulations of liquid water (Medders and Paesani 2015).

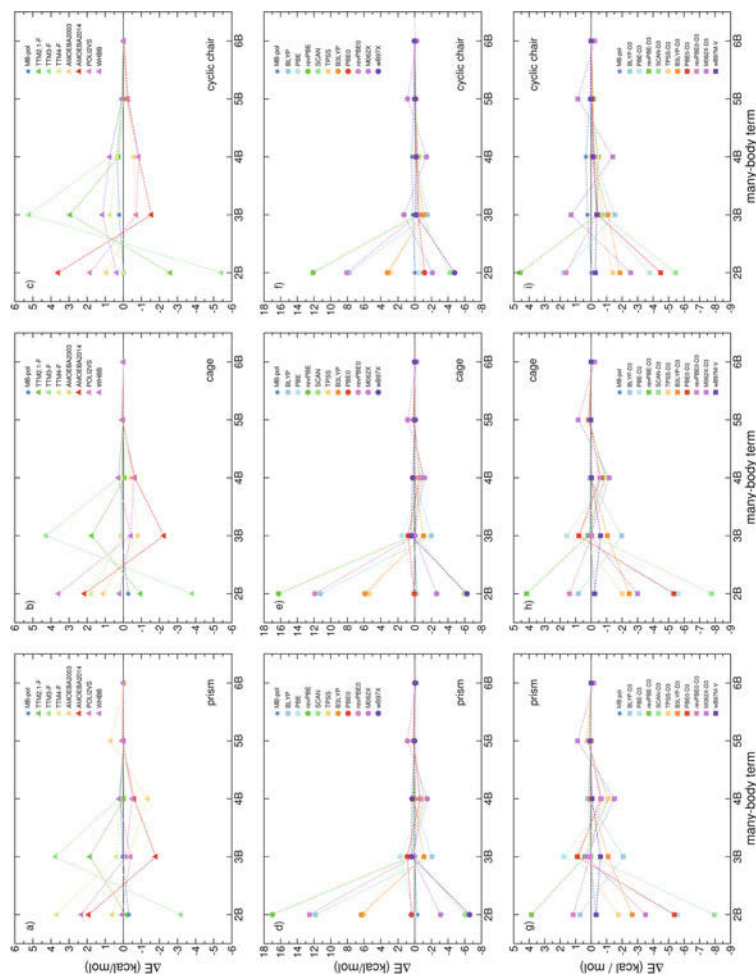
More recently, the energetics of several ice phases was also investigated with MB-pol (Pham et al. 2017). As reported in Table 1, in all cases, the lattice energies


**Fig. 6** Errors, $\left( \Delta E = \Delta E_{nB}^{model} - \Delta E_{nB}^{CCSD(T)} \right)$ relative to CCSD(T)-F12/VTZ-F12 reference values for the individual terms (nB) of the many-body expansion of the interaction energy calculated using MB-pol, polarizable force fields, and DFT models for the (a–c) prism, (d–f) cage, and (g–i) cyclic chair hexamer isomers. The first column (panels a, d, g) reports the results obtained with the polarizable force fields. The second (panels b, e, h) and third (panels c, f, and i) columns report the results obtained with the same DFT models, without and with dispersion corrections, respectively, as in Fig. 5

**Table 1** Space groups and supercell dimensions along with the number of water molecules (N) used in the calculations of the lattice energies (in kcal/mol) for the experimental crystal structures of several ice phases (Pham et al. 2017)

| Ice phase | Space group | Supercell | N | Lattice energy (kcal/mol) | |
|---|---|---|---|---|---|
| | | | | MB-pol | experiment |
| $I_h$ | $P6_3cm$ | (3,3,3) | 324 | −14.09 | −14.07 |
| IX | $P4_12_12$ | (3,3,3) | 324 | −13.86 | −13.97 |
| II | $R\overline{3}$ | (4,4,4) | 768 | −13.90 | −14.04 |
| VIII | $I4_1/amd$ | (4,4,3) | 384 | −13.60 | −13.30 |

calculated using the experimental crystal structures are in good agreement with the corresponding experimental values. Further analysis of the MB-pol results in terms of fundamental energy contributions showed that the differences in lattice energies between different ice phases are primarily dependent on the balance between short-range 2B and 3B interactions, many-body induction, and dispersion energy.

To provide an overall assessment of the MB-pol accuracy, Table 2 reports the results obtained by applying the same scoring scheme that was introduced to compare the ability of various DFT models to predict key properties of the water monomer, dimer, and hexamer and different ice phases (Gillan et al. 2016). Specifically, the properties considered in this analysis are: the harmonic frequency of the monomer symmetric stretch $\left(f_{ss}^{mono}\right)$, the dimer binding energy $\left(E_b^{dim}\right)$, the binding energy per monomer of the cyclic chair hexamer isomer $\left(E_b^{ring}\right)$, the sublimation energy of ice $I_h$ $\left(E_{sub}^{I_h}\right)$, the difference per monomer between the binding energies of the prism and cyclic chair hexamer isomers $\left(\Delta E_b^{prism-ring}\right)$, the difference of sublimation energies of ice $I_h$ and ice VIII $\left(\Delta E_{sub}^{I_h-VIII}\right)$, the equilibrium oxygen-oxygen distance of the dimer $\left(R_{OO}^{dim}\right)$, and the equilibrium volumes per monomer of ice $I_h$ $\left(V_{eq}^{I_h}\right)$ and ice VIII $\left(V_{eq}^{VIII}\right)$. The scores are then assigned by determining the deviations from the corresponding reference data obtained from high-level electronic structure calculations or experimental measurements. A score of 100% is assigned if the magnitude of the deviation is less than a predefined tolerance $\delta x_{tol}$, and a deduction of 10% is applied for each successive increment $\delta x_{tol}$ in $|x - x_{ref}|$. A score of zero is given if $|x - x_{ref}| > 11 \ \delta x_{tol}$. Specific details about the scoring scheme are given in the original study (Gillan et al. 2016). As shown in Table 2, MB-pol scores 90% or higher for all properties except for the difference in binding energies between the prism and cyclic-chair hexamer isomers and the equilibrium volume per monomer of ice VIII. MB-pol's average percentage score is 91% using the reference values reported in the original study (Gillan et al. 2016), which becomes 93% if more accurate reference values for the harmonic frequency of the monomer symmetric stretch and oxygen-oxygen distance in the water dimer are considered. To put things in perspective, the best DFT model among those analyzed in the original study scores 74% (Gillan et al. 2016).

**Table 2** Analysis of the performance of MB-pol and various DFT models in predicting several properties of water according to the scoring scheme introduced by (Gillan et al. 2016). If not indicated otherwise, all reference values and DFT scores are taken from the original study (Gillan et al. 2016). Also listed as reference values (second entries) are the harmonic frequency of the monomer symmetric stretch and oxygen-oxygen distance in the water dimer calculated by Howard et al. (2014). For MB-pol, the first entry corresponds to the value calculated for each property, while the second and, when available, third entries are the percentage scores relative to the corresponding reference values. Specific details about the scoring scheme along with a complete discussion of the DFT results are reported in the original study (Gillan et al. 2016)

# 4    From the Born-Oppenheimer Potential Energy Surface to Experimental Observables

Considering the accuracy with which MB-pol predicts the energetics of water from the gas to the condensed phase, there is reason to wonder if this is sufficient for equally accurate predictions of structural, thermodynamic, dynamical, and spectroscopic properties that can be measured experimentally. Since, by construction, MB-pol effectively provides an analytical representation of the Born-Oppenheimer potential energy surface of water, from a rigorous theoretical standpoint, computer simulations with MB-pol should explicitly account for nuclear quantum effects (Tuckerman 2010). For small clusters, methods based on basis set expansions and finite grids have been shown to be quite effective in describing nuclear quantum dynamics with MB-pol (Babin et al. 2013; Richardson et al. 2016; Brown et al. 2017). For systems with many degrees of freedom, methods based on Feynman's path-integral formalism (Tuckerman 2010), such as path-integral molecular dynamics (PIMD), enable numerically exact calculations of structural and thermodynamic properties for a given a Born-Oppenheimer potential energy surface. To date, exact calculations of quantum dynamical properties (e.g., diffusion and vibrational spectra) are unaffordable for systems with many degrees of freedom. Several approximate quantum dynamics methods for condensed phase systems have been proposed, including centroid molecular dynamics (CMD) (Voth 1996), which has been used extensively in quantum simulations of liquid water and ice using MB-pol (Medders et al. 2014, Medders and Paesani 2015, 2016; Straight and Paesani 2016; Moberg et al. 2017; Reddy et al. 2017).

It was shown that MB-pol quantitatively reproduces the experimental vibration-rotation tunneling spectrum of the water dimer as well as both second and third virial coefficients (Babin et al. 2013, 2014). When combined with PIMD simulations carried out at different temperatures within the replica exchange formalism, it was shown that MB-pol correctly reproduces quantum equilibria between different hexamer isomers, predicting cage and prism to be the (quantum) ground-state structures of $(H_2O)_6$ and $(D_2O)_6$, respectively (Brown et al. 2017). Local-monomer/local-mode calculations (Wang and Bowman 2011; Cheng and Steele 2014; Cheng et al. 2016) were then carried out on the isomeric quantum distributions to monitor the microscopic melting of the water hexamer through the analysis of vibrational spectra and various structural order parameters as a function of temperature (Brown et al. 2017). In two joint experimental-theoretical studies, MB-pol was used to determine the tunneling pathways in the prism isomer of the hexamer cluster (Richardson et al. 2016) as well as to interpret the THz spectra of the octamer cluster (Cole et al. 2016).

Classical MD and quantum PIMD and CMD simulations were also carried out to investigate the properties of liquid water (Medders et al. 2014). Classical and quantum oxygen-oxygen (O-O), oxygen-hydrogen (O-H), and hydrogen-hydrogen (H-H) radial distribution functions (RDFs) calculated, respectively, from MD and PIMD simulations in the isobaric-isothermal (constant number of molecules – constant pressure – constant temperature or NPT) ensemble are compared in Fig. 6 with the corresponding experimental data. Nearly quantitative

agreement is obtained between PIMD and experimental O-O RDFs, indicating that MB-pol predicts the correct structure of liquid water and nuclear quantum effects play a nonnegligble role in determining the properties of the underlying hydrogen-bond network. The importance of nuclear quantum effects becomes more apparent from the analysis of the O-H and H-H RDFs, which are predicted to be significantly more structured by classical MD simulations. PIMD simulations at 298.15 K also predict for liquid water a density of 1.001 g cm$^{-3}$ and an enthalpy of vaporization of 10.1 $\pm$ 0.4 kcal mol$^{-1}$, which are in good agreement with the corresponding experimental values of 0.997 g cm$^{-3}$ and 10.5 kcal mol$^{-1}$, respectively. Furthermore, the diffusion coefficient (D) and orientational relaxation time ($\tau_2$) of liquid water calculated from CMD simulations carried out with MB-pol at 298.15 K were found to be 0.22 $\pm$ 0.03 Å$^2$ ps$^{-1}$ and 2.3 $\pm$ 0.3 ps, respectively, which compare well with the corresponding experimental values of D = 0.23 Å$^2$ ps$^{-1}$ and $\tau_2$ = 2.5 ps.

Classical (MD) and quantum (CMD) simulations were also carried out to model both infrared (IR) and Raman spectra of liquid water (Medders and Paesani 2015; Straight and Paesani 2016; Reddy et al. 2017) and ice (Moberg et al. 2017), as well as the vibrational sum-frequency generation (vSFG) spectrum of the air/water interface (Medders and Paesani 2016; Moberg et al. 2018). Figure 7 shows a comparison between classical and quantum IR spectra of liquid water at 298.15 K and ice at 200 K. In these simulations, MB-pol was combined with a many-body representation of the associated dipole moment (MB-$\mu$) surface to calculate the relevant dipole-dipole correlation function (Medders and Paesani 2013, 2015). Both CMD spectra are in good agreement with the experimental data. By contrast, neglecting zero-point energy effects, the classical spectra are blueshifted compared to experiment, particularly in the high frequency region corresponding to the OH stretching band. As expected from the inverse relationship between temperature and De Broglie's thermal wavelength, the magnitude of the blueshift increases from liquid water at 298.15 K to ice at 200 K. A systematic analysis of the IR lineshapes for both liquid water and ice demonstrated that a rigorous representation of many-body effects is necessary for a quantitative reproduction of the experimental data.

Despite the overall agreement between experimental and simulated vibrational spectra, some differences still remain. In particular, the simulated OH stretching band of the IR spectrum of liquid water misses some intensity on the lower frequency portion. It has been argued that this discrepancy is primarily due to the inability of CMD to quantitatively capture the Fermi resonances between the bending overtone and the stretching vibrations (Medders and Paesani 2015; Straight and Paesani 2016). However, further investigations are needed. Second, the positions of the simulated IR OH stretching bands for both liquid water and ice are slightly blueshifted (60 cm$^{-1}$) compared to experiment, indicating that MB-pol predicts slightly too weaker hydrogen bonds. Finally, it was shown that although the vSFG spectrum obtained from CMD simulations with MB-pol correctly reproduces all spectral features in the OH stretching region, the calculated lineshape corresponding to dangling OH bonds is noticeably broader than in the experimental spectra (Medders and Paesani 2016). This deficiency is
**Fig. 7** Classical (MD) and quantum (PIMD) radial distribution functions calculated for liquid water at 298.15 K. (**a**) O-O, (**b**) O-H, and (**c**) H-H RDFs. The experimental data are from (Skinner et al. 2013) and (Soper and Benmore 2008)

a typical manifestation of approximate quantum dynamics methods based on the path-integral formalism, such as CMD, which, under particular conditions, affects the lineshape of high-frequency vibrational modes (Witt et al. 2009; Paesani and Voth 2010; Rossi et al. 2014) (Fig. 8).

## 5   Summary and Outlook

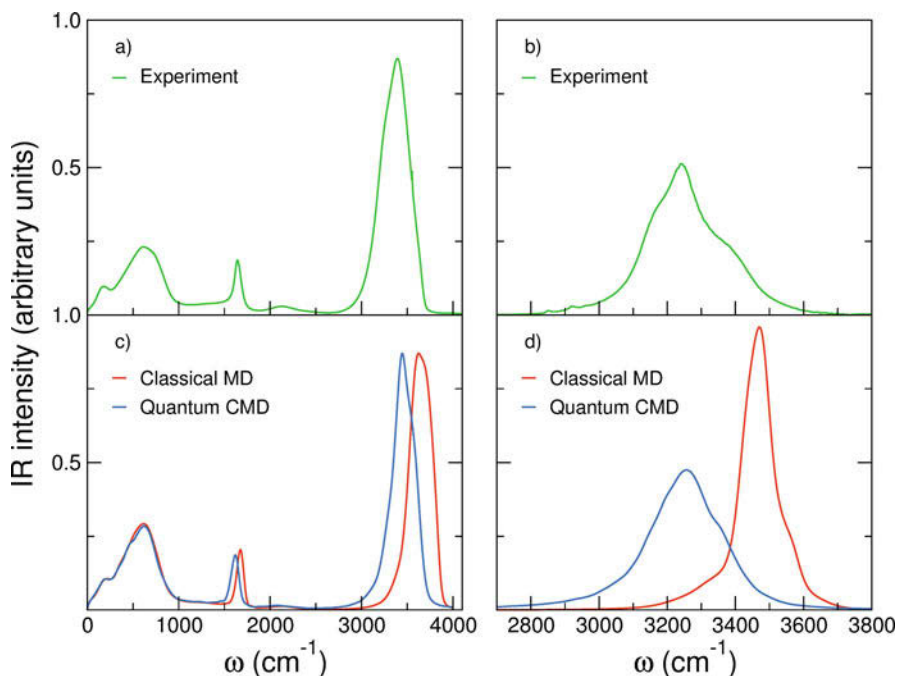
Building upon the pioneering studies by Stillinger and coworkers (Hankins et al. 1970) and Clementi and coworkers (Matsuoka et al. 1976; Evans et al. 1987; Niesar et al. 1990), the last decade has witnessed renewed interest in the development of accurate potential energy functions rigorously derived from many-body expansions of the interaction energies. These efforts have been supported by continued hardware improvements as well as by the development of efficient algorithms for correlated electronic structure methods which nowadays enable routine calculations of interaction energies for small molecular systems, with chemical accuracy. In parallel with these technological and algorithmic developments, there has been tremendous progress in the representation of multidimensional potential energy


**Fig. 8** Comparisons between experimental (panels a and b) and both classical (MD) and quantum (CMD) simulated (panels c and d) IR spectra of liquid water at 298.15 K (left) and ice at 200 K (right). Adapted from Medders and Paesani (2015), and Moberg et al. (2017)

surfaces with a large number of degrees of freedom, using permutationally invariant polynomials (Braams and Bowman 2009), neural networks (Behler 2016), and Gaussian approximation potentials (Bartók et al. 2010).

Given the importance of water as life's matrix (Ball 2008) and considering the key role that water has played in the history of computer simulations since the first studies by Barker and Watts (1969) and Rahman and Stillinger (Rahman and Stillinger 1971), it is not surprising that several many-body potential energy functions for water have recently been developed, such as CC-pol (Bukowski et al. 2007), WHBB (Wang et al. 2011) HBB2-pol (Babin et al. 2012), and MB-pol (Babin et al. 2013, 2014; Medders et al. 2014). When employed in simulations that allow for explicit treatment of nuclear quantum effects, these PEFs have been shown to correctly reproduce the properties of water from the gas to the condensed phase, thus enhancing the predictive ability of computer simulations.

This chapter has provided a critical review of the performance of MB-pol in representing the Born-Oppenheimer potential energy surface of water from the dimer to small clusters, liquid water, and ice (Paesani 2016). It is shown that MB-pol achieves high accuracy by quantitatively reproducing the individual terms of the many-body expansion of the interaction energy through the combination of

explicit short-range representations of 2B and 3B interactions along with a physically correct description of many-body electrostatic interactions at all distances.

Despite representing a step forward toward the long-sought-after "universal model" capable of correctly describing structural, thermodynamic, dynamical, and spectroscopic properties of water across different phases, it should always be kept in mind that MB-pol is still a "model" of water, with its own approximations and limitations. In particular, MB-pol is a physical model of water in the limit $pK_w \rightarrow \infty$, i.e., autoionization events are not allowed. While this is a reasonable approximation of pure water, the situation drastically changes in complex aqueous solutions with pH values lower or higher than pure water. In addition, as demonstrated by the analysis of vibrational spectra, some experimental features are not reproduced quantitatively by quantum dynamics simulations with MB-pol. Although it has been argued that these differences may be related to the approximate nature of quantum dynamics methods, further studies are necessary to address these deficiencies. Finally, the application of MB-pol in studies of complex solutions will require the development of many-body representations for generic molecular systems. Although some progress has already been made along this direction (Bajaj et al. 2016; Riera et al. 2017; Sode and Cherry 2017; Wang and Bowman 2017), further theoretical and computational developments are needed. In this context, given the unconventional functional form adopted by MB-pol, which is not supported by popular software for computer simulations, synergistic efforts between theoretical/computational chemists/physicists and computer scientists will be key to the development of specialized and more efficient software for many-body molecular dynamics simulations which can take full advantage of modern hardware.

**Abstract**

The availability of reliable interatomic potentials is necessary for carrying out computer simulations of complex materials. While electronic structure methods like density functional theory have been applied with great success to many systems, the high computational costs of these methods severely restrict the scientific problems that can be studied. Consequently, in recent years a lot of effort has been spent on the development of more efficient potentials enabling large-scale simulations. In particular, machine learning potentials have received considerable attention, because they promise to combine the accuracy of first-principles methods with the efficiency of force fields. In this chapter an important

e-mail: matti.hellstroem@chemie.uni-goettingen.de; joerg.behler@uni-goettingen.de

class of machine learning potentials employing artificial neural networks will be reviewed and discussed.

# 1 Introduction

Artificial neural networks (NNs) are phenomenally versatile and are at present used in a wide range of machine learning (ML) applications (Bishop 1996; Haykin 2011): speech and hand-writing recognition, self-driving vehicles, business intelligence, industrial process control, and game playing, to name just a few. Neural networks are capable of handling the two major types of problems targeted by ML algorithms: classification and regression. This chapter focuses on how NNs can be used for a particular regression problem, namely, the prediction of the potential energy surface (PES), i.e., the potential energy as a function of the atomic positions in a system. Such a neural network is referred to as a neural network potential (NNPs) (Handley and Popelier 2010; Behler 2011b, 2017).

The PES lies at the heart of many problems in materials modeling, theoretical condensed matter physics, and computational chemistry. It gives the relative stabilities of different atomic configurations and is directly connected to, for example, mechanical properties, defect distributions, reaction rates, thermodynamic equilibria, spectroscopic signatures, and many other properties.

There are multiple ways of calculating the PES, where the most commonly used in the materials modeling community include electronic structure methods, most prominently density functional theory (DFT) (Parr and Yang 1989), and a wide range of atomistic or even coarse-grained potentials. DFT calculations have been proven to have a fairly good predictive capability for many experimental properties. However, DFT calculations become computationally very demanding if large systems are modeled. This typically limits the applicability of DFT to static (single-point) calculations of a few hundred atoms or to short dynamic simulations in the order of several hundred picoseconds. Atomistic potentials, on the other hand, are more approximate and thus provide estimations for the PES at a much lower computational cost than DFT. They can therefore practically be applied to large-scale simulations. The required parameters are typically fitted to reproduce either some experimental properties of the system modeled or to reproduce some key results like energies from DFT calculations. The latter approach is an example of the so-called multiscale modeling, where information from a high level of theory (DFT) is used to parameterize a lower level of theory.

A neural network potential is in many ways similar to a force field. However, unlike force fields, the functional forms of NNPs are not based on any physical approximations. Instead, the great flexibility of NNs is exploited, and the NNP is parameterized to reproduce the PES obtained from DFT reference calculations or from some other electronic structure method. The NNP then provides a computationally inexpensive way to predict the PES, which makes it possible to use NNPs in large-scale Monte Carlo and molecular dynamics simulations to sample configurational and phase space. During the NNP parameterization, the NN "learns"

the stabilities of different molecules and structural motifs. An NNP is thus inherently "reactive," meaning that chemical reactions or significant structural rearrangements including the breaking and forming of covalent bonds can be accurately described, as long as the relevant training data is provided. To the end user, there is no apparent difference between using a neural network potential or a reactive force field. Both types of approaches provide the PES at a similar computational cost and can be applied for similar types of reactive systems.

NNs have been used for more than two decades for the representation of potential energy surfaces starting with the pioneering work of Doren and coworkers (Blank et al. 1995). The first generation of NNPs suffered from a restriction to small molecular systems containing only a few atoms, but this limitation could be overcome in 2007 by the introduction of high-dimensional NNPs (Behler and Parrinello 2007). In recent years also ML methods other than neural networks have found use in a similar fashion to construct potentials for atomistic simulations of complex systems. For example, methods like Gaussian approximation potentials (Bartók et al. 2010), kernel ridge regression (Rupp et al. 2012), and support vector machines (Balabin and Lomakina 2011) can also be used to describe the PES and related quantities. A review of recent advances in machine learning-based interatomic potentials was given by Behler (2016).

A presentation of the entire theory of artificial neural networks, which can be found in many text books (e.g., Bishop 1996; Haykin 2011), is beyond the scope of this chapter. We will therefore focus on the design choices that are typically made for estimating the PES of a given material. The potential energy is a single real-valued number, and the input features representing the atomic structure are real-valued numbers, so the NNP is a function $\chi : \mathbb{R}^n \to \mathbb{R}$.

We will discuss how NNPs can be used to compute the potential energy, how the conversion from a set of atomic positions to a suitable NN input can be made, how a NNP is parameterized, and how a NNP is validated, as well as some of the strengths and weaknesses of NNPs.

## 2 A Feed-Forward Neural Network

Figure 1 shows a schematic representation of a small fully connected feed-forward NN that defines a function $\chi : \mathbb{R}^2 \to \mathbb{R}$, which transforms an input vector $\mathbf{G} = (G_1, G_2)^{\mathrm{T}}$ into the output value $E$. The function has several parameters contained in the weight matrices $\mathbf{a}^{(0)}$, $\mathbf{b}^{(0)}$, $\mathbf{a}^{(1)}$, $\mathbf{b}^{(1)}$, $\mathbf{a}^{(2)}$, and $\mathbf{b}^{(2)}$, defining $E = \chi(\mathbf{G}; \mathbf{a}^{(0)}, \mathbf{b}^{(0)}, \mathbf{a}^{(1)}, \mathbf{b}^{(1)}, \mathbf{a}^{(2)}, \mathbf{b}^{(2)})$. The example NN consists of an input layer with two nodes, two hidden layers that contain three nodes each, and an output layer containing one node. In addition, a bias node with a fixed value of 1 is connected to all nodes in the hidden layers and the output layer (shown in blue). The example NN has an architecture of 2–3–3–1. The input features $(G_1, G_2)$ in layer 0 correspond to the values $(y_1^{(0)}, y_2^{(0)})$.
**Fig. 1** Illustration of a 2–3–3–1 feed-forward neural network along with typical choices of the activation functions $f^{(k)}(x)$. This NN defines a function $E = \chi(G_1, G_2; \mathbf{a}^{(0)}, \mathbf{b}^{(0)}, \mathbf{a}^{(1)}, \mathbf{b}^{(1)}, \mathbf{a}^{(2)}, \mathbf{b}^{(2)})$. Black arrows with empty heads between $y_i^{(k)}$ and $x_j^{(k+1)}$ represent the element $a_{ij}^{(k)}$ in the weight matrix $\mathbf{a}^{(k)}$; this is explicitly shown for a few of the elements of $\mathbf{a}^{(0)}$. Similarly, the blue arrows represent the bias weights. Arrows with filled heads represent the application of the activation function $f^{(k)}$

The computation proceeds left to right: from the input layer values, the first hidden layer values $\mathbf{y}^{(1)} = (y_1^{(1)}, y_2^{(1)}, y_3^{(1)})^{\mathrm{T}}$ are computed, and a bias node is added; those values are then used to compute $\mathbf{y}^{(2)} = (y_1^{(2)}, y_2^{(2)}, y_3^{(2)})^{\mathrm{T}}$ in the second hidden layer and a bias node is added; those values are used to compute the final output value $E$.

The values in a preceding layer, $\mathbf{y}^{(k-1)}$, are used to compute the values of $\mathbf{y}^{(k)}$ in the next layer via an intermediate vector $\mathbf{x}^{(k)}$:

$$\mathbf{x}^{(k)} = (\mathbf{a}^{(k-1)})^{\mathrm{T}}\mathbf{y}^{(k-1)} + (\mathbf{b}^{(k-1)})^{\mathrm{T}}. \tag{1}$$

In Eq. 1, each element of the vector $\mathbf{x}^{(k)}$ is calculated as the sum of a bias weight in $(\mathbf{b}^{(k-1)})^{\mathrm{T}}$ and a linear combination of the elements of $\mathbf{y}^{(k-1)}$, with the coefficients given in the weight matrix $\mathbf{a}^{(k-1)}$. For example, in Fig. 1, $x_1^{(1)} = a_{11}^{(0)}y_1^{(0)} + a_{21}^{(0)}y_2^{(0)} + b_{11}^{(0)}$. The elements of $\mathbf{a}^{(k-1)}$ and $\mathbf{b}^{(k-1)}$ are parameters (NN weights) that must be determined before the NN can be used for energy predictions; how this determination is made is shown later. The purpose of the bias node (with the value of 1, shown in blue in Fig. 1) in layer $k-1$ is to add some desired constants that do

not depend on the values $\mathbf{y}^{(k-1)}$, to each element of $\mathbf{x}^{(k)}$ (i.e., to the next layer). The values of the vector $\mathbf{x}^{(k)}$ are then transformed via an *activation function* (sometimes called transfer function or basis function) $f^{(k)}(x)$:

$$y_i^{(k)} = f^{(k)}(x_i^{(k)}) \tag{2}$$

For the hidden layers, a nonlinear sigmoid activation function is typically used, for example, the logistic function $f(x) = \frac{1}{1+\exp(-x)}$ or the hyperbolic tangent $f(x) = \tanh(x)$. There are also other possible choices for the hidden layer activation functions. For the output layer, the linear activation function $f(x) = x$ is used to avoid a constrained range of output values of the NN.

For a NN to predict the potential energy of the system, the input vector $\mathbf{G}$ must contain all of the information about the system which determines the potential energy. In the absence of any external fields, the potential energy is invariant under rotation and translation. Thus, a poor choice would be to simply select the Cartesian coordinates of the atoms as the input vector, since these do not possess these invariances. A better choice would be internal coordinates like interatomic distances and bond angles that by design are invariant under rotation and translation. This works well as long as the number of internal coordinates is manageable, for example, to describe the PES of small molecules. However, for large systems containing thousands or more degrees of freedom, this approach quickly becomes intractable, since the number of input features becomes very large. Another severe challenge is the inclusion of permutation invariance of the PES with respect to the interchange of atoms of the same element, which is also problematic in case of internal coordinates.

Rather than having the NN describe the PES of the entire system (a "low-dimensional" NNP), it is possible to construct NNs that describe the PES of individual atoms. By combining several such atomic NNs together, the number of input features can be limited while retaining the ability to model large systems with thousands of atoms. These high-dimensional NNPs will be the focus of the rest of this chapter. High-dimensional NNPs are typically used in conjunction with the so-called symmetry functions as input features. They are described in the next section.

## 3　High-Dimensional Neural Network Potentials and Symmetry Functions

In a high-dimensional neural network potential, the total energy is computed as the sum of "atomic" energies $E_i$:

$$E = \sum_{i=1}^{N^{\text{atom}}} E_i \tag{3}$$

where $N^{\text{atom}}$ is the number of atoms in the system. Each atomic energy $E_i$ is determined by means of an element-dependent feed-forward NN, where the input features describe the chemical environment around the atom. This is akin to how the sum over atomic environments (e.g., bond lengths and angles) is used to calculate the total energy in many force fields. However, high-dimensional NNs have a considerably more flexible functional form and can easily capture high-order many-body effects; indeed, the input features are typically computed using particular many-body functions known as symmetry functions.

For a multicomponent system with more than one element, one NN is employed for each element. For example, to describe a CuAgAu alloy, three elemental NNs are created, one for Cu, one for Ag, and one for Au, and each NN is called once for each atom of the respective element. Different NN architectures (number of input features, number of hidden layers, and/or number of nodes per hidden layer) can be used for the different elements. The atomic energies for all the Cu atoms in the system would be evaluated using the same Cu-specific NN, with only the numerical values of the input vectors differing, since the atomic environments around different atoms may vary. This treatment ensures that the total energy is permutationally invariant with respect to the order with which the Cu atoms are provided in the input file. Figure 2 shows schematically how the total energy $E$ is calculated using a high-dimensional neural network potential.

Below, we refer to specific atoms using the indices $i$, $j$, and $k$, and to elements using capital letters $I$, $J$, and $K$, and we use the notation $i \in I$ to specify that atom $i$ is of element $I$. The set of all atomic positions together with the corresponding elements is denoted $\{\mathbf{R}, Z\}$, where $\{\mathbf{R}\}$ denotes the Cartesian coordinates and $Z$ the element. Thus, $\{\mathbf{R}, Z\}$ contains all of the information normally contained in a single frame of a Monte Carlo simulation or of a single frame of a molecular dynamics simulation (without the particle velocities).

For an atom $i \in I$, the atomic energy $E_i$ in Eq. 3 is calculated as

$$E_{i \in I} = \chi^I(\mathbf{G}^I(i)) \tag{4}$$

where $\chi^I$ denotes the NN for element $I$. The input vector $\mathbf{G}^I(i)$ is a vector of symmetry function values:

$$\mathbf{G}^I(i \in I) = \begin{pmatrix} G_1^I(i, \{\mathbf{R}, Z\}) \\ G_2^I(i, \{\mathbf{R}, Z\}) \\ \vdots \\ G_{N^{\text{sym}}(I)}^I(i, \{\mathbf{R}, Z\}) \end{pmatrix} \tag{5}$$

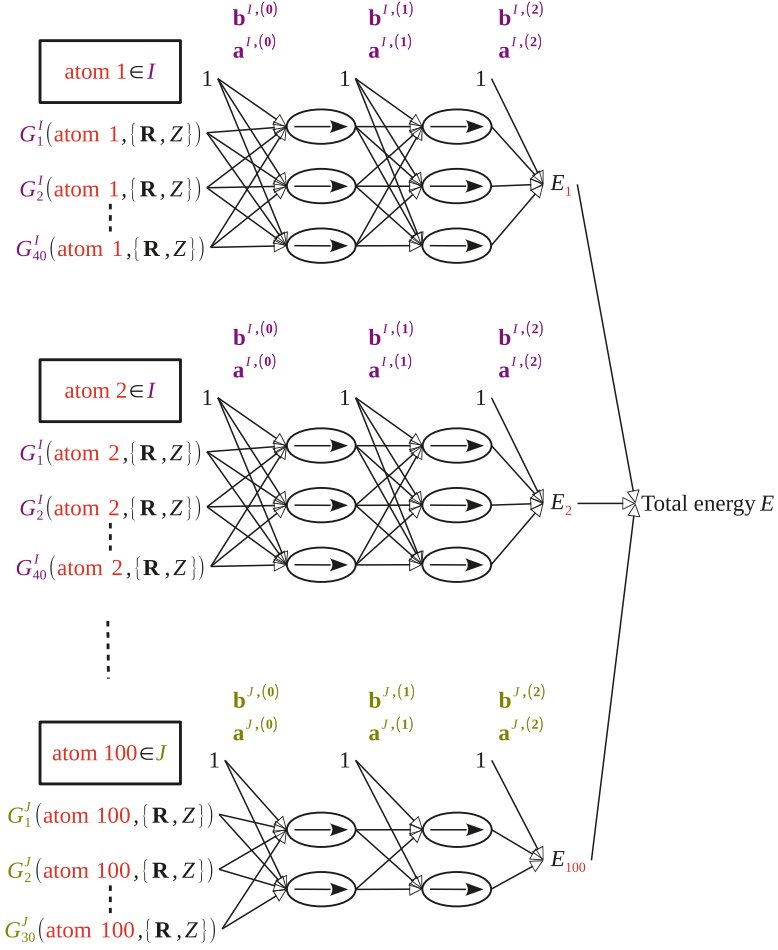
The symmetry functions are descriptors of the chemical environment around the atoms. Typically, only the local environment within a cutoff sphere of radius $R_{\text{cut}}$ is considered. This is achieved by means of a tapering function $f_{\text{cut}}(R)$ that smoothly decays to 0 in value and slope at $R = R_{\text{cut}}$. A common choice for $f_{\text{cut}}(R)$ is


**Fig. 2** Schematic representation of the evaluation of the total energy $E$ for a system with 100 atoms and two elements $I$ and $J$, using a high-dimensional neural network potential. In this example, $N^{\text{sym}}(I) = 40$ and $N^{\text{sym}}(J) = 30$. The evaluation of each atomic energy $E_i$ is performed as in Fig. 1

$$f_{\text{cut}}(R) = \begin{cases} \tanh^3\left(1 - \dfrac{R}{R_{\text{cut}}}\right) & R \leq R_{\text{cut}} \\ 0 & R > R_{\text{cut}} \end{cases} \qquad (6)$$

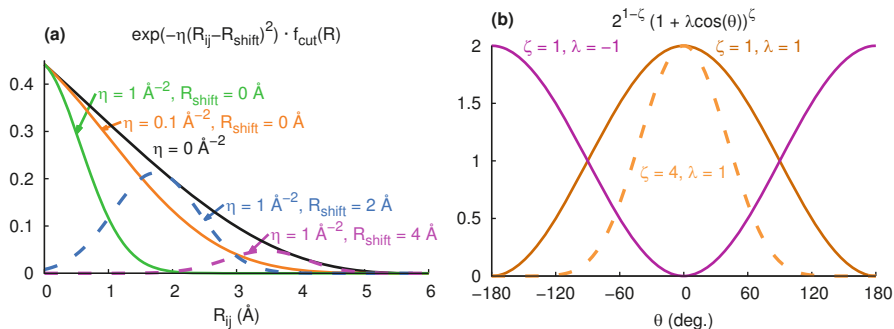
although other forms of $f_{\text{cut}}$ are also possible. An example of a "radial symmetry" function for an atom $i \in I$ is (Behler 2011a)


**Fig. 3** (**a**) The summand of the radial symmetry function in Eq. 7 for some different values of $\eta$ and $R_{\text{shift}}$, using the cutoff function $f_{\text{cut}}(R)$ from Eq. 6. (**b**) The angular part of the summand of the symmetry function in Eq. 8, for some selected values of $\zeta$ and $\lambda$

$$G^I(i \in I, \{\mathbf{R}, Z\}; \ \eta, R_{\text{shift}}, J) = \varphi \left( \sum_{\substack{j \in J \\ j \neq i}} e^{-\eta (R_{ij} - R_{\text{shift}})^2} \cdot f_{\text{cut}}(R_{ij}) \right). \tag{7}$$

This function is a descriptor for how atoms of the element $J$ (that can be same as or different from $I$) are distributed around the atom $i \in I$. It is a sum of Gaussians multiplied by the cutoff function $f_{\text{cut}}(R)$. The optional feature scaling function $\varphi$ modifies the range of values output by the symmetry function $G^I$, which can be useful during the NN parameterization. The scaling function is further discussed in Sect. 4.2. The two parameters $\eta$ and $R_{\text{shift}}$ determine the width and center of the Gaussian functions. Figure 3a shows the value of the summand in Eq. 7 for different distances, for a few selected values of $\eta$ and $R_{\text{shift}}$. Here, the cutoff distance is set to the typical value of $R_{\text{cut}} = 6 \,\text{Å}$, and the cutoff function from Eq. 6 is used. The black line ($\eta = 0 \,\text{Å}^{-2}$) is equivalent to the plain cutoff function $f_{\text{cut}}(R)$.

Typically, for every combination of central element $I$ and neighboring element $J$, several functions of the type in Eq. 7 with different values of $\eta$ and/or $R_{\text{shift}}$ are used as input features to the NN in Eq. 5. Using several such symmetry functions provides a significantly better fingerprint of the atomic environment than could be accomplished with only a single symmetry function. For example, if the single function with $\eta = 0 \,\text{Å}^{-2}$ in Fig. 3 is used, then two neighbors around the atom $i$, both at a distance $R = 3 \,\text{Å}$, yield the same value of $G^I(i) = 0.197$ as a single neighbor at a distance $R = 2 \,\text{Å}$. By using several symmetry functions, the aim is to "encode" all the relevant information about the atomic environment around an atom $i$ into the input vector $\mathbf{G}^I(i)$ and to provide a structural fingerprint of the atomic environment as the input to the NN.

The radial symmetry function in Eq. 7 is only distance-dependent or in other words spherically symmetric. Therefore it is required to incorporate also angular dependencies into the symmetry functions. A common choice for an angular symmetry function is (Behler 2011a)

$$G^I(i \in I, \{\mathbf{R}, Z\};\ \eta, \zeta, \lambda, J, K)$$

$$= \varphi \left( 2^{1-\zeta} \sum_{\substack{j \in J,\ k \in K \\ j \neq i,\ k \neq i \\ k \neq j}} (1 + \lambda \cos \theta_{jik})^{\zeta} \cdot e^{-\eta(R_{ij}^2 + R_{ik}^2 + R_{jk}^2)} \cdot f_{\mathrm{cut}}(R_{ij}) \cdot f_{\mathrm{cut}}(R_{ik}) \cdot f_{\mathrm{cut}}(R_{jk}) \right)$$

(8)

where the interatomic distances $R_{ij}$, $R_{ik}$, and $R_{jk}$ and angle $\theta_{jik}$ between three atoms $i \in I$, $j \in J$, and $k \in K$ are used to compute the value of the symmetry function, for each of the possible unique combinations of neighbors $j$ and $k$ around the central atom $i$. Again, the elements $J$ and $K$ may be the same as or different from $I$, and $\varphi$ is a scaling function. In Eq. 8, $\zeta$ determines the range of angles for which the angular term is approximately 0, and $\lambda$ takes on a value of either $+1$ or $-1$. The angular part of the symmetry function is shown in Fig. 3b, for a few different values of $\zeta$ and $\lambda$. Notably, the angular part is periodic with a period of $360°$ and symmetric around $0°$ and $\pm 180°$.

By using a cutoff radius, long-range interactions like electrostatic interactions are truncated at the cutoff. This can be problematic for many types of systems. An approach for including long-range interactions into the PES using high-dimensional NNPs is described in Sect. 5.

A high-dimensional NNP can also be used to evaluate the analytic forces acting on atoms, which is central to applications like molecular dynamics simulations. The force with respect to some atomic coordinate $\alpha$ is

$$F_\alpha = -\frac{\partial E}{\partial \alpha} = -\sum_{j=1}^{N^{\mathrm{atom}}} \frac{\partial E_j}{\partial \alpha} = -\sum_{J \in \{Z\}} \sum_{j \in J} \sum_{\mu=1}^{N^{\mathrm{sym}}(J)} \frac{\partial E_j}{\partial G_\mu^J(j)} \cdot \frac{\partial G_\mu^J(j)}{\partial \alpha}$$

(9)

where the outermost sum runs over all chemical elements $J$ in the system and where $G_\mu^J(j)$ is the $\mu$th symmetry function for the element $J$ evaluated for the atom $j \in J$.

## 4    Construction of a High-Dimensional NNP

The construction of a high-dimensional NNP for some given chemical system is a procedure involving

- The procurement of training and validation data
- The choice of symmetry functions (including the cutoff radius $R_{\mathrm{cut}}$) for each element
- The choice of network architecture for each element
- The fitting of the weight matrices $\mathbf{a}^{(k)}$ and $\mathbf{b}^{(k)}$ for each element

Moreover, the fitted NNP must be critically evaluated and inspected for regions of the potential energy surface that are not well-described.

In typical applications of high-dimensional NNPs, 1–3 hidden layers and 10–40 nodes per hidden layer are used for each elemental NN. The number of symmetry functions strongly depends on the number of chemical elements in the system. Typically, for an element $I$, 5–10 radial symmetry functions (Eq. 7) per possible neighboring element $J$, and 5–10 angular symmetry functions (Eq. 8) per possible combination of neighboring elements $J$ and $K$, are used. The cutoff distance $R_{\text{cut}}$ is typically set to be in the range from 6 to 10 Å consistently for all symmetry functions.

## 4.1    Procurement of Training Data

The procurement of training data is essential to the successful application of a high-dimensional neural network potential. The neural network can only be as good as the data to which it has been trained. Therefore, it is important to select a reference computational method that is accurate for the modeled material. Often, some form of density functional theory (DFT) is used as the reference method. The training set then consists of a set of structures, with energies that have been determined using DFT. Optionally, the DFT forces acting on the atoms, which contain valuable local information about the PES, can also be used to train the NN. The aim of the training procedure is for the NN to, as closely as possible, reproduce the reference energies and forces; this is achieved by iteratively optimizing the weight matrices $\mathbf{a}^{(k)}$ and $\mathbf{b}^{(k)}$ for each elemental NN.

In a typical setting, more and more training data is iteratively added to the training set, in order to obtain better neural network potentials. From some initial collection of training data, several high-dimensional neural network potentials $\chi_0^{(0)}$, $\chi_0^{(1)}$, etc. are trained (as described in the next section). By applying those potentials to, for example, molecular dynamics simulations, it is possible to identify structures that are poorly described. This can be accomplished in several ways:

1. By monitoring the values of the symmetry functions for the different structures that appear in the simulation. If a symmetry function value lies outside the range of values which appear in the training set, or if the value of the symmetry function only appears very rarely in the training set, then the prediction made by the neural network is likely inaccurate.
2. By comparing the energies and forces predicted by different neural networks $\chi_0^{(0)}$, $\chi_0^{(1)}$, etc. on identical structures. If the energies and/or forces are very different for different fits of the neural network, then the respective part of configuration space is insufficiently sampled.

The structures identified in any of above ways are then recalculated using the reference method and added to the training set, which is followed by new NN

optimizations, yielding new NN potentials $\chi_1^{(0)}$, $\chi_1^{(1)}$, etc. In this manner, more and more training data is iteratively added to the training set, until the NN is deemed to accurately describe the PES of all structures that appear in the simulation.

## 4.2   The Choice of Symmetry Functions

The vector of symmetry functions, $\mathbf{G}^I$ in Eq. 5, for each element $I$, is what allows the NNP to discriminate between different structures. Thus, an important consideration, when designing a NNP for some chemical system, is which symmetry functions $G_\mu^I$ to use when evaluating $\mathbf{G}^I$. If only a few symmetry functions are used, the NNP may not reliably be able to distinguish between different structures.

In practice, the set of symmetry functions is often empirically chosen and refined until the NNP gives satisfactory results. A "good" set of symmetry functions normally contains functions fulfilling the following conditions:

- The value of a given symmetry function is not the same for all atoms in the training set. More generally, the range of values for a certain symmetry function when calculated for different atoms in the training set should not be too small, since the NN could then assign large changes in the total energy to small changes of the symmetry function values. In addition, the distribution of values of a certain symmetry function should be analyzed, so as to ensure that the range of values is not dominated by a few outliers.
- The set of symmetry functions covers a range of chemically meaningful distances. For example, the most quickly decaying radial symmetry function (the one with the largest value of $\eta$, Eq. 7) should decay around the distance of the shortest possible meaningful bond between atoms of elements $I$ and $J$.
- Atoms that experience very different forces (as calculated by the reference method) necessarily exist in substantially different environments and should therefore have substantially different values for at least one of the symmetry functions. If this is not the case, then the set of symmetry functions needs to be augmented.
- The correlation between any two symmetry functions should not be too large.

It can be useful to "precondition" input features to the neural network. The optional scaling function $\varphi$ in the example symmetry functions in Eqs. 7 and 8 could, for example, ensure that the symmetry function values for different structures in training set all lie within some predefined range, for example, $[-1, 1]$. The definition of $\varphi_\mu$ would then, for the symmetry function $G_\mu$, be

$$\varphi_\mu(x) = \frac{2(x - G_\mu^{\circ,\min})}{G_\mu^{\circ,\max} - G_\mu^{\circ,\min}} - 1 \qquad (10)$$

where $G_\mu^{\circ,\text{min}}$ and $G_\mu^{\circ,\text{max}}$ are the minimum and maximum values in the training set obtained for the corresponding unscaled symmetry function $G_\mu^\circ$. This kind of feature scaling helps to balance the relative importances of different symmetry functions. It is also possible to use other types of feature scaling functions.

## 4.3    Optimization of the NN Weights

The optimization of the NN weight parameters $\mathbf{a}^{(k)}$ and $\mathbf{b}^{(k)}$ for each chemical element starts with an initial guess of their values. The initial weights could simply be random numbers, but there also exist several ways in which the initial weights can be chosen so as to minimize the time needed to train the neural network, for example, the scheme developed by Nguyen and Widrow (1990). It can also be useful to set the weights connecting the last hidden layer with the output layer so that the average and standard deviation of the initially predicted energies (before any training) matches the average and standard deviation of the reference energies in the training set. The reference energies are invariably provided with some unit; the weights can be thought of as dimensionless numbers that give NN energies in the correct unit.

The optimization of the weights is achieved by iteratively minimizing the cost function $\Gamma$. An optimization iteration is often referred to as an epoch. The cost function is frequently taken to be the weighted average of the squared differences between the NN-calculated and reference values. For example, the cost function for the energies, $\Gamma_E$, is

$$\Gamma_E = \frac{1}{N^{\text{struct}}} \sum_{i=1}^{N^{\text{struct}}} w_{i,E} \left( \frac{E_i^{\text{NN}} - E_i^{\text{Ref}}}{N_i^{\text{atom}}} \right)^2 \tag{11}$$

where $N^{\text{struct}}$ is the number of structures in the training set, $w_{i,E}$ is a structure-dependent weight parameter, and $N_i^{\text{atom}}$ is the number of atoms in the $i$th structure. By choosing different values of $w_{i,E}$ for different structures in the training set, it is possible to assign a greater importance to some structures in the training set than to others. Note that the weight $w_{i,E}$ which indicates the importance of the structure $i$ in the training set is set by the user and not fitted, unlike the NN weights $\mathbf{a}^{(k)}$ and $\mathbf{b}^{(k)}$. In practice, it is common to assign the same weight $w_{i,E} = 1$ to all structures in the training set.

Similarly, the cost function for the forces, $\Gamma_F$, becomes

$$\Gamma_F = \frac{1}{N^{\text{struct}}} \sum_{i=1}^{N^{\text{struct}}} \left[ \frac{w_{i,F}}{3N_i^{\text{atom}}} \sum_{j=1}^{3N_i^{\text{atom}}} (F_j^{\text{NN}} - F_j^{\text{Ref}})^2 \right] \tag{12}$$

where the inner sum is taken over all $3N_i^{\text{atom}}$ force components in the training set structure $i$. If the NN is optimized to both the energies and forces, it is possible to

either alternate between the $\Gamma_E$ and $\Gamma_F$ cost functions for each optimization step (where the NN weights $\mathbf{a}^{(k)}$ and $\mathbf{b}^{(k)}$ are updated) or to combine them into a single cost function

$$\Gamma = \Gamma_E + \Gamma_F \tag{13}$$

In this case, the structure-dependent weights $w_{i,F}$ are usually set to much smaller numbers than $w_{i,E}$, since for the structure $i$, there is only a single energy $E_i$ but $3N_i^{\text{atom}}$ force components. The expression for the cost function can also depend on the optimization algorithm; for example, some algorithms include history-dependent terms in the cost function.

Many possible optimization algorithms exist. The simplest one, steepest descent (or "backpropagation" (Rumelhart et al. 1986)), updates the weights according to the following rule:

$$a_{ij}^{(k)}(t+1) = a_{ij}^{(k)}(t) - \eta \cdot \frac{\partial \Gamma}{\partial a_{ij}^{(k)}(t)} \tag{14}$$

where $t$ is the epoch number and $\eta$ is the learning rate. This step is performed for each elemental NN. However, other weight optimization algorithms also exist and are frequently used, such as the Levenberg-Marquardt algorithm (Levenberg 1944; Marquardt 1963) and the global extended Kalman filter (Haykin 2001). The description of those algorithms lies outside the scope of the current chapter.

Often, the quality of a set of NN weights is characterized by the root mean squared error, RMSE, for the energies and forces:

$$\text{RMSE}(E) \text{ per atom} = \sqrt{\frac{1}{N^{\text{struct}}} \sum_{i=1}^{N^{\text{struct}}} \left( \frac{E_i^{\text{NN}} - E_i^{\text{Ref}}}{N_i^{\text{atom}}} \right)^2} \tag{15}$$

$$\text{RMSE}(F) = \sqrt{\frac{1}{N^{\text{struct}}} \sum_{i=1}^{N^{\text{struct}}} \left[ \frac{1}{3N_i^{\text{atom}}} \sum_{j=1}^{3N_i^{\text{atom}}} (F_j^{\text{NN}} - F_j^{\text{Ref}})^2 \right]} \tag{16}$$

$\text{RMSE}(E)$ is often reported as a value normalized "per atom," because structures containing many atoms typically have larger absolute errors in the energy as compared to structures containing few atoms. For $\text{RMSE}(F)$, the inner sum is taken over all $3N_i^{\text{atom}}$ force components of the $i$th structure in the training set.

A good NN will have small values for the RMSE. Typical values reported in the literature are about $\text{RMSE}(E) = 1$ meV per atom and $\text{RMSE}(F) = 100$ meV/Å. However, what constitutes a good fit depends on how the NN will be applied. Moreover, the RMSE provides only a simple measure for how well the trained NN performs on the training data. If the training data is very varied, for example, with respect to the chemical composition of the system, the RMSE averaged over all the

structures in the training set does not necessarily help the scientist find structures or chemical compositions that are not well described by the NN. In such cases, it is a good idea to split the training set into several different groups, e.g., according to composition and calculate the RMSE for each group separately. In addition, it is helpful to explore the distribution of errors in the energies and forces made by the NN. If the NN performs poorly for some particular set of structures, it can be helpful to increase their weights $w_E$ and $w_F$ in the training procedure (Eqs. 11 and 12) or to modify the set of symmetry functions so that the atomic chemical environments are better described.

## 4.4    Training Set, Validation Set, Test Set, Overfitting and Underfitting

The procured reference data is typically divided into a *training set* and a *test set*. The training set consists of the structures used to determine the NN weight parameters. The test set consists of additional reference data that is not used to train the NN. By using a test set, the quality of the fitted NN can be evaluated on structures to which it has not been trained by monitoring the cost function of both sets.

The usage of a test set is instrumental for detecting the so-called overfitting (also known as high variance). An example of overfitting is illustrated in Fig. 4a in a simple one-dimensional case: Although the NN represented by the blue line reproduces the reference values at each training point (red circles) very well, the NN makes quite inaccurate predictions for values that lie outside the training set (orange triangles). Therefore, although the RMSE on the training set would be small, the RMSE for a test set would be considerably greater. This indicates that the NN makes poor interpolations between the data points in the training set. Overfitting normally happens as a result of the neural network architecture being too large, e.g., with respect to the number of hidden layers or the number of nodes per hidden layer. The overfitting can be combated by reducing the size of the neural network, by stopping

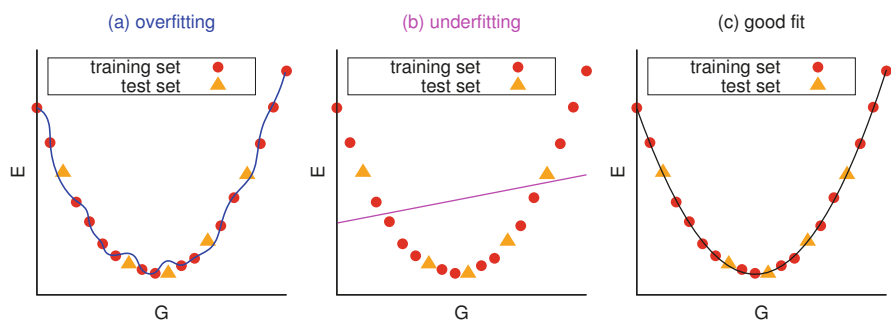

**Fig. 4** Examples of (**a**) overfitting, (**b**) underfitting, and (**c**) a good fit. The red circles represent data points in the training set; the orange triangles represent points in the test set

the NN weight optimization at an earlier epoch, or by including a regularization term to the cost function $\Gamma$. A regularization term penalizes large values of the weights $a_{ij}^{(k)}$, and many types of regularization terms are possible (e.g., the so-called $L_1$ and $L_2$ regularization). A more in-depth discussion on regularization in connection with neural networks can be found in, for example, Haykin (2011).

The opposite of overfitting is underfitting (also known has high bias), illustrated in Fig. 4b. Underfitting is characterized by a high RMSE for both the training and test sets and typically occurs if not enough epochs are run for the NN weight optimization. If running more epochs does not address the underfitting, it can help to make the neural network functional form more flexible, for example, by adding more nodes to the hidden layers.

Figure 4c illustrates a "good fit," where the error between the NN prediction and the reference data is small, as well as roughly equal for both the training and test sets.

If several neural network architectures are evaluated for the purpose of addressing, for example, overfitting, then there is a danger that the finally selected neural network architecture has a deceivingly small error on the test set, since the test set was used to select the neural network architecture. In such cases, the "test set" used to evaluate the NN architecture is commonly referred to as a *validation set*, and the error of the finally selected NN is then evaluated for another, independent, test set.

## 5      Inclusion of Long-Range Electrostatics

The neural network potential described in Sect. 3 relies on a vector of symmetry function values as input, and for any given atom, only atoms in the environment (within the sphere of the cutoff radius $R_{\text{cut}}$) contribute to the symmetry function values. Thus, a fundamental assumption of the type of high-dimensional NNP described in Sect. 3 is that the potential energy of the system can be calculated from local atomic environments. Some type of interactions, in particular electrostatic interactions, decay only slowly with increasing distance and can have considerable impact on energies and forces even if the distance between two interacting atoms is larger than $R_{\text{cut}}$.

The calculation of electrostatic contributions requires information about the charge distribution. This can be achieved by, for example, associating each atom with a point charge. The signs and magnitudes of those charges can either be fixed at some predetermined (element-dependent) values or be determined "on-the-fly" in some manner. One example of the latter type of approach that has been used in conjunction with NNPs, is to use a second, different, NNP (Artrith et al. 2011; Morawietz et al. 2012). This second NNP would then be fitted to reproduce the atomic charges, akin to how the type of NNP previously introduced is used to determine atomic energies. With this approach, some approximation for the atomic charges must be provided in the training set. Typically, one of the many types of atomic charges that can be derived from electronic structure calculations, such

as Mulliken charges (Mulliken 1955), Bader charges (Bader 1985), or Hirshfeld charges (Hirshfeld 1977), is used. Figure 5 illustrates this approach, where one high-dimensional NNP is used to compute the "short-range" energy $E^{short}$ that only depends on the local atomic environments, and a second high-dimensional NNP is used to estimate the atomic charges that are used to compute the "long-range" energy $E^{long}$ (via, e.g., an application of Coulomb's law or Ewald summation). The potential energy is then obtained as $E = E^{short} + E^{long}$. The NN architectures and symmetry functions used for the different elements to calculate atomic charges need not be the same as those used to calculate the atomic energies.

Regardless of the scheme used to generate the atomic charges and to calculate $E^{long}$, it is crucial that the short-range NN is fitted to reproduce only the *difference* between $E^{tot}$ and $E^{long}$, in order to avoid double-counting of contributions to the total energy. In the calculation of $E^{long}$, it has been shown to be beneficial to use a Coulomb potential that is screened at short distances, since otherwise the NN might need to fit a more corrugated potential energy surface for the short-range energies.

The force with respect to some atomic coordinate $\alpha$ becomes

$$F_\alpha = F_\alpha^{short} + F_\alpha^{long} = -\frac{\partial E^{short}}{\partial \alpha} - \frac{\partial E^{long}}{\partial \alpha} \tag{17}$$

where $F_\alpha^{short}$ is calculated as in Eq. 9. For a nonperiodic system, $F_\alpha^{long}$ can be calculated as

$$F_\alpha^{long} = -\frac{1}{2}\frac{\partial}{\partial \alpha} \sum_{i=1}^{N^{atom}} \sum_{\substack{j=1 \\ j \neq i}}^{N^{atom}}$$

$$\frac{q_i q_j}{R_{ij}} = -\frac{1}{2} \sum_{i=1}^{N^{atom}} \sum_{\substack{j=1 \\ j \neq i}}^{N^{atom}} \frac{1}{R_{ij}^2} \left[ \frac{\partial q_i}{\partial \alpha} q_j R_{ij} + q_i \frac{\partial q_j}{\partial \alpha} R_{ij} - q_i q_j \frac{\partial R_{ij}}{\partial \alpha} \right] \tag{18}$$

where $q_i$ is the charge on atom $i$. If a NNP with symmetry functions is used to determine the atomic charges, as in Fig. 5, then it can be shown that

$$F_\alpha^{long} = \sum_{J \in \{Z\}} \sum_{j \in J} \sum_{\substack{i=1 \\ i \neq j}}^{N^{atom}} \frac{q_i}{R_{ij}} \cdot \left[ \frac{1}{2}\frac{q_j}{R_{ij}}\frac{\partial R_{ij}}{\partial \alpha} - \sum_{\mu=1}^{N^{sym}(J)} \frac{\partial q_j}{\partial G_\mu^J(j)}\frac{\partial G_\mu^J(j)}{\partial \alpha} \right]. \tag{19}$$

For a periodic system, where the electrostatic energy is evaluated using, for example, Ewald summation, the expression for $F_\alpha^{long}$ becomes more complicated, although it can be derived in a similar fashion.
**Fig. 5** Illustration of two high-dimensional neural network potentials, using the same chemical system and color coding as in Fig. 2. The upper NN (white background) yields the short-range energy $E^{\text{short}}$; the lower NN (gray background) yields the atomic charges $q_i$ that are used to compute $E^{\text{long}}$. Together they give the total energy $E$

# 6    Applications and Limitations of Neural Network Potentials

NNPs, and in particular high-dimensional NNPs, have been developed and applied to a range of different molecules and materials (for reviews see Behler 2014, 2017). Some examples include silicon (Behler et al. 2008), carbon (Khaliullin et al. 2011), sodium (Eshet et al. 2012), zinc oxide (Artrith et al. 2011), germanium telluride (Sosso et al. 2012), copper (Artrith and Behler 2012), Cu clusters on ZnO (Artrith et al. 2013), Cu-Au nanoalloys (Artrith and Kolpak 2015), water on Cu (Natarajan and Behler 2016), titanium dioxide (Artrith and Urban 2016), gold (Boes et al. 2016), copper-palladium-silver alloys (Hajinazar et al. 2017), $N_2$ on Ru (Shakouri et al. 2017), and water on ZnO (Quaranta et al. 2017).

Because of the unprecedented accuracy that can be obtained at low computational cost with such a flexible method, the development of NNPs, and of the NNP methodology, but also of other similar ML potential methods, is currently a very active research field. Some limitations and drawbacks of high-dimensional NNPs, as they have been presented in this chapter, include the following:

- *The iterative construction of large training sets*. Typical training sets include thousands of structures that must be computed using a reference electronic structure method. Moreover, the generation of new training set structures is often done in an empirical fashion, using, for example, high-temperature molecular dynamics simulations.
- *Limited number of elements in the chemical system*. With more than three or four chemical elements in the system, the number of needed symmetry functions to describe the local chemical environment around an atom becomes exceedingly large. For such systems, another type of input feature might be beneficial.
- *Complicated and time-consuming fitting procedure*. NNPs contain many weights that need to be fitted. Even with the use of advanced fitting algorithms, obtaining a good fit is often a time-consuming procedure. This problem is exacerbated with the inclusion of long-range electrostatics as outlined in Sect. 5.

# 7    Summary

In recent years, neural network potentials (NNPs) have become a very useful tool for atomistic materials modeling simulations. They provide the potential energy surface (PES) of a system at low computational cost, while the accuracy is very close to that of first-principles methods. Because of the flexible functional form of NNPs, they can be used to describe all types of atomic interactions (covalent bonding, dispersion interactions, hydrogen-bonding, etc.) on an equal footing. In case of significant long-range electrostatic interactions, NNPs can be extended with some scheme for determining reference atomic charges or multipoles, to include the long-range contribution to the total energy. While NNPs are fitted to reproduce reference data (typically total energies and atomic forces) from electronic structure

calculations, a careful validation of the obtained potentials is required due to the intrinsically nonphysical but purely mathematical functional form. In case of high-dimensional NNPs, one NN is fitted for each chemical element in the system. The element-specific NN then describes the PES around a particular type of atom. The local atomic environment is transformed into input for the NN using, for example, symmetry functions. The total energy is then calculated by summing over all atomic contributions.

The errors associated with NNPs, as compared to the reference electronic structure method, can be made extremely small ($< 1$ meV per atom), which makes NNPs a promising tool for future applications in materials modeling and simulation.

**Abstract**

Because of their considerable predictive power, atomistic simulations are extremely powerful tools in the computational materials scientist's toolbox. This power however comes at a significant computational price that rather strongly limits the accessible simulation space, especially in terms of the timescales that can be directly simulated. Specialized methods specifically designed to overcome timescale limitations while still faithful to the underlying dynamical behavior of the system are hence essential in order to bridge the gap with experiments. This section summarizes the most recent advances in a class of open-ended long-timescale atomistic simulation techniques that include accelerated molecular dynamics and kinetic Monte Carlo methods. The different chapters introduce the basics of these methods as well as a review of their most recent developments.

# 1 Introduction: The Timescale Limitations of Molecular Dynamics

Molecular dynamics simulations have become a workhorse in the general endeavor of computational materials science. By providing an atomic-scale description of materials, each and every atom can be followed and its behavior tracked computed, a resolution simply not possible with any other technique, experimental or otherwise. These types of simulations have provided unprecedented insight into the behavior of materials. For example, some of the first molecular dynamics simulations were on the problem of collision cascades during irradiation. Indeed, it is from such simulations that the majority of our knowledge about the primary damage state created during a radiation damage event arises. Similarly, knowledge of the complex behavior of dislocations, interfaces, or grain boundaries is in great part due to our ability to carry out direct atomistic simulations.

However, despite the immense popularity of molecular dynamics in materials research, significant shortcomings still limit the types of studies that can be performed. Chief among these is the limited timescales. While heroic efforts can reach microseconds for some systems, most are limited to nanoseconds, and all fall far short of the timescales relevant to most experimental conditions. Coming back to the problem of radiation damage, one would ideally wish to predict the response of the material over years of irradiation, or at least be able to simulate on timescales that correspond to collision cascades hitting the same region of space more than once at realistic fluxes. The art of molecular dynamics therefore often lies in carefully designing simulation protocols or initial conditions such that long-time behavior can be inferred from short simulations. While this is sometimes possible, it is often extremely challenging to do accurately, which severely limits the contribution of molecular dynamics to answering key questions in materials science.

It is important to note that this limitation persists regardless of the size of the computer that is employed. This is due to the intrinsically serial nature of the numerical solution of the atomistic equations of motion: work on a given timestep has to be completed before work on the next can begin. Therefore, effective parallelization of conventional molecular dynamics can only proceed within a timestep, not across. This usually translates into a spatial parallelization scheme where different processing elements are in charge of computing the forces acting on atoms in distinct physical regions, an approach that is efficient only if every computing element is assigned enough work that communication or synchronization costs are negligible; it however breaks down when the number of atoms assigned to each processing element becomes too small. Parallelization of conventional molecular dynamics is therefore a viable approach to extend the simulation length-scales, but typically not their timescales. Thus, there has been a recognized need for methods that retain the full atomistic fidelity of the underlying interatomic model but push the accessible timescale to those more amenable to direct comparison with experiment.

## 2 Accelerating Rare Event Dynamics

With this motivation in mind, a number of scientists have developed fundamentally new simulation approaches with precisely this goal. Such efforts have traditionally been focused on systems that evolve through so-called rare events, where long waiting periods, often corresponding only to vibrational motion, are punctuated by rare but rapid transitions to different configurations. This class of materials is especially crippled by the limitations of standard approaches, as short simulations are extremely unlikely to be informative of their long-time behavior. The exact nature of what makes these events rare can vary between materials and external conditions, ranging from high energetic barriers to entropic constrictions. These obstructions lead to a so-called separation of timescales between fast (corresponding to local exploration of the potential energy surface) and slow (corresponding to rare transitions over the kinetic bottlenecks) components of the dynamics. This separation enables a statistical treatment of the slow events, as local equilibrium with respect to the fast degrees of freedom can be assumed. The simplifications that follow from this assumption are key to enabling most of the long-timescale methods.

Efforts have long been underway in the development of techniques that can exploit the separation of timescales to extend the predictive power of atomistic simulations beyond what can directly be simulated. In broad terms, these techniques can be classified into what we term *kinetic* and *dynamic* methods. Kinetic techniques are designed to compute transition rates or sample from the ensemble of reactive trajectories for rare transitions that occur along pre-specified reaction pathways or that otherwise connect specific regions of configuration space (e.g., the solid and liquid regions). This family contains a very large number of methods, including free energy (see ▶ Chaps. 29, "Variationally Enhanced Sampling" and ▶ 27, "Metadynamics: A Unified Framework for Accelerating Rare Events and Sampling Thermodynamics and Kinetics"), path sampling, and milestone-based approaches. These tools are especially powerful when one is interested in characterizing a process which is known to occur or when the basic nature of phenomena of interest is known a priori, e.g., when one can identify or construct a proper reaction coordinate for the process of interest. These methods are also adept at handling energy landscapes that are largely smooth on energy scales larger than $k_BT$, hence their popularity in the soft matter community. When this is not the case, truly dynamical methods, where a single (or a small number of) unbiased trajectories can be generated – just like in standard molecular dynamics – are preferred. This family of techniques is in comparison much smaller.

## 3 Summary of the Section

In order to allow for a comprehensive overview, we here restrict our attention to the second class of methods, and especially to accelerated molecular dynamics and adaptive kinetic Monte Carlo techniques. These methods are often very effective

for hard materials at moderate temperatures, but they tend to fare less well for softer systems where the topology of the fast-equilibrating regions of configuration space can be very complex. For these systems, kinetic methods, where additional knowledge can be exploited, are often preferred. The most recent developments in dynamical methods are described in this section, written by global leaders in the field. These approaches broadly fall into two categories: (i) bypass the problem altogether by foregoing the integration of the equations of motion in favor of direct searches for escape pathways or (ii) use molecular dynamics as a computational engine, but "trick" it into revealing relevant kinetic information faster.

The first approach requires methods to search and characterize the potential energy surface of the system. Hannes Jónsson is the original developer of the nudged elastic band (NEB) method (Jónsson et al. 1998), a method for finding saddle points on potential energy surfaces given an initial and final state of the system. He and his colleague describe recent developments in such static approaches to finding saddle points and to computing transition rates along these pathways, for example, using transition state theory (TST) (see ▸ Chap. 33, "Exploring Potential Energy Surfaces with Saddle Point Searches"). Given the static nature of these types of calculations, they are more amenable to application with electronic structure approaches such as density functional theory than are dynamics-based methods. While these methods can be characterized as kinetic according to the above discussion, they are instrumental in the design of truly dynamical methods like adaptive kinetic Monte Carlo (KMC) (Henkelman and Jónsson 2001). KMC techniques can generate long trajectories that overcome many of these bottlenecks without having to assume that their nature or kinetics is known a priori. The most recent developments in these types of approaches are described by Normand Mousseau and Graeme Henkelman, two pioneers in this field (see ▸ Chap. 34, "Off-Lattice Kinetic Monte Carlo Methods").

The alternative approach is embodied by the so-called accelerated molecular dynamics (AMD) methods (Voter 1997, 1998; Sorensen and Voter 2000), now over 20 years old. Generally, though not exclusively, based on TST, these approaches sacrifice fidelity on the scale of atomic vibration to describe accurate state-to-state dynamics on timescales longer, in some cases much longer, than molecular dynamics. While some of the AMD methods provide acceleration even in serial, the increased availability of massively parallel platforms has provided unique opportunities to further enhance their reach. ▸ Chapter 35, "Accelerated Molecular Dynamics Methods in a Massively Parallel World" by Richard Zamora, Arthur Voter, and co-workers describes a number of such parallelization strategies that can be employed to extend the temporal reach of molecular dynamics.

Tony Lelièvre delves into recent developments in the fundamentals of the AMD methods, putting them on a solid mathematical foundation (see ▸ Chap. 36, "Mathematical Foundations of Accelerated Molecular Dynamics Methods"). Many of these new insights stem from the crucial concept of quasi-stationary distribution, which has proved extremely powerful to understand the behavior of systems that evolve through rare events. This concept can be used to reinterpret all of the AMD methods and gain new insights on the precise nature of the assumptions that they

each entail and on their relative strengths and limitations. In particular, this formal framework has been used to show that one method, parallel replica dynamics, can be made arbitrarily accurate by adjusting a single free parameter (Le Bris et al. 2012). This chapter also casts the other traditional AMD methods in this new framework.

While AMD and adaptive KMC methods are adept at reaching long timescales on relatively small systems, simultaneously increasing the timescales and length-scales is an ongoing challenge. Ellad Tadmor and Woo Kyun Kim show how concurrent multiscale methods that reduce the number of degrees of freedom that need to be explicitly simulated for systems where capturing the proper elastic response of the environment is crucial (such as the quasicontinuum method (Shenoy et al. 1999)) can be coupled with the AMD methods to yield extended simulation times while preserving the fidelity of the simulation (see ▶ Chap. 37, "Temporal Acceleration in Coupled Continuum-Atomistic Methods").

Finally, Arthur Voter, Tony Lelièvre, Graeme Henkelman, Normand Mousseau, and Hannes Jónsson all come together for a joint chapter on the challenges and best practices associated with the development and use of long-timescale methods (see ▶ Chap. 38, "Long-Timescale Simulations: Challenges, Pitfalls, Best Practices, for Development and Applications"). Broken into four questions that get at the heart of these approaches, each offers his perspective on the state of the art, particular pitfalls that need to be considered when developing and implementing long-timescale methods, and challenges in using them. They also discuss where they think the future of these methods lies.

Together, these chapters provide both a brief introduction but, more importantly, a current perspective on the state of the art of long-timescale atomistic simulations. Each chapter highlights the current capability of each method as well as potential opportunities for next steps in advancing the method and the field. With the advent of massively parallel computing architectures, these approaches will find new application that will extend our collective knowledge of the complex atomic-scale behavior that underlies much of the macroscopic materials properties that scientists worldwide are investigating. Thus, these methods will become even more central in the ongoing quest to understand materials.

**Abstract**

The energy surface of an atomic scale representation of a material contains the essential information needed to determine the structure and time evolution of the system at a given temperature. Local minima on the surface represent (meta)stable states of the system, while first-order saddle points characterize the mechanisms of transitions between states. While many well-known methods make it relatively easy to find local minima, the identification of saddle points is more challenging. In this chapter, methods for finding saddle points are discussed as well as applications to materials simulations. Both doubly constrained search methods, where the final and the initial state minima are specified, and singly constrained search methods, where only the initial state is specified, are discussed. The focus is on a classical description of the atom coordinates, but saddle points corresponding to quantum mechanical tunneling are also mentioned. An extension to magnetic systems where the energy surface depends on the orientation of the magnetic vectors is sketched.

# 1     Introduction

Atomic scale simulations of materials often involve finding likely arrangements of the atoms as well as identifying the mechanism and estimating the rate of transitions between different arrangements such as diffusion events, migration of dislocations, chemical reactions, and phase transformations. These can be obtained by analyzing the energy surface characterizing the system, i.e., the electronic ground-state energy of the system as a function of the location of the atoms (and possibly also the orientation of the moments of magnetic atoms) (Peters 2017). Each state corresponds to a minimum on the energy surface and the potential well surrounding it. Excited electronic states can, in some circumstances, be important, but the discussion here will focus on the electronic ground state. Even so, the energy surface is complex and multidimensional for most material systems of interest, and it requires efficient tools to navigate on the energy surface and extract the desired information.

Given some initial configuration of the atoms and a method for evaluating the energy and its gradient with respect to atom coordinates, the nearest local minimum can readily be identified with any number of available minimization methods. A significant challenge, however, is to find all the relevant minima for given conditions, such as temperature. The lower the local energy minimum of the state, the more likely the system is to be in that state, according to Boltzmann statistics. The width of the energy well around the minimum and the number of equivalent minima relate to the vibrational and configurational entropy, respectively, and also contribute to the stability of the state. The identification of the most likely state of a system requires navigation on the energy surface, for example, advancing from one energy minimum to another.

One way to discover new minima is to move through regions of dips in the energy ridge, i.e., regions around first-order saddle points on the energy surface. At a first-

order saddle point, the gradient of the energy vanishes, and the Hessian, the matrix of second derivatives, has one and only one negative eigenvalue. The eigenvectors are referred to as modes, and the one corresponding to the negative eigenvalue is the unstable mode. A general feature of energy surfaces for atomic systems is that a lower energy saddle point tends to lead to a lower-energy minimum on the other side (the basis of so-called Brønsted-Evans-Polanyi relation). So, more often than not, a low-energy minimum can be discovered by moving over the energy ridge through a low-energy saddle point. Methods for finding first-order saddle points can, therefore, be used to identify local minima and likely states of the system.

It may, however, not be possible to reach some states, such as the one corresponding to the global energy minimum, on a given time scale because of a large energy barrier. The rate at which the system moves from one state to another is the key quantity that is needed to predict the long time scale evolution of the system. On a given time scale, only transitions that are frequent enough are relevant. Classical dynamics simulations based on Newton's equation of motion can be carried out, but the time scale of such simulations is limited by the vibrational frequency of the atoms and even for the simplest description of the energy surface – an empirical potential function – such a simulation can only span a small fraction of a second, while the challenge is often to predict the evolution of a material over years. As is explained in the following section, the first-order saddle points on the energy surface and their vicinity can be used to estimate the rate of transitions between states of the system. The central focus of this chapter is methods for finding first-order saddle points for the purpose of exploring energy surfaces of material systems.

## 2      Estimation of Transition Rates

The dynamics of atoms in materials that are relatively stable under conditions of interest can be characterized by a large number of vibrations back and forth, mostly in the close vicinity of the local energy minimum but occasionally involving large excursions caused by rare fluctuations through coupling to the heat bath. Such fluctuations can be large enough for the system to enter a new state. Since the system spends a long time in each state, a Boltzmann distribution of energy is typically established in all degrees of freedom, and the rate at which the system can transform from one state to another can be estimated to a first approximation by using statistical mechanics.

The basic tool for estimating transition rates in materials is transition state theory (TST) (Wigner 1938; Peters 2017). Assuming the atoms can be described as classical particles and that Boltzmann distribution of energy has been established in all degrees of freedom, the lifetime of a given initial state and possible final states of transitions from it can be estimated in a two-step procedure referred to as Wigner-Keck-Eyring (WKE) dynamics (Wigner 1938; Keck 1967; Eyring 1935). In the first step, a dividing surface in configuration space separating the initial state from other states is defined. The dividing surface should be placed in such a way that it lies through regions of the energy surface where the system is least

likely to be found. The dimensionality of the dividing surface is $D - 1$ where $D$ is the total number of degrees of freedom in the system (in three dimensions, $D = 3N$ where $N$ is the number of atoms). By adding a small width around the dividing surface, a subspace of dimensionality $D$ is generated, and this is referred to as the transition state. Transition state theory assumes that if the system makes it to the transition state and has velocity pointing away from the initial state, a transition will occur and the system enter a new state. This basic TST assumption is an approximation. Dynamical trajectories can be reflected back after crossing the transition state and reenter the initial state. They can, in fact, recross multiple times, and each recrossing to the initial state leads to an overestimate of the transition rate in the TST approximation. As a results, TST is guaranteed to give an upper bound to the transition probability. This gives a variational principle for the placement of the dividing surface. The dividing surface that leads to the lowest TST transition rate estimate is the optimal one. The first step of the WKE procedure should, therefore, involve a variational optimization of the dividing surface in addition to giving an approximation to the transition rate, $k^{\text{TST}}$.

The second step of the WKE procedure involves the calculation of short time scale trajectories started from the dividing surface. Since the transition state represents a region of low probability, the system advances quickly from there to either the initial state or some final state. The trajectories in the second WKE step reveal possible final states of the transition. Note that TST does not specify the final state. The trajectories also serve as a means to correct the TST rate estimate and obtain (in principle) the exact estimate of the rate by evaluating a dynamical correction factor, $\kappa$ (Keck 1967; Voter and Doll 1985). The less the dividing surface was optimized in the first step, the larger the number of trajectories needed in the second step to obtain a statistically converged correction factor. A recrossing of the transition state can occur either because of the shape of the energy surface, such as a curved valley on the energy surface in the final state, or because of a fluctuation from the heat bath resulting in a reversal of the relevant component of the velocity. Both effects are included in the short dynamical trajectories of the second WKE step. The WKE procedure, therefore, provides essentially an exact estimate of the transition rate, $k = \kappa k^{\text{TST}}$. Instead of involving impossibly long dynamical trajectories started near the initial state energy minimum, WKE uses a statistical estimate of the probability of making it to the transition state and then short time scale trajectories for the evolution from the transition state to possible final states.

The full implementation of the WKE procedure is in general challenging because of the need to represent and optimize a high-dimensional dividing surface. Efficient tools for such calculations have not been developed yet. The simplest approach is to use a hyperplanar dividing surface where both the location and the orientation are variationally optimized (Jóhannesson and Jónsson 2001). The orientation specifies which atoms are displaced and by how much at the transition state. The orientational optimization identifies the optimal transition mechanism. A single hyperplane is, however, in general not sufficient to specify the full dividing surface, and either a curved surface (Ciccotti et al. 1995) or a mosaic of hyperplanar segments is needed (Bligaard and Jónsson 2005).

The most commonly used form of TST involves an approximation to the energy surface. By expanding the energy to second order in the vibrational normal modes at both the initial state minimum and at a first-order saddle points on the energy rim surrounding the initial state, an approximation to the rate constant is obtained and referred to as harmonic TST (HTST) (Vineyard 1957):

$$k^{\text{HTST}} = \frac{\prod_j^D \nu_{i,\text{m}}}{\prod_j^{D-1} \nu_{i,\text{s}}} \ \exp\left(-(E_\text{s} - E_\text{m})/k_\text{B}T\right) \tag{1}$$

where $E_\text{m}$ and $E_\text{s}$ are the values of the energy the $\nu_{i,\text{m}}$ and $\nu_{i,\text{s}}$ are the vibrational frequencies at the minimum and at the saddle point, $k_\text{B}$ is the Boltzmann constant, and $T$ is the temperature. This expression agrees with the empirical Arrhenius dependence of the rate constant on temperature:

$$k = A \exp\left(-E_\text{a}/k_\text{B}T\right) \tag{2}$$

showing that the activation energy, $E_\text{a}$, is the energy difference between the first-order saddle point and the initial state minimum and the prefactor is related to the width of the potential energy well at the minimum and the energy valley at the saddle point.

The vibrational frequencies are obtained from the positive eigenvalues of the Hessian. The number of vibrational modes at the saddle point is one less than at the minimum because the dividing surface does not contain the unstable mode, the vibrational mode corresponding to negative eigenvalue. The ratio of the products of vibrational frequencies represents the relative vibrational entropy of the transition state and the initial state. Effectively, the dividing surface is approximated in HTST by a hyperplane going through each one of the first-order saddle points on the energy rim surrounding the initial state minimum with normal vectors pointing in the direction of unstable modes. Strictly speaking these should be finite hyperplanar segments, but the full hyperplane is included for each saddle point in order to obtain a simple analytical expression for the rate constant.

The HTST approximation can give an accurate estimate of the rate constant for materials at not too high or too low temperature. For low enough temperature, nuclear quantum effects need to be accounted for (see below). The energy surface must be smooth enough and the first-order saddle points separated by regions of high enough energy for the harmonic approximation to accurately represent the energy surface in the neighborhood of the extrema where the Boltzmann statistical weight is appreciable. This means that the first-order saddle points on the energy ridge must be separated by second-order saddle points that are significantly higher in energy, by several $k_\text{B}T$, compared to the first-order saddle points. Below, we will describe a method that can be used to check whether the energy landscape satisfies this criterion.

The main challenge is to find the relevant saddle points. The lower the energy of a saddle point, the more probable the corresponding transition is. While the number

of saddle points surrounding a given minimum on the energy surface can easily be enormous, it is enough to find only the lower lying saddle points in order to identify the relevant transitions. The task of finding saddle points can be divided into two categories. In the more general category, only the initial state is known, and the task is to find all relevant saddle points on the energy ridge surrounding the energy minimum. In some cases, the final state of interest is also known, and the task can then be cast in terms of finding the minimum energy path (MEP) between the initial and final state minima. The MEP is a path for which the energy is at a minimum in directions orthogonal to the path. A maximum along the MEP corresponds to a first-order saddle point. The activation energy for the overall transition is then given by the highest rise in energy along the path. We will first discuss methods for finding the MEP when both initial and final states are given. Then, we discuss methods for the more challenging problem of finding relevant saddle points when only the initial state is specified.

## 3    Initial and Final States Specified, CI-NEB

A path between a given initial and final state can be discretized by creating a number of replicas of the system and arranging them in such a way as to trace out a curve between the states. We will refer to the discretization points as "images" of the system. An image labeled $i$ is specified by the coordinates of the atoms, $R_i$. The task is to first generate a reasonable initial path and then apply an optimization algorithm to iteratively move the images to the MEP. There can exist more than one MEP between the given minima, an issue that is addressed below. At this point, the task is just to find the MEP closest to the initial path.

The simplest way to generate an initial path is to make a linear interpolation in Cartesian coordinates between the two minima. This method is frequently used in materials simulations. It can, however, lead to unphysical configurations of the atoms. For example, two atoms may end up being very close to each other leading to a strong repulsive interaction. When the calculation of the energy and atomic forces is carried out using an electronic structure method, such strong overlap may slow down or even prevent the self-consistency calculation from converging. Furthermore, the initial path generated by a linear interpolation may be far from any MEP. A better approach is to generate the initial path by taking the pairwise distances between atoms into account. This can be done with the image dependent pair potential (IDPP) method (Smidstrup et al. 2014). There, the pairwise distances between neighboring atoms are interpolated linearly between the two minima and an initial path generated to match those distances as closely as possible. Since there are many more pairwise distances than atom coordinates, the matching can only be approximate and the initial path is found by minimizing the sum of squared deviations (Smidstrup et al. 2014). Another approach that avoids the problem of overlapping atoms is to generate the initial path by linear interpolation in internal coordinates (Goumans et al. 2009).

In order to find the MEP closest to the initial path, the images are moved iteratively in a direction obtained from the atomic forces, i.e., negative gradient of the energy with respect to atomic coordinates, $-\nabla E(R_i)$. But only the component perpendicular to the path should be used to modify the shape of the path. A force projection is, therefore, required based on an estimate of the local tangent to the path. While it seems natural to estimate the tangent at a given image, $i$, from the coordinates of atoms at the two adjacent images, $i - 1$ and $i + 1$, it turns out to be numerically more stable to use only the coordinates of the neighboring image that has the higher energy (Henkelman and Jónsson 2000). Letting the normalized tangent be denoted $\hat{\tau}_i$, the force acting on the shape of the path at image $i$ is given by

$$F_i^{\mathrm{p}}|_\perp = -\nabla E(R_i) + \nabla E(R_i) \cdot \hat{\tau}_i \, \hat{\tau}_i. \tag{3}$$

By displacing the images in the direction of $F_i^{\mathrm{p}}|_\perp$, the perpendicular component of the atomic forces will vanish, and the images are then on the MEP. At each iteration of the optimization, the atomic forces of all images need to be calculated. The evaluation of the energy and atomic forces is typically the most computationally intensive part of the calculation. However, the calculations can readily be performed simultaneously, using parallel or distributed computing.

It is also necessary to specify how the images are distributed along the path. If the distribution is not controlled, the images tend to slide down to the local energy minima. The distribution is commonly controlled using a restraint method where a harmonic spring acts between adjacent images in the direction parallel to the path:

$$F_i^{\mathrm{s}}|_\parallel = \left( k_i^s \, (R_{i+1} - R_i) - k_{i-1}^s \, (R_i - R_{i-1}) \right) \cdot \hat{\tau}_i \, \hat{\tau}_i. \tag{4}$$

The spring constants, $k_i^{\mathrm{s}}$, can be chosen to produce a desired distribution of the images, for example, with higher density in regions of higher energy (Henkelman et al. 2000a). Most often, though, the spring constants are chosen to have the same constant value resulting in an even distribution of images along the path. For optimal convergence rate, the magnitude of the spring constant should be chosen such that the magnitude of $F_i^{\mathrm{p}}|_\perp$ and $F_i^{\mathrm{s}}|_\parallel$ is comparable. The effective force acting on image $i$ in the path is then given by the sum of the two force components:

$$F_i = F_i^{\mathrm{p}}|_\perp + F_i^{\mathrm{s}}|_\parallel. \tag{5}$$

The force projections, referred to as "nudging," separate the distribution of the images along the path from the displacements of images affecting the shape of the path. The distribution of the images along the path can also be controlled using a constraint method based on an estimate of the total length of the path (Weiqing and Vanden-Eijnden 2002).

The most important part of the MEP is the highest energy point along the path, i.e., the highest first-order saddle point along the path connecting the initial and final

states. The activation energy of transitions between the two states can be estimated from the first-order saddle point using HTST. In order to obtain an accurate estimate of the saddle point, one of the images can be forced to "climb" upward along the path and converge to the highest saddle point. This image is referred to as the "climbing image." Generally, the highest energy image after a few normal iterations (or a certain user-defined threshold) is chosen to become the climbing image, $i = c$. The effective force acting on this image is (Henkelman et al. 2000a)

$$F_c = -\nabla E(R_c) + 2 \left( \nabla E(R_c) \cdot \hat{\tau}_c \right) \hat{\tau}_c \tag{6}$$

The assumption here is that the tangent estimate at the climbing image gives an accurate estimate of the direction of the unstable mode at the saddle point. It is used to transform the gradient of the energy around the first-order saddle point so as to mimic the gradient around a minimum. An ordinary minimization algorithm can then be used with the transformed gradient to converge the climbing image on the first-order saddle point. This method is referred to as the climbing image nudged elastic band (CI-NEB) method (Henkelman et al. 2000a).

## 3.1    Optimization of the Path

Various iterative algorithms can be used to zero the effective force and hence move the images to the MEP.

Note, however, that the objective function, the function that gives the effective force by differentiation, is not known explicitly because of the force projections, i.e., the nudging. The optimization algorithm should, therefore, be based only on the forces, not on the objective function itself. This, for example, makes the usual implementation of line search approaches not applicable and hence complicates the implementation of some of the optimization methods.

In early implementations of the method (Mills et al. 1995; Jónsson et al. 1998), a velocity projection method based on the velocity Verlet dynamics algorithm (Andersen 1980) was used. There, the velocity, $v$, is zeroed in directions orthogonal to the force if $v \cdot F > 0$ and in all directions if $v \cdot F < 0$. A parametrized extension of the algorithm has been devised (Bitzek et al. 2006). The velocity projection algorithm gives fast and reliable performance in the initial stages where the images may be located far from the MEP and the effective forces large (especially when linear interpolation is used to generate the initial path). However, the convergence close to the MEP can be faster by using more advanced approaches (Chu et al. 2003; Sheppard et al. 2008). The limited memory Broyden-Fletcher-Goldfarb-Shanno (L-BFGS) (Nocedal 1980) algorithm has proved to be efficient (Sheppard et al. 2008). If the second derivatives of the energy are available and can be computed in each iteration without large effort (which however is generally not the case), a highly efficient optimization algorithm can be used (Bohner et al. 2013).

An example of a CI-NEB calculation on a modified two-dimensional Müller-Brown energy surface using the L-BFGS algorithm is shown in Fig. 1. The algorithm
**Fig. 1** A climbing image nudged elastic band calculation of the minimum energy path of a model two-dimensional potential surface (a modified Müller-Brown surface (Ásgeirsson and Jónsson 2018)). In addition to the initial and final states, which are fixed (red dots), the path is represented by ten discretization points, referred to as images (black dots). The initial path is generated from a straight line interpolation (in more realistic systems, it is better to use the IDPP method). The position of images is shown after 0, 5, 10, 15, and 21 L-BFGS iterations. The green dashed line shows the minimum energy path. A red dot marks the first-order saddle point to which the climbing image converges. Inset: Energy along the minimum energy path and energy of the images after convergence has been reached

is used here right from the start. A more reliable strategy is to start out with the more stable and conservative velocity projection algorithm and then switch to the faster L-BFGS method once the effective force acting on each atom has dropped below some user-defined threshold, for example, $||F_i|| < 0.5\,\text{eV/Å}$.

A calculation may be considered tightly converged to the MEP when the norm of the force acting on each atom perpendicular to the path $||F_i^{\text{p}}|_\perp||$ is below $0.01\,\text{eV/Å}$ for all images. However, the MEP is mainly needed to identify where the highest energy point is and to estimate the tangent to the path at that point. The tight convergence is really only needed for the climbing image, and a looser threshold can be used for all other images, such as $||F_i^{\text{p}}|_\perp|| < 0.1\,\text{eV/Å}$.

When electronic structure methods, such as density functional theory (DFT) or ab initio quantum chemistry, are used in combination with a CI-NEB calculation, it is particularly important to reduce as much as possible the number of energy and atomic force evaluations. Recently, it has been shown that machine learning approaches can reduce the number of energy and force evaluations by an order of magnitude. Both neural networks (Peterson 2016) and Gaussian process regression

(GPR) (Koistinen et al. 2016, 2017) have been applied. There, an approximate energy surface is constructed with a machine learning model using all previous energy and force evaluations carried out by the electronic structure method. A CI-NEB calculation is carried out on the approximate energy surface and the electronic structure calculation then done for each image or only the image where the estimated uncertainty of the approximate energy surface is largest. The approximate energy surface is then refined using the new information and the CI-NEB calculation carried out again, etc. The GPR has the advantage of having a built-in error estimate which can be used to choose in an optimal way which image should be evaluated by the electronic structure method. The machine learning approach helps make optimal use of each electronic structure calculation, while traditional optimization methods, such as the velocity projection algorithm, only use the forces obtained at the current step and disregard all previous force evaluations. The L-BFGS keeps memory of the last $M$ steps (typically $M = 20$) to construct an approximate Hessian matrix, but the machine learning algorithm constructs an approximate surface of a more general shape. As a result, the machine learning approach can use all previous energy and force calculations and reach convergence with fewer electronic structure calculations than L-BFGS.

## 3.2    Interpolation and Strategy

In order to analyze and visualize the results of a CI-NEB calculation as well as to monitor the progress of the calculation, it is important to not just interpolate the energy of the images but also the derivative of the energy along the path, i.e., the component of the atomic forces parallel to the path. It is convenient to use a cubic polynomial for each interval between adjacent images (Henkelman and Jónsson 2000). An interpolation using the derivative may reveal the presence of an intermediate minimum along the path, while a simple interpolation of only the energy does not. A good strategy in such a case is to locate the energy minimum with a separate minimization calculation and then proceed with CI-NEB calculations of the two segments of the path separately.

In an analogous manner, the atom coordinates can be interpolated to add new images and hence improve the resolution in certain regions along the path (Henkelman and Jónsson 2000). This especially applies to regions of high curvature and rapid changes in the tangent from one image to another which can cause inaccuracies and even non-convergence of the calculation. As any other numerical method that relies on discretization, the CI-NEB method requires the number of images to be large enough. However, instead of doubling the number of images in such a situation, it may be sufficient to simply add an image (or a few images) in the problematic region along the path. Note that the spring constants associated with the new image need to be twice as strong such that the location of the adjacent images does not get disrupted.

When the CI-NEB method is applied to materials where periodic boundary conditions are applied to the simulation cell, the size and shape of the cell can be

made part of the MEP calculation, in addition to the atom coordinates (Sheppard et al. 2012). This is needed if the crystal structure is changing during the transition. When the method is applied to finite systems such as clusters or molecules, it is important to remove the overall translation and rotation of the system from the available degrees of freedom. The optimization of the path could otherwise lead to an artificial lengthening of the path involving translation and/or rotation in order to enable images to slide down from high-energy regions. This can reduce the resolution of the path in regions of high energy and increase the computational effort or even prevent the calculation from converging. A method based on quaternions has been formulated for the purpose of constraining the translation and rotation (Melander et al. 2015).

## 3.3 Application of CI-NEB and WKE Dynamics

An application of the CI-NEB method is shown in Fig. 2. It illustrates how the method can reveal a mechanism that is entirely different from the one implicitly assumed in the initial path. Also, after the MEP and relevant saddle point had been

**Fig. 2** An application of the climbing image nudged elastic band method to a surface reaction where a $CH_4$ molecule is formed on a Ni(111) surface from a subsurface H atom and a $CH_3$ admolecule. While such a transition mechanism had been postulated to be efficient, the calculation shows that a corresponding minimum energy path does not exist on the DFT/PW91 energy surface. While the initial path is consistent with direct addition of the subsurface H atom with the $CH_3$ admolecule, the optimization of the path reveals that the $CH_3$ first hops to the side, the H atom emerges to the surface to a state that corresponds to a deep intermediate minimum, and, finally, the H adatom and the $CH_3$ combine in a regular surface reaction mechanism to form the $CH_4$, which leaves the surface. The calculation illustrates how the method can find at a complex minimum energy path involving several elementary reaction steps even when the initial path is generated with an incorrect mechanism in mind. (From Henkelman et al. 2006)

located, short time scale dynamics were initiated from the transition state to obtain various information about the atomic dynamics.

There had been some suggestions that subsurface H atoms could play an important role in the formation of $CH_4$ molecules from $CH_3$ molecules adsorbed on a catalyst surface. As can be seen from the inset showing the initial state, it seems reasonable that the H atom could add directly to the $CH_3$ as it moves up from the subsurface site. This mechanism appears to be more facile than the typical surface reaction mechanism since an H adatom on the surface cannot easily approach to the C atom in the $CH_3$ admolecule. A CI-NEB calculation for this reaction on a Ni(111) surface was carried out using DFT/PW91 to evaluate the energy and atomic forces (Henkelman et al. 2006). The calculation started from a linear interpolation assuming that the direct addition of the subsurface H atom to the C atom in $CH_3$ could take place. The initial path is simple and mainly involves the displacement of the H atom up from the subsurface site. Optimization of the path, however, revealed that an MEP corresponding to this direct reaction mechanism does not exist on the DFT/PW91 energy surface. Instead, the path converged on a complex multistep mechanism. First, the $CH_3$ hops to the side to a nearby bridge site, freeing up the surface site for the H atom. Then, the H atom hops to the surface. A deep minimum corresponds to this intermediate configuration. Finally, the H adatom and the $CH_3$ admolecule combine in the usual surface reaction step to form a $CH_4$ molecule that leaves the surface.

This is a good example of how a CI-NEB calculation can undo an incorrect preconceived notion of a reaction mechanism. While it can seem plausible that a subsurface H atom attaches directly to a $CH_3$ admolecule, the results obtained for the DFT/PW91 energy surface do not support this notion. The reason appears to be that the Ni atoms do not have catalytic activity where they are bonded to each other. The catalytic activity is confined to the side where the Ni atoms are exposed, i.e., to the surface.

Assuming the system is thermalized in the deep intermediate minimum corresponding to the H adatom and the $CH_3$ admolecule, the critical energy barrier for forming $CH_4$ is the one corresponding to the last saddle point. An interesting observation made from the CI-NEB calculation was a large displacement of the underlying Ni atom, by 0.25 Å. While a similar observation had been made in calculations of $CH_4$ formation on Ir(111) (Henkelman and Jónsson 2001), most surface reaction calculations were at that time carried out with frozen surface atoms.

This raises interesting questions about the atomic dynamics of the transition. For example, how is the 0.85 eV excess energy gained by the system as it advances past the transition state to a gas phase $CH_4$ molecule and clean Ni surface partitioned between the Ni atoms and the $CH_4$ molecule? Also, how is the energy of the $CH_4$ molecule partitioned among its vibrational modes? For the reverse reaction, dissociative sticking of $CH_4$, this reveals to what extent translation and the various vibrational modes of the molecule can enhance the sticking probability. To answer these questions, the second step of the WKE approximation was carried out, using the HTST approximation of the transition state. Only a minimal sampling of trajectories was carried out, starting with small displacements from the saddle

point. The calculations showed that 15% of the excess energy go into Ni atom vibrations, while 79% go into translation, 22% into vibrations, and 4% into rotation of the $CH_4$ molecule. Surprisingly, most of the vibrational energy goes into the stretching modes not the lower frequency deformation modes. This result indicates that excitation of the stretching modes is more likely to enhance sticking than excitation of the deformation modes. The translation is, however, by far most effective in enhancing sticking.

Another interesting dynamics issue that could be addressed in the second step of the WKE procedure is whether the high kinetic energy of the H adatom as it emerges at the surface could enhance the reaction with the $CH_3$. To address this question, dynamical trajectories started at the transition state for the subsurface to surface hop were calculated, but none of the trajectories led to a combination of the H atom with the $CH_3$. The conclusion is that subsurface H atoms do not play an important role in hydrogenation of $CH_3$ admolecules under the conditions simulated.

## 3.4    Variants of the Method

There are several different variants of the method for finding an MEP when both initial and final states are specified, and a few of them will be mentioned here briefly.

When the shape of the MEP has become clear enough for the approximate location of the highest energy saddle point to be located approximately, computational time can be saved by confining the calculations to the region in the vicinity of the saddle point and halting calculations of images in other regions. There have been several different implementations of this approach. In its simplest form, two images on opposite sides of the highest energy image of the partly converged path are chosen to be the fixed endpoints instead of the local minima, but a better approach is to make the new endpoints follow selected equipotential contours to the MEP (Zhu et al. 2007; Zhang et al. 2016). Another approach is to use two climbing images located on opposite sides of the highest energy image so as to bracket the saddle point (Zarkevich and Johnson 2015).

Alternatively, a single-ended saddle point search, discussed below, can be launched from the highest energy image on the partially converged path (Henkelman et al. 2000b).

When dealing with complex energy surfaces with multiple local minima and curved MEPs, the stability of the calculation can be improved by including part of the component of the spring force perpendicular to the path (Jónsson et al. 1998) or by using the so-called double nudging (Trygubenko and Wales 2004; Sheppard et al. 2008). Also, long paths and large number of images can cause the distance between images to become uneven. In such cases, a combination of the restraint and constraint approaches for distributing the images along the path can be used (Maras et al. 2016, 2017). Alternatively, it is good to divide the path calculation and focus on each segment separately whenever there is a sign of an intermediate minimum, as discussed above. An automatic algorithm for adding new images to the discrete representation of the path has been developed (Kolsbjerg et al. 2016).

# 4    Only Initial State Specified, MMF

It can be hard to predict the mechanism and even the possible final states that can be formed in a thermally activated transition. Ideally, a computer calculation should be able to reveal such information given only the initial state of the system. This is a harder problem than the one discussed above where the final state is specified as well as the initial state. One option is to raise the temperature of the system and identify new states that get visited, followed by an NEB calculation to find the minimum energy path from the initial state (Sørensen et al. 1996). But the increase in temperature will place larger emphasis on states with high entropy and the transitions relevant at the low temperature of interest may be hard to find. What is needed is a method for climbing up the energy surface from the initial state to converge onto a first-order saddle point. Such searches need to be carried out several times in order to identify all relevant, i.e., low-lying saddle points on the energy ridge surrounding the initial state minimum. Armed with such a method, the long time scale evolution of a materials system can be simulated, as discussed in chapter "The Chapter on AKMC Methods".

A first-order saddle point differs from a local minimum in that the Hessian matrix has one negative eigenvalue, corresponding to the unstable mode. The atomic forces near a first-order saddle point can be made to mimic atomic forces near a local minimum by reversing the component of the force in the direction of the unstable mode. More generally, let $\hat{\lambda}$ be a unit vector along the eigenvector corresponding to the lowest eigenvalue of the Hessian, the minimum mode (irrespective of the sign of the lowest eigenvalue). If the system is made to follow an effective force given by

$$F^{\text{eff}}(R) = -\nabla E(R) + 2\left(\nabla E(R) \cdot \hat{\lambda}(R)\right)\hat{\lambda}(R) \tag{7}$$

then convergence will be reached at a first-order saddle point. This is analogous to the force on the climbing image in the CI-NEB algorithm except that $\hat{\lambda}$ is used here instead of the path tangent, which is not known in this case. If the second derivatives of the energy can be evaluated easily, then the Hessian matrix can be constructed and its eigenvalues and eigenvectors computed quite readily, although the computational effort can be significant for large systems, as it scales with the third power of the number of degrees of freedom.

In most cases, however, the second derivatives of the energy cannot be obtained easily, and the challenge is to evaluate $F^{\text{eff}}$ using only the first derivatives, i.e., the atomic forces, and without even evaluating the Hessian matrix. There are several ways to do this. One is to construct a dimer, i.e., two replicas of the system held at a small, fixed distance apart. The lowest energy orientation of the dimer is the direction of the minimum mode, $\hat{\lambda}$, and it can be found by iterative minimization of the energy using only the first derivatives (Henkelman and Jónsson 1999). An analogous method was formulated at a similar time (Munro and Wales 1999). Another way to find the minimum mode is to use the iterative Lanczos or,

even better, the Davidson method (Malek and Mousseau 2000; Olsen et al. 2004; Gutiérrez et al. 2016).

Since the system is displaced uphill in energy along the minimum mode, the method is often referred to as minimum mode following (MMF). The first step is to displace the atoms slightly from the initial state minimum and drive the system in some way into the region where the lowest eigenvalue of the Hessian is negative. From then on, the system is displaced in the direction of $F^{\text{eff}}$ until the magnitude of the force drops below a given tolerance. The minimum mode will often change only slightly between iterations. Therefore, it is possible to save computational effort by only evaluating the minimum mode every few iterations (Gutiérrez et al. 2016). The MMF method is discussed in more detail in chapter "The Chapter on AKMC Methods".

Figure 3 shows MMF calculations for two-dimensional test problems. There, a random displacement from the initial state minimum is first applied, and then it is advanced in the direction of the minimum mode until the lowest eigenvalue becomes

**Fig. 3** An illustration of the minimum mode following method for finding first-order saddle points given only the initial state minimum (blue). Saddle points are marked with + signs. Left: Three saddle point searches started from different, random displacements from the minimum. In one of the searches (green), a kink on the path is evident when the lowest eigenvalue becomes negative and the perpendicular relaxation is turned on. After locating the saddle point, the system is displaced in the direction of the unstable mode, followed by minimization to locate the final state minimum. Right: A larger number of saddle point searches started from three different initial states. The region around each saddle point where at least one eigenvalue is negative is illustrated with a lighter color. In some cases, several different search paths trace the same final approach to the saddle point

negative. From that point on, the system is advanced in the direction of $F^{\text{eff}}$, and relaxation perpendicular to the minimum mode is included. This can result in a kink in the path. The figure also shows that several paths can approach a saddle point in a similar way even when they start out being quite different.

An application to a materials problem is shown in Fig. 4 where various different migration mechanisms of a kink on a dislocation in silicon crystal are identified (Pedersen et al. 2009a). The calculation made use of the EDIP empirical potential function (Justo et al. 1998). Three different mechanisms were found from multiple saddle point searches. The optimal mechanism, the one corresponding to lowest activation energy, involves an intermediate state where three Si atoms have fivefold coordination. Two of the mechanisms, including the optimal one, involve an intermediate state.

**Fig. 4** Application of the minimum mode following method to find the mechanism of dislocation kink migration in crystalline silicon, based on the EDIP empirical potential function. Fivefold coordinated atoms are shown in blue and threefold coordinated atoms in red. The three lowest energy saddle points are shown (top row), two of them lead to an intermediate state (middle row). The initial state with two kinks separated by a large distance is shown (bottom), with a red line indicating the dislocation. (From Pedersen et al. 2009a)

Minimum mode saddle point searches have been used in various studies, for example, of the binding and diffusion of $H_2O$ molecules on the surface of proton-disordered ice (Pedersen et al. 2014, 2015) and structure and diffusion in metal grain boundaries (Pedersen et al. 2009b; Pedersen and Jónsson 2009). Several other applications are discussed in chapter "AKMC Methods".

## 5 Additional Characterization of the Energy Surface

In this section, a few additional saddle point search methods that can be used to further characterize the energy surface of a system are discussed.

### 5.1 Search for Optimal MEPs

So far, the discussion of the MEP calculations has focused on finding only the MEP closest to the initial path. Sometimes the energy surface is simple enough, and the initial and final states are similar enough that only a single MEP connects the two. But, more generally, there can be two or more MEPs for a given pair of endpoints. One example is the $CH_4$ formation shown in Fig. 3. The $CH_3$ admolecule could jump to the left instead of jumping to the right in the first step to make room for the H atom on the surface. Also, the subsurface H atom could jump to an adjacent subsurface site before going to the surface, analogous to an MEP found for $H_2$ formation (Henkelman et al. 2006). These various paths would all have the same critical step, namely, the combination of an H adatom and a $CH_3$ admolecule on the surface, so they would, for practical purposes, be equivalent.

For other systems, it may be important to sample the MEPs to find the one that corresponds to lowest overall activation energy. One example of such a system is the nucleation of dislocation on a strained Ge overlayer (Maras et al. 2017). Since the atomic model of the dislocation involves a large number of atoms, there are many possible mechanisms, and each one involves a large number of intermediate minima. A global optimization strategy based on an evolutionary algorithm has been applied to this problem (Maras et al. 2017). There, segments of different paths are mixed and matched and a catalog maintained of all the intermediate minima found so far. More work needs to be done to develop optimal strategies for such complex systems.

### 5.2 Energy Ridge Tracking

The accuracy of the HTST approximation rests on the assumption that second-order saddle points are significantly higher in energy, on the scale of $k_BT$, than the first-order saddle points. In order to check that, a calculation of a path lying along the energy ridge between two first-order saddle points can be carried out. The method, ridge tracking nudged elastic band (RT-NEB), is an extension of the

CI-NEB method where each discretization point is a dimer of images (Maronsson et al. 2012). It combines, in a sense, the technique discussed above for finding an MEP and the dimer method for finding a saddle point given only the initial state. Just as the CI-NEB method can reveal the presence of intermediate minima that were not known beforehand, the RT-NEB method can reveal the presence of first-order saddle points in between known saddle points. It can, therefore, help complete the table of possible transitions a system can undergo (Maronsson et al. 2012).

## 5.3    Saddle Points for Quantum Tunneling

At low enough temperature, quantum mechanical tunneling becomes the dominant transition mechanism rather than hops over the energy barrier. An estimate of the crossover temperature can be obtained from the MEP (Gillan 1987). The larger the curvature of the MEP and the lower the effective mass along the unstable mode at the saddle point, the higher the crossover temperature.

The quantum statistical mechanics of the system can be obtained conveniently from thermal path integrals (Feynman and Hibbs 1965). Within that formalism, the classical energy surface gets replaced by an energy surface for a ring polymer where the beats are replicas of the system connected with temperature-dependent springs. This gives an effective, quantum mechanical energy surface that depends on temperature. The higher the temperature and the larger the mass of the atoms, the stiffer the springs and more classical the system becomes (Feynman and Hibbs 1965). A quantum mechanical extension of transition state theory can be formulated in terms of the rate of transitions of the ring polymer from the initial state to the final state (Mills et al. 1997, 1998; Richardson and Althorpe 2009; Hele and Althorpe 2013). Within a harmonic approximation, the optimal tunneling path is a first-order saddle point on the quantum mechanical energy surface (Benderskii et al. 1994; Mills et al. 1998), and the rate of thermally activated tunneling can be estimated from its properties (Benderskii et al. 1994; Richardson 2016). The optimal tunneling path is often referred to as an "instanton."

Saddle point search methods, such as the MMF method, can be used to find instantons (Andersson et al. 2009; Rommel and Kästner 2011). However, a more efficient approach is to use a path optimization method that minimizes a line integral along the path. This line integral nudged elastic band (LI-NEB) method can be used to find the optimal tunneling path at a given energy based on the semiclassical JWKB approximation. There, the images can be distributed evenly. Then, after the path has been found, a larger number of images need to be distributed unevenly along the path to represent an instanton, the optimal Feynman path for tunneling at a given temperature (Einarsdóttir et al. 2012; Ásgeirsson and Jónsson 2018). The beads of the ring polymer have a higher density in the lower-energy regions, making the direct search for the instanton using the MMF method less efficient than the LI-NEB.

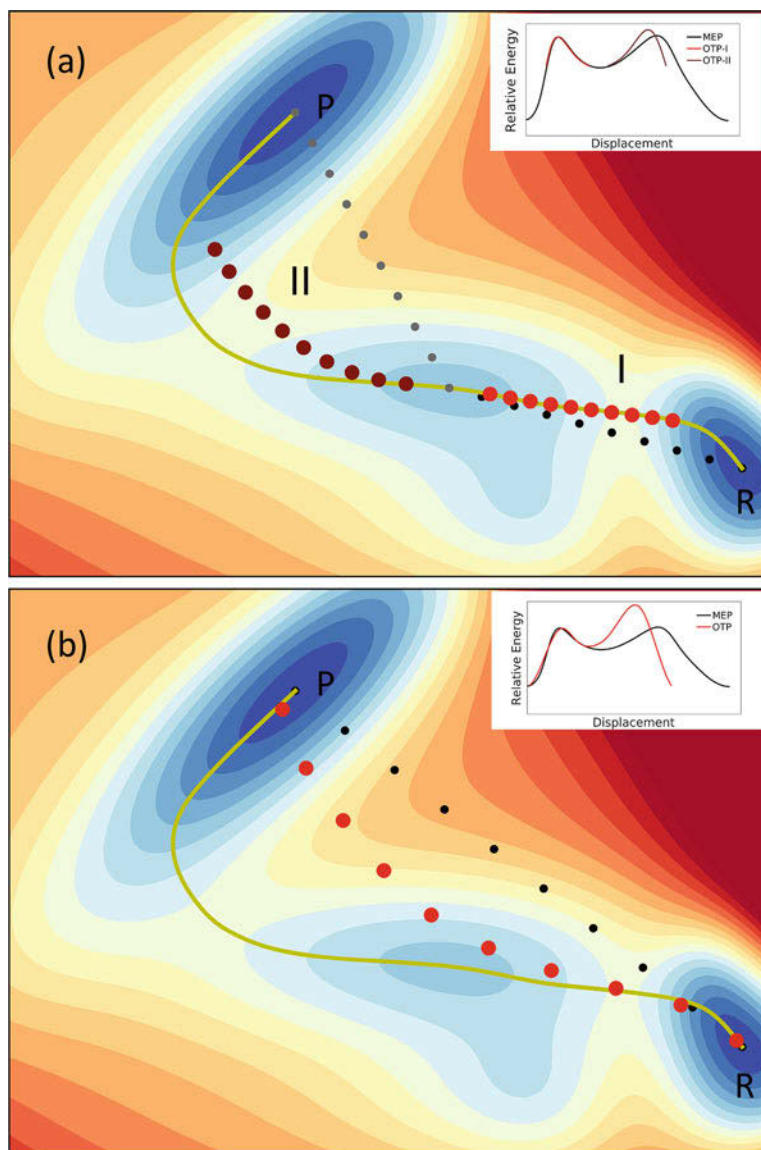
Examples of tunneling paths at two different values of the temperature are shown in Fig. 5 for the same two-dimensional energy surface as in Fig. 1. The calculation


**Fig. 5** Optimal tunneling paths found using the line integral nudged elastic band method. The energy surface is the same as in Fig. 1. (**a**) Tunneling occurs in two steps, first into the intermediate state and then the final state. The initial, straight line interpolation path is shown with black and gray dots, while the optimal tunneling paths are shown with red and brown dots. The corner cutting of the tunneling path is particularly clear at saddle point II where the MEP has a larger curvature. (**b**) Tunneling occurs in one step between states R and P, without visiting the intermediate state. At low enough temperature, this becomes the dominant transition mechanism. The initial, straight line interpolation path is shown with black dots, while red dots show the optimal tunneling path. Insets: Energy along the minimum energy path and along the optimal tunneling paths. (From Ásgeirsson and Jónsson 2018)

of the first-order saddle points on the quantum mechanical surface, the instantons, serves as further explorations of the energy surface. In regions where the MEP is curved, the tunneling path cuts corners. At the higher temperature, the tunneling takes place in two steps, first from the initial state, R, to the intermediate state and then from there to the final state, P. At the lower temperature, the tunneling takes the system directly between states R and P without entering the intermediate state. Results of the LI-NEB calculation are shown where the images are evenly distributed along the optimal tunneling path.

## 6    Saddle Points for Magnetic Transitions

Transitions from one magnetic state of a material to another can also be slow on the time scale of the vibrations of magnetic moments (Braun 2012). The same considerations about time scale differences and rare events discussed above in the context of atomic rearrangements can apply to such transitions. As a result, the characterization of the energy surface as a function of the magnetic degrees of freedom using saddle point searches is also useful when studying magnetic systems. It turns out that a semiclassical, adiabatic approximation can usually be made where the angles specifying the orientation of the magnetic momentum vectors are treated as slow variables while the length of the magnetic momentum vectors is a fast variable, determined by the electronic structure (Antropov et al. 1996). A full semiclassical specification of the configuration of an atomic scale system should, therefore, include the location of the atomic nuclei as well as two angles, for example, the polar and azimuthal angles ($\theta$ and $\phi$) for each atom. A transition can involve simultaneous rearrangement of atoms and reorientation of magnetic moments. Within a harmonic approximation, the mechanism of such a transition can be characterized by a saddle point on this higher-dimensional energy surface.

A brief account will be given here of tools for navigating on magnetic energy surfaces, analogous to the tools presented above for atomic rearrangements. For simplicity, the atom coordinates will be assumed to be fixed and only the orientation of the magnetic moments treated as variables. The configuration space of N magnetic moments is a direct product of N two-dimensional spheres. The fact that the configuration space is curved brings up special considerations for the saddle point search methods. Again, the activation energy for thermally activated transitions is given by the energy difference between a first-order saddle point and the initial state minimum. But the equation of motion for magnetic moments, the Landau-Lifshitz equation, gives a different pre-exponential factor in the HTST approximation for the rate constant (Bessarab et al. 2012, 2013).

### 6.1    Geodesic CI-NEB Method

The distance between two points in the configuration space of magnetic moments is given by the length of the geodesic path connecting the two points. This should be

taken into account in the CI-NEB calculations of minimum energy paths between two local minima on the magnetic energy surface. Also, the nudging needs to include a projection onto the tangent space of the N two-dimensional spheres. This variant of the method for finding MEPs for magnetic transitions is referred to as the geodesic nudged elastic band (GNEB) method (Bessarab et al. 2015).

An example of a calculation of an MEP for a two-dimensional magnetic system is shown in Fig. 6. The Hamiltonian here is of an extended Heisenberg form including the Dzyaloshinsky-Moriya interaction  (Uzdin et al. 2018). The system initially

**Fig. 6** Geodesic climbing image nudged elastic band method calculation of a minimum energy path for a magnetic transition where a skyrmion first attaches to a three-atom nonmagnetic impurity and then collapses. Red (blue) arrows show spins with z-component pointing up (down). Initially, the skyrmion and the nonmagnetic impurity are separated by a large distance, (1). By overcoming a small energy barrier, (2), a more stable state is reached where the skyrmion incorporates the impurity in a region where its magnetic moments lie in the plane (black arrows), (3). The skyrmion then collapses by overcoming a larger energy barrier (4) resulting in the ground-state, ferromagnetic phase (5). (From Uzdin et al. 2018)

contains a localized non-collinear structure called a skyrmion. There is great interest in such states as they represent a pseudo-particle that can be quite stable and could be used for future data storage and even data manipulation. The MEP shows the skyrmion approaching a triatomic, nonmagnetic impurity. By overcoming a small energy barrier, the impurity becomes incorporated in the skyrmion, in a region where the magnetic moments lie in the plane of the system. This lowers the energy of the system slightly. While a skyrmion in a continuous field is rigorously stable due to topological protection, its collapse can occur with a finite energy barrier on a discrete lattice (Bessarab et al. 2015). Here, the collapse occurs in the presence of the impurity. The mechanism involves shrinkage of the skyrmion and finally rotation of the core. For this set of parameters, the uniform ferromagnetic phase is lower in energy.

## 6.2    Mode Following in Curved Space

Since transitions involving reorientations of magnetic moments can be complex, many different types of transitions can be possible; a saddle point search method where only the initial state is specified is useful, just as for atomic rearrangements. The curvature of the configuration space needs to be taken into account when constructing the Hessian and calculating the eigenvalues and eigenvectors. An extension of mode following has recently been formulated for magnetic systems and applied to skyrmions (Müller et al. 2018). In addition to collapse and escape through a boundary, the method identified a transition where the skyrmion divides and forms two equivalent skyrmions. The activation energy for this duplication process was for some parameter values similar to that of collapse and escape. A dynamics simulation based on the Landau-Lifshitz equation showed that a time-dependent external field could induce the duplication process (Müller et al. 2018).

   More work is needed to complete the implementation of the saddle point searches for systems of atoms with magnetic moments. First of all, an efficient method for constraining spin orientations in nonstationary configurations in electronic structure calculations needs to be developed. Then, a formulation of these various saddle point search methods for energy surfaces that are functions of both atomic coordinates and magnetic momentum orientations needs to be developed and implemented.

## 7    Conclusion

This chapter has summarized briefly various frequently used methods for finding saddle points. Such calculations can be used to reveal new states of the system by identifying local energy minima, not just saddle points. The height of the saddle point and the curvature of the energy surface around it as well as around the minimum can, within HTST, be used to estimate the rate of transitions between states. The simplest and most stable way to find saddle points is by finding MEPs

and identifying maxima along the path. This is now routinely done in the context of electronic structure calculations, DFT or ab initio. The MMF method where only the initial state is specified is more challenging and computationally demanding, and most calculations so far have been carried out with empirical potential functions. This will likely change in the future when more computational cores become available since the calculations involve several independent saddle point searches that can easily be carried out simultaneously via parallel or distributed computing (Chill et al. 2014a). Machine learning such as Gaussian process regression will also likely reduce the number of electronic structure calculations, as has already been demonstrated in CI-NEB calculations. Saddle point searches may even become an important component of global optimization algorithms (Pedersen et al. 2012; Plasencia et al. 2014). It is important to keep improving the algorithms to reduce the computational effort. A web page that collects algorithms and performance numbers for saddle point searches has been set up and is a valuable resource in this field (Chill et al. 2014b).

**Abstract**

Exact modeling of the dynamics of chemical and material systems over experimentally relevant time scales still eludes us even with modern computational resources. Fortunately, many systems can be described as rare event systems where atoms vibrate around equilibrium positions for a long time before a transition is made to a new atomic state. For those systems, the kinetic Monte Carlo (KMC) algorithm provides a powerful solution. In traditional KMC, mechanism and rates are computed beforehand, limiting moves to discretized positions and largely ignoring strain. Many systems of interest, however, are not well-represented by such lattice-based models. Moreover, materials often evolve with complex and concerted mechanisms that cannot be anticipated before the start of a simulation. In this chapter, we describe a class of algorithms, called off-lattice or adaptive KMC, which relaxes both limitations of traditional KMC, with atomic configurations represented in the full configuration space and reaction events are calculated on-the-fly, with the possible use of catalogs to speed up calculations. We discuss a number of implementations of off-lattice KMC developed by different research groups, emphasizing the similarities between the approaches that open modeling to new classes of problems.

# 1    Introduction

Modeling the dynamics of chemical and material systems is a fundamental challenge for computational scientists. While the equations of motion of atomic scale systems have been known since the days of Newton, their integration over experimentally relevant time scales still eludes us even given modern computational resources. With empirical potentials, we can achieve nanoseconds of simulation time per day, and with ab initio methods, we are limited to picoseconds. But in most chemical and material applications, we are interested in the human time scales of seconds to minutes, which are relevant for applications including catalysts and batteries. Bridging the time scale gap between what we can model with molecular dynamics (MD) and practical applications is key to making molecular simulations relevant.

Fortunately, many systems in chemistry and material science are what can be described as rare event systems. In this case, atoms in the material vibrate around equilibrium positions for a long time before a transition is made to a new atomic configuration, or state. This might be the hopping of a Li atom between sites in a battery material or a bond-breaking event in a catalytic reaction. With microscopic kinetics taking place on time scale well separated from phonons, rare event systems open the door to the application of various numerical solutions based on the transition state theory that are not available generally: instead of modeling the vibrational dynamics, which occurs on a femtosecond time scale, transition state theory can be used to average over the thermal motion and calculate the rate of the slowest rare event of interest. If all such important rates can be found, the state-to-state evolution of the system can be calculated on the time scale of the rare events.

A powerful approach for modeling the evolution of a system when the rates are known is the kinetic Monte Carlo (KMC) method. In traditional KMC, the mechanism and the rate of every possible event are required before a calculation is started. This requirement essentially limits atomic KMC simulations to be defined on a lattice where interactions between atoms and atomic motion can be defined discretely. In KMC, a table of all possible events is made, and a single event is chosen with a probability proportional to its rate. The amount of time that evolves between KMC steps is, on average, given by the inverse of the sum of the rates. Thus, each KMC step can be accomplished with just a couple of random numbers and the bookkeeping required to keep track of the possible events; this computational efficiency allows for KMC simulations of millions or billions of events and time scale orders of magnitude longer than any single elementary event.

Obvious limitations of traditional KMC are (i) the need to know all possible events a priori and (ii) the representation of atomic configurations on a lattice. Many atomic systems of interest, however, especially in the presence of defects or disorder, are not well-represented by a lattice-based model. Additionally, materials often evolve with complex and concerted mechanisms that cannot be anticipated before the start of a simulation; it is the evolution of the system into unanticipated configuration via unexpected events that make simulations most interesting.

The purpose of this chapter is to describe a class of algorithms, called off-lattice or adaptive KMC, which relaxes both limitations of traditional KMC. Specifically, atomic configurations are represented in the full configuration space, and reaction events are calculated on-the-fly so that the KMC event table is not fixed but rather adapts as the simulation progresses. Thus, off-lattice KMC can be applied to a much wider range of interesting systems, and the calculated evolution of the system can reveal unexpected dynamics that were not anticipated by the modeler.

There are now a number of implementations of off-lattice KMC developed by different research groups. Later in the chapter, we will discuss some of the differences in philosophy and specific algorithms, but a primary objective here is to highlight what is common between off-lattice KMC methods and emphasize that what may appear to be different methods with different names are in fact often minor variations on a common theme.

## 2    Off-Lattice KMC

Off-lattice KMC was inspired by a number of closely related earlier methods. In an approach by Sørensen et al., high-temperature MD simulations were used to determine possible reaction mechanisms between a probe tip and a metal surface (Sørensen et al. 1996). These pathways were refined using the nudged elastic band (NEB) method (Jónsson et al. 1998; Henkelman and Jónsson 2000; Henkelman et al. 2000) to determine the energy barriers and rates at the lower temperature of interest. While the authors did not fully sample a rate table for KMC, their work anticipates the philosophy of off-lattice KMC and, in fact, was later developed into an accelerated molecular dynamics method called temperature-accelerated dynamics (Sørensen and Voter 2000). A second method with close connections to off-lattice KMC is the activation-relaxation technique (ART) (Mousseau and Barkema 1998b) in which local arrangements of atoms were driven away from their minimum positions on the potential energy landscape, over ridges, and into neighboring basins of attraction. Again, no KMC event tables were calculated, but the idea of sampling reaction pathways from local displacements of atoms became a key idea for off-lattice KMC methods. ART was later extended into an off-lattice KMC method called kinetic ART, the details of which will be discussed here (El-Mellouhi et al. 2008; Béland et al. 2011).

The earliest implementation of off-lattice KMC that we know of was in 2001 by Henkelman and Jónsson (2001). In this method, local atomic displacements were made to initiate minimum-mode following saddle point searches; these searches iteratively find the lowest mode of the Hessian and follow this mode to a saddle point.

Over the 15 years since the first introduction of off-lattice KMC, there have been a number of significant improvements to the algorithm. Much of the development has been devoted to identifying and implementing efficient methods for storing and reusing information about reactive events that have been calculated. Another key issue, which will be discussed later, is the so-called low-barrier or flickering problem in which fast events limit the overall time scale that can be achieved by off-lattice KMC. Today, there are a number of approaches associated with different aspects of off-lattice KMC methods. Yet, they can generally be described in the single framework outlined in Fig. 1. In brief, all off-lattice KMC methods start from an initial state and explore configuration space around the state to find reactive events which lead to adjacent states. While not absolutely essential, existing methods tend to focus on finding saddle points on the boundary of the initial state and use the harmonic approximation to TST to calculate the rate of each possible reaction mechanism. Current saddle points can be found using a number of ways: minimum mode following saddle point searches, high-temperature MD, the recycling of saddle point information from previous steps, or informed by a database of topologies or structures. As new reaction mechanisms are found, they are added to the rate table and passed to any database being used to store event information. Also, as the configuration space around the initial state is searched for possible reaction events, and the KMC event table is constructed, an estimation of

**Fig. 1** Flow chart showing the general structure of off-lattice KMC algorithms

- database of local topologies
- database of local structures

New reaction mechanism found?

no

yes

Calculate rate and update kinetic Monte Carlo (KMC) event table

Update any database of kinetic events

Update confidence in the fraction of the KMC event table found

Is the KMC event table sufficiently accurate?

no

yes

Choose event to new state and update the simulation time according to the KMC algorithm

Is the desired simulation time reached?

no

yes

Stop

the completeness of the event table is updated. When there is sufficient confidence in the event table for escaping the current state, a KMC move is made to a new state, and the process is repeated.

The various off-lattice KMC implementations differ in the specifics in how saddle points are found and stored for reuse and how low barriers are managed. A number of the different philosophies and methods will be discussed next.

# 3 Search for Saddle Points Leading to Neighboring States

Even for relatively simple systems such as diffusing interstitials in metals, the complexity of the energy landscape is such that it is not possible to identify by hand all mechanisms (Henkelman and Jónsson 1999; Marinica et al. 2011). Open-ended event search methods are therefore necessary to identify the diffusion mechanisms and their associated barriers. There are two main classes of open-ended methods: (1) minimum-mode following methods and (2) molecular-dynamics based methods. Furthermore, local structures and topologies can be classified in order to identify where saddle points searches should be performed and also in order to classify and reuse these events in subsequent steps.

## 3.1 Minimum-Mode Following Methods

The minimum-mode following approach stabilizes first-order saddle points by finding the direction of lowest curvature on the potential energy surface, inverting the force in that direction, and relaxing the system, guided by these modified forces. A number of such methods have been proposed. The method used by Henkelman and Jónsson was named the dimer method because two images, separated by a finite displacement, were used to approximate the local curvature (Henkelman and Jónsson 1999). The dimer method was later shown to be equivalent to a method developed at the same time in the Wales' group, called the hybrid-eigenvector following method (Munro and Wales 1999). In fact, both methods use a Raleigh-Ritz quotient for iteratively determining the lowest curvature mode and a force inversion along this mode to stabilize first-order saddle points. Around the same time, ART was proposed, using a force projection approach to move the conformation toward saddle point (Barkema and Mousseau 1996). For better stability and convergence, the force projection was replaced by a Lanczos-based algorithm a few years later, forming ART nouveau (ARTn) (Malek and Mousseau 2000). It was subsequently further optimized, as described in details in Machado-Charry et al. (2011). Through benchmarking (Chill et al. 2014a) and a mathematical analysis (Zeng et al. 2014), it is now clear that these minimum-mode following methods are essentially equivalent in terms of computational efficiency for finding saddle points and that they differ mostly in their specific implementation.

A typical minimum-mode following search occurs in three steps:

1. From a local minimum, an atom and possibly its neighborhood are displaced in a direction that can be initiate randomly or systematically which aim to push the system out of the local harmonic state. To avoid collisions between atoms, the system can be partially relaxed in the hyperplane perpendicular to the displacement. This procedure can also be repeated until the lowest eigenvalue becomes negative or falls below a given threshold (typically between $-1$ and $-10 \, \text{eV/Å}^2$ for bulk semiconductors and metals).

2. The system is iteratively maximized along the negative (lowest) eigenvector and minimized in the hyperplane orthogonal to this direction. In the dimer and hybrid-eigenvector following methods, this is accomplished by following an effective force with the component along the negative mode inverted. Any optimizer, such as L-BFGS (Nocedal 1980), can then be used to converge to a first-order saddle point. In the ARTn method, the system is moved along the direction of the negative eigenvalue away from the initial minimum, and the energy is minimized in the orthogonal hyperplane at each iteration. In ARTn, if at any point the lowest eigenvalue becomes positive, iteration is stopped, and a new event search is launched, going back to (1). If the lowest eigenvalue becomes positive in the dimer method, the system is pushed up along the lowest positive mode until a negative mode is recovered. For either of these methods, a saddle point is considered located when the total force on the system falls below a given threshold (typically 0.01 eV/Å) with a negative lowest eigenvalue.
3. From the saddle point, the system is displaced along the negative mode and relaxed to find the connecting final minimum, completing the event.

Although the initial deformation is often limited to an atom and its surroundings, all the atoms in the box are allowed to respond to this change and to move, avoiding constraints on the nature and the size of the transition state. As the system leaves the harmonic basin and converges onto a first-order saddle point, however, many atoms initially displaced fall back close to their original position as events tend to be local in nature. In ARTn typically 50% of the time the negative eigenvalue is lost as the system is pushed along the eigenvector associated with the lowest eigenvalue, and it falls back into the initial minimum, as the structure of the energy landscape can include shoulders and bumps that do not lead to transition state. Any attempt to eliminate these lost events requires large initial deformations that typically bring the system to saddle points that are not directly connected to the initial minimum, breaking the continuity of the trajectory. With the dimer method, when a negative mode is lost, the system follows the lowest mode up the potential until a negative mode is recovered. While this approach allows minimum-mode following searches to push through positive curvatures, there is a greater chance of finding saddles that are disconnected from the minimum. The recently developed $\kappa$-dimer method, (Xiao et al. 2014) which uses the isocontour curvature to detect boundaries of the initial state, largely eliminates the problem of disconnected saddles.

The discovery of disconnected saddles is not always a problem. Wales and collaborators, for example, use large deformations to facilitate the construction of a transition matrix and can be then used to extract global kinetic information (Wales 2002). For other applications, however, it is essential to produce a continuous trajectory, and all transition states are tested to ensure that they are directly connected to the initial minimum.

As long as the lowest eigenvalue remains negative, moving to the saddle point is straightforward. While a convergence force of 0.01 eV/Å is generally chosen, ensuring convergence of the energy barrier to less than 0.01 eV within a few hundred force evaluations, the convergence criterion can be tightened.

## 3.2    High-Temperature Molecular Dynamics

An alternative to minimum-mode following methods for finding saddle points is to perform high-temperature MD initiated within the current state and use periodic quenching to see if a transition has been made. When a transition to a new state is detected, a double-ended saddle search method is used to find the minimum energy path between the two states. An efficient strategy for this is to use the climbing-image nudged elastic band method (Henkelman and Jónsson 2000; Henkelman et al. 2000) and then optionally, to save computational time, switch to a minimum-mode following search from within the neighborhood of the saddle.

The MD approach for finding saddle points from an initial state is very similar to the temperature-accelerated dynamics method (Sørensen and Voter 2000). The difference is that temperature-accelerated dynamics uses high-temperature MD to find for the first escape that would take place at the low temperature of interest, using harmonic TST to extrapolate to the low-temperature escape time. For off-lattice KMC, high-temperature MD is used to find all of the low-energy escape mechanisms and rates. What is common to both methods is that the use of MD to search for saddles can provide a rigorous confidence measure in the accuracy of the simulation. In the case of off-lattice KMC, this confidence measure is the fraction of the rate table which has been found using the MD saddle searches (Chill and Henkelman 2014).

Each MD saddle search typically takes more computational work to find a saddle than a minimum-mode following search. For off-lattice KMC, however, the cost of finding any one saddle is less important than the cost of evaluating the full rate table. For that, MD and minimum-mode following searches are competitive. If there is sufficient knowledge about the system to target minimum-mode following searches, they can find the rate table more efficiently. However, if there are many processes available to the system, MD searches can selectively find those which are most important because events with a higher rate are found more rapidly than slow events with MD searches (Chill and Henkelman 2014). Independent of efficiency, however, the main benefit of the MD searches is the confidence measure that it provides and the simplicity of having just one parameter to set, the high temperature, although anharmonicity may induce a false sense of completeness as discussed below.

## 4    Classifying Local Off-Lattice Environments

It is a good practice to classify local structures in order to identify those on which the saddle point searches should be centered, as well as to catalog events to be reused for future use. Several strategies for classifying structures and storing saddle point information are described here.

## 4.1    Lattice-Based Classification

To be useful, structural classification must be able to reduce a wide range of global conformations onto a finite set of locally defined variables. When atomic motion is limited to a discrete set of positions, there is no ambiguity when comparing two states: they're the same or they're not. For off-lattice calculations, atomic positions can occupy a continuous range of values. In effect, it is highly unlikely for two different global conformations to present identical local environments. To classify and compare structures in an off-lattice system, it is possible to define a discretization procedure that will map the continuous array of solutions into a discrete set of states while ensuring that these states share sufficient similarity when it comes, for example, to their list of diffusion mechanisms.

Pattern recognition approaches, such as the one adopted by Trushin et al. (2005) with the self-learning kinetic Monte Carlo method (SLKMC), are a step away from standard predetermined catalogs, allowing to treat a wider range of conformations and, therefore, better include local strain effects. Nevertheless, this algorithm still requires an underlying lattice to ensure the discretization of the configurations and events, and, while barriers are constructed on the fly, the event catalog consists only of single-atom nearest-neighbor hops characterized using the drag method.

With the self-evolving atomistic kinetic Monte Carlo (SEAK-MC), Xu et al. (2011) propose an off-lattice approach limited to near crystalline configurations with an on-the-fly event searching step. A particular feature of this approach is the construction of *active volumes* associated with defects or noncrystalline environments. These defects are identified using a geometric criterion. Focusing on these defective regions reduces the computational effort for constructing an event catalog. Dimer (or ARTn Béland et al. 2015a) searches are used to search for mechanisms, starting from each defect in the active volume. After a KMC step, only the defects in the affected active volume are sampled for diffusion; events associated with other regions are simply carried over from the previous step. Although SEAK-MC can handle more complex environments than SLKMC, because of its reliance on defects to identify active volume, the method is not applicable to fully disordered configurations. Since it does not reconstruct all barriers after each step, moreover, SEAK-MC does not fully take into account long-range elastic effects.

## 4.2    Topological Classification

Introducing a topological classification, the kinetic activation-relaxation technique (k-ART), first published in 2008 (El-Mellouhi et al. 2008), lifts these limitations and is the first fully off-lattice KMC approach with on-the-fly cataloging.
**Fig. 2** The topological classification of each atom, in k-ART, is determined by its local environment. (**a**) An atom and its neighborhood are first identified; (**b**) vertices are drawn between atoms within a cutoff distance generally selected between first and second neighbor; (**c**) the resulting graph is then sent to NAUTY, which returns an identifier characterizing the automorphic class its belongs too and a set of transformation onto a reference graph

K-ART attributes a topological key to each atom in a cell based on its local environment (see Fig. 2): all neighboring atoms within a sphere centered on the reference atom are considered as vertices of a graph, with edges drawn between atoms within a specific cutoff, typically, but not always, set between first and second nearest distances. As a function of the system's complexity, the sphere radius is generally set between 6 and 8 Å, including around 50 to 80 atoms. The graph, as generated, is then sent to NAUTY, a rich topological analysis code developed over many decades by McKay (McKay et al. 1981; McKay and Piperno 2014) used as a library by k-ART. NAUTY returns a key characteristic of the graph's automorphic class as well as a mapping list into a reference graph. This list is used by k-ART to map specific local environments onto reference configurations found in the event catalog.

For each key, a series of ART nouveau event searches is launched centered on the atom associated with this key. Saddle points with different topological keys are considered unique and stored. The topological key associated with a specific atom defines the list of possible events it can undergo. Using the mapping list, it is possible to assign a correspondence between the specific environment and the atoms in the catalog associated with the generic event. Using this correspondence and the

atomic positions of the generic configuration at the saddle point, one can reconstruct an approximate saddle point for the specific configuration. In the presence of strain, this saddle point will be close to the reference event, but not exactly the same, and a few steps of ART nouveau relaxation are needed to converge onto the specific saddle point, providing a precise information on the geometry and energetics of the transition state.

K-ART's basic assumption poses that local minima in the same automorphic class share a unique set of events, characterized by the topological classifications, with the geometrical details at the saddle point depending on the elastic deformation. This allows k-ART to store events based on the local topology and reconstruct their specific geometry at these specific points on the energy landscape. This assumption is valid most of the time for three reasons: (i) the correspondence is set to work only at specific points on the energy landscape – minima and first-order saddle points; (ii) the correspondence holds therefore only for a given forcefield or, equivalently, a unique energy landscape; and (iii) the local graph is reconstructed after it is embedded within the larger two- or three-dimensional space and attached to the rest of the network. This one-to-one correspondence between topology and geometry can fail. However, this failure can be identified readily as activated configurations reconstructed from a reference geometry will not show a first-order saddle point in their vicinity. In general this error indicates that more than one geometries is associated with the topology. To lift this degeneracy, k-ART reduced the edge cutoff criterion until these geometries are assigned to different classes.

PESTO, by Louis Vernon (Vernon et al. 2011; Vernon 2010, 2012), is a variation on adaptive KMC, which has integrated a number of k-ART's features. While topological classification in k-ART is based on the local environment of *atoms*, PESTO is based on the local environment of *defects*. This is a three-step process. First, defects are identified using a variety of schemes including comparison to a reference lattice. These defects can be point or extended defects. Second, NAUTY is used to identify the defect's topology. While k-ART looks at cluster of atoms centered on individual atoms, PESTO looks at cluster of atoms centered on defects. Third, the positions of the atoms in this cluster are compared to those of previously stored clusters for this topology. If they match those of the stored cluster, the configuration is considered to be known. If they do not, the configuration is considered to be new and it is stored.

In 2016, Alexander and Schuh developed a version of k-ART that used a systematic and orderly search and classified transition based on atomic motion vectors, rather than a topological classification. Displacement vectors of each atom between the saddle point and the initial state and between the final and the initial states are stored for future comparisons. Comparison of two transitions is performed by comparing the $x$, $y$, and $z$ displacement of each atoms of both transitions. The goal pursued by Alexander and Schuh is to evaluate the convergence of the residence time by assessing the completeness of search for any configuration in the potential energy landscape.

## 4.3    Geometric Classification

An alternative to characterizing local environments by the bonding topology is
to directly use the atomic geometry of the atoms which participate in a reactive
event. In the kinetic database (KDB) approach (Terrell et al. 2012), all atoms
that move by more than a specified distance are considered part of the reaction
mechanisms. The position of those atoms in the initial, saddle, and final states, as
well as their direct neighbors, is stored in the KDB. Figure 3 shows a calculation
of CO oxidation on Au(111) in the presence of hydroxyl, using forces from density
functional theory (Ojifinni et al. 2008). When a hydroxyl formation mechanism is
discovered, the local geometry of the reacting atoms are stored in the KDB. Later
in the simulation, or in an entirely different simulation, the KDB tries to match the
reaction mechanisms stored to the current geometry. Specifically, matching is done
using a geometric fingerprint of each atom in the database structure (initial or final
state geometries). Using a depth-first tree search, neighboring atoms in both the
database and current configuration are matched. If a complete match is made, the
optimal alignment is calculated, and a score is assigned to each candidate, based
upon the difference in atomic positions between those in the database and those in
the current configuration. In Fig. 3, the final hydroxyl structure in the database was
matched to a hydroxyl on the surface in a subsequent step in the off-lattice KMC
simulation. The KDB is then used to predict possible saddle points by moving the
local atoms to their saddle point configuration from the database. These suggested
saddle geometries are used as initial configurations for minimum-mode following

**Fig. 3** Kinetic database example of OH and CO reacting on Au(111). When a new reaction
mechanism is found, the configurations of the moving atoms and their first neighbors are stored in
the database. In any subsequent state, the database is queried to see if any known initial or final
states match

searches so that the true saddle point and rate of the event in the new environment are calculated. Importantly, the KDB is used to provide approximate saddle point configurations for the current geometry based upon what has been seen before. Only if an exact saddle can be found is the mechanism entered into the rate table. In this way, there is no additional approximation for off-lattice simulations using the KDB. As the database stores a greater number of kinetic events, saddle suggestions become more accurate and converge more rapidly to true saddles, when they exist, so that the cost of the off-lattice KMC simulation approaches that of KMC.

There are some key differences between the topological classification of reactive events used in k-ART and the geometric classification in the KDB. K-ART has the advantage that matching structures from the database to the current simulation is extremely efficient. Also, if there is sufficient trust in the catalog of events in the database, then new saddle searches need only to be done when an unknown topology is reached. In the KDB, on the other hand, the structure matching is not discretized; geometries which are close, but not exact, are used to suggest saddle point structures. When these structures are converged, the exact geometry of the saddle and the activation energy are calculated. If no saddle point is found, the loss is only the computational time required for the saddle search. Both methods can be used to store and recover information that has been learned to accelerate off-lattice simulations.

## 4.4     Challenges in the Event Reconstruction

Reconstruction of saddle points is crucial in any scheme that creates a generic catalog built either on geometrical or topological keys as symmetry operations and elastic deformations in an off-lattice system must be taken account.

To describe this challenge, we focus here on the topological approach used in k-ART, which creates a catalog based on reference geometries at the initial minimum and saddle point and uses the knowledge of current geometry at the minimum and the correspondence between the reference and the current topologies at the minimum to reconstruct a new saddle point.

1. Atoms of the current minimum configuration are matched with the reference minimum using the correspondence between the two graphs drawn by NAUTY.
2. A reference frame is then constructed, by comparing the relative positions of the various atoms in the two configurations.
3. Atoms in the current minimum are then displaced using this reference frame, according to the difference between the reference saddle point and energy minimum.
4. The energy and forces are evaluated on the reconstructed activated state. If the activation energy difference between the reconstructed and the reference state and the absolute forces in the reconstructed state are below given thresholds, the reconstruction is considered successful ARTn is applied to converge to the nearby saddle. If not, then the possibility that many correspondences between the

reference and current graphs exist is considered and a number of permutations in the correspondence labeling are attempted, based on various reconstructed reference frames.

5. When no attempted reconstruction is accepted, k-ART concludes that the correspondence between topology and geometry for this environment is not unique. The cutoff for defining edges between atoms is then modified, and the topology is split. If a new topology is found in the way, it is then populated by events, if a known topology is generated, the algorithm starts over for generating a specific event (Fig. 4).

The success in reconstruction depends closely on the graph. For compact systems, such as bulk metals or semiconductors, a graph containing between 50 and 70 atoms, with edges drawn between nearest neighbor atoms, is sufficient. For an anisotropic system such as graphene, however, it is necessary to define long-enough cutoff to ensure that planes are linked. Reconstruction also requires that a specific saddle point related to the generic one exist. For high-enough barriers, typically above 0.1 eV, a deformation strong enough to make such a barrier disappear would lead to a change in topology. For low barriers, particularly surrounding unstable points, this is not always the case. To avoid this problem, one can systematically recreate the event catalog associated with a given topology when such a low-energy barrier disappears, either automatically cross or simply ignore them.

**Fig. 4** Reconstruction of a saddle point from the topological classification. (**a**) ART nouveau generates an event from the initial topology of a central atom (red sphere). (**b**) Once ART nouveau search is done, k-ART reconstructs each event associated with the same initial topology: topological correspondence of two central atoms (blue and red spheres). (**c**) Applying geometrical symmetry is needed to the initial structure of the second central atom (blue sphere) as well as the saddle point and final structures. (**d**) Finally, guess structures (i.e., saddle point and final applied of the second central atom) are then refined using ART nouveau to include elastic deformations

# 5  Confidence in the Completeness of the Saddle Point Catalog

An important parameter for off-lattice KMC is determining how many saddle point searches must be done. Too few searches will lead to incorrect kinetics, but searches can be computationally wasteful if all important transitions are already known. Some methods – such as k-ART and SEAK-MC – perform a finite number of searches for each defect that is encountered. In the case of k-ART, the event catalog is reused for all know topologies; new searches are performed to complete the catalog or to complete it, if a new topology is added. New searches are also performed to improve the event catalog, for very common topologies (searchers are added every log-10 times a topology is found). In SEAK-MC, the event catalog for a given defect is destroyed after the execution of one of those events and is rebuilt from scratch every time a defect is encountered.

When using minimum-mode following searches to find saddles, the completeness of the KMC catalog can be estimated from the statistics of how often new saddles are found. For example, if an increasing number of searches are done without finding any new events, there should be a growing confidence that the rate table is complete. Importantly, however, there can be a wide range in the frequency at which different saddles are found, and this bias can lead to unquantifiable uncertainties in the completeness of the catalog (Henkelman and Jónsson 1999).

Another way to estimate the completeness of the event table is to use MD saddle searches, as discussed previously. The key difference between MD searches and minimum-mode following searches is that the probability of finding any event using MD is proportional to its rate. Since we are interested in rare events, basin-constrained MD at an artificially high temperature is used to determine possible reaction mechanisms, and harmonic TST is used to calculate the rate of the events at the low temperature of interest. To the extent that harmonic TST holds, one can calculate a well-defined estimator for the fraction of the rate table that is missing, based upon the amount of MD time that is used to determine the rate table and the events that have been found (Chill and Henkelman 2014).

It should be noted that while high-temperature MD searches can provide an estimate of the completeness of the catalog, the high-temperature event catalog may miss events for which the rate decreases as temperature increases. Such non-Arrhenius behavior would be due to strong entropic effects. Examples of such behavior include thermal stabilization of nano-voids (Perez et al. 2013) and dislocations (Kim and Tadmor 2014).

# 6  The Low-Barrier Problem and Coarse Graining

While off-lattice KMC is able to coarse grain over the fast atomic vibration time scale and model the slower time scale of the state-to-state dynamics, it is ubiquitous to have another separation of time scales between the fastest state-to-state events and

slower time scales of interest. This so-called low-barrier problem describes how off-lattice KMC simulations can spend all of the computational time on fast events so that they are not able to reach long time scales.

A key idea that has been used to bridge the gap between fast and slow events is the framework of the Monte Carlo with adsorbing Markov chains (MCAMC), which was described by Novotny in 1995 (Novotny 1995). In this pioneering work, Novotny showed how the kinetics of a system that was partitioned into a set of transient states and adsorbing states could be solved to give a specific time for the transition from a transient state to a specific adsorbing state. Remarkably, this was shown to be possible without adding any approximations beyond the rates that are used in KMC regardless of the partitioning between transient and adsorbing states. This means that in an off-lattice KMC simulation, any set of states can be identified as transient, and the time to transition to a neighboring adsorbing state can be calculated using the MCAMC approach without additional approximations.

The exact calculation of transition times from transient states to adsorbing states requires an iterative set of matrix calculations each with dimension of the size of the total number of states involved. Novotny also showed that it was possible to simplify this calculation and instead calculate the average escape time from the transient states via the first moment of the escape time distribution (Novotny 2001). This approximation was later referred to as the mean-rate method (MRM) by Puchala et al. (2010) since the escape time from the set of transient states is characterized by a single rate. The mean-rate approximation works well when there is a separation of time scales between the transient and the adsorbing states. In this regime, the set of transient states has been referred to as a superbasin. The mean-rate method reduces the computational cost of escaping a superbasin to a single matrix inversion.

The MCAMC approach allows off-lattice KMC simulations to switch, at any point, between a KMC description of the state-to-state dynamics to a transition between any specified state of transient states to the neighboring adsorbing states. When MCAMC is done exactly, any set of transient states can be chosen, and so different definitions of the set of transient states have been proposed. On one extreme, all visited states can be considered transient so that every transition is made to a new state. This strategy was described in the Markov web, proposed by Boulougouris and co-workers (Boulougouris and Frenkel 2005; Boulougouris and Theodorou 2007). While advantageous in terms of being able to visit new states as rapidly as possible, this comes at the cost of losing the state-to-state detail of the trajectory to states that have been visited. Additionally, for simulations which are out of equilibrium and explore new parts of configuration space, including all states in the transient space add unnecessary cost to the matrix operations. Another possibility is to count the number of times that each state has been visited and combine states into a superbasin when the visit-count exceeds a specified threshold (Chill et al. 2014b). It is also possible to consider the energy of the states and the saddles between them (Pedersen et al. 2012) or combine states into a superbasin when they are connected by rates above a specified value, as in the basin-autoconstructing MRM (bac-MRM) (Brommer et al. 2014). However the superbasins are defined, they can grow as more transient states are explored.

# 7        How to Reduce Computational Costs

The main computational costs of a typical on-the-fly KMC run are associated with the evaluation of forces and energies and the construction of neighbor lists. Neighbor-list costs can be decreased using standard cell and Verlet neighbor list methods. Computational cost reduction, for force evaluations, requires taking advantage of the fact that the reference states, in KMC, are effectively at zero temperature, allowing algorithms to exploit the local nature of activated events. Given the large literature on the neighbor-list cost-reduction techniques, this section will focus on the forces.

A number of studies (Mousseau and Barkema 1998b; Pedersen and Luiser 2014; Xu et al. 2015; Guterrez et al. 2016) found that initial deformations applied to search for saddle points should be local in order to successfully lead faster to a diverse set of activated events. No more than a few hundred atoms should initially be involved in the event search, and usually less. As the positions of atoms are optimized while reaching the saddle point, more atoms will be deterministically displaced (typically, a few thousand); an even larger number will be displaced as the system is relaxed into a new minimum. Notably, extended cascade-type concerted events can take place during this phase (Béland and Mousseau 2013). In other words, while relaxation should be performed globally, activation can generally be performed locally to maximize the probability of successfully finding saddle points.

Search algorithms can exploit the locality of activated events (Mousseau and Barkema 1998b). The simplest way is to impose activation volumes. For instance, Xu et al. (2011, 2015) showed that a spherical active volume of 4 lattice parameters is sufficient to capture the activation barrier for vacancy diffusion in BCC iron within 0.001 eV, while an active volume of 6 lattice parameters was sufficient for the case of the dumbbell interstitial, and an active volume of 7.5 Å could capture the kinetics of 37-interstitial clusters (Xu et al. 2013). In other words, saddle searches can yield accurate results by calculating forces and energies over a subset of a few hundred atoms. It is also possible to find saddle points using small active volumes and then refine them using increasingly larger ones.

Imposing strict active volumes does have drawbacks. For instance, such an approach imposes static long-range elastic interactions, preventing a dynamical reaction of the whole system. To avoid this bias, it is possible to dynamically update a list of active atoms during the event search (Béland et al. 2011; Joly et al. 2012) defined by those atoms with a minimum force acting upon them and their neighbors. As the search progresses, an increasing number of atoms will have non-negligible forces. This procedure can effectively make computational time scale sublinearly with system size, with no strong assumptions to be made about the size of the active volume involved during event searches (Joly et al. 2012).

Such an approach, while elegant, is difficult to implement with standard force field libraries such as LAMMPS (Plimpton 1995). In this case, one turns to a partial use of active volume. After a global energy minimization of the whole structure, to ensure that all elastic effects are fully incorporated in the local minimum, a sphere is drawn around the central atom in the topology. An inner radius defines the set of
**Fig. 5** Graphical description of the local force calculations. Two spheres are centered on the same atom associated with a given topology. In the inner sphere (green atoms), all atoms can move following the activation. Atoms in the outer sphere (blue atoms) are fixed and contribute to ensuring that the correct forces apply to the inner atoms

atoms that are allowed to move during activation; a second, outer radius includes fixed atoms needed to ensure that the forces are accurate in the inner part. As a general rule, the inner sphere contains between 500 and 2000 atoms, while the outer shell is determined by the force field cutoff radius (Fig. 5) (Trochet et al. 2017). As with large enough active volumes, the error on the energy is small, and generic events are generated without further global relaxation at the saddle point nor the final minimum. Specific events, for their part, see by default the barrier fully relaxed at the saddle point after a first local relaxation, with the final configuration also relaxed globally. For systems with simple localized defects, it is possible to avoid a global relaxation at the saddle point for specific events, provided that the active volume is large enough, reducing the global relaxation only to accepted minimum states. The parameters to ensure a given error threshold must then be assessed specifically for each system. As a general rule, however, the use of local forces on systems containing 10,000 to 1 million atoms makes the event search almost order 1, considerably accelerating the algorithm without any significant loss in information or precision (Raine et al. 2017).

For the simulation of large systems, parallelization is crucial. An advantage of MC is that every event search can be performed independently, which means that many computer cores can simultaneously generate events to be added to the catalog. As mentioned in Sect. 7, one can accelerate the saddle searches by exploiting the locality of events. By increasing the number of "worker" computer cores proportionally to the number of saddle points to be generated, and by considering a local subset of atoms during saddle searches, the runtime between KMC steps will be approximatively independent of system size, if event management and KMC overhead costs are negligible.

# 8    Advantages of MC: Tricks and Shortcuts Available

Monte Carlo methods present a major advantage over molecular dynamics: it is much easier to use tricks to focus on the problems of interest, since the system's

evolution is event-based, instead of being continuous, offering a much better control on the rules that are used. In this section, we review a number of approximations, solutions, and tricks that make these off-lattice approaches more competitive that could be expected through a simplistic evaluation of their computational costs.

**The Low-Barrier Problem**  We have already presented the approach for handling processes with low barriers. Such methods are crucial for long-time simulations of complex materials, with many low-barrier events. By solving analytically the in-basin kinetics, it is possible to effectively perform billions of jumps without having to compute them directly, allowing the simulation to reach the relevant time scale instead of being slowed down to a halt by irrelevant mechanisms.

**Constant prefactor**  The use of constant prefactor is not essential, and some of us compute the prefactor for every event using the harmonic approximation. Nevertheless, for most compact system, the prefactor varies relatively little compared with the barrier, so it can be given a constant value, leaving the cost of evaluating a barrier to converging to a saddle point (Valiquette and Mousseau 2003). Clearly, however, as shown by Koziatek et al. (2013), the harmonic approximation fails in systems with significant density fluctuations, and it is generally necessary to, at least, demonstrate the validity of this approximation before using it. Prefactors can be affected by temperature, when barriers are low with respect to $k_{\mathrm{B}}T$, as discussed previously. Overcoming this limitation requires likely to turn to thermodynamical integration, which is computationally heavy and has not yet been automated.

**Restricting event searches to specific environments**  To decrease computational costs, it is possible to prevent off-lattice KMC calculations from searching for events in very stable environments. For example, when we are interested by a phenomena occurring on time scales of vacancy or interstitial diffusion, identifying events from perfectly crystalline environment, with barriers that are many eVs high, does not contribute to the dynamics. In some case, also, we can focus on specific regions, near a defect, for example, so that we may want to ignore the rest of the box, knowing that it will not contribute to the kinetics of interest. Off-lattice KMC calculations can therefore be instructed to ignore all crystalline topologies, specific atomic species, or regions when constructing its catalog.

**Biasing pathways**  While the previous shortcuts do not significantly affect the kinetics of the system on the time scale selected, it is also possible to give up the correct kinetics in exchange for exploring specific pathways. This can be done in many ways. First, a general bias in a given direction can be imposed, either through a selection bias from a complete event catalog or through the construction of an event catalog that only allows moves along a given pathway, specific mechanisms or a general direction. It is also possible to hand select, at every step, the event of interest among the list and evolve the system along a biased path.

   The list of tricks with Monte Carlo approaches is largely limited only by the researcher's imagination. In many ways, it is through these shortcuts that allow a
