Preface

Antimicrobial drug resistance is a global health problem that continues to expand as micro-organisms adapt to the antibiotics we use to treat them and as new classes of antimicrobial agents have been harder to discover and advance into the clinic. The second edition of *Antimicrobial Drug Resistance* grew out of a desire by the editors and authors to provide an updated, comprehensive resource of information on antimicrobial drug resistance that would encompass the current information available for bacteria, fungi, protozoa, and viruses. The two volumes have been extensively revised with many new authors and chapters as the field of drug resistance has evolved. We believe that this information will be of value to clinicians, epidemiologists, microbiologists, virologists, parasitologists, public health authorities, medical students, and fellows in training. We have endeavored to provide this information in a style that is accessible to the broad community of persons who are concerned with the impact of drug resistance in our clinics and across broader global communities.

Antimicrobial Drug Resistance is divided into two volumes. Volume 1 has sections covering a general overview of drug resistance and mechanisms of drug resistance, first for classes of drugs and then by individual antimicrobial agents, including those targeting bacteria, fungi, protozoa, and viruses. Volume 2 addresses clinical, epidemiologic, and public health aspects of drug resistance, along with an overview of the conduct and interpretation of specific drug resistance assays. Together, these two volumes offer a comprehensive source of information on drug resistance issues by the experts in each topic.

We are very grateful to the 197 international experts who have contributed to this textbook for their patience and support as the work came together. The editors would like to especially thank Michelle Feng He for her exceptional support and encouragement to the editors in bringing this revised textbook to print. Finally, the book would never have been completed without the patience and support of our wives and families.

Cambridge, MA, USA — Douglas L. Mayers, M.D.
Detroit, MI, USA — Jack D. Sobel, M.D.
Québec, Canada — Marc Ouellette, M.D.
Ann Arbor, MI, USA — Keith S. Kaye, M.D., M.P.H.
Tel Aviv, Israel — Dror Marchaim, M.D.

Part VII

Gram Positive Bacterial Drug Resistance: Clinical

Resistance in *Streptococcus pneumoniae*

49

Lesley McGee and Keith P. Klugman

1 Introduction

Streptococcus pneumoniae (the pneumococcus) has been an important human pathogen for over 100 years and continues to cause a wide variety of infections, ranging from mild otitis media and sinusitis to serious lower respiratory infections, as well as life-threatening invasive infections such as meningitis or pneumonia. Worldwide, morbidity and mortality due to pneumococcal infections are highest among young children below the age of 5 years, accounting for approximately one-third of the estimated 1.3 million deaths from pneumonia in 2011 [1]. The pneumococcus is a common colonizer in the respiratory tract, especially in the nasopharynx of children where it is often exposed to antimicrobials. As well as affecting the young, *S. pneumoniae* is an important cause of morbidity and mortality in the elderly; it is the most common etiological agent of community-acquired pneumonia, often resulting in hospitalization of previously healthy individuals.

Infections caused by *S. pneumoniae* were for many years traditionally treated with penicillin or ampicillin, to which this species was exquisitely sensitive when penicillin was first introduced in the 1940s. However, exposure to antimicrobials has led to the selection of resistant strains and clones, some of which have a global distribution; resistance, which was first seen in the 1960s, has continued to increase throughout the world in more recent decades. The emergence of resistance to penicillin and other beta-lactam antibiotics in pneumococci in the 1980s and 1990s led to the increased use of macrolides, fluoroquinolones (FQs), and other non-beta-lactam antibiotics for pneumococcal infections. Pharmacodynamics predicts that high doses of parenteral β-lactams with good Gram-positive activity will currently treat most penicillin-resistant pneumococci. In contrast, oral β-lactams may fail, and high doses of amoxicillin are the best oral β-lactam drugs currently available to treat penicillin-resistant infections. Neither oral nor parenteral macrolides are able to treat macrolide-resistant pneumococcal infections. Fluoroquinolone resistance remains rare, but in patients previously exposed to these drugs, there is an increased risk of treatment failure due to selection of first-step mutants. Efforts to treat pneumococcal disease in both adults and children have been complicated by this increasing resistance to antimicrobials. The increase in antimicrobial resistance rates has been in part due to the selective pressures associated with the widespread use of antibiotics [2, 3] and the clonal expansion and spread of multiresistant pneumococcal clones [4]. More recently, the introduction of conjugate vaccine immunization of infants reduces the burden of resistance by eliminating vaccine types from invasive infections, but resistance continues to be selected in non-vaccine types. New classes of antimicrobials are needed to ensure long-term treatment options for pneumococcal infections.

This chapter will describe the emergence and incidence of antibiotic resistance in pneumococci, mechanisms, clinical implications, and impact of vaccines on resistance.

2 Epidemiology of the Pneumococcus and Risk Factors for Resistance

The incidence of pneumococcal disease remains the highest in children <2 years of age and in adults >65 years of age. Other important risk factors include underlying medical conditions such as chronic heart and lung disease, cigarette smoking, and immunodeficiency states such as asplenia, HIV, and sickle cell disease.

S. pneumoniae colonizes the upper respiratory tract and is part of the normal flora of healthy individuals. Pneumococcal colonization is a dynamic process. A particular serotype can be carried for many months before being eradicated or replaced by a different serotype. Carriage increases in the

first few months of life, and universally, carriage rates are highest in young children (40–60 %), compared with older children (12 %), adolescents (6–10 %), and adults (3–4 %) [5, 6]. Factors associated with increased carriage include winter season, situations of overcrowding such as day-care attendance, and living in crowded conditions [7]. Prior antibiotic use does not appear to alter the rate of carriage but does promote carriage with antibiotic-resistant strains, particularly to β-lactam antibiotics [8].

Investigations of serotype prevalence from various parts of the world have shown that serotype distribution varies with geographical location and age [9]. The distribution of serotypes also varies between carriage isolates and invasive disease, and antibiotic resistance (at least in the pre-conjugate vaccine era) is most frequent in pneumococcal serotypes that are carried by children (types/groups 6, 9, 14, 19, and 23) [9]. The probable reason is the frequent use of antibiotic therapy in small children and hence exposure of strains of these serotypes to antimicrobial drugs, providing a selective advantage to resistant mutants [10].

There are multiple risk factors for acquisition of infection with antibiotic-resistant pneumococci. Most of these factors have a commonality in exposure to the drugs that select the resistance. This exposure to β-lactams can be at the level of a country [11, 12], province [13], day care [14], family [15], or individual [16]. Macrolide resistance is also a function of exposure, particularly of long-acting drugs such as azithromycin [17]. The selection of resistant strains is complicated by multiple resistances where macrolides appear to be better selectors of multiresistant strains than do β-lactam drugs [16]. Antimicrobial resistance may be seasonal, with higher rates detected during increased antibiotic use in the winter months [18]. The issue of cross-resistance extends to treatment of such diverse organisms as the malaria parasite, where treatment with Fansidar selects trimethoprim-sulfamethoxazole resistance in pneumococci [19].

Most resistance is selected as mentioned above in children, but the exception is fluoroquinolone resistance which is selected in adults [20–22] as these agents are not usually given to children. In the unusual circumstance of fluoroquinolone treatment of children, for example, as treatment of drug-resistant tuberculosis, the selection of fluoroquinolone-resistant pneumococci occurs, and these strains are associated with invasive disease [23].

Children in rural settings generally have less access to antibiotics and therefore have less resistant strains [24, 25], while in some large cities, where poorer children live in the city center with less access to care and more affluent children live in the suburbs, there may be more resistance outside the city [26].

Little is known about the impact of drug dose on the selection of resistant strains, but there is a prospective study that suggests that high dose and short duration of amoxicillin therapy may select less resistance than the same total dose given over a longer period of time [27].

Nosocomial acquisition is a major risk for resistant pneumococci [28], and the first multiply resistant strains were selected in hospital [29]. Recent hospitalization is also a risk for infection with multiply resistant pneumococci [25].

HIV infection is a risk for increased resistance in pneumococcal infections due to the frequent exposure of these patients to antibiotic prophylaxis with trimethoprim-sulfamethoxazole [30], as well as the fact that these patients, especially HIV-infected women, are at risk due to the antibiotic-resistant serotypes carried by children [31].

Children exposed to conjugate vaccine, as well as adults living in countries where these vaccines are routinely administered to children, are at lower risk for pneumococcal infections due to resistant strains as described in Sect. 10.

3 The Role of Clones in Resistance

The increase in antibiotic resistance and the introduction of conjugate vaccines have focused attention on the epidemiology of *S. pneumoniae*. Molecular typing data from numerous studies over the past few decades has added to our knowledge by showing that although there is considerable diversity among resistant strains within most serotypes, a small number of highly successful clones have emerged within countries and in some cases have achieved massive geographical spread [4]. In response to this, the Pneumococcal Molecular Epidemiology Network (PMEN) was established in 1997 with the aim of standardizing nomenclature and classification of pneumococcal clones worldwide. At present, PMEN has documented 43 international clones, 26 of which are multidrug-resistant. The best characterized, and most widely spread of these international clones, is the Spain^{23F}-1 or PMEN1 originally described in Spain during the 1980s. Intercontinental spread of this clone to the USA was described in 1991 and shortly thereafter in the UK, South Africa, Hungary, and South America [32]. By the late 1990s, it was estimated that approximately 40 % of penicillin non-susceptible pneumococci circulating in the USA were members of this clone [33], and while strains belonging to this genotype continue to be isolated today in many countries all over the world, their prevalence has decreased in countries where conjugate vaccines have been introduced [34, 35]. Recent studies [32, 36, 37] looking at whole genome sequencing of pneumococci representing PMEN1 show that there is a considerable amount of genetic diversity within this lineage. This diversity, which largely results from hundreds of recombination events, indicates rapid genomic evolution and presumably allowed rapid response to selective pressures such as those imposed by vaccine and antibiotic use [36].

Clonal analyses of large surveillance collections of pneumococci have revealed the remarkable dominance of a small number of clones among the antimicrobial-resistant population. As these global clones have spread, they have been exposed to new selective pressures applied by regional variations in the use of different antibiotics. This has led to the further selection of strains belonging to these clones with varying antimicrobial resistance patterns. These resistant clones have also been exposed more recently to conjugate vaccines, and shifts in both serotype and clonal types have been documented [34, 35, 38]. For example, in the USA serotype 19A strains have been identified as the main cause of serotype replacement in both carriage and invasive disease post-PCV7 introduction; this has coincided with a significant increase in penicillin resistance and multidrug resistance among 19A clinical strains [34, 35, 39]. The majority of penicillin-resistant 19A strains belonged to emerging clonal complex 320 (CC320), which is descended from multidrug-resistant Taiwan^{19F}-14 (PMEN14). In 1999, prior to PCV7 introduction, only CC199 and three minor clones were apparent among 19A strains. In 2005 post-PCV, 11 clonal complexes were detected, including ST695 capsular variants of serotype 4 [38, 40].

4 Laboratory Detection of Resistance

Even though we can now identify pneumococci and many resistances based upon genetic features, bacterial culture and phenotypic susceptibility tests remain the gold standard approaches in clinical laboratories. Because it is a fastidious organism, however, specific methods and interpretative criteria developed by a variety of professional bodies such as the Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards, NCCLS), the British Society for Antimicrobial Chemotherapy (BSAC), and the European Committee on Antimicrobial Susceptibility testing (EUCAST) must be used to ensure accurate and consistent susceptibility results [41]. Because the breakpoints are determined on the basis of microbiological, pharmacological, and clinical outcome data and since patterns of resistance to antimicrobial drugs continue to evolve, changes to breakpoints can occur during the lifetime of an antibiotic. A good example is the CLSI revised breakpoints for penicillin adopted in January 2008 to redefine the susceptibility of meningeal and non-meningeal pneumococcal isolates [42].

Culture of clinical specimens and antibiotic susceptibility testing are often slow, taking up to 48 h, and are often negative due to prior antibiotic use before sampling or autolysis of the organism. Rapid tests, based mainly on immunological or molecular techniques, have gained importance for the detection of bacteria and antibacterial resistance over the last two decades. PCR has been shown to be a useful tool for the rapid identification of *S. pneumoniae* from both clinical specimens and bacterial isolates [43, 44]. The increased use of molecular tests such as PCR for the diagnosis of bacterial infections has led in turn to an increased demand for antibiotic susceptibility testing using molecular methods. However, unlike phenotypic testing for antibiotic susceptibility, which examines all resistance mechanisms for a particular antibiotic simultaneously, molecular testing can detect only known resistance mechanisms. A variety of assays has been described to detect the presence of specific resistance genes in pneumococcal isolates and also directly from clinical specimens [44–50]. The majority of these assays are PCR based [44–47], although sequencing approaches and microarrays have also been used [49, 50].

5 Resistance to β-Lactams

With the advent of penicillin G therapy in the 1940s, the case fatality rate for pneumonia fell dramatically [51]. Pneumococcal isolates were initially extremely sensitive to the drug with MICs of ≤0.01 mg/L. Penicillin resistance was demonstrated in laboratory mutants soon after the introduction of penicillin G into clinical use but was not reported in clinical strains until 20 years later when investigators in Boston reported penicillin resistance in 2 of 200 strains [52]. Initially, the observation was not considered relevant, until a report by Hansman and Bullen [53] describing a penicillin-resistant strain (MIC 0.6 mg/L) isolated in Australia from the sputum of a patient with hypogammaglobulinemia. Subsequently, resistant strains were identified in New Guinea and Australia, and in 1974, the first clinical infection due to a penicillin non-susceptible strain was reported in the USA [54, 55]. In 1977, pneumococci resistant to penicillin began to appear in South Africa, and in 1978, the first multidrug-resistant pneumococci were documented in Johannesburg, South Africa [29, 56]. In between and after these initial reports, detection of penicillin-resistant pneumococci among clinical isolates began to be reported with increasing frequency in the clinical and microbiological setting. Today, penicillin-resistant strains are encountered in all countries in which adequate surveys are conducted. Recombination appears to be an essential mechanism in the evolution of beta-lactam resistance in nature, and resultant clonal spread of resistant strains plays an enormous role in the increase in beta-lactam resistance globally [4].

β-lactam antibiotics inhibit the growth of pneumococci by inactivation of cell wall synthesizing penicillin-binding proteins (PBPs). β-lactam resistance in pneumococci occurs by alterations in the key cell wall PBPs and the creation of *pbp* genes with decreased affinities for these antimicrobials. Six PBPs have been identified in *S. pneumoniae* (PBPs 1a, 1b,

2a, 2b, 2x, 3), of which PBP2X and PBP2B have been confirmed to be essential for cell growth [57, 58]. Resistance to β-lactams is complex and involves a multifactorial process. Depending on the selecting β-lactam, different combinations of *pbp* genes and mutations within these *pbp* genes are involved in conferring resistance. Little data exist for the role of PBPs 1b, 2a, and 3 [59, 60] as resistance determinants, and altered PBPs 2x, 2b, and 1a are the major players in the development of β-lactam resistance in most clinical isolates. The altered PBPs are encoded by genes with a mosaic structure and can undergo inter- and intraspecies recombination so that parts of the genes are replaced by allelic variants that differ by up to 20 % in DNA sequence [61]. Mosaic sequences of *pbp* genes are very difficult to classify and organize. In general, the resistance profile of particular isolates results from interactions between various combinations of altered PBPs, in conjunction with a functional *murMN* operon which encodes enzymes involved in the synthesis of branched structured muropeptides. Several other genes have been implicated in β-lactam resistance in selected clinical isolates that contribute to resistance in addition to mutations in PBP genes [61], although certain combinations of these three altered PBP genes alone appear to confer resistance.

Resistance to penicillin is associated with some degree of non-susceptibility to all β-lactam antibiotics. Mutations in PBP2x confer low-grade penicillin resistance and may be sufficient for the cell to become non-susceptible to oral cephalosporins. Alterations in PBP2b result in even higher MICs to penicillin [62], while changes in PBP1a are required for high-level penicillin resistance [60, 63] and extended-spectrum cephalosporin resistance [64, 65]. Isolates with very high levels of penicillin resistance (MICs ≥ 8 mg/L) require changes in all three PBPs (i.e., 1a, 2b, and 2x) and sometimes in additional non-PBP resistance determinants such as MurM [66].

Resistance rates reported for amoxicillin are relatively low (<5 %) as a result of the favorable pharmacodynamic properties of this agent [67, 68]. Generally, MICs to amoxicillin are equal to or two to four times less than the MIC of penicillin [69]. In the past, there have been numerous reports of strains with amoxicillin MICs (4–16 mg/L) higher than penicillin MICs (2–8 mg/L) [68, 70–72]. In particular, PBP2b appears to play a significant role in mediating the expression of this resistance phenotype [73]. In addition to typical changes in PBP1a and PBP2x, these strains have unique mutations in the 590–641 region of the PBP2b gene in close proximity to the active binding site [68, 72, 73].

Resistance to cephalosporins may develop with mutations in the pbp1a and pbp2x genes, and the close linkage of these two genes on the chromosome is conducive to the transfer of both genes in a single transformation step [64, 74]. PBP2b is not a target for cephalosporins so would remain unaltered in isolates expressing cephalosporin resistance and susceptibility to penicillin [75]. Most, but not all, extended-spectrum cephalosporin-resistant strains are also penicillin-resistant, and as with amoxicillin, the MICs of cefotaxime and ceftriaxone are usually lower than the MICs of penicillin. Newer antibiotics such as ceftaroline and ceftobiprole appear to be more active and have greater affinity for altered *pbp* genes allowing it to be active against strains with elevated MICs to other β-lactams [76, 77]. In the early 1990s in the USA, pneumococci with high-level cefotaxime and ceftriaxone (2–32 mg/L) resistance were detected [78], and this high-level resistance was due to alterations in PBPs 1A and 2X [65]. The cephalosporin MICs were in excess of the MICs of penicillin for these isolates, and specific point mutations ($Thr_{550}Ala$) in the *pbp2x* gene were associated with this phenotype [65]. These cephalosporin-resistant strains emerged within a few preexisting clones and demonstrate that point mutations as well as recombinational events are important in the development of resistance to β-lactam antibiotics in pneumococci.

6 Resistance to Macrolides

The macrolides have been used extensively to treat community-acquired respiratory tract infections worldwide, and in recent years, resistance to macrolide antibiotics (e.g., erythromycin, clarithromycin, and azithromycin) in *S. pneumoniae* has escalated dramatically. Macrolide-resistant *S. pneumoniae* are now more common than penicillin-resistant *S. pneumoniae* in many parts of the world [79]. However, both macrolide resistance rates and resistance mechanisms may vary considerably depending on location [80]. Erythromycin resistance rates range from about 15 % in Latin America to as high as 80 % recorded among isolates in Far East [81], and these differences probably reflect, in part, the variation in antibiotic prescribing behavior between different countries.

Macrolide resistance in *S. pneumoniae* is mediated primarily by two mechanisms: target modification and active efflux. The most common form of target modification is usually the result of dimethylation of the adenine residue at position 2058 on the 23S rRNA by a methylase enzyme [82]. This mechanism confers constitutive high-level resistance (MIC, >256 mg/L) to 14-, 15-, and 16-member macrolides, lincosamides, and streptogramins B, the so-called MLS_B phenotype. In *S. pneumoniae*, methylation is *erm*(B) mediated in almost all cases, although, more rarely, a methylase encoded by *erm*(A) subclass *erm*(TR) has been implicated [83]. Target modification by point mutations in domain II and V of 23S rRNA and in the genes encoding riboproteins L4 and L22 can also confer macrolide resistance and has been documented in clinical isolates from widely distributed global sites [84–86].

In certain countries, such as the USA [87], active efflux is the major mechanism for macrolide resistance. It confers low-level resistance (MIC, 1–16 mg/L) to 14- and 15-member macrolides but not to 16-member macrolides, lincosamides, and streptogramin B and is phenotypically referred to as the M phenotype. Active efflux is encoded by *mef*-class genes, which include several variants, the abundant *mef*(A) and *mef*(E), which share 90 % sequence identity, and the rare variant *mef*(I) which has only been described in two Italian clinical strains [88].

In pneumococci the three subclasses of *mef* are carried on a number of similar but distinct genetic elements. *mef*(A) is located on the defective transposon Tn*1207.1* or the closely related Tn*1207.3* [89], whereas *mef*(E) is typically carried on the mega (macrolide efflux genetic assembly) element [90]. The *mef*(I) gene exhibits 91.4 and 93.6 % homologies to the *mef*(A) gene of Tn*1207.1* and the *mef*(E) gene of the mega element, respectively [88], and is carried on a nonmobile composite structure, designated 5216IQ complex [91].

Worldwide *erm*(B) and *mef* (A or E) mechanisms account for the majority of macrolide resistance among pneumococci, and the prevalence of these genes varies considerably among countries. In recent years, the presence of both the *erm*(B) and the *mef* genes in *S. pneumoniae* clinical isolates has been increasingly recognized, particularly in Asian countries but also in Europe, S. Africa, and the USA [92, 93]. The PROTEKT study reported a 12 % global prevalence of macrolide-resistant isolates positive for both *erm*(B) and *mef*(A) in 2003–2004 [81].

The majority of dual-positive isolates exhibit multidrug resistance and are clonal lineages of Taiwan^{19F}-14, mostly multilocus sequence type 320, 271, and 236 [4, 92–94]. It appears that the global increase in macrolide-resistant strains carrying both the *erm*(B) and *mef* genes is being driven in part by the diversification and expansion of this Taiwan^{19F}-14 clone following conjugate vaccine introduction. This was especially true of the major 19A ST320 variant in the USA, which became the single most common IPD causing genetic complex in the USA prior to PCV13 implementation.

7 Resistance to Fluoroquinolones

Due to the increased rates of resistance to β-lactam and macrolide antibiotics among pneumococcal strains, fluoroquinolones (FQs) are now included among the choices for first-line therapy in clinical guidelines for the treatment of respiratory tract infections and pneumonia. A direct correlation between the use of FQs and the prevalence of resistance in *S. pneumoniae* has been described [95–97]; however, despite the increased use of FQs, the resistance of *S. pneumoniae* to the newer members of the family is uncommonly found. Reports from Europe, the USA, and Canada showed levels of resistance to levofloxacin and moxifloxacin below 2 % [95–97]. Three major events may have contributed to this low level of resistance: the replacement of the old FQ ciprofloxacin by the more active levofloxacin and moxifloxacin, the introduction of the pneumococcal conjugate vaccine, and, probably, the fact that children who are the main reservoir of pneumococci are not generally treated with FQs. This is supported by a recent study from South Africa showing a rise in FQ resistance in pneumococci isolated from children treated with FQ due to MDR tuberculosis [98]. In countries that report increasing incidence of resistance, the proportion of resistant isolates is much higher among older subjects and patients with chronic lung disease, a patient population that is frequently exposed to FQ [99].

Two mechanisms that decrease susceptibility to FQs in pneumococci have been identified: target alteration and reduced accumulation due to efflux. Resistance associated with target modification requires a combination of mutations in the quinolone resistance-determining region (QRDR) of the genes encoding the DNA gyrase and DNA topoisomerase IV subunits. First-step mutants generally result from spontaneous mutations in the preferential target for a given FQ, ParC for ciprofloxacin, and levofloxacin or GyrA for moxifloxacin, gatifloxacin, and gemifloxacin [100, 101]. Some isolates with a first-step mutation in *par*C gene have ciprofloxacin MICs that would indicate they are clinically susceptible (MIC, <4 mg/L) and these strains would not be identified using routine antibiotic susceptibility testing [102]. The population of isolates with first-step mutations is important because, compared with strains without these first-step mutations, they are more likely to develop high-level resistance during therapy with the acquisition of a second-step mutation [103, 104]. In the second-step mutants, amino acid substitutions are present in both topoisomerase IV and gyrase, most frequently affecting ParC and GyrA and less so ParE and GyrB [105].

Several mutations have been described in these enzymes, but only a few have been shown by in vitro studies to confer resistance: S81F or Y, C, or I and E85K in *gyr*A; E474K in *gyr*B; A63T, S79F, or Y or L and D83G or N in *par*C; and E474K and D435N or H in *par*E [100, 106]. Other frequently described mutations are K137N in *par*C and I460V in *par*E, which appear to not contribute to FQ resistance because they are commonly found in susceptible strains, and no evidence exists for their conferring FQ resistance in vitro [107]. A Q118K in *gyr*A together with S79F in *par*C in a FQ-resistant isolate resulted in treatment failure [108].

Another mechanism underlying non-susceptibility to FQs in some pneumococcal isolates is an increase in active efflux which affects quinolones such as ciprofloxacin [109]. In contrast to the *mef*A gene conferring macrolide resistance, the efflux mechanisms in FQ resistance are poorly characterized and have primarily been demonstrated in isolates with low-level quinolone resistance [101]. They are not encoded by

resistance genes but are thought to be overexpressed in 8–45 % of pneumococcal strains [110]. Little is known about the mechanism of the expression regulation of PmrA, but the efflux pump can be blocked by the plant alkaloid reserpine and, to a lesser degree, by verapamil [111]. Efflux may not confer complete resistance but may be able to lower intracellular FQ to sublethal concentrations, fostering the occurrence of QRDR mutations [112].

In contrast to β-lactam resistance, horizontal gene transfer and the role recombination plays in the evolution of FQ resistance are uncertain. Both intra- and interspecies transfers of FQ resistance loci have been found to occur in vivo, but the frequency of such events appears to be rare. In vitro models report a higher frequency for recombination of QRDRs between viridans group streptococci and *S. pneumoniae* compared to that of spontaneous mutations [113]; however, this level of recombination does not appear to be replicated in vivo [114]. Published studies addressing this question of recombination found evidence for horizontal gene transfer in 0–11 % of FQ-resistant isolates, and interestingly, this ratio seems to be higher in respiratory isolates than in invasive isolates [115–118].

Fluoroquinolone resistance has been reported in a number of international pneumococcal clones that have been associated with the evolution of resistance to penicillin and macrolides [119, 120]. However, the role that clonal spread plays in the increase of FQ resistance is controversial, with studies placing different significance on its importance. The increased prevalence of levofloxacin resistance that was reported from Hong Kong between 1995 and 2001 was suggested to be associated with the dissemination of strains related to the Spain^{23F}-1 clone. However, several studies have shown that clonal spread does not play a significant role in the increase of FQ resistance [120–122]. Data on levofloxacin-resistant pneumococci from 25 countries analyzed as part of the PROTEKT study (1999–2000) showed the majority were genetically unrelated, although 34 % belonged to the Spain^{23F}-1 clone [120]. These studies suggest that both clonal dissemination and the emergence of newly resistant strains contribute to the spread of FQ resistance.

8 Resistance to Newer Classes of Antibiotics

Telithromycin was the first ketolide drug approved for clinical use; however, safety issues have limited the clinical utility of this drug [123]. Both cethromycin (ABT-773) and solithromycin (CEM-101), a novel fluoroketolide, have shown improved activity against macrolide-resistant as well as telithromycin-intermediate and telithromycin-resistant organisms [124–126]. This enhanced potency shows promise for future clinical use for these compounds, subject to pharmacokinetic/pharmacodynamic, toxicity, and animal infection model studies. High-level telithromycin resistance in *S. pneumoniae* has been experimentally generated by mutations in domain II or V of 23S rRNA gene and ribosomal proteins L4 and L22 [127] and is easily created from a macrolide-resistant strain by the deletion or mutation of the region upstream of *erm*(B) [128]. In contrast, clinical telithromycin resistance in *S. pneumoniae* remains rare. Farrell reported that among a worldwide collection of 13 874 *S. pneumoniae* isolates, isolated between 1999 and 2003, only ten were resistant, with MICs ≥4 mg/L and all contained *erm*(B) gene [129]. Mutations in 23S rRNA, L4, and L22 have also been found in clinical telithromycin-resistant isolates [130, 131], and a combination of mutated genes can result in a higher telithromycin resistance than mutation of only one gene [132, 133]. Wolter and colleagues demonstrated that *erm*(B) with a deletion in the leader sequence was responsible for high-level telithromycin resistance in a strain isolated in Canada in 2007 [134].

Linezolid is the first in the class oxazolidinone that was approved for clinical use in 2000 for the treatment of nosocomial and community-acquired pneumonia. Linezolid binds to the 50S subunit of the bacterial ribosome via interactions with the central loop segment of domain V of the 23S rRNA to block the formation of protein synthesis initiation complexes. To date, linezolid non-susceptible pneumococcal strains are extremely rare [129, 135]. Recent data from the US LEADER and global ZAAPS surveillance systems show no linezolid non-susceptible isolates among 2150 *S. pneumoniae* isolates tested in 2011 [136, 137]. Reports of non-susceptibility to linezolid have been sporadic among clinical isolates of staphylococci and enterococci, and resistance has been found to be conferred by mutations in domain V of 23S rRNA [138]. In pneumococci, Wolter et al. [139] have described two clinical isolates with decreased susceptibility to linezolid (MICs 4 mg/L) which were found to contain 6-bp deletions in the gene encoding the riboprotein L4. The L4 deletions were also found to confer a novel mechanism of simultaneous resistance to macrolides, oxazolidinones, and chloramphenicol. A more recent study identified two additional linezolid non-susceptible pneumococci from the USA within the Centers for Disease Control and Prevention (CDC) Active Bacterial Core Surveillance (ABCs) program with mutations and deletions within the *rplD* gene [140]. Whole genome sequencing of linezolid-resistant laboratory-generated mutants has also revealed a role in resistance for a 23S rRNA methyltransferase (spr0333) and for the ABC proteins PatA and PatB [141]. A proteomic and transcriptomic screen suggested increased energy requirement needs associated with the burden of resistance in these laboratory-derived mutants [142]. Second-generation oxazolidinones like tedizolid, which is a protein synthesis inhibitor, are in clinical development for the treatment of

Gram-positive infections. Tedizolid has demonstrated potent in vitro activity against penicillin-resistant *S. pneumoniae*, including linezolid-resistant strains [143].

Resistance to quinupristin-dalfopristin among Gram-positive cocci has been very uncommon. Two clinical isolates among 8837 (0.02 %) *Streptococcus pneumoniae* isolates were discovered in 2001–2002 with MICs of 4 mg/L. Each had a 5-amino acid tandem duplication (RTAHI) in the L22 ribosomal protein gene (rplV) preventing synergistic ribosomal binding of the streptogramin combination [144].

9 Resistance to Other Agents

One class of antimicrobial agents previously used often in clinical practice is the tetracyclines, which are broad-spectrum bacteriostatic drugs shown to be active against pneumococci. Reflecting patterns of past usage, in some countries reported rates of non-susceptibility to tetracyclines remain the most frequently observed resistance phenotype [145]. In *S. pneumoniae* tetracycline resistance is due to the protection of the bacterial 30S ribosome subunit against antibiotic binding by the TetM or TetO [146, 147] proteins, with the *tet*(M) gene being far more common than the *tet*(O)gene in pneumococci. In streptococci, *tet*(M) is usually associated with highly mobile conjugative transposons of the T*n916*–T*n1545* type and large composite structures like T*n5253* and T*n3872*. A recent study discovered the oldest known examples of two different Tn*916*-like, *tet*(M)-containing elements identified among pneumococci dated from 1967 and 1968 [145]. These transposons often carry other resistance genes, such as *erm*(B) coding for resistance to macrolides, lincosamides, and streptogramins B which explains the persistence of tetracycline resistance (these transposons continue to be selected by macrolides). The comparison of *tet*(M) sequences in multidrug-resistant isolates reveals a high degree of allelic variation [148]. There is evidence of clonal distribution of selected alleles as well as horizontal movement of the mobile elements carrying *tet*(M) [149, 150].

The use of rifampin combined with either β-lactam antibiotics or vancomycin has been recommended for the treatment of meningitis caused by multiresistant pneumococci. Rifampin has been used in combined therapy to treat tuberculosis and resistant staphylococci, and it is extensively used in the prophylaxis of *Neisseria meningitidis* and *Haemophilus influenzae* type b exposure. The prevalence of rifampin resistance among pneumococcal isolates is low at present, and reported rates vary between 0.1 % and 1.5 % [151, 152]. Rifampin resistance has been described in several bacterial species and is caused by an alteration of the β-subunit of RNA polymerase, the target for the antibiotic. Resistance to rifampin in pneumococci has been linked to mutations in clusters N, I, II, and III of the *rpo*B gene, which encodes the β-subunit [153, 154].

Resistance to chloramphenicol in *S. pneumoniae* is due to the acetylation of the antibiotic by the production of a chloramphenicol acetyltransferase (CAT). The cat gene in pneumococcal isolates is carried on the conjugative transposon *Tn*5253, a composite transposon consisting of the tetracycline resistance transposon, *Tn*5251, and *Tn*5252 which carries the chloramphenicol resistance determinant [155]. Chloramphenicol-resistant strains have been shown to contain sequences homologous to cat_{pC194} and other flanking sequences from *S. aureus* plasmid pC194 [156].

Trimethoprim and sulfamethoxazole are used extensively in combination as the drug co-trimoxazole. Co-trimoxazole has been used in the treatment of a range of *S. pneumoniae* diseases, especially in children, because it is inexpensive and generally effective. Resistance to co-trimoxazole has increased dramatically in many regions of the world, and recent surveillance studies show rates ranging from 19 % in Europe to around 50 % associated with HIV infection in Africa and >60 % in Asia [29, 157, 158]. Resistance to co-trimoxazole is often associated with resistance to other antibiotics, especially to penicillin. Trimethoprim resistance in pneumococci has been reported to result from a single amino acid substitution (Ile-100 → Leu) in the dihydrofolate reductase (DHFR) protein [159] and often associated with mosaic alleles. Additional mutations have also been reported which seem to enhance resistance and modulate the effects of existing alterations on the affinity of DHFR for its natural substrates [160]. In many cases, resistance to sulfonamides is associated with chromosomal mutations within the gene encoding dihydropteroate synthase (DHPS). Different studies have reported the occurrence of single and/or multiple amino acid mutations in the DHPS of sulfonamide-resistant clinical isolates of *S. pneumoniae* [161–163]. The use of Fansidar therapy for malaria in Africa has been shown to increase co-trimoxazole resistance in pneumococci [19].

10 Clinical Relevance of Antibiotic Resistance

When penicillin-resistant pneumococci were first isolated from adults, there was an implicit assumption that such strains would fail intravenous penicillin therapy [164, 165]. As our appreciation of pharmacodynamics has allowed the understanding of the time-based mode of action of β-lactams, it is clear that the very high levels of penicillin achieved by intravenous therapy exceed the MICs of strains up to 8 mg/L for most of the short 4–6 h dosing interval for high-dose intravenous penicillin [166]. Such highly penicillin-resistant strains remain rare, and there is little evidence for the failure of intravenous penicillin, amoxicillin, cefotaxime, or ceftriaxone [167, 168] due to penicillin resistance. It is possible that less active intravenous agents such as cefuroxime [169]

may fail to treat penicillin-resistant infections, and β-lactams with a more Gram-negative spectrum such as ticarcillin [164] and ceftazidime [170] should not be used to treat penicillin-resistant pneumococcal infections. It is likely that oral β-lactam therapy may fail in the management of pneumococcal infections such as otitis media when the strains become intermediately (MIC ≥ 0.1 mg/L) resistant to penicillin. Poorly active cephalosporins such as cefaclor fail more often than cefuroxime [171, 172], and high-dose amoxicillin is the most active oral agent available against penicillin-resistant pneumococcal otitis media [173]. It is likely that the inferences made for otitis will be similar for sinusitis [174]. β-lactam resistance is clinically important for meningitis treatment where penicillin has been shown to fail [175, 176] even for intermediately resistant strains because of the poor penetration of penicillin through the blood-brain barrier. Extended spectrum cephalosporins fail too when there is full penicillin resistance in meningitis (MIC ≥ 2 mg/L; associated with cefotaxime or ceftriaxone MIC's ≥ 1 mg/L) [177, 178]. The empiric therapy therefore of penicillin-resistant pneumococcal meningitis is cefotaxime plus vancomycin or ceftriaxone plus vancomycin, based on the observation that these drugs in combination are able to eradicate cephalosporin-resistant pneumococci from the CSF better [178] than either drug alone [179, 180].

Macrolide resistance is associated in most instances with MICs > 2 mg/L regardless of the mechanism of macrolide resistance, and treatment of these strains with macrolides has been shown to fail [181, 182], both in the management of otitis media [171, 172] and of pneumonia [183]. These failures are in keeping with our knowledge of the pharmacodynamics of these agents [184].

Trimethoprim-sulfamethoxazole has been shown to not be able to eradicate from the middle ear, strains resistant to that agent [185].

Fluoroquinolones fail to successfully treat pneumococcal infections when preexisting resistant strains are present or even when first-step mutations in the *parC* gene are present [186]. Immunocompromised patients may be most at risk for repeated infections due to fluoroquinolones-resistant strains [187].

11 Impact of Conjugate Vaccine

The introduction of conjugate pneumococcal vaccine has not only reduced the burden of invasive disease in children [188] but has impacted on carriage and thus on the burden of disease in adults by preventing the spread of vaccine-type resistant strains to adults [189]. Direct demonstration of the impact of conjugate vaccine on antibiotic-resistant invasive disease was demonstrated in the 9-valent conjugate vaccine trial in South Africa [190], while multistate studies [191] have demonstrated a significant reduction in the proportion and absolute incidence of antibiotic-resistant pneumococci isolated from blood. Antibiotic resistance however emerged in non-vaccine-type pneumococci causing both ear infections and invasive disease following the 7-valent conjugate vaccine introduction in the USA, particularly among serotype 19A strains [192, 193]. The increase in serotype 19A post-conjugate vaccine in the USA was significantly increased among states with higher rates of community antimicrobial use in children [194]. In addition to direct protection of children from antibiotic-resistant pneumococci, and herd protection of adults to these resistant strains, through interruption of their transmission, conjugate vaccine may also contribute to reduction in selection of resistance by reducing the antimicrobial prescriptions written for vaccinated children, compared to controls [195–197].

12 Concluding Remarks

The multiply resistant pneumococcus continues to have a global distribution. Antimicrobial resistance within the pneumococcal population emerges and is maintained through a complex interplay of many factors. Attempts to reduce the burden of resistance in this pathogen are frustrated by widespread empiric therapy for respiratory infections. Both appropriate and inappropriate antibiotic uses continue to select resistance in this pathogen. Although the conjugate vaccine has reduced the burden of resistance in invasive isolates, continued antibiotic exposure is leading to the emergence of resistance in non-vaccine types.

Antibiotic Resistance of Non-pneumococcal Streptococci and Its Clinical Impact

50

Nainee Desai, Judith Steenbergen, and David E. Katz

1 Introduction

The taxonomy of streptococci has undergone major changes during the last two decades. The present classification is based on both phenotypic and genotypic data. Phylogenetic classification of streptococci is based on 16S rRNA sequences [1], and it forms the backbone of the overall classification system of streptococci. Phenotypic properties are also important, especially for clinical microbiologists. The type of hemolysis on blood agar, reaction with Lancefield grouping antisera, resistance to optochin, and bile solubility remain important for grouping of clinical *Streptococcus* isolates and therefore treatment options [2]. In the following chapter, two phenotypic classification groups, viridans group streptococci (VGS) and beta-hemolytic streptococci, will be discussed.

Antimicrobial resistance is common among VGS and beta-hemolytic streptococci isolates. Beta-lactam resistance is widespread among VGS, and resistance rates to other antimicrobials are continuously increasing. Beta-lactam resistance is uncommon in beta-hemolytic streptococci. Macrolide resistance, however, presents a clinical concern in the outpatient setting. High-level beta-lactam resistance in VGS is a real threat to the treatment of infective endocarditis and empirical treatment of sepsis in neutropenic patients. Treatment of infections, including pharyngitis, caused by macrolide-resistant beta-hemolytic streptococci may also become challenging if resistance rates continue to rise.

Infections caused by Gram-positive organisms have increased in frequency over time and are almost as common as Gram-negative infections. This has been linked to greater use of invasive procedures and the increasing proportion of hospital-acquired infection. The regular use of broad-spectrum antibiotics in increasingly sick patients has likely resulted in increased bacterial resistance over time [3]. As a result, implementation of antimicrobial stewardship and infection control processes has become progressively more important in protecting patients, health-care providers, and communities.

This chapter summarizes the general characteristics of the streptococci groups, the current antimicrobial resistance trends, resistance mechanisms, and the clinical implication of resistance for viridans and beta-hemolytic streptococci.

2 Characteristics of Non-pneumococcal Streptococci

2.1 Viridans Group Streptococci

Viridans group streptococci form a phylogenetically heterogeneous group of species belonging to the genus *Streptococcus* [1]. However, they have some common phenotypic properties. VGS are a group of catalase-negative, Gram-positive cocci with a chaining morphology upon microscopic examination. They can be grouped as alpha- or nonhemolytic. They can be differentiated from *S. pneumoniae* by their resistance to optochin and lack of bile solubility, though the distinction between the two groups remains difficult due to similar sequence homology [2, 4]. They are leucine aminopeptidase positive, pyrrolidonylaryl amidase negative, and can be differentiated from *Enterococcus* species by their inability to grow in medium containing 6.5 % sodium chloride [2]. Nutritionally variant streptococci were once included in VGS but based on molecular data been removed to a new genus *Abiotrophia* [5]. VGS belong to the normal microbiota of the oral cavities and upper respiratory tracts of humans and animals. They can also be isolated from

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_2

the female genital tract and all regions of the gastrointestinal tract [2, 5]. Although historically VGS are poorly classified, there are many species within the group. The six major groups include *S. mutans*, *S. salivarius*, *S. anginosus*, *S. mitis*, *S. sanguinis*, and *S. bovis* group. The *S. anginosus* group has been the source of much controversy and ambiguity regarding taxonomy and classification. This group of organisms can be alpha-, beta-, or nonhemolytic, and it is the isolates lacking beta-hemolysis that are generally considered to be a part of VGS. Due to the diverse nature of VGS, the rates and patterns of antimicrobial resistance vary greatly. Differences in species identification and patient population contribute to this variability [4].

Streptococcus mitis group organisms are resistant to more antimicrobial agents than the other VGS species [4]. The most clinically relevant species belonging to VGS are *S. mitis*, *S. sanguis*, and *S. oralis*. Lack of alpha-hemolysis does not seem to correlate with clinical outcome or severity of disease and no enzymatic or toxigenic effect has been documented as a by-product of alpha-hemolysis [4].

2.2 Beta-Hemolytic Streptococci

Beta-hemolytic streptococci can be differentiated from the heterogeneous group of streptococci by the pattern of hemolysis on blood agar plates, antigenic composition, growth characteristics, biochemical reactions, and genetic analyses. Beta-hemolytic streptococci commonly produce hemolysins, which cause complete lysis (beta-hemolysis) of red blood cells when cultivated on blood agar plates. Traditional subdividing into serological groups is based on the detection of group-specific antigenic differences in cell-wall carbohydrates. The serologic scheme of classification by Lancefield is used [6], and serogroups A, B, C, D, F, and G are those most commonly found in humans [7].

2.2.1 Group A *Streptococcus* (*Streptococcus pyogenes*)

Group A *Streptococcus* (GAS, *Streptococcus pyogenes*) is an important pathogen confined almost exclusively to human hosts [8]. *S. pyogenes* is generally associated with acute pharyngitis or localized skin infections. *S. pyogenes* is highly communicable and can cause disease in healthy people of all ages without type-specific immunity against the serotype responsible for infection [9]. Transmission can occur from those with acute infections or from asymptomatic carriers generally through hand contact or respiratory droplets. Food and waterborne outbreaks have also been documented [8]. Impetigo and pharyngitis are more likely to occur among children living in crowded homes or in suboptimal hygienic conditions. Multiple streptococcal infections may be found in the same family due to the highly contagious nature of the infection [9].

The diseases are commonly self-limiting, localized infections of the pharynx and skin. A ubiquitous organism, *S. pyogenes*, is the most common bacterial cause of acute pharyngitis, accounting for 15–30 % of cases in children and 5–10 % of cases in adults [9]. Invasion from the skin can lead to septicemia or severe deep-seated tissue infections, such as necrotizing fasciitis and myositis. Other clinical manifestations of GAS include scarlet fever, peritonsillar and retropharyngeal abscesses, otitis media, sinusitis, myositis, lymphangitis, meningitis, suppurative arthritis, endocarditis, osteomyelitis, pneumonia, erysipelas, cellulites, streptococcal toxic shock syndrome, vaginitis, and balanitis [10–13]. Primary suppurative infections may also lead to serious nonsuppurative sequelae, acute rheumatic fever, rheumatic heart disease, and acute glomerulonephritis [2, 14, 15].

Group A *Streptococcus* can be distinguished from other groups by susceptibility to bacitracin. A kirby-bauer disc contains 0.04U of bacitracin inhibits the growth of more than 95 % of group A strains, whereas 80–90 % of non-group A strains are resistant to this antibiotic [9]. Serologic typing of the M [16] and T [17] proteins has traditionally been used in epidemiologic typing of GAS [18]. More recently, molecular typing methods such as *emm* sequence typing, multilocus sequence typing, pulse field gel electrophoresis, inversion gel electrophoresis, restriction length polymorphism analysis of the *mga*-regulon (vir-typing) and random amplified polymorphic DNA analysis have provided more discriminatory power for studying the clonal relationships between GAS strains.

2.2.2 Group B *Streptococcus* (*Streptococcus agalactiae*)

Group B streptococci (GBS, *Streptococcus agalactiae*) are the most common cause of neonatal sepsis. It is one of the primary causes of bacteremia and meningitis in neonates and can cause infections in pregnant women [19, 20]. Vaginal colonization of nonpregnant and pregnant women is the principal source of GBS. However, it also can colonize the gastrointestinal tract and the upper respiratory tract of healthy humans. The portal of entry is not apparent, but possible areas include the skin, genital tract, urinary tract, and respiratory tract [21].

Neonates can acquire the organism vertically in utero or during delivery from the maternal genital tract. Although the transmission rate from mothers colonized with *S. agalactiae* to neonates delivered vaginally is approximately 50 %, with antibiotic prophylaxis, only 1–2 % of colonized neonates develop invasive group B streptococcal disease [21].

GBS may also cause invasive infections in the elderly and in nonpregnant adults with underlying or chronic diseases. The broad clinical spectrum of invasive GBS disease in adults includes skin and soft tissue infections, primary bacteremia, urosepsis, pneumonia, osteomyelitis, peritonitis, septic arthritis, meningitis, endocarditis, and intravenous catheter infection [21].

GBS has been classified into different serotypes on the basis of different chain structures of its capsular polysaccharide. Several serotypes are known—Ia, Ib, Ic, II, III, IV, V, VI, VII, and VIII. Isolation of group B streptococci from blood, cerebrospinal fluid (CSF), and/or a site of local suppuration is the only method for diagnosing invasive group B streptococcal infection [21].

2.2.3 Groups C and G Beta-Hemolytic Streptococci

Most of the Lancefield group C streptococci (GCS) produce beta-hemolysis on blood agar although nonhemolytic strains also exist [2]. Group C streptococci are mainly animal pathogens; however, beta-hemolytic strains have been isolated from normal human microbiota of the nasopharynx, skin, and genital tract [22]. The majority of group G streptococci (GGS) are beta-hemolytic [2].

More recently, group C streptococci and group G streptococci of human origin are thought to comprise a single subspecies, *Streptococcus dysgalactiae* subsp. *equisimilis*. It can be found in normal flora of the upper airways and are often asymptomatic colonizers of other areas. It may also be implicated in skin and soft tissue infections, pharyngitis, bacteremia, endocarditis, septic arthritis, osteomyelitis, puerperal infections, and meningitis [22].

3 Antimicrobial Resistance in VGS

For the purpose of this chapter, we will use data from contemporary large-scale surveillance studies to show recent resistance trends for relevant antibiotics. As both the European Committee on Antimicrobial Susceptibility Testing (EUCAST) and Clinical and Laboratory Standards Institute (CLSI) breakpoints will be presented, epidemiology and resistance rates will primarily be described as defined by CLSI criteria.

3.1 Beta-Lactam Activity

Among streptococci, beta-lactam resistance is mediated by point mutations in penicillin-binding proteins (PBPs). PBPs are membrane-bound transpeptidases. They are active-site serine hydrolases, which catalyze cross-linking of the peptidoglycan subunits during bacterial cell-wall synthesis [23, 24]. Beta-lactams serve as substrates for PBPs. The active-site serine reacts with the beta-lactam ring and generates a covalently linked enzyme-beta-lactam intermediate. This acyl enzyme intermediate is not able to catalyze cross-linking of the peptidoglycan subunits [23]. In streptococci there are low and high molecular weight PBPs [25, 26]. Both of these enzymes are important for the cell-wall synthesis, but only the high molecular weight PBPs are important for the bacterial killing activity of the beta-lactam antibiotics [24]. In VGS there are two kinds of high molecular weight PBPs, PBP1 (PBP1a and PBP1b), and PBP2 (PBP2a, PBP2b, PBP2x) [25]. Homologous molecules can be found in *S. pneumoniae* and naming conventions for PBPs of VGS are adapted from *S. pneumoniae* [24–26].

VGS with wild-type PBPs are susceptible to beta-lactam antibiotics [27]. Resistance results when the high molecular weight PBPs have decreased affinity for beta-lactams. Decreased affinity can be achieved by amino acid substitutions in the transpeptidase domain of the PBPs [24, 27]. A single point mutation can result in an increase in the penicillin minimum inhibitory concentration (MIC) value. Normally more than one mutation is needed for intermediate level beta-lactam resistance. Highly resistant strains have accumulated several mutations in the PBPs, altering the PBPs significantly so the beta-lactams can no longer bind to the PBP. Accumulation of several mutations in the PBPs may also result in lethal mutations if cell-wall integrity is compromised. Based on the data obtained in *S. pneumoniae*, these highly resistant strains may also have mutations beyond those found in PBPs [24]. Streptococci have overcome this problem by horizontal transfer of functional mutated PBP coding genes or gene fragments. Transformation and subsequent homologous recombination has produced beta-lactam-resistant VGS with mosaic PBP genes. In these mosaic PBP genes, there are gene regions obtained from resistant strains dispersed through the wild-type PBP genes [28].

Penicillin resistance among VGS isolated from blood has been extensively studied. Farrell et al. at JMI laboratories performed a large-scale surveillance study to examine the susceptibility profiles of various antibiotics against 60,084 clinical isolates from 33 European region medical centers. Over 1200 viridans group streptococci isolates were collected between 2005 and 2010 and were tested for susceptibility to a range of antibiotics. The penicillin MIC_{50} and MIC_{90} was 0.06 and 1 mg/L, respectively. Per CLSI breakpoints, 77.5 % VGS were susceptible, 17 % intermediate, and 5.5 % resistant [29] (Table 50.1). The 2012 LEADER surveillance study evaluated 7429 isolates, including 526 VGS, from 60 US sites. The penicillin MIC_{50} was ≤0.06 mg/L and the MIC_{90} was 0.5 mg/L, similar to the European susceptibility pattern [30].

Overall, in VGS cephalosporins have similar susceptibility rates, MIC_{50} and MIC_{90}. The cefepime MIC_{50} and MIC_{90} were ≤0.12 mg/L and 1 mg/L, respectively, with 92.1 % of isolates susceptible. Between 3 % and 5 % of isolates showed intermediate susceptibility or were considered resistant. Ceftriaxone MIC_{50} was ≤0.25 mg/L with an identical MIC_{90} and similar percent resistance [29] (Table 50.1). US surveillance data were similar with MIC_{50} and MIC_{90} values of 0.25 mg/L and 0.5 mg/L with only 1.2 % resistance rates [30].

Table 50.1 Antimicrobial activities of ceftobiprole and comparator agents when tested against bacterial isolates from European medical centers (2005–2010)

	MIC			% of isolates susceptible/intermediate/resistant	
Organism (no. of isolates tested) and antimicrobial agent	MIC_{50}	MIC_{90}	Range	CLSI	EUCAST

Ceftobiprole medocaril is described as a fifth-generation cephalosporin with a wide spectrum of antibiotic activity. Per European surveillance data, the ceftobiprole MIC_{50} and MIC_{90} are ≤0.06 mg/L and 0.25 mg/L, respectively, for VGS [29] (Table 50.1). Ceftaroline fosamil is a broad-spectrum parenteral cephalosporin which treats certain skin infections and community-acquired bacterial pneumonia (CABP). A recent report from the SENTRY antimicrobial surveillance program tested ceftaroline against 1273 streptococci isolates between 2008 and 2011. Ceftaroline showed activity against all VGS species with the highest MIC, 1 mg/L, observed in *S. oralis*, *S. mitis*, *and S. parasanguinis* [31].

3.2 Macrolide, Lincosamide, and Ketolide Activity

Macrolides, ketolides, lincosamides, and streptogramin B antibiotics, although having different chemical structures, have similar, although not identical, antimicrobial activity against VGS since the resistance mechanisms developed by bacteria against these antimicrobials is similar. These antibiotics inhibit protein synthesis by binding to bacterial ribosomes. Macrolides can be divided into different groups according to the number of carbon atoms in their lactone ring. Fourteen- and 15-membered ring macrolides such as erythromycin and azithromycin have similar antibiotic properties. Sixteen-membered ring macrolides including spiramycin differ from 14- and 15-membered ring macrolides in their antimicrobial activity against VGS. Lincosamides such as clindamycin and streptogramins also have some differences in their activity against bacteria when compared to macrolides.

In streptococci, there are two well-characterized macrolide resistance mechanisms. These are target site modification and active drug efflux. Target site modification is mediated by methylases encoded by the *erm* (erythromycin ribosome methylation) genes or by mutations at the 23S ribosomal RNA or ribosomal proteins L4 and L22. Methylation of adenine 2058 of the peptidyl transferase

loop of 23S rRNA causes resistance to macrolides as well as to lincosamides and streptogramin B antibiotics [32]. The active efflux mechanism encoded by the *mef* (macrolide efflux) genes is more specific and causes resistance only to 14- and 15-membered ring macrolides [33]. Mutations at the macrolide binding domains of the 23S ribosomal RNA and at the ribosomal proteins L4 and L22 lower the affinity of macrolides to ribosomes [34]. Mutations can cause several different kinds of resistance phenotypes. Both *erm* and *mef* genes can be horizontally transferred between different streptococci [35].

3.2.1 Erythromycin

Erythromycin A has similar in vitro activity against VGS strains as other 14- and 15-membered ring macrolides including azithromycin [36]. Erythromycin resistance is quite common among clinical VGS isolates. In Europe, the MIC_{50} and MIC_{90} for erythromycin for VGS is ≤0.25 mg/L and >2 mg/L. Resistance levels continue to remain high with 36.2 % of isolates resistant to erythromycin [29] (Table 50.1). In the United States, macrolide MIC values and resistance rates continue to rise. Approximately 50 % of VGS isolates in the LEADER study were resistant to erythromycin with MIC_{50} and MIC_{90} values of 0.5 mg/L and 16 mg/L, respectively [30]. The most common erythromycin resistance mechanism is mediated by *mef*(A) genes azithromycin [36, 37]. Roughly 70–80 % of the erythromycin-resistant VGS strains are carrying *mef*(A) gene and about 16–20 % are carrying *erm*(B) gene [36–38]. However, the situation may vary. There is one report from France, where *erm*(B) was reported to be much more common than *mef*(A) among blood isolates of VGS [35]. The continuous surveillance of invasive VGS isolates is warranted and can guide better treatment options especially in patients with underlying diseases [39].

3.2.2 Clindamycin

Resistance to clindamycin is much less frequent among blood and normal microbiota VGS than resistance to erythromycin [40]. MIC_{50} and MIC_{90} values were similar to erythromycin (≤0.25 mg/L and >2 mg/L, respectively), with up to 12 % of VGS isolates resistant to clindamycin in both Europe and the United States [29, 30] (Table 50.1). Resistance levels are similar among both blood and the normal microbiota isolates. The reason for lower resistance levels is that the efflux mechanism mediated by *mef*(A) resistance gene does not confer resistance to clindamycin [40]. An autopsy report of a patient with a S. *mitis* strain found that the pattern of resistance in this isolate resembled an induced macrolide, lincosamide, and streptogramin B resistance (MLSB) phenotype as a result of short-term use of clindamycin. This mechanism induces resistance to both clindamycin and minocycline [41].

3.2.3 Ketolide

The binding of telithromycin to the bacterial ribosomes is much stronger than the binding of erythromycin. This is the reason why methylation of the ribosomal RNA does not increase the MIC values as much for telithromycin compared to erythromycin [42]. Mef(A) efflux pumps transport telithromycin out of the bacterial cell as well as they pump erythromycin. However, in streptococci, Mef(A) efflux does increase telithromycin MIC values when compared to the strains without *mef*(A) gene [43].

3.2.4 Streptogramin

Quinupristin-dalfopristin, a combination of streptogramin B and streptogramin A, is available for intravenous use. It has good in vitro activity against VGS. However, resistance rates vary considerably between studies. In some studies, resistant strains have not been isolated, whereas other studies show reduced susceptibility in as much as 70 % of strains and resistance in 28 % [44, 45]. VGS strains with quinupristin-dalfopristin MIC values of 16 mg/L have also been described [44]. Resistance to quinupristin-dalfopristin is linked to the streptogramin A (dalfopristin) resistance. Therefore in order to be resistant to the antibiotic combination, a strain must be resistant to streptogramin A. Streptogramin A resistance is mediated by *vga*(A), *vga*(B), *lsa*, and various *vat* genes. Thus far, these genes have been found in clinical *Staphylococcus* and *Enterococcus* strains, but the presence of the genes in VGS has not been reported [46]. Although not studied in detail [44, 47], it is possible that the resistance is mediated by ribosomal mutation as in *S. aureus* [48].

3.3 Tetracyclines and Trimethoprim-Sulfamethoxazole Activity

Tetracycline resistance in VGS is quite common. In the European surveillance study, the VGS MIC_{50} was ≤2 mg/L and MIC_{90} was >8 mg/L. Up to 36 % of VGS strains are tetracycline resistant [29] (Table 50.1). Tigecycline activity is much higher with 99.9 % of isolates susceptible and an MIC_{50} and MIC_{90} of ≤0.03 mg/L and 0.06 mg/L, respectively [29] (Table 50.1). Trimethoprim-sulfamethoxazole is not used for treatment of VGS infections but has been commonly used for prophylaxis in neutropenic patients [49]. Decreased susceptibility for trimethoprim-sulfamethoxazole is quite common among VGS strains.

3.4 Fluoroquinolone Activity

In streptococci, there are two fluoroquinolone resistance mechanisms: mutations at the quinolone resistance-determining regions (QRDRs) of the topoisomerase IV and

DNA gyrase molecules and an efflux mechanism [50–52]. In streptococci, the topoisomerase IV molecule has two subunits coded by *par*C and *par*E genes. DNA gyrase has two subunits, GyrA and GyrB, coded by corresponding genes. Topoisomerase IV is the primary target for fluoroquinolones in VGS [50]. Mutations at the topoisomerase IV genes confer low-level resistance (MIC 4 mg/L). A combination of topoisomerase IV mutations and the fluoroquinolone efflux mechanism is needed for high-level fluoroquinolone resistance (MIC ≥ 16 mg/L). Fluoroquinolone resistance determinants can be horizontally transferred between VGS and *S. pneumoniae* strains [50, 53–55]. Levofloxacin was the only fluoroquinolone evaluated in the European and US surveillance studies. Data demonstrated high susceptibility rates with a MIC_{50} of 1 mg/L and MIC_{90} of 2 mg/L. Approximately 2% of VGS isolates were determined to be resistant in Europe and 6% in the United States [29, 30] (Table 50.1).

3.5 Glycopeptide Activity

3.5.1 Vancomycin

Vancomycin, a glycopeptide antibiotic, has retained its activity against VGS. Not a single vancomycin-resistant VGS has been reported thus far [36, 56–62]. The vancomycin MIC_{50} was 0.5 mg/L and MIC_{90} was 1 mg/mL in both Europe and the United States [29, 30] (Table 50.1).

3.5.2 Oritavancin and Dalbavancin

Newer glycopeptides include oritavancin and dalbavancin. Oritavancin, a bactericidal lipoglycopeptide, was assessed in the SENTRY surveillance program in order to expand current limited in vitro data. Oritavancin has activity against many Gram-positive pathogens including streptococci with oritavancin MIC_{50} and MIC_{90} results of ≤0.008 mg/L and 0.06 mg/L, respectively, for the VGS studied [63]. The SENTRY program also evaluated in vitro activity of dalbavancin. VGS isolates were tested using CLSI reference broth microdilutions and interpretations. The MIC_{50} and MIC_{90} ranges were ≤0.03–0.25 mg/L and 0.06–0.12 mg/L, respectively [64]. Overall, all currently existing glycopeptides are potent against the VGS.

3.6 Aminoglycoside Activity

In general, the activity of the aminoglycosides against VGS is limited [65]. Aminoglycosides including gentamicin, amikacin, streptogramin, and netilmicin have been used in combination with penicillin or a cephalosporin for the treatment infective endocarditis [66] and sepsis in neutropenic patients [67]. High-level gentamicin resistance in VGS is rare. This is true with VGS isolates of blood origin [59–61] and normal microbiota [68]. MIC values are typically between 0.25 and 96 mg/L [59, 60, 69] and the MIC_{90} values are between 0.5 and 32 mg/L [59, 68]. Few high-level aminoglycoside-resistant *S. mitis* strains have been detected. In these strains gentamicin MIC values have been as high as 1000 mg/L [69].

3.7 Oxazolidinone Activity

3.7.1 Linezolid

Linezolid belongs to the oxazolidinone group of antibiotics [70]. Linezolid has been used in the treatment of vancomycin-resistant *Enterococcus faecium* infections, hospital-acquired pneumonia, and complicated skin infections [71]. The activity of linezolid against VGS strains has not been well studied. However, ongoing surveillance programs that monitor the in vitro activity of linezolid against comparator agents with Gram-positive coverage do exist. The LEADER surveillance study demonstrates MIC values of linezolid against VGS to be predominantly 1 mg/L and 100% susceptible in the United States [72]. International data through the ZAAPS program revealed similar findings [73].

3.7.2 Tedizolid

Tedizolid is the active moiety of the prodrug tedizolid phosphate. It is a novel oxazolidinone whose in vitro activity has been studied against viridans group streptococci. Fifteen VGS isolates from a phase 2 trial were obtained and tested in patients with complicated skin and skin structure infections. Susceptibility testing from phase 2 data resulted in a MIC_{50} and MIC_{90} of 0.25 mg/L [74].

3.8 Daptomycin Activity

Daptomycin is a bactericidal lipopeptide with activity against streptococci. It is used successfully to treat endocarditis caused by vancomycin-resistant enterococci and methicillin-resistant staphylococci. It is the only agent indicated for *S. aureus* bacteremia and endocarditis. Large surveillance studies have demonstrated daptomycin MIC_{50} of 0.25 mg/L and MIC_{90} of 0.5 mg/L [29] (Table 50.1). VGS has historically been considered uniformly susceptible to daptomycin; however, the development of high-level daptomycin resistance (HLDR; MIC >256 mg/L) after exposure to daptomycin has recently been reported among these isolates. In vitro studies were performed and 114 VGS strains were tested from patients diagnosed with infective endocarditis. Daptomycin susceptibilities of the baseline clinical isolates by Etest ranged between 0.03 and 1.5 mg/L for S. *mitis*, 0.023–0.12 mg/L for

S. *bovis*, 0.12–0.5 mg/L for S. *anginosus*, 0.25–0.5 mg/L for S. *mutans*, and 0.016–0.047 mg/L for S. *salivarius.* HLDR was only observed after 24 h of exposure to daptomycin in 27 % of *S. mitis* isolates, 47 % of *S. oralis* isolates, and 13 % of *S. sanguis* isolates [75]. No clinical isolates have been identified or reported to date.

4 Antimicrobial Resistance in Beta-Hemolytic Streptococci

4.1 Resistance to Macrolides

4.1.1 Incidence of Macrolide Resistance in GAS, GBS, GCS, and GGS

In 1959 Lowburry and Hurst reported the first isolate of erythromycin-resistant GAS from burns of four patients in the United Kingdom [76]. During the following years in Europe, mainly sporadic cases and small epidemics of erythromycin-resistant GAS were reported from the United Kingdom, Sweden, Italy, and Spain [76–81]. In the 1970s a large outbreak of erythromycin-resistant GAS occurred in Japan, where the proportion of resistant strains increased from 12 % in 1971 to 82 % in 1977 [82]. These strains were characterized as highly resistant (MIC values >100 mg/L) to macrolides and lincomycin and were often resistant to tetracycline and chloramphenicol as well. Strains were exclusively of the T12 serotype. From 1985 to 1987, an increase from 1 % to 17.6 % in the frequency of erythromycin-resistant GAS was seen in Australia's Fremantle area [83]. These strains represented different serotypes and exhibited overall low-level resistance to erythromycin (MIC range 2–8 mg/L) Resistance to clindamycin and tetracycline was rare. Sporadic isolates and family outbreaks with 22 % erythromycin-resistant GAS, predominantly of T4M4 serotype, was reported between 1988 and 1989 from Dundee area in the United Kingdom [84].

Resistance to erythromycin continues to be reported in GBS since 1962. The first description was from the United States [85], and in the same country macrolide resistance in GBS increased from 1.2 % among isolates collected from 1980 to 1993 to 18 % in 1997 and 1987. Increasing resistance has been reported from other countries as well. In Spain, the frequency of macrolide resistance in GBS increased from 2.5–5.6 % in 1993–1996 to 14.5–18 % in 1998–2001 [86] and in Taiwan from 19 % in 1994 to 46 % in 1997 [87]. Since the end of the 1990s, frequencies of 15–21 % have been reported in France [88–90], 13–18 % in Canada [91, 92], 40 % in Korea [93], and 22 % in Turkey [94].

Macrolide resistance among group C and G streptococci varies between different countries. Resistance is uncommon in Finland with 1 % and 3.6 % of group C streptococci found to be resistant to clindamycin and erythromycin, respectively. The most common resistance mechanism to macrolides has been via the *mef*(A) gene [95]. Similar to group C streptococci resistance rates, 3.5 % and 0.3 % of the group G streptococci have been resistant to erythromycin and clindamycin, respectively. Most of these strains have had *erm*(TR) resistance gene and one with the *erm*(B) resistance gene [95]. Higher numbers of erythromycin resistance among group C and G streptococci have been reported from Turkey. Ergen et al. reported that 1.4 % and 16.2 % of GCS and GGS, respectively, were resistant to erythromycin [28]. Erythromycin resistance among GCS and GGS in Taiwan is even more common. Resistance has been seen in 41.7 % of GCS isolates and 53.3 % of GGS isolates reported [96].

Macrolide resistance continues to rise in both European and North American countries. A total of 2981 beta-hemolytic streptococci isolates were collected from Europe, Turkey, and Israel and 950 isolates from the United States. Current cumulative surveillance data, accounting for all beta-hemolytic streptococci groups, show 7.6 % resistance to clindamycin and 17 % resistance to erythromycin in European countries. This rate is increased in the United States, with 19.4 % and 38 % resistance to clindamycin and erythromycin, respectively [29, 30] (Table 50.1).

4.1.2 Mechanisms of Macrolide Resistance in Beta-Hemolytic Streptococci

The macrolide resistance mechanism by ribosomal methylation encoded by *erm* genes was first identified in 1956 in *Staphylococcus aureus* [97]. This resistance mechanism affects macrolides, lincosamides, and streptogramin B (MLSb) antibiotics. The inducible and constitutive forms of MLSb resistance have been found in beta-hemolytic streptococci since the early 1970s [98–100]. The *erm*(B) methylase gene was the only *erm* gene class found in streptococci [101–103] until 1998, when the sequence of *erm*(TR) in *S. pyogenes* was published [104]. Its nucleotide sequence is 82.5 % identical to staphylococcal *erm*(A) and 58 % identical to *erm*(B) and, therefore, *erm*(TR) belongs to *erm*(A) methylase gene class [105]. The inducible or constitutive production of the methylase is dependent on the sequence of the regulatory region situated upstream from the structural methylase gene. Resistance is associated to structural changes in the regulatory sequence. Exposing *S. pyogenes* harboring the inducible *erm* gene to clindamycin results in highly resistant mutants of *S. pyogenes* [106].

The phenotypic expression of macrolide resistance in streptococci has been commonly studied by MIC determinations and induction tests including the double-disc test (erythromycin and clindamycin disks placed in vicinity on inoculated agar). Analysis of the Finnish GAS strains isolated in 1990 revealed a new erythromycin resistance phenotype with low- or moderate-level resistance (MIC range 1–32 mg/L) to 14- and 15-membered macrolides only

(M-phenotype). Thirty-four percent of the studied isolates represented the new M-phenotype [80]. Subsequently, the active efflux mechanism causing this phenotype and the encoding *mef*(A) and *mef*(E) (macrolide efflux) genes were characterized in *S. pyogenes* and *S. pneumoniae* [33, 107]. Isolates with this mechanism have been found among beta-hemolytic streptococci in different parts of the world. Countries where strains of GAS carrying *mef*(A) have been observed now account for the majority of macrolide-resistant isolates. These countries include Spain [108, 109], Germany [110], Greece [111], Finland [112], Taiwan [113], the United States [114], Chile [115], and Argentina [116]. Predomination of GAS strains carrying *erm*(A) have been reported from Russia, Slovakia, the Czech Republic, and Croatia [117, 118]. GBS isolates with MLS resistance caused by *erm*(B) and *erm*A predominate in most reports in Canada and other parts of the Western Hemisphere [92, 119], France [88, 89, 120], Spain [86, 121], and Taiwan [87] In both GBS and GCS, the highest proportion of isolates carrying *mef*(A) have been reported from Taiwan (37 %) and Finland (95 %) [95, 96].

In addition to familiar macrolide resistance determinants including *erm*(B), *erm*(A), and *mef*(A), a more rare mechanism has also been shown to cause resistance to macrolides. This mechanism involves mutations in the *S. pyogenes* ribosomal protein L4 and in positions 2611 and 2058 of the 23S rRNA encoding gene. Mutations in positions 2611 and 2058 of the 23S rRNA gene cause resistance to clindamycin and streptogramin B (quinupristin). Additionally, a mutation at position 2058 confers resistance to telithromycin [122–124].

The presence of a putative novel efflux system associated with *erm*(TR) in *S. pyogenes* has also been found [125]. Another gene, *mre*A, which was originally described as a macrolide efflux gene in *S. agalactiae* [107], encodes riboflavin kinase and is also found in erythromycin-susceptible GBS strains [126]. Strains with two different macrolide resistance mechanisms (*mef* and *erm*) within a single bacterial cell may coexist among GAS and more commonly among GBS [88, 94, 108, 126–129]. The phenotype of these strains is usually determined by the *erm* gene.

Resistance gene *erm*(B) has been shown to be either plasmid or chromosome associated in streptococci [105]. In earlier studies conjugative plasmids with erythromycin resistance determinants were found from group A, B, C, and G streptococci and were shown to transfer by conjugation between streptococcal species [130]. Transfer was also seen by transduction among VGS [131, 132]. However, most antibiotic resistance genes in streptococci are currently thought to be chromosomal in origin. Beta-hemolytic streptococci belonging to groups A, B, C, and G have been shown to transfer their chromosomal macrolide resistance determinants by conjugation [126, 133–135]. A composite chromosomal conjugative element, Tn3701, encoding resistance to erythromycin and tetracycline has been described in GAS [136]. Within this element the resistance genes are carried by a Tn*916*-like transposon. The presence of Tn916-Tn1545-like conjugative transposons carrying *erm*(B) and *tet*(M) has been verified, and an association of chromosomal *erm*(A) with *tet*(O) has been noted among GAS [137, 138]. An unusual chimeric genetic element containing DNA identical to *Tn*1207.1, a transposable element carrying *mef*(A) in macrolide-resistant *S. pneumoniae*, has also been found in different GAS strains. The mechanism of horizontal transfer in these strains was suggested to be transduction [139]. Furthermore, analysis of the genetic environments of the *mef*(A) and *erm*(B) genes by Southern blot experiments have indicated a remarkable heterogeneity of genetic elements carrying these genes, particularly *erm*(B). This suggests that different mobile elements can be recruited into the chromosomes of the circulating GAS population and that genetic rearrangement may also occur after a strain has acquired the resistance determinant [138]. Macrolide resistance mechanisms differ among streptococcal Lancefield groups and geographical area. New gene sequences demonstrating resistance continue to evolve.

4.1.3 Epidemiology of Macrolide-Resistant Beta-Hemolytic Streptococci

A large variety of clones of GAS are drug resistant [113, 138, 140, 141]. Increased resistance rates may be caused by clonal spread of resistant strains and by horizontal transfer of resistance determinants among the circulating microbial population. Macrolide-resistant GAS of the same clone have been found from different countries and even different continents [140]. Same clones have been found among susceptible isolates as well, but in general the heterogeneity of GAS clones seems to be lower among resistant than susceptible isolates [138, 140, 141]. Single clones of GAS with a macrolide-resistant determinant may become predominant or cause outbreaks both regionally and nationwide [128, 142–144]. For example, in 1994, 82 % of erythromycin-resistant GAS isolates collected in Finland expressed the M-phenotype. Although multiple clones were found among these isolates, increased regional resistance rates were clearly associated to T4M4 serotype with *mef*(A) [112, 134]. In the United States, isolates carrying *mef*(A) of an emm6 (M6 serotype) clone caused an epidemic among schoolchildren in 2001. In April–May of 2002, this serotype was not found in the same region when the resistance rate was high. Thirty-five percent of isolates were resistant to erythromycin, with an emm75 (M75 serotype) clone predominating [114, 143]. Cresti et al. found that a steady increase of erythromycin-resistant GAS from 9 % in 1992 to 53 % in 1997 in an area in central Italy was caused by an increase of the proportion of strains carrying inducible and constitutive *erm*(B) and *erm*(TR) determinants. These strains were of multiclonal origin. Correlation of the

erythromycin-resistant GAS clones to the heterogeneity of genetic elements carrying the *erm*(B) indicated identical genetic environments of *erm*(B) in clonally unrelated strains, but on the other hand also considerable diversity of these genetic elements both among clonally unrelated and within clonally identical strains [138]. The increase of resistance includes a complex genetic interaction within circulating streptococcal population and may be between streptococci and other species [145]. Macrolide consumption, differing immunities, and other host factors of populations may also contribute to this interplay and spread of resistance determinants and resistant clones [146–148].

4.1.4 Resistance to Clindamycin

Clindamycin resistance is almost exclusively related to MLS resistance found in beta-hemolytic streptococci. It is thus mediated by *erm* genes. In some studies, among GBS, the frequency of clindamycin resistance exceeds that of macrolide resistance suggesting another mechanism of clindamycin resistance may exists [86, 93, 149]. In one isolate of GBS from Canada, the *linB* gene encoding a lincosamide-inactivating nucleotidyltransferase was found [92]. This gene has previously been identified in *Enterococcus faecium*.

Both constitutive and inducible clindamycin resistances have increased in recent years, especially in group A and B streptococci [150]. Inducible clindamycin resistance in beta-hemolytic streptococci remains an under-recognized phenomenon of unknown clinical significance. Lewis et al. evaluated inducible clindamycin resistance through an animal model and retrospective patient chart review. In the animal model, inducible resistance impaired killing of beta-hemolytic streptococci and bacterial load by 48 h were similar to the control isolated that were constitutively clindamycin resistant. Eight of these cases resulted in both microbiological and clinical failure [151]. Thus, inducible and constitutive resistance should be detected during routine antimicrobial susceptibility testing.

European surveillance data demonstrated a clindamycin MIC_{50} and MIC_{90} of ≤0.25 mg/L with 91.9 % susceptible isolates, 0.5 % intermediate, and 7.6 % resistant [29] (Table 50.1). US data suggests a similar MIC_{50} of ≤0.25 mg/L and a MIC_{90} of >2 mg/L. Eighty percent of the 960 beta-hemolytic streptococci isolates were susceptible. Susceptibility rates in other commonly used macrolides tend to be lower [30].

4.1.5 Resistance to Erythromycin

Increased levels of erythromycin resistance in GAS have been reported in Europe. The mechanisms of erythromycin resistance in *S. pyogenes* include target site modification and active drug efflux. Target site modification is mediated by an erythromycin resistance methylase, encoded by an *erm* gene, which reduces binding of macrolide, lincosamide, and streptogramin B (MLS_B) antibiotics to the target site in the 50S ribosomal subunit. Resistance in other beta-hemolytic streptococci groups can also be seen with recent surveillance data suggesting MIC_{50} and MIC_{90} values of ≤0.25 mg/L and >2 mg/L, respectively [29] (Table 50.1). MIC values in the US deviate from those found in other countries. Recent data report MIC_{50} values of ≤0.12 mg/L and MIC_{90} of >16 mg/L. Resistance is high with 60 % of isolates susceptible to erythromycin [30].

4.1.6 Resistance to Telithromycin

Resistance to telithromycin is currently uncommonly (<6 %) rare [152]. Few resistant strains have been isolated to date. This is due to either a constitutively expressed *erm*(B) gene or an adenine to guanine mutation at position 2058 [43, 124].

4.2 Resistance to Tetracycline

Resistance to tetracycline is common among beta-hemolytic streptococci, especially among macrolide-resistant strains. Resistance is caused by tetracycline resistance ribosomal protection proteins encoded by *tet*(M) or *tet*(O). The *tet*(M) gene is the most widely distributed and is found in GAS often in linkage with *erm*(B) on mobile elements [137]. In GBS, it is found both among macrolide-susceptible and macrolide-resistant organisms with all different macrolide resistance determinants [127]. *Tet*(O) has been found in GAS carrying chromosomal *erm*(A) or *mef*(A), and it can transfer with or without *erm*(A) and with *mef*(A) [137]. Surveillance data shows a tetracycline MIC_{50} of 4 mg/L and MIC_{90} of >8 mg/L. Of 2981 beta-hemolytic streptococci isolates tested, approximately 50 % were susceptible and 50 % resistant [29] (Table 50.1).

5 Clinical Significance of Resistance

5.1 Infections Caused by VGS

VGS are a part of the normal flora and can be found in the oropharyngeal, urogenital, and gastrointestinal microbiota. They are generally considered to have a low pathogenic potential and, however, can cause disease in immunocompromised patients as well as patients with cardiac abnormalities. As antibiotic resistance continues to rise, VGS infections are associated with significant morbidity and mortality [4]. Though other infections have been noted, this review will focus on the two predominate clinical presentations of VGS infections: infective endocarditis (IE) and neutropenic fever. It will also highlight rising challenges associated with resistance in treatment of cystic fibrosis.

5.1.1 Infective Endocarditis

Infective endocarditis most frequently presents acutely, and complete history and physical examination should be performed for source identification. The diagnosis is based off a combination of factors and may be straight forward with culture-positive endocarditis. Viridans streptococci are a common causative agent. Among 2781 patients with infective endocarditis, VGS was the underlying pathogen in 17 % of patients [153]. Several different VGS species have been reported to cause infective endocarditis, a life-threatening condition [154]. Of the VGS, *S. bovis*, *S. sanguis*, *S. mitis*, *S. oralis*, and *S. gordonii* remain some of the most common species isolated from blood or infected valves in both adults and children [66, 155, 156]. Infective endocarditis caused by S. *mitis* is a relatively common event and is empirically treated with penicillin or macrolides in immunologically stable patients. The etiology of infective endocarditis varies according to the age of the patient and the clinical nature of the disease [154, 155, 157, 158].

In adults, the epidemiology of IE caused by VGS is changing. From 1987 to 2009, the mean age of patients with native-valve endocarditis increased from 38 ± 22 years to 60 ± 16 years ($P < 0.001$). The proportion of IE cases without predisposed heart disease has progressively increased from 25 % to 67 % ($P < 0.001$) [159]. Other risk factors include dental infection as well as injection drug use, although VGS does not play a significant role in IE among intravenous drug users [155]. Although less virulent than other microorganisms, VGS continues to be the predominant cause of community-acquired IE. VGS and *Streptococcus bovis* account for 40–60 % of native-valve endocarditis in the community. In children, VGS was noted as the most common cause of IE, accountable for 32–43 % of cases [4].

Historically VGS were susceptible to many commonly administered antimicrobials including beta-lactams, macrolides, tetracycline, and aminoglycosides. As noted in the section above, there has been an increase in resistance including multiple-drug-resistant strains of *S. mitis* among patients with bacteremia. As with other pathogens, drug resistance in VGS is most clinically prevalent in patients with immunocompromised conditions. This is likely a result of exposure to hospital settings where resistant organisms are present or patients have increased exposure to multiple courses of antibiotics.

For treatment and prophylaxis, penicillin is an important antibiotic in treating VGS infections though resistance continues to present a clinical concern. A recent survey of children with Gram-positive cocci isolated in North America showed that of 182 VGS, 28.6 % were nonsusceptible to penicillin, 4.9 % of which were fully resistant [4].

Treatment recommendations depend on susceptibility patterns. The treatment recommendation per The American Heart Association (AHA) guidelines for adults with native-valve infective endocarditis caused by highly penicillin-susceptible (MIC ≤ 0.12 mg/L) VGS is intravenous penicillin G. Among the elderly, penicillin or ceftriaxone for 4 weeks is preferred. Uncomplicated episodes can also use gentamicin in combination with penicillin or ceftriaxone for 2 weeks. Patients with penicillin allergies can usually be treated with ceftriaxone; however, if patients experience immediate hypersensitivity, vancomycin for 4 weeks may be considered. Susceptibility testing of pathogens as well as repeat cultures is recommended [153].

Intermediate susceptibility is defined as MIC >0.12 mg/L and ≤0.5 mg/L. AHA guidelines recommend the same treatment as penicillin-susceptible *Streptococcus* with the addition of gentamicin in the first 2 weeks of the 4-week course. This combination has been demonstrated to be synergistic against VGS [160]; however, higher doses of penicillin and longer treatment times (4–6 weeks) are recommended [66, 160, 161]. As before, vancomycin should be considered for penicillin-allergic patients. Bacterial eradication rates greater than 98 % can be anticipated in patients who complete appropriate therapy [162]. Fully resistant strains have MICs >0.5 mg/L and recommended treatment is intravenous gentamicin for 4–6 weeks plus intravenous penicillin (4–6 weeks), ampicillin (4–6 weeks), or vancomycin (6 weeks) [153].

In recent years, beta-lactam and macrolide resistance rates among clinically isolated VGS have increased. Antimicrobial susceptibility testing for beta-lactams and macrolides suggest that mutated PBP genes in combination with the acquisition of certain macrolide resistance genes may underlie a broader resistance phenotype [41]. This is a challenge because there is limited clinical data to support alternative regimens to optimize endocarditis treatment for penicillin-resistant VGS. However, options are available and antidotal data is presented below.

The majority of VGS strains tested are susceptible to vancomycin [66, 160]. There are reports where vancomycin alone and vancomycin used in combination with ceftriaxone and gentamicin have been successfully used for treatment of endocarditis caused by resistant VGS [163, 164]. Treatment of penicillin-resistant VGS can present a more challenging clinical picture. One case showed that vancomycin treatment alone or in combination with cefotaxime and gentamicin did not completely eradicate a highly penicillin-resistant *S. mitis* strain in a human immunodeficiency virus positive man with endocarditis [165]. Vancomycin and gentamicin in combination also failed to cure endocarditis caused by highly penicillin-resistant *S. sanguis* in a 65-year-old woman with multiple medical problems. [166]. Though case reports tend to be biased toward negative outcomes, these data do demonstrate the need for new therapeutic options.

Additional antibiotics with demonstrated in vitro activity against VGS isolates include levofloxacin, moxifloxacin, quinupristin/dalfopristin, linezolid, and daptomycin. Though rare, in vitro resistance has been documented for these

antimicrobials as well. As with other antibiotics, culture and susceptibility should guide treatment. Limited clinical outcome data exists for some of the other, newer antimicrobials though typical resistance mechanisms will play a role in these antibiotics as potential treatment options. Linezolid-resistant strains are uncommon and it has been used successfully to treat endocarditis caused by vancomycin-resistant enterococci and methicillin-resistant staphylococci [71, 167]. However, oxazolinones are bacteriostatic antibiotics, and as a result their usage for treatment of infective endocarditis may be compromised [70]. Currently there is no information supporting the efficacy of linezolid in the treatment of endocarditis caused by VGS [38].

One case report of an immunocompromised patient with infective endocarditis revealed multidrug-resistant (MDR) VGS as the causative pathogen. Recurrent cycles of therapy to treat bacterial infections throughout the patients' lifecycle could have resulted in the penicillin, cephalosporin, carbapenem, macrolide, and fluoroquinolone-resistant *S. mitis*. Due to multiple complications, the patient died from pulmonary thromboembolism [41]. Another case report of a levofloxacin-resistant *S. mitis* manifested into endogenous endophthalmitis in the setting of mitral valve endocarditis as the presumed source of infection. The patient fully recovered after 6 weeks of intravenous ceftriaxone therapy based on the 2005 treatment guidelines of the AHA for patients with native-valve endocarditis caused by viridans streptococcal isolates with a penicillin MIC of 0.12–0.5 mg/L [168].

Increasing numbers of penicillin-resistant VGS strains among normal microbiota may also challenge prophylactic treatment of infective endocarditis. Amoxicillin or ampicillin is the current recommendation for endocarditis prophylaxis [66]. The prophylactic use of these antibiotics may select for penicillin-resistant VGS strains among normal microbiota, and these strains may be able to cause infective endocarditis [165]. Clindamycin is recommended for prophylaxis for patients allergic to penicillin [66]; however, it should be noted that use of macrolides can also select for clindamycin-resistant strains among streptococci in the normal flora. Telithromycin is very active against VGS strains in the normal microbiota. Despite resistance patterns, penicillin continues to serve as a widely used classical antimicrobial agent in the treatment of infective endocarditis. In patients with infective endocarditis, among other diseases, continuous surveillance of VGS isolates is warranted and can help guide appropriate treatment.

5.1.2 Neutropenic Fever

Neutropenic fever is defined as an absolute neutrophil count of less than 1500 cells/μL with a single oral temperature of >38.3 °C (101 °F) or a temperature of >38.0 °C (100.4 °F) sustained for >1 h [169]. There have been changes in the etiology of bacteremia in febrile neutropenic patients, and infections are an important cause of morbidity and mortality among this population. Gram-negative pathogens was historically the primary cause; however, up to 70 % of bacteremia cases in neutropenic patients are now associated with Gram-positive bacteria [170–173]. Bacteremia is identified in 10–27 % of febrile neutropenic patients with hematologic malignancies, and 18–29 % of the bacteremia is caused by viridans streptococci. Possible reasons for this shift are use of prophylactic antibiotics, increased use of intravenous catheters, and aggressive chemotherapies resulting in prolonged neutropenia and mucositis [171, 172, 174, 175]. VGS are an important cause of bacteremia among neutropenic patients. One study assessed 528 episodes of bloodstream infections, 15 % of which were associated with neutropenia. Thirty-five percent of the blood stream infections were caused by Gram-positive pathogens, with VGS being the most frequent causative pathogen at 22 % [176]. The proportion of VGS as a cause of bacteremia ranges between 3 % and 30 % [56, 172, 173, 177–179]. *S. mitis* followed by *S. oralis* or *S. sanguis* are the most commonly isolated species [173, 179–182]. Bacteremia caused by VGS strains often originate from the oral mucosa [183, 184]. Predisposing factors for VGS infections are severe and prolonged neutropenia, prophylactic antibiotic treatments with quinolones or trimethoprim-sulfamethoxazole, mucositis, and treatment of chemotherapy-induced gastritis with antacids or histamine type 2 antagonists [174, 182]. VGS infections can be rather asymptomatic, fever being the most common symptom [174, 181, 185–187]. Eighteen to 39 % of the patients with VGS infections develop serious complications, including septic shock, acute respiratory distress syndrome (ARDS), or both. Viridans streptococci are currently one of the most common pathogens in both adults and children, and bacteremia caused by this bacteria can result in death in up to 20 % of patients [188].

Multiple guidelines exist to combat neutropenic fever. Guidelines continue to be revised based on continued clinical evidence, experience, and advances in drug development. The Infectious Diseases Society of America's (IDSA) most recent update in recommendations in treatment of patients with fever and neutropenia discuss risk assessment. Once fever is detected, risk and severity infection should be assessed in order to help guide type, venue, and duration of empirical treatment. Updated European guidelines review the importance of appropriate initial antibiotic therapy in febrile neutropenia to minimize the collateral damage associated with antibiotic overuse and the further selection of drug-resistant pathogens. The guidelines suggest that infection control procedures and new antibiotic regimens based on local epidemiology, risk factors, escalation and de-escalation approaches, duration of empiric therapy, nonconventional therapies against MDR, and other bacterial management issues are vital to optimize antibiotic choice. For the purposes of this chapter, we will focus on IDSA-based recommendations.

Low-risk patients are defined as those having neutropenia for less than 7 days and no or few comorbid conditions. Oral empiric therapy is warranted in this population. In both low- and high-risk patients, empiric therapy should appropriately cover both Gram-positive and Gram-negative bacteria with special attention to VGS and *Pseudomonas aeruginosa* strains because infection may progress rapidly. Ciprofloxacin plus amoxicillin-clavulanate in combination is the treatment of choice, and antibiotic prophylactic treatment is not recommended in low-risk patients [189].

Per IDSA guidance, risk is affected by duration of neutropenia. High-risk is defined as neutropenia for greater than 7 days in duration with an absolute neutrophil count of ≤100 cells/mm [3] and/or significant comorbid conditions. For these patients, hospitalization and intravenous empirical treatment may be necessary. Preferred agents include an antipseudomonal beta-lactam, carbapenem, or piperacillin-tazobactam, although initiation of monotherapy with an antipseudomonal beta-lactam agent, such as cefepime, meropenem, imipenem-cilastatin, or piperacillin-tazobactam, may be used. Ceftazidime monotherapy has also been shown to be effective and continues to be used at some cancer centers. However, many experts avoid ceftazidime monotherapy because of rising resistance rates among Gram-negative bacteria and its limited activity against Gram-positive bacteria, such as streptococci, compared with newer alternatives [169]. Glycopeptides should be avoided first-line because of limited Gram-negative coverage, and empirical addition of vancomycin did not give extra benefit when compared to piperacillin-tazobactam therapy [190]. Regardless, the addition of this agent could benefit those with suspected catheter-related infection, skin or soft tissue infection, pneumonia, or hemodynamic instability [169].

For patients with methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), extended-spectrum b-lactamase (ESBL)-producing gram-negative bacteria, and carbapenemase-producing organisms, including *Klebsiella pneumoniae* carbapenemase (KPC), other agents may be added for adequate coverage. Fluoroquinolone prophylaxis should be considered for high-risk patients [191]. In multiple institutions, the use of quinolone prophylaxis in high-risk neutropenic patients is considered standard of care but the rapid development of resistance on therapy is a concern. Garnica et al. analyzed outcomes associated with quinolone prophylaxis and observed fewer episodes of febrile neutropenia and bacteremia, shorter duration of antibiotic therapy and hospitalization, as well as increased use of carbapenems and higher rates of quinolone resistance [192]. Although IDSA, among other treatment guidelines, recommend beta-lactam therapy as drug of choice, it is uncertain whether these practice guidelines can be applied to both adults and children due to potential differences in complication frequencies and antibiotic susceptibilities.

Han et al. compared clinical characteristics and antibiotic susceptibility patterns in patients with bacteremia caused by VGS in febrile neutropenic adults and children. Among the 202 episodes of viridans streptococcal bacteremia in adults and children, there were 20.8 % of cases with severe complications including 6.9 % identified deaths. Approximately 13 % of these episodes were attributable to bacteremia caused by VGS. Susceptibility testing results demonstrated that 80 % of the 199 isolates were susceptible to cefepime, and there was no association with patient age and pathogen susceptibility. This data suggests that it may not be necessary to adjust treatment guidelines between adults and children. In pediatric cancer patients, VGS strains are predominantly *S. mitis* and *S. oralis. S. mitis is* the most frequent VGS species causing bacteremia and is also most likely to be penicillin resistant [188].

Antimicrobial resistance in streptococci is rising. Studies have shown penicillin resistance is greater than 50 % and imipenem resistance is up to 25 % of *Streptococcus* from bone marrow transplant recipients [171]. As a result, some institutions may include vancomycin in the initial empiric treatment of febrile neutropenia. Studies have shown increased mortality in patients with viridans streptococcal bacteremia when vancomycin was not included in the initial empiric regimen [173]. More recently, Shelburne et al. developed a clinical prediction model for beta-lactam resistance in VGS causing bloodstream infection. The study validates use of Gram-positive spectrum antibiotics, including vancomycin, for empiric therapy of febrile neutropenia. Several assumptions were made including the definition of penicillin non-susceptibility, an MIC value ≥2 mg/L, increased risk of shock syndrome, and mortality. It was also assumed that vancomycin administered at onset of fever in neutropenic patients with VGS bacteremia will improve outcomes. Beta-lactam use in the prior 30 days, beta-lactam prophylaxis, and inpatient status at onset of febrile neutropenia correlated with a predicted MIC value ≥2 mg/L and non-susceptibility. It was determined in this one study that glycopeptides can be safely deferred until documentation of a resistant Gram-positive bacterial infection is made, despite IDSA guidelines stricter criteria [193].

5.1.3 Cystic Fibrosis

Cystic fibrosis (CF) is an inherited condition which affects the cells that produce mucous, sweat, and digestive secretions. Secretions become thick and plug passageways in the lungs and sinuses. Bacteria can adhere to this thick mucus and result in sinusitis, bronchitis, and pneumonia. Although CF has no cure, antibiotics are a staple in the treatment and prevention of lung infections. Evidence suggests S. *anginosus*, among other VGS organisms, may be important pathogens in this population. Recent studies have compared resistance patterns in CF and non-CF patient populations and have shown that both penicillin- and erythromycin-resistant VGS isolates in fibrotic

patients have reached 38.4 % and 87.9 %, respectively. Among CF isolates, resistance rates are increasing as patients are living longer and continuously face antibiotic exposure. Moreover, as the physiology of the lung is affected in these patients, so is drug penetration into their lungs. This may result in suboptimal drug concentrations at the site of infection, leading to increased selection of resistance [194].

5.2 Infections Caused by Beta-Hemolytic Streptococci

Beta-hemolytic streptococci are causative of a wide-range of diseases, both invasive and noninvasive. Some of these include streptococcal pharyngitis, neonatal sepsis, endocarditis, meningitis, and urinary tract infections. For the purpose of this review, we will focus on two clinically relevant presentations: pharyngitis and neonatal sepsis.

5.2.1 Pharyngitis

Severity of pharyngitis may vary but is traditionally defined by discomfort and pain in the throat, making it difficult to swallow. It is caused by swelling in the pharynx and may be bacterial in nature. Five to 15 % of pharyngitis cases are caused by GAS [195]. Penicillin is the drug of choice for treatment of streptococcal infections and macrolides are considered as alternative treatment for patients allergic to penicillin. Susceptibility testing should be used to confirm treatment choice and repeated cultures should be monitored for resistance development while on therapy.

Treatment eradication rates are associated with pathogen susceptibility. Specifically, studies have demonstrated the eradication rate is only 38–60 % when macrolides are used to treat macrolide-resistant strains in comparison to an eradication rate of 80–92 % when these agents are used against macrolide-susceptible organisms. [196–198]. The use of a macrolides for the treatment of macrolide-resistant GAS pharyngitis is also associated with a significantly lower clinical cure rate compared to that achieved with amoxicillin, amoxicillin-clavulanate, or cefaclor [198]. Again, emphasizing the importance of culture and susceptibility results in treatment selection. A recent study has also shown *erm* and *emm* 90 to be important resistance genes in invasive GAS [199]. Few resistant strains exist and the knowledge of resistance and resistance mechanisms is important. For example, use of clindamycin against an erythromycin-resistant isolate requires knowledge of the result of both the susceptibility testing and the determination of the macrolide resistance phenotype for a given isolate, because clindamycin should not be used to treat isolates with the MLSb-phenotype [106].

There has been debate of the remarkable stability of penicillin susceptibility in GAS and other beta-hemolytic streptococci and whether these high susceptibility rates will remain stable. Resistance to penicillin occurs in related species, such as *S. pneumoniae*, VGS, and enterococci at high rates. Reasons for the continued high susceptibility rates to penicillin in GAS include the inefficient mechanisms for genetic transfer in GAS, barriers to DNA uptake and replication, and the findings that altered PBPs expressed by penicillin-resistant laboratory mutants of GAS have defective cell-wall biosynthesis thus decreasing the viability of the penicillin-resistant organism [200, 201].

Beta-hemolytic streptococci, especially GAS and GBS, may cause serious infections and alternatives to macrolides are scarce. Limiting use of these agents should be encouraged [202, 203]. The selective pressure caused by the amount of macrolides used in the community has been shown to correlate to the level of macrolide resistance in GAS in the community, and reduction of use of these agents has been shown to lead in reduction of macrolide resistance [146–148, 202–204]. Macrolide-resistant GAS strains remain susceptible to telithromycin and therefore could be a better treatment option.

5.2.2 Neonatal Sepsis

GBS is the leading cause of neonatal infections and intrapartum antibiotic prophylaxis. Per guidelines, all pregnant women in the United States are screened and are prophylactically treated. For those at risk, intrapartum penicillin therapy is recommended, with ampicillin, clindamycin, erythromycin, and vancomycin as acceptable alternative treatments, with penicillin G being the drug of choice [205]. Previously considered a genitourinary pathogen, it has emerged as a non-nosocomial opportunistic pathogen causing serious clinical complications including bloodstream infection, endocarditis, and CNS infections. Sunkara et al. evaluated the epidemiology of GBS in nonpregnant adults. It was found that GBS is associated with younger age, higher incidence of beta-lactam allergy, and independently linked to immunosuppression. GBS are susceptible to commonly used antimicrobials including penicillins and cephalosporins and therefore are not associated with a delay in initiation of appropriate antimicrobial therapy. Resistance rates in second-line treatment options, including macrolides and clindamycin, continue to rise and should be closely monitored [206].

6 Conclusion

In this review, we discussed key global resistance data, including incidence and mechanisms of resistance. Beta-lactam resistance is primarily mediated by point mutations in penicillin-binding proteins (PBPs) and presents clinical challenges due to its role in treatment of infective endocarditis and neutropenic fever. Common macrolide resistance genes include *erm* and *mef*. Resistance with this class of antibiotics may be responsible for a variety of infections including phar-

yngitis and neonatal sepsis. Both resistance genes and mechanisms continue to evolve, and new sequences have been discovered in recent years. Antibiotic overuse, inappropriate antibiotic use, and delayed antibiotic administration are contributing factors to the rise in antibiotic resistance. Clinical studies and drug development continue to provide guidance and new treatment options; however, use of local antibiograms, implementation of infection control procedures, and antimicrobial stewardship are critical in treating patients with invasive streptococcal infections including VGS and beta-hemolytic streptococci.

Enterococcal Infections in Adults

51

Katherine Reyes, Marcus Zervos, and Jisha John

1 Introduction

Enterococci (once called group D streptococci) were first described as human pathogens in 1899, historically thought to be endogenously acquired pathogens from human intestinal flora. *Enterococcus faecalis* is the most common pathogen, while *Enterococcus faecium* has become prevalent in hospital-acquired infections. Enterococci have resurfaced with reports of changes in epidemiology, treatment failures, and increasing complexity in antimicrobial resistance patterns. Enterococci have a variety of intrinsic antibiotic resistances and have shown the ability to acquire new resistance genes and mutations. Vancomycin resistance in enterococci is predominantly a healthcare-associated phenomenon. Urinary tract infections and bacteremia are the most common infections caused by enterococci, while endocarditis is the most serious. Enterococci are also commonly found in intra-abdominal, pelvic, and soft tissue infections, often part of a mixed flora. Less common infections are meningitis, osteomyelitis, and septic arthritis. Immunosuppression, long-term colonization, the ability to disseminate widely between patients, and the capacity to form biofilms have made enterococci major pathogens in hospitals, prompting enhanced efforts to identify optimal infection control measures and best therapeutic approaches to improve outcomes.

2 Microbiology

Enterococci are gram-positive, facultative anaerobic cocci that are morphologically similar to streptococci, appearing on blood agar plates as gray colonies and are usually alpha-hemolytic (Fig. 51.1). Their ability to hydrolyze pyrrolidonyl-β-naphthylamide distinguishes them from certain streptococci species. For identification of newer species of enterococci, a combination of conventional biochemical tests and evaluation of DNA content is used. Twenty-three enterococcal species have been identified [1]. Sixty percent of isolates are *E. faecalis*, and 20 % are *E. faecium*. The others constitute less than 5 % of enterococcal infections, including *E. gallinarum*, *E. casseliflavus*, *E. avium*, *E. cecorum*, *E. durans*, *E. hirae*, *E. malodoratus*, *E. mundtii*, *E. pseudoavium*, and *E. raffinosus.*

Identification of enterococci to the species level is important because of resistant strains and the need to define appropriate therapy, not just for vancomycin-resistant enterococci (VRE) but also for vancomycin-susceptible enterococci (VSE). Most *E. faecalis* are susceptible to ampicillin but resistant to quinupristin-dalfopristin. Most *E. faecium* are resistant to ampicillin, susceptible to quinupristin-dalfopristin, and resistant to high levels of vancomycin. Newer tools to differentiate *E. faecalis* from other enterococcus species in blood samples include the *E. faecalis*/OE PNA FISH probe with claims of 100 % sensitivity and specificity over 90 min, and in a study, it was shown to provide the species information 2.3 days earlier than traditional phenotypic methods [2]. Pulsed-field gel electrophoresis and spa typing are used for delineation of the relatedness of strains, and polymerase chain reaction methods are used for evaluation of the possibility of gene dissemination.

3 Epidemiology

Enterococci are colonizers and can survive for long periods of time in the environment. Vancomycin-resistant strains have been endemic in large hospitals with epidemics reported as well. Risk factors for colonization with VRE include antibiotic use during admission, surgery, dialysis, and discharge to another healthcare facility [3]. A systematic review showed a model-estimated median time of 26 weeks to clear colonization with VRE [4]. Asymptomatic colonization of the gastrointestinal tract is more common than is clinically recognized infection by a ratio of 10:1.

The National Healthcare Safety Network [5, 6] ranks enterococci as the second most common organism (after staphylococci) isolated from hospital infections. *E. faecalis* remains most common, but the incidence of *E. faecium* has increased. Hospitalization rates for VRE infection doubled from 2003 to 2006 [7]. The most important risk factor for VRE infection is prior antimicrobial use, with vancomycin use being both an independent risk for infection and mortality in patients with enterococcal bacteremia. Other risk factors for VRE infection include severity of illness, admission to the intensive care unit, prolonged hospital stay, exposure to other patients and contaminated surfaces with VRE, presence of invasive device, and residence in long-term care facilities. A single-institution study showed that each intensive care unit day increased the risk of acquiring VRE *faecium* by a factor of 1.03, with incidence of 21.9 newly acquired VRE cases per 1000 patient days [8]. VRE *faecalis* has been shown to occur in the community, with risk factors including non-home residence, chronic skin ulcers, previous invasive procedures, exposure to antibiotics, and presence of indwelling devices [9].

The epidemiology of spread of antimicrobial resistance is complex. It includes not only patient-related risks but also clonal transmission of strains between patients, and plasmid and transposon dissemination of resistance determinants. VRE has been shown to co-colonize or co-infect patients with methicillin-resistant *Staphylococcus aureus* [10]. Though VRE *faecalis* are relatively uncommon, isolates containing Inc18 plasmids and the vancomycin resistance transposon Tn1549 have been identified as precursors for vancomycin resistance in *S. aureus.*

4 Pathogenesis and Resistance Mechanisms

Known pathogenic determinants for enterococci include aggregation substances, cytolysis, collagen-binding proteins, *E. faecalis* endocarditis antigen, enterococcal surface protein, gelatinase, hyaluronidase, and the stress response protein G1s24 [11]. High-level gentamicin resistance (minimum inhibitory concentrations (MICs) of 600–2000 mg/ml) in enterococci is usually due to the presence of the "bifunctional" aminoglycoside-modifying enzyme [12]. Vancomycin resistance, in turn, is due to the synthesis of modified peptidoglycan precursors that have decreased affinity for vancomycin [13]. There are five major types of vancomycin resistance [14] in enterococci. VanA is the most predominant strain in the United States, Europe, and Korea. VanB retains susceptibility to teicoplanin and is predominant in Singapore and Australia [15]. VanD has low-level resistance to vancomycin and may be susceptible or intermediate resistance to teicoplanin. VanD and vanA have the same clinical and microbiological characteristics and that vanD isolates may convert to vanA phenotype after exposure to glycosides [16]. Linezolid resistance has been associated with G2576T mutations [17]. Quinupristin-dalfopristin resistance has been linked to agricultural use of streptogramin [18]. Daptomycin-non-susceptible enterococci have been associated with prior exposure to daptomycin and vancomycin resistance [19]. Infections due to enterococcal strains that demonstrate in vitro susceptibility to daptomycin but fail daptomycin therapy have been associated with vancomycin heteroresistance, cardiolipin synthase mutation, and liaF codon deletions [20–22].

5 Clinical Syndromes

5.1 Urinary Tract Infections

Urinary tract infections (UTIs) are the most common infections caused by enterococci and are usually associated with urinary catheters [23]. Among catheter-associated UTIs reported to the National Healthcare Safety Network, *E. faecalis* ranks fifth, while *E. faecium* ranks tenth among frequent pathogens [6]. It is necessary to distinguish colonization from infection, and lower tract from upper tract UTI. Diagnosis is made in the presence of signs and symptoms of infection and concurrent findings in urinalysis and quantitative urine culture. Enterococcal UTIs not accompanied by bacteremia generally require only single drug therapy, with oral agents when possible. If the organism is susceptible, amoxicillin is the drug of choice. Other oral agents include nitrofurantoin and fosfomycin which have intrinsic activity against most urinary enterococcal isolates including VRE strains [24]. Vancomycin can be used if the organism is ampicillin resistant. Linezolid or daptomycin are alternatives if the enterococcus is resistant to both ampicillin and vancomycin, and in the presence of upper UTI or bacteremia [25]. Tigecycline does not achieve good urinary concentrations and should not be used. A quinolone with a low MIC for a particular isolate may be considered as an alternative. The susceptibility of isolates to chosen agents must be determined.

5.2 Meningitis

Infections of the central nervous system, due to enterococci, are rare and are associated with older age, serious underlying diseases, presence of other sites of enterococcal infection and colonization, and indwelling central nervous system devices. Fever and changes in mental status are common presenting symptoms. The cerebrospinal fluid usually demonstrates low-grade neutrophilic pleocytosis, mild hypoglycorrhachia, elevated protein, and gram-positive stain and cultures [26]. Combination therapy is often used to achieve maximal bactericidal activity [27]. Intraventricular and intrathecal therapy are also commonly used. Antimicrobials used include penicillin or ampicillin, chloramphenicol, quinupristin-dalfopristin, daptomycin, and linezolid. Gentamicin and rifampin are used in combination regimens. Removal of an indwelling central nervous system device if present is recommended.

5.3 Intra-abdominal Infections

Enterococci when present in intra-abdominal infections are usually part of a polymicrobial infection, in which coverage for enteric bacteria and anaerobes must also be empirically administered. It used to be not necessary to routinely provide antimicrobial coverage for enterococci in the setting of intra-abdominal infection where more virulent organisms are present; however, due to increase in nosocomial infections and complexity of patients, anti-enterococcal therapy is now considered for hepatobiliary or pancreatic infections, immunosuppressed patients, and those at risk for enterococcal bacteremia. VRE enteritis after severe acute pancreatitis has been reported [28].

5.4 Skin and Soft Tissue Infections

The presence of enterococci in soft tissue cultures presents a challenge in differentiating colonization from infection. Co-colonization and/or co-infection of VRE and methicillin-resistant *S. aureus* are reported from chronic wounds, in which prior antimicrobial use is the most common risk factor. The National Healthcare Safety Network reports enterococci to cause one-third of surgical site infections after transplant surgery [6].

5.5 Bacteremia and Infective Endocarditis

Enterococcal bloodstream infections (BSI) rank second among healthcare-associated BSI [5] and are commonly associated with intravascular catheters and other devices. Also common sources of enterococcal bacteremia are hepatobiliary and genitourinary tract infections and to a lesser degree skin and soft tissue infections. The clinical presentation of enterococcal BSI varies depending on the source, and if a patient presents with shock, a workup for co-infection with more virulent organisms or a deep-seated infection source should be made. *E. faecalis* was previously a much more common BSI pathogen than *E. faecium*; however, *E. faecium* is now isolated at a rate approaching that of *E. faecalis*, with a ratio of 1 *E. faecium* for every 1.8 *E. faecalis* in blood cultures [5, 29]. Vancomycin resistance among enterococcal isolates has increased with consequent increase in the rate of VRE bacteremia from 0.06 to 0.17 infections per 1000 patient days [30]. VRE BSI when compared to VSE BSI has higher recurrence rates, mortality, and costs [31]. To distinguish endocarditis as the source of enterococcal bacteremia, a scoring system was proposed to determine the need for trans-esophageal echocardiography: heart murmur, 1 point; prior valve disease, 2 points; unknown source of bacteremia, 4 points; and continuous bacteremia, 5 points (abbreviation: NOVA, number of positive blood cultures, origin of the bacteremia, previous valve disease, auscultation of heart murmur). A NOVA score of $\geq$4 points indicates the need for trans-esophageal echocardiography [32].

Enterococcal infective endocarditis (IE) was once considered a community-acquired disease of older Caucasian men; however, now, it is more healthcare related. Enterococci are the third leading cause of IE and the second leading cause of healthcare-associated IE [5]. There is higher mortality and prolonged bacteremia with VRE *faecium* endocarditis compared with VRE *faecalis* endocarditis [2]. Risk factors for enterococcal IE include older age, male sex, immunosuppression, cancer, prosthetic valve, and presence of a central venous catheter. Older age, heart failure, and nosocomial acquisition are predictors of mortality. Enterococcal IE usually presents subacutely; the Infectious Diseases Society of America guidelines include the duration of symptoms to determine the duration of therapy [33]. *E. faecium* IE presents more frequently with stroke than *E. faecalis* [34]. The International Collaboration on Endocarditis reports that enterococcal IE is associated more commonly with heart failure than with embolic events and has an associated 1-year mortality of 28.9 % and that cardiac valve surgery is not associated with improved outcome [35]. Relapse rate from enterococcal IE is up to 3 % [15].

6 Therapy

The challenge in enterococcal antimicrobial management lies in the organisms' intrinsic resistance to numerous agents. Management of enterococcal infections includes aggressive control of the source of the infection, such as debridement of wounds and removal of invasive devices. There is no consensus whether to use monotherapy or combination therapy for enterococcal bacteremia, while it is the standard of practice to use combination therapy for endocarditis.

Cell wall-active agents inhibit enterococci. When susceptible, ampicillin is the drug of choice, and vancomycin is recommended only if the enterococcus is ampicillin-resistant and vancomycin-susceptible. *E. faecalis* can be resistant to ampicillin and penicillin when beta-lactamase production is present which usually occurs in infections with heavy burden of organisms similar to endocarditis. Nafcillin, ertapenem, aztreonam, and most cephalosporins are not active against enterococci. Ceftaroline has in vitro activity against *E. faecalis* but is inactive against *E. faecium* [36].

The Infectious Diseases Society of America recommends linezolid or daptomycin for catheter-related bacteremia caused by enterococci resistant to ampicillin and vancomycin [37]. For enterococcal endocarditis, bactericidal activity is achieved by a combination of beta-lactam antibiotics and also enhanced by combining beta-lactams and aminoglycosides [33]. For enterococci resistant to vancomycin, aminoglycosides, and penicillin, susceptibility testing for alternative antimicrobials, such as daptomycin and linezolid, is necessary.

The standard of care for enterococcal IE involves a 6-week course of combination therapy. For enterococci without high-level aminoglycoside resistance, the treatment regimen usually is ampicillin plus gentamicin; however, *E. faecalis* strains with high-level aminoglycoside resistance have increased resulting to the loss of the synergism between the aminoglycoside and the beta-lactams. An added challenge in combination therapy involving aminoglycosides is the high likelihood of nephrotoxicity [21], with prolonged therapy. One study reported that 2–3 weeks of an aminoglycoside (in combination with ampicillin) might be sufficient [38]. For *E. faecalis* endocarditis, ampicillin combined with ceftriaxone has been shown to be as effective as ampicillin combined with gentamicin, including for treatment of high-level aminoglycoside resistance strains [39, 40]. The combination of ampicillin with daptomycin has also been used for *E. faecalis* IE [41]. For patients who are at risk for gentamicin-associated nephropathy, alternative regimens to consider include the use of streptomycin instead of gentamicin, short-course gentamicin therapy (2–3 weeks), and use of a non-aminoglycoside-containing double beta-lactam regimen [33].

Treating *E. faecium* differs considerably from treating *E. faecalis* due to limited antimicrobial agents (Tables 51.1 and 51.2). Vancomycin resistance in *E. faecium* has been reported up to 80 % [5]. The Food and Drug Administration (FDA)-approved drugs for resistant enterococci include quinupristin-dalfopristin (approved in 1999) and linezolid (approved in 2000). Non-FDA-approved drugs include daptomycin and tigecycline.

The use of quinupristin-dalfopristin is limited by its adverse effects and the need for a central line. Quinupristin-dalfopristin has no activity against VRE *faecalis.*

Linezolid is a synthetic oxazolidinone agent that exhibits bacteriostatic activity against enterococci by inhibition of protein synthesis [42]. In a non-randomized program for linezolid, clinical and microbiological cure rates for enterococcal infections were 81 % and 86 %, respectively [43]. A study comparing linezolid and daptomycin for VRE bacteremia showed no significant difference in mortality [44]. Reports on linezolid for treatment of left-sided endocarditis, mostly as part of combination therapy and mostly for *E. faecalis*, show similar outcomes and good tolerability [45]. Linezolid has high oral bioavailability and may be given orally or intravenously. Toxicities associated with linezolid include development of thrombocytopenia, peripheral neuropathy, ocular involvement, and serotonin syndrome when taken with selective serotonin reuptake inhibitors. Resistance to linezolid has been reported in enterococci.

Daptomycin is a mainstay of therapy of VRE bacteremia because of its potent bactericidal activity in vitro [46]. Daptomycin is a cyclic lipopeptide that acts at the bacterial cytoplasmic membrane with multiple effects on cellular function including inhibition of lipoteichoic acid synthesis, dis-

Table 51.1 Suggested antimicrobial therapy for *Enterococcus faecalis*

E. faecalis	Antibiotic	Dose	Comments
Cystitis			
PCN-S	Amoxicillin	500 mg PO q6h	For cystitis
VRE	Nitrofurantoin	100 mg PO q6h	If isolate is susceptible
			Not for use in renal failure
	Fosfomycin	3 g PO × 1	If isolate is susceptible
Systemic infection, not endocarditis			
PCN-S	Ampicillin	3–4 g IV q6h	Adjust dose of ampicillin base on CrCl
	Penicillin G	3 million units IV q4h	
PCN-R	Vancomycin	15–20 mg/kg IV q8–12h	Monitor vancomycin serum trough levels
			Monitor CrCl
VRE	Daptomycin	8–10 mg/kg IV q24h	Monitor CPK
	Linezolid	600 mg PO/IV q12h	Monitor platelet count
Endocarditis			
PCN-S	Ampicillin plus	2 g IV q4h	PenG is also recommended 4–6 weeks duration
AMG-S	Gentamicin	3 mg/kg in 2–3 doses	To achieve serum
			Peaks of 3–4 μg/ml
			Trough <1 μg/ml
			Monitor CrCl
	Ampicillin plus	2 g IV q4h	Recommended for patients with impaired renal function
	Ceftriaxone	2 g IV q12h	Minimum of 6 weeks
PCN-allergy	Vancomycin	15–20 mg/kg IV q8-12h	Consider allergy consultation for desensitization
PCN-S or low-level resistance	Plus		Monitor vancomycin serum trough levels
AMG-S	Gentamicin	1 mg/kg q8h	Monitor gentamicin serum
			Peaks of 3–4 μg/ml
			Trough <1 μg/m
			Monitor CrCl
PCN-S	Ampicillin plus	2 g IV q4h	Adjust dose of ampicillin base on CrCl
AMG-R	Ceftriaxone	2 g IV q12h	Minimum of 6 weeks of therapy
VRE	Daptomycin +/−	8-10 mg/kg IV q24h	Monitor CPK
	Another antimicrobial		Use ampicillin or penG if susceptible

Note: PCN, penicillin; S, susceptible; AMG, aminoglycoside; R, resistant; VRE, vancomycin-resistant enterococcus; gm, grams; IV, intravenously; PO, by mouth; q, every; h, hours; UTI, urinary tract infection; IE, infective endocarditis; CrCl, creatinine clearance; CPK, creatinine phosphokinase

ruption of membrane potential, and inhibition of peptidoglycan synthesis. It displays rapid concentration-dependent killing and is bactericidal even for enterococci in the stationary phase of growth. The FDA has approved daptomycin in the United States for complicated skin and soft tissue infections at a dose of 4 mg/kg/day. Clinical trials of serious staphylococcal and enterococcal infections have used daptomycin at 6–12 mg/kg/day. Daptomycin has been reported to show synergism in vitro with aminoglycosides, rifampin, and beta-lactams against some VRE.

Issues that surround daptomycin for use in VRE infections include dosing regimens, treatment failures for isolates with high MICs to daptomycin, development of resistance on therapy, monotherapy versus combination therapy, and suitable secondary agents for combination regimens. A meta-analysis on VRE bacteremia comparing linezolid and daptomycin showed no difference in clinical and microbiological cure and adverse events [47], and another large retrospective study comparing daptomycin, linezolid, and beta-lactams did not show significant difference in mortality [48]. In a national retrospective cohort study, daptomycin was associated with better outcomes than linezolid for treatment of VRE BSI [49].

There is currently no standard recommended dosing for daptomycin for serious VRE infections. Studies using daptomycin above 6 mg/kg/day have shown clinical and microbiological success [50]. Recent evidence suggests clinical and microbiological benefit of adjunctive β-lactam therapy with daptomycin. For enterococcal blood isolates with daptomycin MIC of 3–4 mg/ml, daptomycin has shown to be less effective, suggesting concomitant beta-lactam therapy may improve clinical outcomes in this setting. The combination of ampicillin with daptomycin has shown to enhance the killing of VRE even in cases of VRE *faecium* resistant to ampicillin [51]. Daptomycin with ampicillin have been reported effective for *E. faecalis* endocarditis [41].

Table 51.2 Suggested antimicrobial therapy for VRE, usually *Enterococcus faecium*

VRE	Antibiotic	Dose	Comments
Cystitis			
	Nitrofurantoin	100 mg PO q6h	If isolate is susceptible
			Not for use in renal failure
	Fosfomycin	3 g PO × 1	If isolate is susceptible
Systemic infections, not endocarditis			
VRE	Daptomycin	10 mg/kg IV q24h	Monitor CPK
			Reports of resistance
			Developing while on
			Therapy
			+/− Another agent
	Linezolid	600 mg PO/IV q12h	Bacteriostatic Monitor platelet count
	Quinupristin-Dalfopristin	7.5 mg/kg IV q8h	Via central line
Endocarditis			
VRE	Daptomycin +/−	10–12 mg/kg per dose	Monitor CPK
	Ampicillin		Ampicillin has been shown to enhance daptomycin killing of VRE strains
	Linezolid	600 mg IV/PO q12h	Bacteriostatic
			Cardiac valve replacement may be needed for cure
	Quinupristin-dalfopristin	7.5 mg/kg IV q8h	Via central line
			Minimum of 8 weeks of therapy
			Combination therapy with ampicillin has been reported

Note: VRE, vancomycin-resistant enterococcus; AMG, aminoglycoside; S, susceptible; R, resistant; gm, grams; IV, intravenously; PO, by mouth; q, every; h, hours; UTI, urinary tract infection; IE, infective endocarditis; CrCl, creatinine clearance; CPK, creatinine phosphokinase

Ceftaroline in combination with daptomycin increases the daptomycin surface binding and also is associated with an increase in membrane fluidity and an increase in the net negative surface charge of the bacteria, resulting in increased binding and killing of daptomycin-non-susceptible VRE [52, 53]. Toxicities related to daptomycin include development of myopathy and eosinophilic pneumonia [54].

Tigecycline is a semisynthetic agent that is bacteriostatic and inhibits both *E. faecalis* and *E. faecium* at low concentrations [55]. Tigecycline is FDA approved in the United States for complicated skin soft tissue and intra-abdominal infections. The use of tigecycline for bacteremia and endocarditis is limited by inadequate serum drug concentrations. It has been used as part of combination therapy with linezolid [56] and daptomycin [57] with success, adding in vitro efficacy without demonstrating antagonism with other agents. Tigecycline is administered by intravenous infusion only and often causes nausea.

Newer agents against multidrug-resistant gram-positive bacteria include dalbavancin, telavancin, oritavancin, and teicoplanin [58]. Dalbavancin and telavancin are more potent than vancomycin against vancomycin-susceptible organisms. Dalbavancin, which is given once weekly, has shown non-inferiority to standard of care for bacteremia (it inhibits vanB type VRE at low concentrations but is not active against vanA type VRE). Telavancin, a cidal dual-action glycopeptide, is less active against VRE than against VSE, but MICs are lower than those of vancomycin against VRE [55]. Although telavancin is FDA approved, it is no longer available in the United States. Oritavancin, which has a longer half-life than dalbavancin, acts on both cell wall binding and biosynthesis and, thus, has potent in vitro activity plus synergistic activity with gentamicin for VRE but possible limitations due to protein binding [29, 59]. Teicoplanin has been shown to have activity against *E. faecalis* [60].

7 Endpoints of Monitoring Therapy

Duration of antimicrobial therapy for enterococcal infections depends on the site of infection and the clinical response. Treatment for simple UTI may require only a few days of oral or intravenous antibiotics. Bacteremia without endocarditis may require 10–14 days of antibiotics and typically depends on how quickly clinical and microbiological cures are achieved and if the source of infection is promptly removed. Echocardiography is of use in distinguishing endocarditis from bacteremia due to other foci. If the source of infection cannot be removed, such as central venous catheters that must remain in place or abscesses that cannot be drained, the duration of antimicrobial therapy may be longer. A 4-week therapy is recommended for native valve enterococcal IE, while 6 weeks is recommended for patients with

more than 3 months of symptoms or for prosthetic valve endocarditis. For endocarditis due to multidrug-resistant enterococcus, surgical valve replacement may be necessary.

Antimicrobial Resistance in *Staphylococci aureus*: Mechanisms of Resistance and Clinical Significance

52

Donald P. Levine and Jisha John

Staphylococcus aureus has remained one of the most important human pathogens since the time it was discovered. The unique characteristics of the pathogen, virulence, resistance mechanisms, adaptability, and volatile nature have all been areas of interest for both basic and clinical scientists all over the world. Interestingly, despite being discovered more than two centuries ago and studied ever since, this bacterium remains a mysterious and challenging pathogen that is responsible for both substantial morbidity and major mortality. In this chapter we aim to discuss the basic epidemiology, clinical significance, resistance mechanisms, and treatment options for this pathogen and as well as the newer frontiers in infection control and prevention that are now developing.

1 Epidemiology

1.1 History

After the discovery of *Staphylococcus* in 1880 by the Scottish surgeon Alexander Ogston who was seeking the cause of suppuration [1, 2], it was further speciated by the German physician Friedrich Rosenbach who named it *Staphylococcus aureus* because of the golden pigment it produced on culture plates [3]. Over the next two centuries, this fascinating bacterium demonstrated its versatility as a pathogen both in terms of the diseases it causes and for the antibiotic resistance patterns that have emerged. Indeed, almost immediately after research began on penicillin in 1941, resistance was quickly demonstrated as early as 1942 [4]. Methicillin and vancomycin were approved for use almost simultaneously in 1958 and 1959, respectively. By 1961 the first methicillin-resistant *S. aureus* (MRSA) was reported [5]. Consequently vancomycin became the "go-to" drug for MRSA and remained so for more than half a century. Isolates with reduced susceptibility to vancomycin, called vancomycin intermediate *S. aureus* (GISA/VISA), strains were reported in 1996. The first truly vancomycin-resistant *S. aureus* (VRSA) was identified in 2002.

2 Incidence and Distribution

S. aureus is a major cause of infection throughout the healthcare spectrum, including the community as well as in the hospital setting. The true incidence of *S. aureus* infections is unknown. MRSA was initially a concern only in settings where patients were exposed to antibiotics and medical devices, becoming a widespread nosocomial pathogen by the late 1970s. However, by the early 1980s, a shift occurred, and the organisms frequently caused infections in patients who were not hospitalized and had no obvious reason for a MRSA infection. Gradually these strains became pandemic all over the world.

Although as noted, outbreaks of MRSA infections were reported from US hospitals in the late 1970s, and it was not until the 1980s that so-called healthcare-associated MRSA (HA-MRSA) became endemic in US hospitals [6, 7].

The 1990s witnessed the emergence of community-acquired MRSA (CA-MRSA) as a major pathogen in invasive infections. The most common epidemic clone reported in CA-MRSA infections in the United States is USA300 [8, 9]. The CA-MRSA has unique characteristics in regard to virulence and susceptibility when compared to HA-MRSA. From both an epidemiological and clinical point of view, the designations of healthcare-associated or community-associated have become less relevant due to mixing or combining of the genetic characteristics of the strains, making it likely a nosocomial infection could be caused by a CA-MRSA strain and a community-acquired infection could be due to HA-MRSA.

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_4

Between 1995 and 2005, hospitalizations associated with MRSA infections in the United States more than doubled, mostly for treatment of skin and soft tissue infections and necrotizing pneumonia [10]. National Healthcare Safety Network (NHSN) data from 2003 showed that the methicillin resistance among *S. aureus* causing nosocomial infections increased to 60 % compared to the previous 5 years [11].

Emerging Infections Program/Active Bacterial Core Surveillance Activity (EIP-ABSC) at CDC started tracking invasive MRSA infections in 2005 in nine US metropolitan areas. Interestingly, although still a leading cause, recent reports show that the incidence of invasive blood stream infections from MRSA is on the decline [12]. Although the reasons are not entirely clear, an 11 % annual decline occurred in the incidence of hospital onset blood stream infections between 2005 and 2008 [13]. Overall, a 31 % decrease in the incidence of invasive MRSA infections was noted when compared to the 2005 incidence [14].

3 Colonization and Carrier State

Humans are considered the natural reservoir for *S. aureus*. Secondary analysis of data from the National Health and Nutrition Examination Survey (NHANES) showed that 31.6 % of the US population is colonized with *S. aureus*. The same data showed that the prevalence of MRSA nasal colonization in 2003–2004 was 1.5 %, up from 0.8 % in 2001–2002 [15, 16]. Additional sites of colonization are now recognized, with the throat, axilla, groin, perineum, and vagina considered important sites.

Risk factors for MRSA colonization include type 1 diabetes mellitus, hemodialysis or peritoneal dialysis, intravenous drug use, rheumatoid arthritis, and chronic sinusitis. In addition, patients receiving repeated injections for allergies, those infected with HIV and other primary immunodeficiencies, and even old age are also recognized risk factors [17, 18].

The exact risk of invasive infection among colonized patients is not clear but has been demonstrated in previous studies [19, 20].

4 Clinical Significance

S. aureus remains a major cause of community and healthcare-associated infections. The spectrum of diseases is extensive, including skin and soft tissue infections, pneumonia, blood stream infections, endocarditis, osteomyelitis, prosthetic joint, and other device-related infections. It is a major cause of prolonged hospital stay and adds to the healthcare expenditure [21, 22]. The mortality rate for MRSA exceeds that of MSSA and is in fact the highest from any infectious agent [10, 23, 24].

Recently concerns have been raised about increasing MICs to available antibiotics and the lack of appropriate validated tests and studies to guide antibiotic therapy. The Clinical Labs and Standards Institute (CLSI) decreased the breakpoint MIC for vancomycin susceptibility from 4 μg/mL to 2 μg/mL in 2006 [25], but many experts now recommend an even lower MIC cutoff for invasive infections [26]. As noted above, both vancomycin intermediate- and true vancomycin-resistant isolates have now been identified. Heteroresitance, in which a clone with vancomycin MIC between 4 and 8 μg/mL exists within apparently vancomycin-susceptible *S. aureus* (hVISA) colony, is another major concern because of lack of standardized methods for early identification [27]. It is recognized that the closer to the 2 μg/mL breakpoint, the greater the likelihood of encountering such hVISA strains [28]. The clinical significance of intermediate resistance is unclear, although studies do suggest a higher failure rate among patients treated for serious infections whose organisms possess such elevated MICs. Of even greater significance, data is increasingly accumulating that even within the susceptible range (MIC <2 μg/mL) failures of therapy are becoming common [29].

With increasing concern about the utility of vancomycin, clinicians have turned their attention to newer approaches. However, despite a plethora of recently approved antibiotics with activity against MRSA, the lack of significant advantage over vancomycin and the increasing resistance to even these newly developed antibiotics are of great concern.

Asymptomatic nasal carriage and colonization with MRSA, even among healthy individuals, could lead to persistence and spread of these organisms to vulnerable populations. Currently, there is not enough data to support universal screening and decolonization of healthy people in the community. However, screening and decolonization of healthcare workers (HCW) could have benefits although, in the absence of efficacy data, the concept is still being debated [30, 31].

As noted above, risk factors for MRSA colonization have been described; therefore, our best hope is to identify such high-risk populations and target them when planning infection control and preventive measures.

Spread of MRSA from food, the agriculture industry and even household pets is another area of major concern. Further studies are needed to understand the full clinical significance of this [32].

5 Mechanisms of Resistance

S. aureus has been described as one of the most versatile bacterium. It has been rightly called an evolving pathogen [33] in view of its adaptability and development of resistance to multiple antibiotic classes through a variety of different mechanisms. Much remains unclear about the mechanisms of resistance, but we will summarize what has been described thus far (see Table 52.1).

Table 52.1 Mechanisms of antimicrobial resistance

Antibiotic	Site of action	Mechanism of resistance	Responsible gene product	Genetic basis
Beta-lactams	Cell wall synthesis	(1) Hydrolyze the peptide bond in the beta-lactam ring and inactivate the drug	(1) Beta-lactamase (penicillinase)	(1) blaZ gene-plasmid
Penicillin		(2) Reduce affinity of binding to the PBP	(2) PBP2a	(2) mecA
Cephalosporin				
Carbapenem				
Glycopeptides	Cell wall synthesis	Vancomycin trapping in the thickened cell wall (VISA)	Thicker peptidoglycan layer with more exposed D-Ala-D-Ala residues	(1) Unclear-? agr group III polymorphism
Vancomycin		Alteration of cell wall precursor (VRSA)	Novel cell wall precursor ends in D-Ala-D-Lac	(2) Van A gene acquisition from VRE
Daptomycin	Cell membrane	Alteration of cell membrane charge	Increased L-PG (lysyl-phosphatidylglycerol) synthesis	mprF gene
Linezolid	Protein synthesis	Point mutation at 23S rRNA or 50 S L3/L4 ribosomal proteins	23S rRNA subunit target site changes	rrn gene
		Methylation of 23S rRNA subunit		cfr gene - plasmid mediated

6 Resistance to Beta-Lactams

Penicillin resistance was identified in *S. aureus* in 1942, quite immediately after the discovery of penicillin [34, 35]. It was first noted in the hospital setting followed by its appearance in the community setting. Penicillin binds to the penicillin-binding-proteins (PBPs) in the bacterial cell wall and blocks the ability of the PBPs to function, thereby inhibiting cell wall synthesis. *S. aureus* produces a penicillinase enzyme which inactivates the beta-lactam ring of penicillin by hydrolyzing the peptide bonds. This beta-lactamase is encoded by the -blaZ gene located on a plasmid that often carries additional resistance genes as well (erythromycin and gentamicin). More than 90 % of the staphylococcus isolates are now penicillin resistant.

Methicillin was introduced in 1961 as the first semisynthetic penicillinase-resistant penicillin, and reports of methicillin-resistant isolates immediately followed. The bacteria altered its cell wall content and acquired a new PBP, called penicillin-binding protein 2a (PBP2a or PBP2'), which has a lower affinity for all beta-lactam antibiotics. Accordingly, MRSA are inherently resistant to all cephalosporins and carbapenems. The PBP2a is encoded by the mecA gene that is part of a large mobile genetic element called staphylococcal cassette chromosome mec (SCCmec) [36].

It has been assumed that the mecA gene was acquired through transfer from coagulase-negative staphylococci (CONS) since no homologue of this gene exists in MSSA [37, 38]. Eleven SCCmec types have been identified to date [39].

SCCmec types 1, 4, and 5 are smaller subtypes and are only responsible for genes conferring resistance to methicillin. SCCmec subtypes 4 and 5 are smaller and are associated with community-associated CA-MRSA isolates; it has been speculated that the smaller size enhances mobility and ease of transfer between strains. SCCmec subtype 4 carries the gene responsible for production of Panton-Valentine leucocidin or PVL. A possible role for PVL in the virulence of CA-MRSA, especially in relation to serious skin-soft tissue infections and necrotizing pneumonia, has been proposed but has been challenged based on the results of recent animal studies [40].

CA-MRSA differs from HA-MRSA in regard to antibiotic susceptibility and virulence. CA-MRSA is generally considered susceptible to non-beta-lactam antibiotics (except macrolides) and appears to be more virulent. The predominant clones of CA-MRSA circulating in the United States are pulsed-field type USA300 followed by USA400. The typical USA300 clone isolate is susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), clindamycin, and tetracycline and is resistant to erythromycin and gatifloxacin. Increasingly non-beta-lactam resistance has been described in USA300. Multidrug resistance in USA300 clones, conferred by large plasmids encoding resistance to mupirocin, macrolides, and clindamycin, have been described in men having sex with men in the San Francisco and Boston areas [41]. Up to 77 % of these isolates harbor chromosomally encoded resistance to ciprofloxacin as well.

SCCmec subtypes carrying additional genetic elements conferring resistance are found most notably in HA-MRSA [42].

Strains that are resistant to erythromycin occasionally possess inducible clindamycin resistance. These strains are typically identified by the phenotype of erythromycin resistance and clindamycin susceptibility. Therefore, when such isolates are found, CDC recommends further testing for inducible clindamycin resistance by the use of the D-test. SCCmec (type 2 and type 4) is most important in determining resistance, but its direct effect on virulence or invasiveness of MRSA is unknown [43].

7 Resistance to Vancomycin

Vancomycin was FDA approved in 1958 and has been the gold standard for treatment of MRSA infections ever since. In addition, due to its antimicrobial spectrum, it was increasingly used to treat a variety of other infections including *Clostridium difficile* diarrhea, MSSA infections, and enterococcal infections. Antibiotic selection pressure resulting from the widespread use of this slowly bactericidal glycopeptide resulted in emergence of resistance. Slow response to vancomycin treatment of invasive infections was reported [44] but was not considered due to reduced susceptibility. However, vancomycin intermediate-resistant *S. aureus* (VISA) infection was reported in 1996 from Japan and was followed by additional case reports [45]. Notably, this form of resistance has been associated with diminished clinical activity and treatment failures.

VISA strains were found to have increased thickness of the cell wall arising from changes in the peptidoglycan biosynthesis. These strains appear to have additional peptidoglycan in their cell wall with less cross-linking of the strands leading to exposure of more D-Ala-D-Ala residues [46, 47]. These residues bind and trap the vancomycin and prevent it from reaching the target cytoplasmic membrane. Previous exposure to vancomycin appears to be related to the development of VISA strains, and in vitro studies showed that following removal of antibiotic selection pressure the organisms may revert to a susceptible state [48]. It is interesting to note that not all VISA strains are MRSA [49].

Despite extensive study, the genetic mechanism of resistance in VISA remains unclear [50].

As noted above, reports of clinical failure of vancomycin in MRSA infections and improved understanding of pharmacodynamics led to the reevaluation of vancomycin minimal inhibitory concentration breakpoints. In 2006, CLSI redefined the breakpoints as follows: susceptible, $\leq$ 2 mg/mL; intermediate (VISA), 4–8 mg/mL; and resistant (VRSA), This should be the symbol for equal or greater than (> with a line under the >) I don't find this symbol in the options allowed. 16 mg/mL [51]. Despite this change, increasing reports of vancomycin failures even when the organisms treated were within the susceptible range caused many experts to debate whether the breakpoints should be lowered further. A phenomenon called MIC "creep" characterized as a slow increase in the median MIC to vancomycin over time was also described from many centers [52, 53]. However, there are conflicting data about this phenomenon and it appears now that "creep" may be limited to a few select centers where elevated MICs may be playing an important role in clinical practice [54, 55]. Previous antibiotic exposure and clonal replacement are considered possible reasons for the MIC creep where it exists, but its clinical significance is not established.

MRSA isolates which appear to be sensitive to vancomycin but with a subpopulation (1 in 10^5 organisms) that actually has intermediate resistance to glycopeptides called heteroVISA (hVISA) have now been reported. Although found infrequently when the MIC of the population is low, the closer the MIC approaches the 2 mg/mL breakpoint, the more likely it is to have hVISA isolates [52]. The clinical effect of hVISA infections is becoming elucidated as they are associated with persistent bacteremia, vancomycin treatment failure, metastatic complications, and high inoculum infections [56]. An association between hVISA infections and increased mortality has not yet been established [57]. A recent report describes an outbreak of infections due to hVISA organisms [58].

Vancomycin-resistant *S. aureus* (VRSA) was first reported in 2002. To date only 13 cases have been reported [59, 60]. The mechanism of resistance in VRSA strains appears to result from conjugal transfer of the vanA operon from vancomycin-resistant *Enterococcus faecalis (VRE).* The acquisition of the vanA gene allows the VRSA isolate to synthesize a cell terminal peptide D-Ala-D-Lac instead of D-Ala-D-Ala, the target site for vancomycin. This new cell wall precursor has decreased affinity to vancomycin, leading to MIC >16 mg/mL and often to >250 mg/mL [61]. Based on clinical reports, it appears these organisms are produced after prolonged exposure to vancomycin, often over months, in patients with persistent infections and co-colonization of MRSA and VRE.

8 Linezolid

Linezolid, the first oxazolidinone agent, was approved in 2000 for the treatment of MRSA infections. This protein synthesis inhibitor binds to the 50S ribosomal subunit and is 100 % bioavailable. It is available as an oral and intravenous agent and has extensive tissue penetration. Clinical uses include treatment of MRSA pneumonia, and complicated and uncomplicated SSSIs. Although linezolid has shown higher cure rates compared to vancomycin in some prospective randomized control studies [62, 63], the superiority still remains controversial secondary to conflicting studies [64, 65].

Resistance to linezolid in *S. aureus* has been observed most frequently as a result of point mutations in the binding site of the antibiotic, the 23S rRNA subunit [66]. It has also been proposed that mutations in L3/L4 proteins in the ribosomal subunit may also cause resistance alone or along with the 23S rRNA mutations [67]. In 2008, an outbreak involving 12 cases of linezolid-resistant *S. aureus* was reported from an intensive care unit in Madrid, Spain [68]. The mechanism of resistance was found to be plasmid-mediated acquisition of cfr (chloramphenicol/florfenicol resistance gene) [69]. The cfr gene mediates the methylation of the 23S rRNA subunit and the mutation can confer resistance to multiple antimicrobials including chloramphenicol, lincosamides, oxazolidinones, pleuromutilins, and streptogramin A. This is concerning because of the potential for transmissibility and

development of resistance against other antimicrobials that act against protein synthesis.

The 9-year LEADER (Linezolid Experience and Accurate Determination of Resistance) surveillance program ranging from 2004 to 2012 detected only low-level resistance to linezolid among the *S. aureus* isolates tested (<0.03–0.15 %) [70]. Risk factors for development of resistance included previous linezolid therapy, prolonged exposure to linezolid, intensive care unit stay, and concomitant use of multiple antibiotics. This underscores the importance of antibiotic stewardship and infection control practices in preventing the development of resistance.

9 Daptomycin

Daptomycin is a lipopeptide antibiotic that is bactericidal and acts by initiating cell membrane depolarization. It was approved by FDA in 2003 for SSSIs and in 2006 for bacteremia and right-sided endocarditis. The MRSA guidelines recommend a dose of 4 mg/kg for the treatment of SSSI and 6 mg/kg for the treatment of bacteremia and endocarditis [71]. Previous vancomycin exposure, higher bacterial burden, and deep-seated infections are risk factors for daptomycin failure during treatment of MRSA infections [72, 73]. Some experts recommend using higher dose (8 or 10 mg/kg) for the treatment of bacteremia and endocarditis when vancomycin MIC > 1 or even 10 mg/kg for persistent bacteremia with resistant isolates possessing high vancomycin MICs [74–76].

Several genetic changes have been identified as reasons for daptomycin resistance, the most common being the multipeptide resistance factor (mprF) gene mutation. It involves accumulation of a variety of single nucleotide polymorphisms (SNPs) resulting in alteration of cell membrane charge leading to decreased binding of daptomycin. It has been suggested that VISA phenotypes may be associated with thicker cell wall leading to deceased daptomycin penetration to reach the cell membrane. Recently combination of daptomycin with beta-lactams has been tried in various centers for treatment of persistent bacteremia despite daptomycin treatment [77–79]. A theoretical explanation for the apparent improvement in activity is the beta-lactams' ability to reduce the positive surface charge on the organism, thus contributing to better adherence of daptomycin [80].

10 Newer Agents

Newer agents recently approved for the treatment of SSSI caused by *S. aureus* include ceftaroline, telavancin, dalbavancin, tedizolid, and oritavancin. Ceftaroline, a cephalosporin, is the first beta-lactam antibiotic that has activity agains MRSA due to its affinity for PRB2a. Telavancin was also FDA approved for the treatment of pneumonia caused by *S. aureus*. Each of these agents has simpler dosing regimens, in some cases (dalbavancin and oritavancin) due to extremely prolonged serum half-life, but no therapeutic advantage over the currently available agents. Further clinical experience would reveal clinical safety and other unique features of each of these agents.

11 Vaccine Development

Continued efforts to develop an effective vaccine against *S. aureus* have been hugely unsuccessful. Animal model studies have shown great results, but they failed to translate into clinical trials in human beings. Both passive and active immunization have been tried and failed in human studies. Fowler suggested that the limited knowledge of human protective immunity might be the reason for the inability to develop an effective vaccine against this evolving pathogen [81]. Newer studies identifying biomarkers that have a role in the virulence of *S. aureus* may ultimately influence the development of a successful vaccine [82].

12 Conclusion

The threat raised by antimicrobial resistance is real and imminent. *S. aureus*, although discovered more than two centuries ago, still remains an enigmatic organism. The study and dialogue on resistance mechanisms will help us understand this pathogen better. Much has been explained, but much remains to be discovered.

Resistance in Aerobic Gram-Positive *Bacilli*

53

David J. Weber, Melissa B. Miller, and William A. Rutala

1 Introduction

Aerobic Gram-positive *bacilli* comprise a variety of organisms including *Bacillus*, *Listeria*, *Erysipelothrix*, *Lactobacillus*, *Corynebacterium*, *Gardnerella*, *Actinomyces*, *Nocardia*, and *Mycobacterium*. In addition to describing the epidemiology and microbiology of *Listeria* and *Nocardia*, this chapter will focus on the *Bacillus* spp. in three different contexts: the threat of anthrax as a bioterrorist weapon, the significance of *Bacillus cereus* as an agent of foodborne illness, and the *Bacillus* spp. as occasional but important pathogens. *Bacillus* spp. are aerobic Gram-positive bacteria that are an important source of human infections. *Bacillus anthracis* is a potential bioterrorism weapon as demonstrated by the outbreak of *B. anthracis* in the United States in 2003 transmitted via intentionally contaminated letters that infected 22 persons. *Bacillus anthracis* may produce β-lactamase, and clinical failure may result when such strains are treated with penicillin. *Bacillus cereus* is a well-described cause of gastroenteritis and is usually acquired from contaminated food. *Bacillus* spp., other than *B. anthracis*, are usually resistant to penicillins and cephalosporins; they may cause serious infections including posttraumatic endophthalmitis, wound infections, bone and joint infections, and bacteremia especially in immunocompromised patients with central venous catheters. *Bacillus* spp. are generally susceptible to vancomycin, carbapenems, and quinolones. Therapy is guided by the exact infecting species, type and severity of infection, and in vitro susceptibilities.

2 *Bacillus* spp.: Microbiology, Epidemiology, and Clinical Manifestations

2.1 Microbiology

Historically, most aerobic endospore-forming bacteria were classified as *Bacillus*. However, the use of new phylogenetic methods has led to a taxonomic transformation with the creation of a new class, *Bacilli*, within the phylum *Firmicutes* which comprises two orders, *Bacillales* and *Lactobacillales* [1]. Currently, the aerobic endospore-forming bacteria are distributed among >60 genera and seven families within the order *Bacillales* [1].

Bacillus is the type genus of the *Bacillaceae*. Members of the genus *Bacillus* are characterized as endospore forming, aerobic, catalase positive, and motile by means of peritrichous flagella. However, the genus is phenotypically diverse, and some species are asporogenous, facultatively anaerobic or strictly anaerobic, and thermophilic or psychrophilic. Although usually Gram-positive, some species show a variable reaction, especially when the stain is prepared from samples taken from the later stages of growth. When viewed under the microscope, *Bacillus* may appear as single organisms or in chains of considerable length. The size of individual rods may range from small (0.5 × 1.2 mm) to large (2.5 × 10 mm), and rod ends may appear as round or square. Formation of a single endospore in the vegetative bacterium is a dominant feature of *Bacillus*. The spore may be oval or cylindrical and may be located centrally, subterminally, or terminally. Frequently encountered species include *B. subtilis* (the type species), *B. cereus*, *B. licheniformis*, *B. megaterium*, and *B. pumilus*.

2.2 Clinical Syndromes

Bacillus spp. are capable for causing a variety of clinical infections (Table 53.1). Clinical infections due to *Bacillus* spp. can be categorized into three broad groups: infections caused by *Bacillus anthracis* including cutaneous infections, pneumonia, and disseminated infections such as meningitis and injection related; food poisoning due to *Bacillus cereus*; and invasive infections due to non-*anthracis Bacillus* spp.

2.2.1 *Bacillus anthracis* Infection

B. anthracis is the causative agent of anthrax, which is primarily a worldwide epizootic or enzootic disease of herbivores (e.g., cattle, goats, and sheep) that acquire the disease from direct contact with contaminated soil [2–7]. However, all mammals, including humans, are susceptible. In the United States, endemic anthrax is a rare disease with only eight non-outbreak cases reported between 1989 and 2012 [8]. In 2003, the United States had 22 cases of anthrax as a result of an intentional release of *B. anthracis* [9]. Anthrax is now recognized as a potential bioterrorism agent [10, 11]. It is classified as a Category A agent by the Centers for Disease Control and Prevention: easily disseminated or transmitted person-to-person, causes high mortality, with potential for major public health impact, might cause public panic and social disruption, and requires special action for public health preparedness [12, 13].

The ultimate reservoir of *B. anthracis* is the soil (especially soil with high calcium and pH>6.1), where under proper conditions spores may persist for decades [5]. Dormant spores are highly resistant to adverse environmental conditions including heat, ultraviolet and ionizing radiation, pressure, and chemical agents and may persist in the environment for years [2, 14, 15]. In a suitable environment, spores reestablish vegetative growth. Vegetative bacteria have poor survival outside of an animal or human host; colony counts decline to an undetectable level within 24 h following inoculation into water.

Table 53.1 Classification of *Bacillus* Infections

	Blood cultures	Prognosis
A. Infections due to *B. anthracis*		
1. Cutaneous (contact)	Rarely positive	Excellent with therapy
2. Pneumonia (inhalation)	Often positive	Frequently fatal
3. Gastrointestinal (ingestion)	Sometimes positive	
4. Injection	Sometimes positive	Frequently fatal
5. Metastatic (bacteremic)	Always positive	Frequently fatal
B. *B. cereus* food poisoning	Always negative	Generally mild and self-limited disease
1. Short incubation		
2. Long incubation		
Infections due to opportunistic *Bacillus* spp.		
C. Superficial	Rarely positive	Good, occasional fasciitis or myositis
1. Wound (surgical, burn, traumatic)		
2. Skin (impetigo-like lesions)		
D. Closed space	Sometimes positive	Infection occasionally fatal and affected organ may be permanently damaged
1. Panophthalmitis/endophthalmitis		
2. Brain abscess		
3. Cholecystitis		
4. Soft tissue abscess		
5. Urogenital infection		
6. Peritonitis		
7. Necrotizing fasciitis		
8. Osteomyelitis		
9. Septic arthritis		
10. Fasciitis		
11. Myositis		
E. Severe systemic infection	Frequently positive	Frequently fatal
1. Pneumonia		
2. Empyema		
3. Meningitis/meningoencephalitis		
4. Endocarditis		

Classically, human anthrax was described as often a fatal bacterial infection that occurred when *Bacillus anthracis* endospores entered the body through abrasions in the skin, by inhalation or by ingestion [16, 17]. Recently, a fourth syndrome has emerged that is characterized by severe soft tissue infection in injection drug users [18, 19]. The source of human anthrax is direct contact with infected animal product (e.g., wool, hides, bone) or soil, ingestion of contaminated meat, or inhalation of aerosolized endospores. Rarely, direct human-to-human spread may occur [20]. The clinical manifestations of anthrax depend on the mode of acquisition being primarily coetaneous [21–25], respiratory [26–28], and gastrointestinal [29, 30]. Following initial infection *B. anthracis* may spread via the bloodstream resulting most commonly in sepsis and/or meningitis [31, 32]. The virulence of the organism is variable, determined by at least two factors: the polysaccharide capsule that prevents phagocytosis and an extracellular toxin. The anthrax toxin is comprised of three polypeptides: protective antigen (PA) binds to cellular receptors where it is cleaved by cellular furin, and oligomerizes and transports lethal factor (LF, a protease) and edema factor (EF, an adenyl cyclase) into cells [33–35]. These toxins are sufficient to produce many of the symptoms of anthrax.

Cutaneous anthrax is the most common naturally occurring form, with an estimated 2000 cases reported annually worldwide [10]. Cutaneous anthrax follows deposition of the organisms into the skin via contamination of previous cuts or abrasions. An initial pruritic macule or papule enlarges into a round ulcer by the second day. This develops into a painless, black eschar often with extensive local edema. In most cases, the eschar begins to resolve in about 10 days with complete resolution by 6 weeks. However, lymphangitis and painful lymphadenopathy may occur with associated systemic symptoms, and uncommonly cutaneous anthrax may be associated with toxemic shock [36]. The treatment of choice is medical, with ciprofloxacin or doxycycline the preferred antibiotics, but surgical biopsy may be necessary to confirm the diagnosis [37]. Without antibiotic therapy, the mortality rate has been reported to be as high as 20 % [10]. With appropriate therapy, the mortality rate is under 1 %.

Although gastrointestinal anthrax is uncommon, outbreaks continue to be reported from Africa and Asia following ingestion of insufficiently cooked meat [38–40]. The incubation period is 2–5 days. Two clinical forms of disease have been described: oral–pharyngeal and abdominal. The oral–pharyngeal form of anthrax is characterized by an oral or esophageal ulcer and development of regional lymphadenopathy, edema, and sepsis. Disease in the lower gastrointestinal tract manifests as primary intestinal lesions most commonly in the terminal ileum or cecum. Patients present with nausea, vomiting, and malaise that rapidly progresses to bloody diarrhea, development of an acute abdomen, or sepsis.

Inhalation anthrax follows deposition of spore-bearing particles into alveolar spaces. Spores are ingested by macrophages that are transported via the lymphatics to mediastinal lymph nodes, where germination occurs after a period of spore dormancy of viable and possibly extended duration [10]. Once germination occurs, clinical symptoms follow rapidly. Replicating *B. anthracis Bacilli* release toxins that lead to hemorrhage, edema, and necrosis. The mortality of inhalation anthrax, even with antibiotic therapy, remains greater than 50 %. Symptoms associated with inhalation anthrax commonly include fever and chills, sweats, fatigue, nonproductive cough, dyspnea, chest pain or pleuritic pain, and myalgias. Most patients demonstrate fever and tachycardia. Patients who present with atypical anthrax (nasal or nasopharyngeal, larynx or laryngopharyngeal, primary meningoencephalitis) present with less cough, less chest pain, or are less likely to have an abnormal lung examination than patients with typical inhalation disease [41]. Laboratory findings most commonly include a normal or slightly elevated white blood cell count often with a left shift, elevated liver transaminases, and hypoxia. The classic radiographic finding of a widened mediastinum is found in approximately 70 % of patients. Chest radiographs often demonstrate a pleural effusion and infiltrates or consolidation. The finding of mediastinal widening or pleural effusion on chest radiography is 100 % sensitive for inhalation anthrax and 71.8 % specific compared with community-acquired pneumonia and 95.6 % specific compared with influenza-like illness [42]. A chest computed tomography (CT) scan is more sensitive for detection of anthrax-associated pulmonary disease than a standard chest radiograph.

Since 2000 ~70 cases of injection of anthrax associated with intravenous drug use (principally heroin) have been reported from Europe with a case fatality rate of ~35 % [43–45]. Many of these cases have presented with severe soft tissue infection with substantial swelling or edema. Erythema and pain were not essential features at presentation, and none of the cases showed the typical eschar (i.e., a black-crusted painless lesion) of cutaneous anthrax. Laboratory-acquired anthrax has also been reported [46].

2.2.2 *Bacillus cereus* Food Poisoning

B. cereus is a well-described, but uncommon, cause of foodborne disease accounting for 3 % of outbreaks with a confirmed or suspected etiology (1 % of reported illnesses) in the United States from 1998 to 2008 [47]. Although the Centers for Disease Control and Prevention reported no deaths in these cases, death from *B. cereus*-associated food poisoning has been reported [48], including sudden death [49]. *B. cereus* strains can cause two types of food poisoning syndromes [50–57]. Type 1, "short incubation" or "emetic" syndrome, has an incubation time of 0.5–6 h; the predominant symptoms are vomiting and cramps, and less frequently,

diarrhea. The duration of illness is usually 8–10 h (range, 6–24 h). "Short incubation" strains elaborate a heat-stable peptide (toxin), "cereulide," which is capable of causing vomiting when fed to monkeys. Type 2, "long incubation" or "diarrhea" syndrome, has an incubation time of 6–24 h (occasionally >24 h); the predominant symptoms are diarrhea and abdominal cramps, and less frequently, vomiting. The duration of illness is usually 12–24 h (occasionally several days). "Long incubation" strains elaborate a heat-labile enterotoxin(s) (Hbl, Nhe, CytK implicated), which activate intestinal adenylate cyclase and results in intestinal fluid secretion. Clinical manifestations of both syndromes are usually mild and self-limited; fever is uncommon. There is no seasonality to *B. cereus* food poisoning, and secondary cases do not occur. "Early incubation" disease has most commonly been associated with contaminated fried rice or pasta, and "late incubation" disease has most commonly been associated with contaminated meats or vegetables. The usual source of contamination is raw food, rather than food-handlers or the food preparation environment. Inadequate cooking is the most important factor leading to disease outbreaks.

2.2.3 Opportunistic *Bacillus* Species Infections

Bacillus spp. have often been dismissed as contaminants in clinical specimens. However, it is now well recognized that non-*anthracis Bacillus* spp. are capable of causing serious human infections [50, 51, 58–60]. Local and systemic infections are most commonly caused by *B. cereus* and less commonly by *B. subtilis*.

Bacillus spp. have been isolated from surgical and traumatic wounds, often as part of mixed infections [61, 62]. The clinical significance of *Bacillus* in such cases is often unclear. However, *Bacillus* spp. may cause severe fasciitis and myositis resembling gas gangrene. In addition, *Bacillus* spp. may colonize or infect burn wounds. Rarely, bacteremia may accompany cutaneous or burn infection. Nosocomial wound infections have resulted from the use of contaminated plaster [63] used for preparing casts or contaminated incontinence pads [64]. Nosocomial infections have also resulted from the use of contaminated hospital linens and towels [59, 65].

Bacillus spp. may cause a variety of closed-space infections, especially ocular infections including conjunctivitis, iridocyclitis, dacryocystitis, keratitis, endophthalmitis and panophthalmitis [51, 66–71]. *B. cereus* is a well-recognized cause of panophthalmitis following penetrating ocular trauma and in intravenous drug users. Exogenous *B. cereus* panophthalmitis is characterized by rapid onset (18–24 h after injury), severe pain, chemosis, proptosis, periorbital swelling, and fever. Infection often results in evisceration and blindness. Other closed-space infections include cholecystitis, septic arthritis, osteomyelitis, intra-abdominal infection, soft tissue abscesses, and urinary tract infections.

Serious systemic infections include central nervous system infection [72–75], lower respiratory tract infections [76, 77], endocarditis [78] including prosthetic valve endocarditis [79], spontaneous bacterial peritonitis [80], and primary bacteremia with clinical sepsis [81–83]. Most patients with meningitis have predisposing factors including remote site infections, recent neurosurgery often with the use of a ventriculostomy, cancer, endocarditis, or intravenous drug use [72]. The mortality with central nervous system infection is high, approximately 50 %.

The prevalence of positive blood cultures for *Bacillus* spp. has ranged from 0.1 to 0.9 %. *Bacillus* organisms are common laboratory contaminants due to their hardy growth characteristics. Sources of *Bacillus* pseudoinfections have included contaminated broth culture, syringes, alcohol swabs used to disinfect the tops of blood culture bottles, and gloves. Approximately, 10 % of patients who have *Bacillus* isolated from a blood culture will have either recurrent *Bacillus* bacteremia or evidence of significant *Bacillus* infection. Most bacteremic patients will have underlying predisposing medical conditions, such as prematurity, intravenous drug use, indwelling central venous catheters, immunosuppressive medication, or neutropenia [84, 85]. Bacteremia has been commonly associated with clinically significant foci of infection such as meningitis and pneumonia. Endocarditis may accompany bacteremia, especially in intravenous drug users.

3 Therapy of *Bacillus* Infections

3.1 Infections due to *Bacillus anthracis*

3.1.1 In Vitro Antibiotic Susceptibility

Four caveats should be mentioned in evaluating the reports of the in vitro susceptibility of *B. anthracis* to antibiotics. First, multiple methods for determining the in vitro susceptibility have been used. The Clinical and Laboratory Standards Institute (CLSI) currently recommends that broth microdilution susceptibility testing be performed using cation-adjusted Mueller–Hinton broth (CAMHB) with incubation at 35 ± 2 °C ambient air for 16–20 h [86]. Second, CLSI provides an interpretative standard (i.e., breakpoints) only for penicillin, tetracycline and doxycycline, and ciprofloxacin [86]. Third, β-lactamase testing of clinical isolates of *B. anthracis* is unreliable and should not be performed [86]. Fourth, if MIC susceptibility testing using CLSI methods indicates that *B. anthracis* isolates are susceptible to penicillin, amoxicillin may still be considered for prophylactic use in children and pregnant women [86]. Mohammed and colleagues compared the CLSI broth microdilution method to the Etest® agar gradient diffusion method and reported no statistically significant differences between the results of these two methods for

any of the tested antibiotics; however, results for penicillin obtained by the Etest® method were 1–9 dilutions lower than those obtained by the broth microdilution method [87]. In addition, they noted that reading Etest® results through the glass of a biological safety cabinet was difficult. More recently, Luna and colleagues compared the Etest® with Sensititre® (an automated microbroth dilution method) and reported that both methods yielded "near-identical results for all antimicrobials except trimethoprim-sulfamethoxazole" [88]. A rapid susceptibility test for *B. anthracis* has been reported that yields results within 6 h [89].

Testing of clinical isolates of *B. anthracis* has revealed that strains are generally susceptible to first-generation cephalosporins, tetracyclines, quinolones, carbapenems, clindamycin, chloramphenicol, and vancomycin (Table 53.2) [88, 90–103]. *B. anthracis* also appears to be susceptible to the newer antibiotics tigecycline, linezolid, dalbavancin, and oritavancin [102–105]. Most strains are susceptible to penicillin, but clinical strains may produce a β-lactamase (see below). Most strains are resistant to second and third-generation cephalosporins, aztreonam, and trimethoprim–sulfamethoxazole.

The rapid killing of antibacterial against selected strains of *B. anthracis* has been determined using the time-kill method [106]. The most rapid bacterial killing was achieved by quinupristin–dalfopristin, rifampin, and moxifloxacin with a 4-$\log_{10}$ reduction in 0.5–4 h. The β-lactams and vancomycin demonstrated a 2–4 $\log_{10}$ reduction within 5–15 h. The macrolides, tetracyclines, and linezolid demonstrated a lower kill rate, while chloramphenicol did not kill at all. In vitro synergy of antibiotics against *B. anthracis* has also been evaluated [107]. Against two strains of *B. anthracis*, only the combination of rifampin and clindamycin were synergistic. All other combinations were either indifferent or antagonistic.

The post-antibiotic effects of a variety of antibiotics have been determined against two strains of *B. anthracis* [108]. The post-antibiotic effects observed were as follows: fluoroquinolones 2–5 h; macrolides 1–4 h; clindamycin 2 h; tetracyclines 1–3 h; β-lactams (penicillin G, amoxicillin, ceftriaxone), vancomycin, linezolid, and chloramphenicol 1–2 h; and quinupristin–dalfopristin 7–8 h.

3.1.2 Antimicrobial Resistance in *Bacillus anthracis*

Surveys of clinical and soil-derived strains have revealed resistance to penicillin G in up to 16 % of isolates tested [87, 90–92, 96, 97]. Human infection due to naturally occurring penicillin-resistant strains has been reported [109–111]. Exposure to β-lactams have been reported to induce penicillin resistance in *B. anthracis* [87, 91, 93]. The mechanism

Table 53.2 In vitro susceptibility of *B. anthracis* to antimicrobials

Highly active	Variable activity	Often resistant
First-generation cephalosporins	Penicillins	Second-generation cephalosporins
Cefazolin	Macrolides	Cefuroxime
Cefalothin	Erythromycin	Cefamandole
Carbapenems	Azithromycin	Third-generation cephalosporins
Imipenem	Clindamycin	Cefotaxime
Meropenem	Aminoglycosides	Ceftazidime
Tetracycylines	Gentamicin	Ceftriaxone
Tetracycline	Netilmicin	Fourth-generation cephalosporins
Doxycycline	Amikacin	Cefepime
Glycylcyclines		Aztreonam
Tigecycline		Trimethoprim–sulfamethoxazole
Quinolones		
Ciprofloxacin		
Levofloxacin		
Moxifloxacin		
Ofloxacin		
Macrolides		
Clarithromycin		
Rifamycins		
Rifampin		
Chloramphenicol		
Glycopeptides		
Vancomycin		
Dalbavancin		
Oritavancin		

underlying β-lactam resistance in *B. anthracis* is due to the presence of two β-lactamases, bla1 and bla2 [112]. These two β-lactamase Genes were found in the Sterne strain of *B. anthracis* and were evaluated by cloning into *E. coli* [113]. *Bla1* is a penicillinase that confers high-level resistance to ampicillin, amoxicillin, and penicillin G, while *bla2* is a cephalosporinase that confers low-level resistance to ceftriaxone, cefazolin, cefoxitin, and cefotetan [113]. More recent work has further characterized the β-lactamases of *B. anthracis* [114, 115]. Bla1 was found to preferentially hydrolyze penicillins and to be inhibited by tazobactam and clavulanic acid. *Bla1* exhibited carbapenem-, penicillin-, and cephalosporin-hydrolyzing activities.

B. anthracis has variable in vitro susceptibility to macrolides. The inducible macrolide–lincosamide–streptogramin B resistance determinant, *ermJ*, from *B. anthracis* has been cloned in *E. coli* [116].

Sequential subcultures in sub-inhibitory concentrations of antibiotics led to the development of resistance to quinolones and macrolides [117, 118]. Although the MIC of tetracycline increased, it did not reach a level that yielded clinical resistance [118]. A more recent study demonstrated that serial passages on brain heart infusion agar led to the development of resistance to quinolones, macrolides, tetracyclines, clindamycin, vancomycin, and linezolid [119]. Strains resistant to a quinolone exhibited cross-resistance to other quinolones, but not to doxycycline.

3.1.3 Recommended Antibiotic Therapy

Penicillin G has long been the standard therapy for anthrax, despite the fact that penicillin resistance was well described [17]. Prior to the intentional anthrax release in the United States in 2003, recommended therapy for anthrax included penicillin (provided the strain was penicillin susceptible), tetracycline, doxycycline, erythromycin and other macrolides, chloramphenicol, ciprofloxacin, streptomycin, first-generation cephalosporins, gentamicin, and vancomycin [10, 16]. The exact drugs, dose, and route depended on the clinical syndrome being treated (i.e., inhalation, cutaneous, or gastrointestinal).

Bacillus anthracis infections should be immediately reported to the local health department. The current therapy recommended for anthrax depends on the clinical syndrome being treated [120]. It is important to note that there are no controlled studies for the treatment of inhalation anthrax in humans. Further, there are only limited animal data using primate models of inhalation anthrax to guide therapy decisions. Ciprofloxacin, levofloxacin, and doxycycline are approved by the FDA for the treatment of inhalation anthrax in adults with ciprofloxacin and doxycycline being considered first-line therapy. If first-line agents are not available or are not tolerated, therapy could include levofloxacin or moxifloxacin, clindamycin, or amoxicillin or penicillin VK if the isolate is penicillin susceptible (the risk for development of resistance must be considered if using β-lactam drugs). Monkeys were shown to be protected from exposure to a lethal aerosol challenge (i.e., 8 LD_{50}) of *B. anthracis* by penicillin, ciprofloxacin, and doxycycline [121].

The CDC currently subdivides therapy for anthrax (systemic disease) into patients with and without possible meningitis [120]. Empiric treatment for systemic anthrax in which anthrax meningitis is suspected or cannot be ruled out should include ≥3 antimicrobial drugs with activity against *B. anthracis*, ≥1 drug should have bactericidal activity, ≥1 should be a protein synthesis inhibitor, and all should have good CNS penetration. Intravenous combination treatment for systemic anthrax with possible meningitis should be provided for ≥2 weeks or until the patient is clinically stable, whichever is longer. Preferred drugs include ciprofloxacin (alternatives: levofloxacin or moxifloxacin), meropenem (alternatives: imipenem or doripenem), and linezolid (alternatives: clindamycin, rifampin, or chloramphenicol). If the *B. anthracis* strain is susceptible to penicillin (MIC <0.125 μg/mL), penicillin G and ampicillin are acceptable alternatives to carbapenems.

With the following four exceptions, antimicrobial drug options for patients with systemic anthrax if meningitis is ruled out are similar to those for patients with suspected meningitis or when meningitis cannot be ruled out. First, treatment should include ≥2 antimicrobial drugs with activity against *B. anthracis*, ≥1 should have bactericidal activity, and ≥1 should be a protein synthesis inhibitor. Second, initial intravenous combination treatment should be given for ≥2 weeks or until the patient is clinically stable, whichever is longer. Third, if the *B. anthracis* strain is susceptible to penicillin, then penicillin G is considered equivalent to the fluoroquinolone options for primary bactericidal treatment. Fourth, treatment with antimicrobial drugs that have good CNS penetration is not a crucial factor. Thus, meropenem is recommended as an acceptable alternative option than as a first-line antimicrobial drug, and vancomycin is also an acceptable alternative. Clindamycin and linezolid are considered equivalent first-line choices for protein synthesis inhibitors. Doxycycline is added as an alternative protein synthesis inhibitor option if linezolid or clindamycin are contraindicated or unavailable.

Once patients with systemic illness who were exposed to aerosolized spores have completed initial combination treatment, they should be transitioned to single-agent oral treatment to prevent relapse from surviving *B. anthracis* spores. Antimicrobial drug options are the same as those for post-exposure prophylaxis.

The CDC provides excellent guidance on post-exposure preventive therapy for anthrax, and treatment for children, pregnant women, and immunocompromised persons [120].

In general, similar drugs are advised for children (with appropriate dose adjustment), pregnant women, and immunocompromised persons. The total duration of recommended therapy is 60 days (IV and orally combined) for bioterrorism-related cases and 7–14 days for naturally acquired cases depending on response and site of infection. The prolonged duration of bioterrorism-related cases is based on evidence such as the Sverdlovsk outbreak that following point exposure to aerosolized anthrax patients may not develop inhalation anthrax for up to 6 weeks post-exposure [122]. This is felt due to late germination of *B. anthracis* spores colonizing the upper respiratory tract. Management algorithms for the clinical assessment of patients with suspected inhalation or cutaneous anthrax are available [123].

3.1.4 Recommended Clinical Management

The CDC recommends that the initial evaluation of patients suspected of having anthrax should be similar to the standard evaluation for patients with an acute febrile illness and should have an emphasis on obtaining pretreatment blood and other appropriate cultures [120]. However, failure to fulfill systemic inflammatory response syndrome criteria should not decrease concern for sepsis because patients with systemic anthrax might not initially appear critically ill. Inhalation anthrax can have a prodromal phase followed by a fulminant phase. Patients with systemic anthrax have had debilitating symptoms, followed first by transitory improvement, and then by precipitous hemodynamic deterioration. Because of this potential for sudden decompensation, hospitalized patients should have careful hemodynamic monitoring, including continuous pulse oximetry and telemetry. Unless contraindicated, lumbar puncture should be performed to rule out meningitis.

Although there are no animal data or randomized trials to support the use of corticosteroid for human anthrax, small observational studies and the absence of apparent side effects suggest that adjunctive corticosteroids should be considered in patients who had a history of the use of corticosteroid therapy; edema, especially of the head or neck; evidence of anthrax meningitis; or vasopressor-resistant shock [124, 125]. Antitoxins used in the pre-antibiotic era have been reported to improve patient outcomes [120]. There are currently 2 antitoxins in the CDC Strategic National Stockpile: raxibacumab (GlaxoSmithKline, London, UK) and anthrax immune globulin intravenous (AIGIV) (Cangene Corporation, Winnipeg, Manitoba, Canada) [120]. Both antitoxins inhibit binding of PA to anthrax toxin receptors and translocation of the two primary toxins (LT and ET) into cells. Raxibacumab is a recombinant, fully humanized, IgG1λ monoclonal antibody. AIGIV is a human polyclonal antiserum made from plasma of persons immunized with anthrax vaccine absorbed (AVA), which might have some direct effect on LF and EF. Based on available data, an expert panel has stated that "an antitoxin should be added to combination antimicrobial drug treatment for any patient for whom there is a high level of clinical suspicion for systemic anthrax." Although there is some experience with AIGIV use in humans, "there are no major medical, operational, or logistical considerations that clearly favor the use of 1 antitoxin over another in adults with systemic anthrax" [120].

3.2 Infections Due to *Bacillus* Species Other Than *B. anthracis*

3.2.1 In Vitro Antibiotic Susceptibility

CLSI has issued guidelines for performing susceptibility testing of *Bacillus* spp. (other than *B. anthracis*) [86]. Susceptibility testing should be performed using broth microdilution using cation-adjusted Mueller–Hinton broth (CAMHB); disk diffusion testing is not recommended. Breakpoints have been provided by CLSI for selected penicillins (penicillin, ampicillin), cephalosporins (cefazolin, cefotaxime, ceftazidime, ceftriaxone), carbapenems (imipenem), glycopeptides (vancomycin), aminoglycosides (gentamicin, amikacin), macrolides (erythromycin), tetracyclines (tetracycline), quinolones (ciprofloxacin, levofloxacin), lincosamides (clindamycin), folate antagonists (trimethoprim–sulfamethoxazole), and miscellaneous agents (chloramphenicol, rifampin). Andrews and Wise reported that gradient tests (i.e., Etest®) for *Bacillus* spp. have been found to be unreliable [126]. They also demonstrated a poor correlation between penicillin resistance and detection of β-lactamase. Detection of β-lactamase production by a double-disk method was more reliable than nitrocefin or intralactam.

The in vitro antimicrobial susceptibility *of Bacillus* spp. has been evaluated in human isolates' studies as part of a comprehensive study of *Bacillus* spp. [127, 128], evaluation of specific clinical infections [70, 83, 85, 129–135], and assessments of new antimicrobials [136, 137]. *Bacillus* spp. are generally susceptible to vancomycin, imipenem, ciprofloxacin, and aminoglycosides (Table 53.3). They are generally resistant to β-lactams including third-generation cephalosporins. Preliminary studies suggest that they are susceptible to daptomycin and linezolid [127]. In vitro susceptibility testing of 10 ocular isolates of *Bacillus cereus* demonstrated that vancomycin, clindamycin, and gentamicin were all active [138]. A clindamycin–gentamicin combination demonstrated a higher rate of bactericidal synergy than a vancomycin–gentamicin combination.

3.2.2 Antimicrobial Resistance

B. cereus typically produces β-lactamases and so is resistant to β-lactam antibiotics including the third-generation cephalosporins [51, 139]. Other *Bacillus* spp. also often produce β-lactamase [126, 133]. For example, Uraz and colleagues

Table 53.3 Susceptibility of *Bacillus* to selected antibiotics

Bacillus spp.	Highly susceptible	Moderately susceptible	Rarely susceptible
B. cereus	Imipenem	Erythromycin	Penicillin
	Meropenem	Clarithromycin	Oxacillin
	Doripenem	Azithromycin	Cefazolin
	Vancomycin		Cefoxitin
	Linezolid		Cefuroxime
	Chloramphenicol		Cefotaxime
	Ciprofloxacin		Ceftazidime
	Levofloxacin		Tetracycline
	Ofloxacin		Trimethoprim–sulfamethoxazole
	Gentamicin		Clindamycin
			Amoxicillin–clavulanate
Other Bacillus spp.	Imipenem	Cefazolin	Penicillin
	Vancomycin	Cefoxitin	Ampicillin
	Erythromycin	Cefuroxime	Amoxicillin–clavulanate
	Trimethoprim–sulfamethoxazole	Cefotaxime	Oxacillin
		Chloramphenicol	
	Gentamicin	Tetracycline	
	Ciprofloxacin	Piperacillin–tazobactam	
	Levofloxacin	Clindamycin	

Highly susceptible, >95 % strains susceptible; moderately susceptible, 70–95 % strains susceptible; rarely susceptible, <70 % strains susceptible

isolated 19 *Bacillus* strains from milk of which five demonstrated β-lactamase activity [140]. Little attention has been devoted to evaluating the β-lactamases of *Bacillus* spp., and little is known except that most strains are broadly resistant to penicillins and cephalosporins including third-generation cephalosporins. Many strains are also resistant to antibiotics containing β-lactamase inhibitors (e.g., clavulanic acid) [136, 137]. However, most strains are susceptible to carbapenems.

3.2.3 Recommended Therapy

Vancomycin is generally considered the drug of choice for serious *Bacillus* infections. Alternatives include a carbapenem or a fluoroquinolone. Endophthalmitis due to *Bacillus* usually requires both intravenous and intravitreal therapy. For patients with meningitis or endocarditis, a combination of vancomycin plus gentamicin has often been used in the past. A carbapenem would be a reasonable alternative, but there is only limited clinical experience. Whether monotherapy is adequate for serious *Bacillus* infections or combination therapy is superior has not been assessed in animal models or clinical trials.

The duration of therapy for most *Bacillus* infections ranges from 7 to 14 days, depending on the site of infection, severity of illness, and underlying host defense abnormalities. Catheter removal is often required for patients with catheter-related bloodstream infections. Patients with endocarditis and osteomyelitis require prolonged therapy. For bone and soft tissue infections, oral clindamycin or ciprofloxacin may be an appropriate choice for prolonged therapy.

4 Germicide Susceptibility of *Bacillus* spp.

The Centers for Disease Control and Prevention (CDC) has estimated that healthcare-associated infections (HAIs) account for an estimated 720,000 infections and 75,000 deaths [141]. Key interventions to control healthcare-associated infections include surveillance, isolation of patients with communicable diseases or multidrug-resistant pathogens, proper skin antisepsis and hand hygiene, and appropriate disinfection and sterilization of medical devices and environmental surfaces.

Multiple nosocomial outbreaks have resulted from inadequate antisepsis or disinfection. Inadequate skin antisepsis may result from lack of intrinsic antimicrobial activity of the antiseptic, a resistant pathogen, over-dilution of the antiseptic, or use of a contaminated antiseptic. Inadequate disinfection of medical devices or environmental surfaces may result from lack of intrinsic antimicrobial activity of the disinfectant, a resistant pathogen, over-dilution of the disinfectant, inadequate duration of disinfection, lack of contact between the disinfectant and the microbes, or the use of a contaminated disinfectant.

Spore-forming *Bacilli* such as *Bacillus* spp. are intrinsically resistant to alcohols [142]. In a human challenge model, an alcohol-based hand hygiene agent did not have activity against *Bacillus atropheus* (a surrogate of *B. anthracis*) [143]. Despite the attempted decontamination with alcohol of the outside of vials containing *B. anthracis*, in one instance, these surfaces remained contaminated, resulting in cutaneous infection in a laboratory worker [144]. The use of a 70 %

ethanol solution for skin disinfection led to pseudo-outbreak of *Bacillus cereus* [145]. However, *Bacillus anthracis* has been demonstrated to be inactivated by chlorine [146–149], 4 % formaldehyde [148], 2 % glutaraldehyde [147, 149], ethylene oxide [149], and 0.025 % peracetic acid [147, 149].

5 *Listeria monocytogenes*

5.1 Microbiology and Clinical Disease

The genus *Listeria* consists of Gram-positive, non-spore-forming, facultative anaerobic, rod-shaped bacteria [150–152]. The primary habitat of *Listeria* is the environment where they exhibit a saprophytic lifestyle. *Listeria* can survive in multiple diverse habitats, including soil, water, vegetation, sewage, and food processing facilities, as well as humans and a variety of animal species. *Listeria* is an important cause of zoonoses, especially in herd animals [152]. The principal human pathogen in this genus is *L. monocytogenes*. In adults, *L. monocytogenes* causes principally sepsis, meningitis, and encephalitis [152–154]. Focal infections have been infrequently described and include endocarditis, pericarditis, arthritis, osteomyelitis, intra-abdominal abscesses, peritonitis, cholecystitis, respiratory tract infections, and brain abscesses [151, 153].

In pregnant women, *L. monocytogenes* may cause a mild, self-limited influenza-like illness or serious infection [151–154]. Infection may result in placentitis and/or amnionitis, and infection of the fetus may cause abortion, stillbirth, or, more commonly, preterm labor. It has been estimated that invasive listeriosis during pregnancy is 13-fold to more than 100-fold more frequent than in the general population [154]. Neonatal infection occurs in two forms: an early-onset sepsis syndrome often associated with prematurity and which is probably acquired in utero and late-onset meningitis that most commonly occurs ~2 weeks postpartum in full-term babies and is most likely due to acquisition of *Listeria* present in the maternal vagina at the time of parturition [152].

L. monocytogenes is a common cause of foodborne illness characterized by gastroenteritis that may be accompanied by fever, headache, arthralgias, and myalgias. The incubation period is approximately 24 h, and the duration of illness is usually around 2 days.

5.2 Antibiotic Susceptibilities and Mechanisms of Resistance

Antimicrobial testing of clinical isolates of *L. monocytogenes* should be performed using the broth microdilution method [86]. The recommended medium is cation-adjusted Mueller–Hinton broth with lysed horse blood (2.5–5 % v/v). Tubes are incubated at 35 °C, ambient air, for 20–24 h. Breakpoints are available for penicillin, ampicillin, and trimethoprim–sulfamethoxazole.

Penicillin and aminopenicillins (i.e., ampicillin or amoxicillin) are the drugs of choice for *L. monocytogenes* [151]. Although, in vitro resistance of *L. monocytogenes* to ampicillin has occasionally been reported, the methods used in these studies have been noted to be inadequate for susceptibility testing of *Listeria* [151]. In multiple studies and reviews, in vitro resistance to penicillin G and ampicillin was not detected [155–158]. *L. monocytogenes* is susceptible to trimethoprim–sulfamethoxazole [156]. Recent well-done studies of human isolates have not demonstrated emerging resistance to penicillin, ampicillin, or trimethoprim–sulfamethoxazole [158, 159]. Most *L. monocytogenes* strains isolated from the environment have been demonstrated to be fully susceptible to penicillins, gentamicin, linezolid, rifampin, and vancomycin but are intrinsically resistant to cephalosporins [157].

Rarely environment-derived strains have demonstrated resistance to erythromycin, tetracycline, and trimethoprim–sulfamethoxazole [157]. Erythromycin resistance has been due to the presence of erm(B) and erm(C). High-level trimethoprim–sulfamethoxazole resistance due to *dfrD* has been reported [160]. Resistance to tetracyclines in *Listeria* is mediated by efflux proton antiporters and ribosome protection [161].

6 *Nocardia*

6.1 Microbiology and Clinical Disease

The order *Actinomycetales* includes the family *Nocardiaceae*. At some stage all members of the order form Gram-positive rods. In direct Gram smears, organisms generally appear as very long, branching, thin, and finely beaded Gram-positive rods [162]. *Nocardia* is the most commonly isolated aerobic actinomycete from human infections. Approximately 50 species of the 85 validly names species of *Nocardia* have been reported to cause disease in humans [162].

Nocardia infections generally result from either trauma-related introduction of the organism or from inhalation with establishment of a pulmonary focus (especially in immunocompromised persons) [162]. Hematogenous spread may occur from the pulmonary focus to a variety of secondary sites, especially the central nervous system. The most common clinical syndromes are pleuropulmonary disease, central nervous system infection, and skin/soft tissue infection [163, 164]. Reviews of the clinical features and outcomes of pulmonary nocardiosis [165], central nervous system infection [166], and skin/soft tissue infection [167] have been published. The majority of patients with nocardiosis are immunocompromised [163, 164, 168]. The frequency of

nocardiosis in solid organ transplant recipients has varied between 0.7 % and 3 % and has largely been reported in heart, liver, and lung recipients [163].

6.2 Antibiotic Susceptibilities and Mechanisms of Resistance

Susceptibility testing should be performed on all isolates of *Nocardia* thought to be of clinical importance [162]. Antimicrobial testing of clinical isolates of *Nocardia* should be performed using the broth microdilution method [169]. Breakpoints are available for many antibiotics and are subdivided into primary antibiotics (amikacin, amoxicillin–clavulanic acid, ceftriaxone, ciprofloxacin {levoflocxacin}, clarithromycin {class representative for newer macrolides}, imipenem, linezolid, minocycline, moxifloxacin, trimethoprim–sulfamethoxazole, and tobramycin) and secondary antibiotics (cefepime, cefotaxime, doxycycline, and gentamicin) [169].

The antimicrobial susceptibility of both common and uncommon clinical strains of *Nocardia* have recently been published [170–173]. Susceptibility to the most commonly used therapy, trimethoprim–sulfamethoxazole, was observed in 97–98 % of isolates [172, 173]. Strains of *N. transvalensis* complex were less susceptible to trimethoprim–sulfamethoxazole (~80 %) [172, 173]. One study reported that 31 % of *N. pseudobrasiliensis* also were less likely to be susceptible (69 %) [173]. Linezolid and amikacin were also highly effective (>99 %) against all strains of *Nocardia* except *N. transvalensis* complex and *N. pseudobrasiliensis* [171–173]. For other antimicrobials, resistance was species specific. Resistance to more than one of the commonly used drugs (amikacin, ceftriaxone, trimethoprim–sulfamethoxazole, and imipenem) was highest for *N. pseudobrasiliensis* (100 %), *N. transvalensis* complex (83 %), *N. farcinica* (68 %), *N. puris* (57 %), *N. brasiliensis* (51 %), *N. aobensis* (50 %), and *N. amikacinitolerans (*43 %) [172]. Among carbapenems, doripenem and meropenem are more active than ertapenem and impenem [170]. Tigecycline has been shown to be very active in vitro [170, 173]. In conclusion, while antimicrobial resistance can often be predicted, susceptibility testing should still be considered when combination therapy is warranted, for less well-characterized species or those with variable susceptibility profiles and for patients with trimethoprim–sulfamethoxazole intolerance [172].

Trimethoprim–sulfamethoxazole is the most commonly used therapy for *Nocardia* infections, although other combination therapy and alternative antimicrobials may be used when there is a lack of response or resistance [174]. Treatment is recommended for 1–3 months in cutaneous nocardiosis, 6–12 months in pulmonary or disseminated disease, and ≥12 months for central nervous system infections [174]. Linezolid has been used to treat strains resistant to standard antibiotics but long-term use may be limited by myelosuppression, peripheral neuropathy, lactic acidosis, and retinitis [174].

As noted above, the great majority of *Nocardia* strains are susceptible to trimethoprim–sulfamethoxazole. However, there have been multiple reports of widespread resistance [175, 176]. Brown-Elliott and colleagues have re-analyzed a large number of *Nocardia* strains included in these reports and noted that 0.5 % were trimethoprim–sulfamethoxazole resistant [177]. They ascribed this difference to technical difficulties in correctly performing *Nocardia* susceptibility testing. A study of intra- and interlaboratory susceptibility testing of *Nocardia* demonstrated unsatisfactory overall reproducibility of broth microdilution testing with *N. cyriacigeorgica* and *N. wallacei* and reproducibility of tigecycline testing with *N. brasiliensis* and *N. cyriacigeorgica* and sulfonamides with *N. farcinia* and *N. wallacei* [178].

Little scientific work has been done to define the mechanisms of trimethoprim–sulfamethoxazole resistance in *Nocardia*. Valdezate and co-workers have assessed clinical strains of *Nocardia* that were resistant to trimethoprim–sulfamethoxazole by Etest® (CLSI recommends broth dilution for testing susceptibility) and reported the presence of the following resistant Genes *sul1* 93.4 %, *sul2* 78.9 %, *dfrA* (S1) 14.7 %, *bla*TEM-1 2.6 %, blaZ 2.6 %, VIM-2 1.3 %, *aph*(3')-*111a* 40.8 %, *ermA*, 2.6 %, *armB*, 77.6 %, *mefA* 14.4 %, and *msrD* 5.2 % [179].

7 Conclusions

Several genera of Gram-positive *bacilli* are capable of causing a variety human infection including *Bacillus, Listeria, Erysipelothrix, Lactobacillus, Corynebacterium, Gardnerella, Actinomyces,* and *Nocardia*. This chapter focuses mainly on *Bacillus* spp. because *B. anthracis* is considered one of the most important potential bioterrorist agents, *B. cereus* is an important cause of foodborne infections, and non-*B. anthracis* species are an unusual but important source of human infection, especially in immunocompromised patients. Reviewed also are *Listeria monocytogenes* and *Nocardia* spp. because of their importance as human pathogens.

Understanding the antibiotic spectrum of these pathogens and their common mechanisms of antibiotic resistance is crucial to the proper therapy for these pathogens.

Gram Negative Bacterial Drug Resistance: Clinical

Antibiotic Resistance in *Neisseria*

54

Margaret C. Bash and Kathryn A. Matthias

1 Introduction

The genus *Neisseria* includes both pathogenic and commensal species. *N. meningitidis* and *N. gonorrhoeae* are obligate human pathogens with no reservoir outside of the human host. Commensal species *N. lactamica*, *N. sicca*, *N. subflava* (biovars subflava, flava, and perflava), *N. mucosa*, *N. flavescens*, *N. cinerea*, *N. polysaccharea*, and *N. elongata* (subspecies *elongata*, *glycolytica*, and *nitroreducens*) are likewise specific to the human niche but are rarely associated with disease. Commensal *Neisseria* species can also be found in animal respiratory tract or oral flora and include *N. canis* and *N. weaveri* in dogs, *N. denitrificans* in guinea pigs, *N. macacae* in rhesus monkeys, *N. dentiae* in cows, and *N. iguanae* in iguanid lizards.

N. meningitidis most frequently colonizes the human host without causing disease. It is only when the bacterium is able to bypass the nasopharyngeal epithelium that severe and characteristic syndromes associated with invasion, including sepsis and meningitis, develop. Likewise, acquisition of *N. gonorrhoeae* oftentimes results in asymptomatic infection (roughly 50% of women exhibit no disease symptoms) [1]. When localized disease is detected, it often presents as cervicitis in women and urethritis in men. Extension to the upper genital track can occur, leading to pelvic inflammatory disease (PID) and epididymitis, both of which are associated with long-term complications. Extragenital infections of the pharynx and rectum are also common. More rarely, disseminated infections occur, resulting in gonococcal arthritis-dermatitis syndrome, septic arthritis, and other localized forms of disseminated disease including endocarditis and meningitis [2].

Antibiotic resistance represents a substantial threat in the treatment and control of *Neisseria gonorrhoeae*. Exhibiting high transformability, resistance mechanisms have spread rapidly throughout the species, resulting in the development of clinically significant resistance to every class of antibiotics used in the treatment of gonorrheal disease. Resistance to third-generation cephalosporins, the only remaining class suitable as a single-dose single-agent therapy, has developed, and effective treatment regimens vary depending on the geographic origin of infection.

DNA analysis of *N. gonorrhoeae* and *N. meningitidis* indicates that they are closely related and very similar organisms. Diversification through genetic exchange is an important aspect of adaptation for both organisms. However, vast differences exist in the role that antibiotic resistance plays in disease treatment and prevention. While antibiotic resistance has been a major consideration in control of gonococcal disease almost since the advent of antibiotic use, it has had less dramatic effects on approaches to treating *N. meningitidis* infections.

2 *Neisseria gonorrhoeae*

N. gonorrhoeae causes one of the most common communicable diseases in humans. It is a sexually transmitted organism that usually infects mucosal surfaces. Disease presentation is highly variable, and although asymptomatic infections are common, complications of gonococcal infections are particularly burdensome in terms of both health costs and patient sequelae. Substantial evidence now suggests that gonococcal infection is also associated with increases in both the acquisition and transmission of human immunodeficiency virus (HIV), implying a direct relationship between acquisition of *N. gonorrhoeae* and other sexually transmitted pathogens [3].

2.1 Overview of Gonococcal Disease

2.1.1 Worldwide Distribution

Gonorrhea is a disease of tremendous global public health importance. A 2008 World Health Organization (WHO) report estimated that approximately 106 million new cases occur each year, a number that adjusts for the underdiagnosis and underreporting that is characteristic of this disease [4]. Deficiencies in diagnosis and surveillance are of particular concern in settings where the disease is most prevalent, including developing nations in Africa and Asia where surveillance mechanisms are poor and treatment options are oftentimes limited. Indeed, though gonorrheal disease is distributed worldwide, both the incidence rate and the prevalence of the disease vary greatly according to geographic location. For example, the incidence rate of individuals 15–49 years of age was estimated to be approximately 13.5-fold higher in the Western Pacific Region compared to the Eastern Mediterranean in 2008 (Table 54.1) [4].

While a number of factors likely contributed to these differences, including adult population size, availability of antibiotics, and cultural attitudes regarding sexual practices, the most influential consists of the socioeconomic conditions of a given population. Even in western industrialized countries where rates of disease are considerably lower, the most marginalized communities in terms of racial and economic status exhibit the highest rates of disease. In Great Britain, for example, the overall incidence rate of gonorrhea is relatively low (63/100,000 persons), but increases substantially in urban settings, particularly in London where the incidence rate can be as high as 634/100,000 persons [5]. In the same geographic region, black ethnicity is associated with a >fourfold higher rate of diagnosis compared to white ethnicity, and rates also vary by age and gender. Similarly, in the USA in 2012, the highest rates of gonorrhea were observed among African-American men and women, with 467.7 and 456.3 cases recorded per 100,000 population, respectively (compared to an overall incidence of 107.5 cases per 100,000) [6]. The majority of cases were reported in densely populated metropolitan areas and rural, impoverished counties where public health resources are sparse or, if available, consistently overburdened.

Table 54.1 Disease burden of gonorrhea (values represent millions of individuals)

	Incidence	Prevalence
Western Pacific Region	42	13.3
Southeast Asia Region	25.4	9.3
African Region	21.1	8.2
Region of the Americas	11	3.6
European Region	3.4	1
Eastern Mediterranean Region	3.1	1

High rates of gonorrhea are currently either being maintained or increasing despite global control efforts. A resurgence of gonorrhea in homosexually active men has been noted in many parts of the developed world [7–9], and high rates of disease have been recorded in former Eastern bloc countries despite the collapse of mechanisms for case reporting [10]. Studies suggest, however, that the most significant indicators for disease acquisition include the amount of poverty and income inequality within a particular social setting [11]. These findings highlight the need for both increased surveillance mechanisms and access to cost-effective healthcare systems if the threat of gonococcal transmission is to be stemmed in the most vulnerable of communities.

2.1.2 Clinical Manifestations

Gonococcal disease is defined by the demonstration of *N. gonorrhoeae* in clinical samples. The gonococcus is an organism found only in humans and is highly adapted to its ecological niche. Most often it infects mucosal surfaces, causing sexually transmitted urethritis in men and endocervicitis in women. Anorectal and pharyngeal infections, which are more difficult to treat, may occur in both sexes, and in neonates, ophthalmic infection is acquired during passage through an infected birth canal. Endocervical, anorectal, and pharyngeal infections are commonly asymptomatic so that clinical presentation is delayed and reservoirs of infection and transmission are established.

Extension of mucosal infection may give rise to epididymo-orchitis in men or PID in women, both of which may result in infertility. In women specifically, complications may lead to an increased risk of spontaneous abortion, ectopic pregnancy, and chronic pelvic pain. Likely due to the high rate with which they experience asymptomatic infection, women are also fourfold more prone to develop disseminated gonococcal infections (DGIs), which occur in 0.5–3% of all infected patients [12]. DGIs have been associated with strains that are resistant to killing by normal human serum, and dissemination within the bloodstream may lead to infections that present as tenosynovitis, septic arthritis, or in rare cases, even endocarditis and meningitis [13]. If left untreated, gonorrhea may be transmitted to sexual partners and, in the case of pregnant women, to newborns during birth. Most often, neonatal disease presents as conjunctivitis, which may lead to corneal perforation and blindness unless antibiotics are administered.

Infection with *N. gonorrhoeae* has also been shown to significantly amplify acquisition and transmission of HIV, increasing the spread of the virus by up to fivefold [14]. Enhanced transmission is a result of the recruitment of inflammatory cells to the mucosal surface during gonococcal infection. It is these same phagocytic and CD4+ T cells that comprise the targets of HIV invasion, increasing the risk of viral acquisition. Viral load estimates of HIV in the semen of

HIV- and gonococcal-infected men are up to eightfold those of HIV-infected men without gonorrhea. This results in an increased inoculum of HIV and a greater risk of transmission. Importantly, this risk can be diminished with simple therapeutic treatment, as high viral loads revert to levels comparable to those of the uninfected cohort when effective antibiotics are administered [15].

2.1.3 Treatment and Control Strategies

It has long been recognized that a comprehensive program aimed at decreasing disease burden, transmissibility, duration of infection, and the number of sexual contacts is required for control of gonococcal disease [16, 17]. The emergence of multidrug-resistant and potentially untreatable strains of *N. gonorrhoeae* has brought a renewed focus and sense of urgency to the control and prevention of gonorrhea. Efforts have intensified in recent years to evaluate promising candidates for construction of preventative vaccines. Until such a time when a safe and efficacious vaccine becomes available, however, control of the spread of the disease must remain a primary objective.

In 2012, the World Health Organization crafted a global action plan with just such a goal in mind [17]. In addition to providing broader public awareness of existing multidrug-resistant gonococcal strains, a myriad of goals were established in an effort to successfully prevent and treat gonorrheal infections. Some of these include (1) behavioral changes, (2) improved diagnostic capabilities, (3) adequate surveillance, and (4) enhanced health-care delivery (including the provision of appropriate antibiotic treatment).

The requirement for early and effective treatment is central to this integrated approach. The treatment strategies recommended are for single-dose therapy on first presentation or diagnosis that should, at a minimum, cure 95% of all cases. The rationale behind this approach is twofold: to achieve compliance rates not possible with multidose treatments and to reduce any further disease transmission as quickly as possible (gonococci are no longer viable 12 h after effective antibiotic treatment) [16, 18, 19]. Since adequate treatment of gonorrhea is essential to the overall control of the disease, extensive efforts have been made to define, monitor, and address antimicrobial resistance in *N. gonorrhoeae*.

2.2 Antibiotic Resistance in *N. gonorrhoeae*

N. gonorrhoeae has a well-recognized potential to rapidly develop resistance to antibiotics. The organism's capacity for genetic recombination and phenotypic diversity enhance transmission and evasion of host immune systems and are essential for survival in the human host [20–22]. This propensity for genetic transformation and recombination also results in rapid spread of antibiotic resistance genes that have rendered numerous treatments ineffective in many parts of the world. This includes the penicillins, tetracyclines, quinolones, and more recently the cephalosporin group of antibiotics [23–25].

The gonococcus was originally highly susceptible to antibiotic treatment [26]. Now, in many parts of the world, only the third-generation cephalosporins, most notably ceftriaxone, remain effective and decreased susceptibility to these antibiotics has started to appear in most geographic regions. Cases of high-level cephalosporin resistance including some treatment failures have been reported [27–36]. Widespread resistance to penicillins in gonococci has necessitated demonstration of their efficacy in a given case or setting before their use is considered. The use of quinolone antibiotics is similarly restricted in many parts of the world. This means that cheap and effective oral therapy has had to be replaced by expensive and/or injectable agents. Thus, in resource-poor settings, effective antibiotics may be unavailable because the cost of the agent precludes its use [37].

In many areas where there are high rates of gonococcal disease, access to antibiotics is by means of the informal health sector. In this environment, adulterated antibiotics, off-patent preparations, and improperly stored antibiotics are all available [37–41]. The ready accessibility of these preparations means that inadequate doses may be purchased with resultant underdosing. Ironically, unrestricted drug availability leads to overuse and misuse, contributing significantly to the problem of antibiotic resistance. It is no accident that the WHO Western Pacific Region, where unregulated antibiotics are readily obtainable, has seen the sequential emergence of gonococci resistant to penicillins, tetracyclines, spectinomycin, quinolones, and now cephalosporins. Curbing these practices and ensuring proper compliance of health-care providers and their clients are of paramount importance in the WHO global action plan to control the spread and impact of antimicrobial resistance in *Neisseria gonorrhoeae* [17].

2.2.1 Development and Spread of Antibiotic Resistance in *N. gonorrhoeae*

Antibiotic resistance in general involves reduced access of the antibiotic to the target site or alteration of the target site itself. Access of antibiotics to the target site in gonococci may be limited by (1) reduced permeability of the cell envelope caused by changes in porin proteins, (2) active export of antibiotics from the cell by means of efflux pumps, or (3) destruction of the antibiotic before it can interact with the target [24, 25]. Alteration or deletion of the target site of the antibiotic generally results in a reduction of its affinity for the antibiotic. Genetically, these changes may be mediated by either chromosomal or extrachromosomal elements (plasmids). Multiple resistance determinants may coexist in a single organism, resulting in increased levels of resistance or, in some cases, resistance to a number of different antibiotics.

In gonococci, chromosomally mediated resistance is generally slow to emerge and disseminate. While genetic transformation (i.e., the mechanism of acquisition of these determinants) is common in *N. gonorrhoeae*, clinically relevant resistance requires multiple gene transfers [42]. Plasmid-mediated resistance in gonococci spreads more rapidly than chromosomally mediated resistance and is at present limited to penicillins and tetracyclines. Transmission requires the presence of a conjugative plasmid to mobilize the resistance plasmid. If a bacterium does not possess a conjugative plasmid, it may acquire it as a recipient strain. Once acquired, the recipient can become a donor in its own right, perpetuating dissemination not only of conjugative plasmids but also extrachromosomal resistance genes [25, 42].

Resistance to Penicillins (Penicillin, Ampicillin, Amoxicillin, Penicillin/β-Lactamase Inhibitor Combinations)

The penicillins have been widely used for the treatment of gonorrhea. Originally, *N. gonorrhoeae* was extremely sensitive and treatment with 150,000 units of penicillin was efficacious in most instances [26]. Not long after its introduction, decreased in vitro susceptibility appeared and was associated with treatment failure as early as the mid-1950s. Increasing the recommended dose of penicillin resulted in improved efficacy, but enhanced levels of resistance rapidly emerged and large numbers of treatment failures again occurred, even with high-dose regimens [19, 43]. This was a result of the additive accrual of multiple chromosomal changes to multiple loci over the span of multiple decades. The genetic basis for high-level chromosomally mediated penicillin resistance has been described and is caused by the contributions of mutations in five different genes or loci [44].

The targets of β-lactam agents are the penicillin-binding proteins (PBPs), enzymes located in the cell envelope that participate in cell wall peptidoglycan metabolism. Alterations in PBP-2 decrease their affinity for the penicillins and, thus, the susceptibility of the organism [45]. PBP-2 is encoded by the *penA* locus [46]. Changes in other loci such as *mtr* and *penB* produce additive effects. The *mtr* locus mediates resistance to a wide range of antibiotics, detergents, and dyes through an active efflux system [47, 48]. Mutations in the *penB* locus, in turn, affect the major outer membrane porin protein, resulting in reduced permeability of the cell envelope to hydrophilic antibiotics and other compounds [42, 49–51]. An additional contribution to resistance by *ponA1* encoding a mutation in PBP-1 has been shown, but only in the presence of a mutation in *penC* (*pilQ2*), which interferes with the formation of the high molecular weight PilQ secretin complex [44, 52]. The combined effect of *penA, penB, mtr, penC,* and *ponA1* is to increase the minimum inhibitory concentration (MIC) of penicillin by 120-fold. Gonococci exhibiting these changes are termed chromosomally resistant *N. gonorrhoeae* (CMRNG) [53]. The CMRNG phenotype has been associated with strains expressing the P1. B allele of the porin that is the target for serologic typing antibodies and is found in strains designated serotype IB (or WII/WIII) [54, 55].

Resistance to penicillin is also mediated by a plasmid-borne, inducible TEM-1 type β-lactamase which is believed to have been initially acquired by the gonococcus from *Haemophilus* species [56–60]. This enzyme hydrolyzes the β-lactam ring of penicillins, thus inactivating them. In contrast to the slow evolution and incremental increase in resistance associated with chromosomal changes, acquisition of the plasmid confers resistance in a single step. In 1976, penicillinase-producing *N. gonorrhoeae* (PPNG) were detected at the same time in both the UK [61] and the USA [62]. The first isolates were imported, respectively, from Africa and the Far East. Although the same TEM type of β-lactamase was present in both instances, the gene was carried on plasmids of different sizes which became known as the "African" and "Asian" plasmids, respectively. Transmission of resistance by conjugation required the presence of a mobilizing plasmid that was present in the Asian PPNG upon initial isolation, but was not found in the African strains until 1981 [60]. Thus, resistance due to the Asian plasmid disseminated more quickly and widely compared to the African plasmid. A number of related PPNG carrying plasmids of different sizes have since been described [42].

Lactamase production (PPNG) and chromosomal changes (CMRNG) can coexist in the same isolate. Attempts have been made to negate the effects of penicillinase production by combining a β-lactamase inhibitor with a penicillin, e.g., amoxicillin with clavulanic acid. Treatment of gonorrhea with such a combination has met with only limited success [63, 64]. Although lactamase inhibitors may neutralize the effect of the hydrolyzing enzyme and leave the penicillin to act on the organism unhindered, if underlying chromosomally mediated mechanisms of resistance are also present, the organism will still be intrinsically resistant [65].

Tetracyclines

Tetracycline antibiotics are generally not recommended for treatment of gonorrhea because they must be administered in multiple doses over several days, often resulting in decreased compliance or an inadequate regimen. Despite these problems, tetracyclines remain widely used, particularly in the informal health sector where poverty makes them especially appealing due to their inexpensive cost.

Both chromosomal and plasmid-borne tetracycline resistance mechanisms are found in gonococci, the latter being responsible for high-level resistance. As with the penicillins, chromosomal resistance is linked to alterations in the *mtr* and *penB* loci [42]. In addition, a third locus, tet-2, has been identified as a single point mutation in the *rpsJ* gene

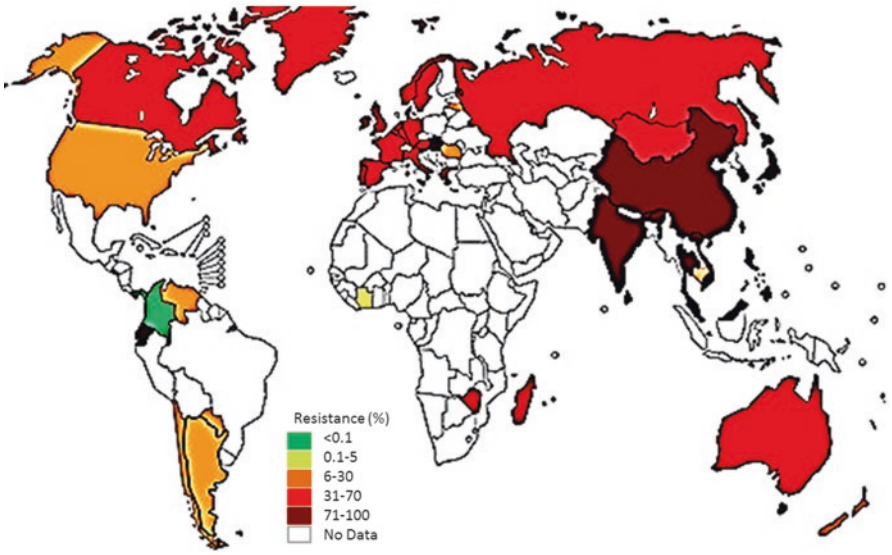

Fig. 54.1 Monitoring gonococcal antimicrobial susceptibility. Proportion of *N. gonorrhoeae* strains resistant to ciprofloxacin and/or other quinolones reported in countries, 2010 [154].

encoding the ribosomal protein S10 [46, 66]. The combination of these and other chromosomal mutations result in clinically significant resistance [67].

High-level tetracycline resistance in gonococci (TRNG) results from the acquisition of the *tetM* determinant and was first reported in 1986 [68]. *tetM* exists as two slightly different "Dutch" and "American" types, located on a self-mobilizing plasmid [69] that is widely dispersed in the normal genital tract flora. A study of the molecular epidemiology of the *tetM* genes by PCR suggests that the Dutch type may have originated in the Far East and the American type on the African continent [70]. The mobility of the plasmid and the selective pressure created by the use of tetracyclines to treat other sexually transmitted infections (STIs) has contributed greatly to the widespread distribution of the TRNG phenotype [53, 71–75].

Sulfonamide-Trimethoprim Combinations

Sulfamethoxazole and trimethoprim (co-trimoxazole) have been combined in an oral formulation that is used as a multidose treatment for gonorrhea. As discussed above for the tetracyclines, the need for multiple doses has implications for the development of resistance due to poor compliance. Trimethoprim is not particularly active against gonococci and is in fact used for bacterial growth in primary culture plates, a result of the reduced affinity of gonococcal dihydrofolate reductase for the microbial agent. Increased production of dihydrofolate reductase or decreased cell permeability may also contribute to resistance [76]. Resistance to the sulfonamides can develop separately [42, 77].

Quinolone Antibiotics

Oral, single-dose fluoroquinolone therapy, such as ciprofloxacin and ofloxacin, was recommended for the treatment of genital *N. gonorrhoeae* infections starting in the early 1990s [78]. Over the past two decades, quinolone-resistant gonococci (QRNG) have been isolated with increasing frequency worldwide (Fig. 54.1), diminishing the usefulness of quinolone antimicrobials [24, 25, 79, 80]. In 2007, the Centers for Disease Control and Prevention (CDC) called for the discontinuation of their use for treatment of gonorrhea in the USA [81].

Fluoroquinolone resistance has been attributed to point mutations in bacterial genes *gyrA* and *parC*, which code for the target enzymes DNA gyrase and topoisomerase IV, respectively [82]. Sequence analysis suggests that multiple mutations in *gyrA* or the combination of *gyrA* and *parC* mutations are generally associated with ciprofloxacin resistance (ciprofloxacin MIC $\geq$ 1 μg/mL) and are clinically expressed as treatment failure [82–88]. Additionally, porin changes and efflux mechanisms may contribute to resistance [89, 90]. Newer quinolones with enhanced ParC activity have been released. However, this target site is less important in gonococcal resistance than GyrA, so these agents are unlikely to be effective in areas where high-level resistance to quinolones is already well established [91].

Cephalosporin Antibiotics

Increased resistance of *N. gonorrhoeae* to fluoroquinolones and the subsequent discontinuation of their use have left the cephalosporins as the sole remaining single-dose single-agent antibiotic class to which widespread gonococcal resistance has not developed. As β-lactam agents, they function like the penicillins to bind PBPs present in the cell membrane and inhibit the synthesis and cross-linking of the bacterial cell wall. Cephalosporins, however, exhibit less susceptibility to the action of β-lactamases than penicillin antibiotics, and cephalosporinases, which are constitutively expressed by many Gram-negative genera, have not been detected in *Neisseria sp.* [23]. Thus, altered susceptibility to cephalosporins in gonococci is chromosomally mediated and

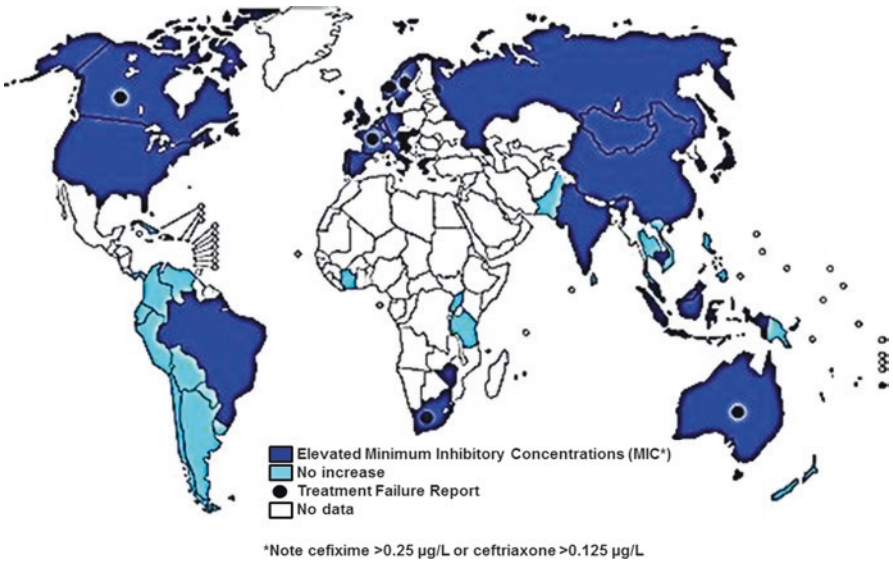

Fig. 54.2 Monitoring gonococcal antimicrobial susceptibility. Countries with documented elevated minimum inhibitory concentrations to cefixime and/or ceftriaxone, 2010 [154].

is due to similar changes that account for decreased penicillin susceptibility in CMRNG [42, 92].

Data suggest that, like penicillins, mutations in multiple genes including *penA*, *ponA*, *mtrR*, and *penB* (*porB*) [93–95], contribute to increased cephalosporin resistance, though *pilQ* is unlikely to affect susceptibility [96]. Indeed, cross-resistance between penicillins and early generation cephalosporins (such as cefuroxime) has been demonstrated [42, 92, 97], though this is not the case for third-generation cephalosporins like ceftriaxone and cefixime [98]. Resistance to these extended spectrum cephalosporins (ESCs) is most often associated with multiple mutations in the *penA* gene that likely induce a conformational change in the β-lactam binding site of PBP-2 [99]. This mosaicism alone is sufficient to significantly increase gonococcal resistance to ESCs, but the effect is enhanced in the presence of *ponA*, *mtrR*, and *penB* mutations.

penA mosaicism in *N. gonorrhoeae* is believed to have arisen from recombination events with the *penA* genes of closely related commensal species, including *N. flavescens*, *N. perflava*, *N. subflava*, *N. cinerea*, and *N. meningitidis* [100]. Regions of homology were identified in the *penA* transpeptidase domain when the sequence of ESC-resistant isolates was compared to that of the commensals [95, 101]. Since the niche of these commensals is oropharyngeal, it is likely that genetic transfer takes place at that site, a hypothesis bolstered by the steady increase in the recovery of ESC-resistant isolates from sex workers and men-who-have-sex-with-men (MSM), in addition to multiple reported treatment failures of pharyngeal infection with ceftriaxone [28, 42, 92, 102].

The first verified treatment failure of a patient administered oral cefixime was recorded in Japan in 2002 [36]. Since that time, further treatment failures have been reported in countries including South Africa, Canada, Austria, France, Spain, the UK, and Norway [27, 29, 30, 34, 35]. Concurrent with treatment failures, the percentage of isolates exhibiting elevated MICs to cefixime (≥0.25 µg/mL) continued to rise (Fig. 54.2) until a decade later when, in 2012, the CDC ceased recommendation of the antibiotic for use in gonococcal treatment [103]. Currently, the CDC recommends dual therapy treatment, utilizing injectable ceftriaxone in combination with either oral azithromycin or doxycycline. Yet, treatment failures of ceftriaxone-based therapies [33, 102, 104] and the emergence of extensively drug resistant (XDR) gonococcal strains [28, 32, 33] have recently been reported, highlighting the anticipated loss of these treatment options in the future.

Spectinomycin and Aminoglycosides

In *N. gonorrhoeae*, high-level resistance to spectinomycin or aminoglycosides occurs via linked single-step chromosomal mutations in ribosomal genes, allowing bacterial translation to continue unimpeded [42, 105, 106]. Spectinomycin-resistant gonococci appeared in Korea in the 1980s following widespread use. When spectinomycin treatment was discontinued, however, antibiotic-resistant strains disappeared. Spectinomycin-resistant strains of *N. gonorrhoeae* are uncommonly encountered and specifically have not been seen in Korea for many years following discontinuation of their use [75], suggesting the possibility that they may constitute effective agents for therapy in the future. Yet, apparent treatment failure has been reported where in vitro sensitivity to the antibiotic was demonstrated, likely due to inadequate dispersal from the site of injection [77]. Additionally, though spectinomycin is efficient in treating urogenital and anorectal gonorrhea, it is less effective in the treatment of pharyngeal infections [107], demonstrating the importance of the site of infection in selecting a proper antibiotic regimen.

Aminoglycoside antibiotics, primarily kanamycin and gentamicin, are low-cost injectable agents, sometimes used as first-line treatments. Susceptibility testing data indicates, however, the emergence of low-level gentamicin resistance, and a 2012 study of documented urogenital gonorrhea cases demonstrated that while single-doses of gentamicin were effective at treating the majority of infections, the percentage of subjects that cleared *N. gonorrhoeae* without requiring further treatment fell below the current CDC criteria for recommended therapy (≥95% efficacy) [108]. As the MIC for defining gentamicin resistance has still not been well defined [109, 110], future studies examining the correlation of in vitro susceptibility to clinical treatment failures are clearly needed.

Newer Macrolides

A number of newer macrolides have been made available for treatment of gonococcal infection concomitant with *Chlamydia trachomatis*, most notably azithromycin. As with erythromycin [47], chromosomal resistance to azithromycin is dependent on expression of the *mtr* phenotype [111]. Mutations encoding resistance to erythromycin have been localized to the ribosome [112, 113] and promoter region of *macAB*, which promote unimpeded translation and increased transcription of the genes encoding the MacA-MacB efflux pump [114]. Treatment failures have been reported with low-dose (1 g) azithromycin regimens [115–117]. However, a recent dual therapy study utilizing oral azithromycin has proven much more promising, as combination treatment with injectable gentamicin or oral gemifloxacin resulted in 100% and 99.5% efficacy, respectively, in clearing urogenital gonorrhea [118]. One hundred percent efficacy was also demonstrated against pharyngeal and anorectal infections for both combinations, highlighting the importance of dual therapy treatments in the elimination of bacterial reservoirs that may contribute to antibiotic resistance.

Chloramphenicol/Thiamphenicol

Data on in vitro susceptibility is often lacking, but that which does exist suggests gonococcal resistance to these agents [71, 119].

2.2.2 Laboratory Determination of Resistance

In principle, laboratory methods for susceptibility testing of gonococci are similar to those for other bacteria. However, *N. gonorrhoeae* has specialized growth requirements that have led to the development of tests with numerous variations in methodology.

Agar Dilution (Agar Incorporation) Methods

The agar dilution MIC is the definitive susceptibility test. It is a labor-intensive method and is only performed in specialized laboratories, but is relatively inexpensive when large numbers of strains are tested in batches. The methods currently in use are not uniform and different MIC values expressed in mg/l may be obtained in different laboratories [120]. MICs are generally accepted to be accurate to a value of plus or minus one doubling dilution.

Disk Diffusion Methods

Disk diffusion susceptibility tests are widely used and are practical because of low cost and technical simplicity. Their utility and accuracy in assessing gonococcal susceptibility is debated since the method was initially standardized for rapidly growing organisms and the slow rate of bacterial growth and increased time of incubation for *N. gonorrhoeae* greatly affect inhibition zone diameters. Attempts have been made to correlate inhibitory zones with MICs in order to develop interpretive criteria. Although not standardized, comparable data can be generated in different laboratories [16].

E-Test

This is a quantitative susceptibility test that uses a strip impregnated with a predefined antibiotic gradient. When performed under reference laboratory conditions, the E-test has compared favorably with the conventional agar dilution MIC. However, the methods were less comparable in a field study in Malawi [109]. MICs obtained with this method in reference laboratories tend to be slightly lower than those obtained by conventional agar dilution methods.

Comparability of MIC Data

Many problems with comparability of MIC data exist. Recently, however, it has been suggested that resistance rates obtained by different methods can be compared if certain test parameters are defined and controls that are internationally agreed upon are used [77, 90]. For example, the MIC value for chromosomal resistance to penicillin is defined as ≥2 μg/mL in the USA and Canada and ≥1 μg/mL in the UK and Australia. However, qualitative classifications of the strains (i.e. as sensitive or resistant) are the same when the relevant interpretive criteria are applied. The validity of this approach has been demonstrated in the quality assurance aspects of the continuing program of surveillance in the WHO Western Pacific Region [121, 122].

Detection of β-Lactamase (Identification of PPNG)

PPNG express an inducible TEM-type β-lactamase that is encoded on plasmids and can be detected by a number of methods, including a commercially available chromogenic test. The clinical utility of these tests may be limited since resistance to the penicillins is widespread, and CMRNG are not detected by this means. Resistance due to chromosomal mutations can only be detected in PPNG after strains are cured of plasmids.

Special Test Requirements for Some Antibiotics

Although not generally recommended, co-trimoxazole has been used extensively in some regions to treat gonorrhea because of its availability and low price. Testing susceptibility to this drug requires that the growth medium be free of substances that interfere with its activity. Azithromycin susceptibility testing is pH dependent. Since carbon dioxide (needed for the growth of *N. gonorrhoeae*) can alter the pH of the medium, robust controls must be used when assessing the activity of azithromycin.

DNA Probe and Hybridization Techniques for Susceptibility Determination

Chromosomally mediated resistance in *N. gonorrhoeae* is the result of multiple genetic changes, for which there is no simple probe. Probes have been tested that identify known mutations in *gyrA, parC*, and *gyrB* genes associated with QRNG [123–125] and those of *penA* and *ponA* that are associated with penicillin resistance [126]. Because new mutations that affect levels of resistance are continually being discovered, an alternative approach that uses probes to identify the absence of mutations (wild-type sequence) in resistance determining regions may be a useful screening strategy for detecting antibiotic susceptibility [127]. Mutations that may partially reverse resistance (e.g. suppressed expression of the *mtr* phenotype by the *env* mutation) [42] illustrate the complicated nature of identifying phenotypic resistance by molecular-based methods. Yet, identification of resistance markers by DNA testing will add significantly to conventional susceptibility tests if the ability to reliably and rapidly test non-cultured direct clinical specimens can be developed.

2.3 Clinical Significance of Resistance in *N. gonorrhoeae*

2.3.1 Epidemiology

The epidemiology of *N. gonorrhoeae* is complex. Although gonococci are generally considered to be non-clonal, outbreaks of antibiotic-resistant gonorrhea have been caused by strains that are phenotypically and/or genotypically related [67, 128, 129]. Studies suggest that the establishment of antibiotic-resistant gonorrhea in a community progresses through several characteristic stages. Initially, resistant isolates are primarily imported and are sporadic with little or no secondary spread. At this stage, resistant isolates are diverse. Sustained local transmission of a resistant strain may develop, establishing endemic transmission. This transition is usually associated with infection of core transmitters, such as sex workers [130]. During this stage, one strain or a few closely related strains account for a large proportion of resistant isolates, suggesting a unique window of opportunity for public health intervention before resistance genes become widely distributed in the population. In regions where high rates of resistance have been established for several years, multiple genetically diverse resistant strains can be found.

The spread of QRNG is an interesting example. The emergence of QRNG has been remarkable, particularly in Asia, and since 1999 has accounted for over 50% of Southeast Asian isolates [122, 131–133]. Analysis of variability in mutation patterns and typing characteristics demonstrate worldwide isolate diversity [84, 91, 134, 135], and the initial introduction of QRNG to communities has been characterized by low numbers of diverse strains imported from endemic regions via travelers [134]. Rapid increases in the prevalence of QRNG in a community signal the beginning of endemic transmission, which is typically clonal. The pattern of clonal spread of a highly resistant strain establishing high rates of endemic QRNG has been shown in studies conducted in the UK, Australia, Japan, the USA, Israel, and Sweden [84, 133, 134, 136–139].

2.3.2 Surveillance

Since antibiotic-resistant gonococci arise and spread rapidly, crossing national and regional boundaries with ease, data on in vitro susceptibility of prevalent gonococci are needed to establish and maintain effective treatment guidelines [140–145]. While in vitro susceptibility data reliably predicts clinical outcome, these examinations are generally not performed on an individual basis and treatment must routinely be provided before results of this testing become available. To circumvent these problems, an epidemiological approach is utilized to determine susceptibilities of prevalent gonococci and trends in gonococcal resistance patterns. The spread of antimicrobial resistance has been exacerbated by international travel, as documented by the abundance of data on PPNG and QRNG [146, 147]. In the absence of reliable in vitro testing, therefore, it is of critical importance for successful disease treatment to understand both the origin of an infection and the local and global patterns of gonococcal-specific antimicrobial resistance.

Unfortunately, severe limitations in resources impact the surveillance process. While national schemes have been in existence in developed countries for several decades [6, 148–152], there are few examples of adequate data arising in less developed countries [4]. Some regional activity has been implemented, however, and data are progressively being generated, assessed, and validated by international groups [121, 153]. Widespread use of nucleic acid-based amplification assays for the diagnosis of STIs, while a powerful tool, has diminished the use of culture-based techniques that permit the performance of susceptibility testing. Protocols that require bacterial isolation and antibiotic susceptibility testing will need to be adopted in the future if gonococcal surveillance programs are to remain successful.

Regional Surveillance Data

Due to the substantial regional differences in rates of gonococcal antibiotic resistance, a number of surveillance programs for *N. gonorrhoeae* currently exist [4, 121]. The Gonococcal Antimicrobial Surveillance Program (GASP) has continuously monitored the emergence of antibiotic resistance in the WHO Western Pacific Region since 1992 [75, 121]. Similar, less developed programs exist in Latin America and Southeast Asia, and a West African GASP has been established, as well. Attempts are underway to establish a global program of gonococcal susceptibility surveillance [154, 155].

Country-Based Data

In addition to regional programs, there are also a number of national programs that conduct surveillance for the progression of antibiotic resistance in *N. gonorrhoeae*. The Australian Gonococcal Surveillance Program (AGSP), for example, was established in 1979 [151] with the US Gonococcal Isolate Surveillance Program (GISP) [148] following in 1986. Additional country-based programs exist in Canada, the UK (Gonococcal Resistance to Antimicrobials Program, GRASP) [152], Sweden, Denmark, Singapore, China, Hong Kong, Bangladesh, and France, among others. The current data from the AGSP, GISP, and GRASP is sufficient alone to reveal the loss of utility of penicillins, quinolones, and increasingly cephalosporin antibiotics in gonococcal treatment [6, 149, 150]. Surveillance from other countries has likewise demonstrated clinically significant trends in diminished antibiotic susceptibility. In Scandinavian surveys, for instance, multi-resistant gonococcal infections acquired overseas are prominent, while data from China, Hong Kong, and Bangladesh all point to major problems with multiply resistant strains. In data available from Africa and Latin America, quinolone resistance is not as pronounced as in Asia, but penicillin and tetracycline resistance rates are high [77]. Clearly, improved surveillance results in a greater ability to monitor global trends in antibiotic resistance and to use that knowledge to treat gonorrhea at a local level.

2.4 Treatment

2.4.1 Management of *N. gonorrhoeae* Infections

In developed countries, the usual practice is to establish an etiological diagnosis in individuals presenting with symptoms of STIs. Bacterial culture was the typical diagnostic approach, but DNA-based diagnostic techniques are increasingly becoming the standard diagnostic method. Nucleic acid amplification tests (NAAT) have improved case finding, particularly in reference to asymptomatic infection common among women. In contrast, in many parts of the world where diagnostic facilities are nonexistent or rudimentary, treatment algorithms based on syndromic approaches have been developed [156]. Treatment is aimed at those infecting agents most likely to be involved in a particular clinical situation. The syndromic approach presumes that clinical symptoms are not only present but also that they are of sufficient magnitude to induce the patient to seek treatment. However, in the case of asymptomatic women or those that only experience minimal discomfort, patients who fail to present often place themselves at risk of complications and can serve as a reservoir of infection for others [156, 157].

Regardless of the level of diagnostic capability, initial treatment is empiric and the choice of antibiotic used is predetermined by the patterns of antibiotic resistance demonstrated in recently isolated gonococci. Disaggregated local information, as opposed to pooled country-based information, is relevant to tailoring treatment schedules to specific geographic regions. For example, while penicillins remained suitable for use in some remote settings in rural Australia, treatment regimens in Sydney were adjusted to utilize ceftriaxone to account for high rates of penicillin resistance as well as significant increases in QRNG [158]. In practice, once resistance to an individual antibiotic in a gonococcal population reaches 5% or more, it is recommended to be removed from treatment schedules [145].

Concomitant infection of *N. gonorrhoeae* with other treatable STIs is common. In particular, infection with *Chlamydia trachomatis* frequently accompanies gonococcal infection and can be asymptomatic or produce symptoms similar to those seen with gonorrhea. As some population studies have demonstrated coinfection in 20–40% of those with gonorrhea, it is common to include anti-chlamydial treatment with initial anti-gonococcal therapy, unless the presence of chlamydia has been specifically excluded [144, 159–161].

Follow-up evaluation of treated patients is standard practice in developed countries. This does not uniformly include a repeat laboratory examination, but cultures should be obtained if symptoms persist or recur to ensure that the individual patient is cured and, in the case of treatment failure, to determine antibiotic susceptibility [162]. It is important to identify treatment failures due to new or spreading forms of resistance so that control measures may be implemented in a local setting. Oftentimes though, it is difficult to differentiate between failure of antibiotic treatment and gonococcal reinfection. Comparisons of pre- and posttreatment cultures can assist in this distinction. Controlled monitoring can also alert practitioners to the existence of novel forms of resistance in the gonococcus. The timing of repeat evaluation needs to be carefully considered. Even if the organism is resistant to an antibiotic or antibiotic combination, symptoms and signs may be temporarily relieved and recur after cessation of therapy. In this context, anti-chlamydial therapy administered at the same time may have a suppressive, but not curative, effect [116, 163]. In less developed settings, access to treatment and clinics is often limited and follow-up assessments are infrequent.

While the focus here is on antibiotic resistance and treatment strategies, individual case management should include a comprehensive approach to the patient's needs for reproductive health. Counseling, contact tracing, and identification of other possible STDs are all essential to the management of gonorrhea.

2.4.2 Current Antibiotic Recommendations

Optimal practice requires cure of a minimum of 95% of cases by single-dose antibiotic therapy on initial presentation. Ideally, the selected regimen should be cost-efficient and orally administered under direct supervision, followed by an appropriate clinical review. Due to the propensity for *N. gonorrhoeae* to develop resistance rapidly, any treatment regimen should also be designed and administered so as to prevent emergence of new forms of resistance. Standard protocols that fulfill the above criteria have been developed either for universal application or else for use in individual countries [141, 142, 144, 145, 164]. Recommendations incorporate different requirements for treatment of genital and extragenital disease (pharyngeal, rectal, and ophthalmic infection), for complicated gonococcal disease, and for the special cases of infections in neonates, children, and during pregnancy. These recommendations are regularly revised to take account of changing susceptibility of gonococci to existing antibiotics, the introduction of new agents or new experience with older agents, the availability of currently used treatments, and the different prevalence of disease in different settings. Updated treatment recommendations for the USA are provided by the CDC (http://www.cdc.gov/std/tg2015/). Published protocols also include procedures for the prophylaxis of neonatal ophthalmia neonatorum. Treatment protocols generally utilize the antimicrobial agents described below.

Cephalosporins

Of the antibiotics currently recommended for the treatment of gonorrhea, the third-generation cephalosporins are the most efficacious. Prior to 2012, regimens including oral cephalosporins to treat gonorrhea were recommended, but the rapid development of resistant strains has in recent years diminished their use. The CDC now recommends administration of a single intramuscular injection of ceftriaxone (250 mg) in conjunction with a single dose of oral azithromycin (1 g) or a 7-day course of doxycycline (100 mg, twice a day) [144]. If oral cefixime is instead administered, a follow-up appointment is recommended one week later to confirm the absence of treatment failure. Ceftriaxone is suitable for use in all forms of gonococcal disease, including pharyngeal gonorrhea, which is often difficult to treat. Intravenous inpatient treatment is usual for DGI, including meningitis and endocarditis. Ophthalmic infections of neonates, older infants, and adults also respond to ceftriaxone. This class of antibiotics can be administered during pregnancy.

Quinolones

Fluoroquinolones, primarily ciprofloxacin or ofloxacin, are widely recommended as standard treatments for gonorrhea in geographic regions where resistance remains low. Recommended doses include 500 mg of ciprofloxacin or 400 mg of ofloxacin administered as a single oral dose. Initially, low-dose regimens (e.g., 250 mg doses of ciprofloxacin) were used, but the higher dose recommendation was implemented following reports of treatment failures due to low antibiotic levels. Fluoroquinolone agents given orally are effective in the treatment of anogenital and pharyngeal infection, but should not be administered during pregnancy/lactation or given to prepubertal children. Parenteral ciprofloxacin (500 mg) or ofloxacin (400 mg) may be administered every 12 h to treat DGI and systemic gonococcal infection. However, ceftriaxone is used preferentially for this complication. Earlier generation non-fluorinated quinolones, which are less efficacious, are not recommended.

Spectinomycin

Spectinomycin is an aminocyclitol compound given by intramuscular injection as a 2 g dose. It is relatively expensive but effective in the treatment of anogenital infection. Use in the treatment of pharyngeal gonorrhea is not recommended. Side effects are few, and as such, spectinomycin is usually regarded as a "reserve" agent in the treatment of gonorrhea (e.g. for those intolerant of cephalosporins or quinolones). It can also be administered to pregnant women in standard doses and for DGI if given twice daily for up to seven days.

Suboptimal or Obsolete Treatments

Some previously efficacious regimens have become ineffective due to developing resistance and should only be used if the infecting organism has clearly been demonstrated to be susceptible. However, in some regions, antibiotic susceptibility screening is not possible and inefficient, readily available treatments continue to be used because more effective therapy is simply unaffordable. Penicillins, including ampicillin and amoxicillin (with or without clavulanate and/or probenecid), were once standard treatments for gonorrhea but are now rarely used as a consequence of resistance. The most effective form of administration is a single 3 g oral dose of amoxicillin. Probenecid (1 g), if given at the same time, will delay renal excretion of the penicillins.

Azithromycin is widely used as a treatment for chlamydia as a single 1 g dose. It is now routinely recommended as a component of dual therapy for gonorrhea based on the theoretical benefit of using two antibiotics with different mechanisms of action to improve effectiveness and delay the development of resistance to the cephalosporins [144]. As a single agent, this antibiotic exhibits some anti-gonococcal activity but treatment failures are unacceptably high, and resistance has appeared during therapy [165]. The additive

anti-gonococcal effect of azithromycin combined with a specific gonococcal therapy is unquantified and should not be relied upon to affect a cure for gonorrhea [116, 117, 166]. Oral tetracyclines, like azithromycin, are also used as anti-chlamydial agents in conjunction with anti-gonococcal treatments and have been shown to exhibit some anti-gonococcal activity. Yet tetracyclines, when used for gonorrhea treatment, require multidose regimens and thus are not generally recommended due to insufficient compliance.

Despite this, the ready availability of tetracyclines and their low-cost result in their continued use in some settings. Some guidelines also mention kanamycin (2 g, intramuscular injection) as an alternative treatment where in vitro resistance rates are low. However, data on efficacy and in vitro criteria of resistance are poorly documented [109, 110]. Co-trimoxazole (trimethoprim/sulfamethoxazole combination), like the tetracyclines, is a multidose oral treatment and as such is not recommended. Its use should be guided by in vitro data demonstrating susceptibility to the agent, though considerable technical requirements must be fulfilled before reliable in vitro data can be obtained. Chloramphenicol/thiamphenicol antibiotics are still widely used for the treatment of many diseases in resource-poor settings, even though they are not recommended.

2.4.3 Infection Control Measures

Availability of proper treatment in a community contributes significantly to reductions in both disease and complication rates, including those of enhanced HIV transmission. It has been estimated that effective treatment of 100 women with gonorrhea, 25 of whom were pregnant, would prevent 25 cases of PID, one ectopic pregnancy, six instances of infertility, and seven cases of neonatal ophthalmia [16]. These estimates have been supported by results of longitudinal studies in Sweden where a decrease in the incidence of gonorrhea coincided with a reduction in the incidence of PID [167–169]. It has also been estimated that proper treatment of gonococcal disease in a cohort of 100 high-frequency gonorrhea transmitters would cumulatively prevent 425 new cases of HIV over a period of 10 years [170]; the decreased incidence of new HIV infection observed in a study of improved STD treatment in Mwanza, Tanzania, lends support these projections [171].

The multidisciplinary approach needed for control of antimicrobial resistance in *N. gonorrhoeae* includes (1) rapid and accurate diagnostic testing, (2) ready access to effective antibiotics administered in a setting with an established regulatory framework that oversees drug evaluation and approval, (3) enforcement of prescription-only drug access, (4) reliable drug delivery systems, (5) and an informed prescriber base and laboratory systems with good and evaluable diagnostic standards [172]. Prevention measures are also essential, including those aimed at effecting behavioral changes. While control was seemingly achieved in some countries when a concerted effort combining these elements was in place, the reduction in rates has been reversed as "safe sex" practices have been abandoned [7, 173].

Some progress has been made in efforts to control gonococcal antimicrobial resistance. For example, the WHO is developing systems of inexpensive diagnostics to underpin syndromic management algorithms for STIs. Additionally, a series of easily accessible color-density maps showing distribution of gonococcal-specific antibiotic resistance by region and country has been developed. The data for these maps have been provided by effective gonococcal surveillance systems, which have been implemented in settings with few resources at relatively little cost [4, 121]. Utilization of these control measures and others aimed directly at treatment on a local level has been demonstrated in practice to be effective at reversing gonococcal resistance trends. In Hawaii, for example, a reduction in the rate of fluoroquinolone-resistant gonococci was observed in the 2001–2002 period (from19.6% to10.1%) after initiation of control measures including universal antimicrobial resistance testing, followed by partner identification, and treatment of all cases of fluoroquinolone-resistant gonorrhea [174]. Reversal of resistance trends is rare though, and effective measures frequently only succeed in slowing the rate of emerging resistance.

3 *Neisseria meningitidis*

3.1 Overview of Meningococcal Disease

3.1.1 Epidemiology and Clinical Manifestations

Neisseria meningitidis causes both endemic and epidemic disease worldwide but, as with gonococcal infections, there are significant differences between developed and less developed settings. The clinically significant serogroups, as determined by their capsular polysaccharides, are groups A, B, C, W, Y, and recently serogroup X. Group A is particularly associated with recurrent epidemics and hyperendemic meningococcal disease in sub-Saharan Africa often called the "meningitis belt" and parts of Asia. It is estimated that in the 10 years from 1995 to 2004, outbreaks of meningococcal disease in Africa caused about 700,000 cases and 60,000 deaths [175]. Serogroup X is also primarily localized to the meningitis belt, but was considered to be only a source of sporadic disease until it was determined to be responsible for an outbreak in Niger, Uganda, Kenya, Togo, and Burkina Faso during the 2006–2010 period [176]. In western industrialized countries, infections with serogroup B or C meningococci predominate. In the USA, serogroup Y accounts for over one third of meningococcal disease [177] and has been increasing recently in the UK [178]. For endemic disease, the peak incidence is in the very young (less than four years)

with a predominance of serogroup B infections; a secondary peak occurs in adolescents and young adults, and serogroup C clusters and outbreaks are common in this age group.

Asymptomatic carriage of the organism in the nasopharynx is common. In a study of healthy individuals observed over 32 months, 18% were found to be carriers at some point [179]. Invasive meningococcal disease occurs when the organism penetrates the epithelial surface of the nasopharynx. Sepsis and meningitis are the most typical presentations of invasive disease, but pneumonia, arthritis, and recurrent bacteremia can occur. Mortality rates vary and are influenced by many factors, including type of care available, clinical presentation, age of patient, and serogroup. Case-fatality rates in industrialized countries in non-epidemic situations are around 8% [180, 181] but are often much higher during epidemics in less developed countries. Morbidity is substantial, even in the setting of optimal medical treatment, and can include hearing loss, neurologic sequelae, and limb loss from auto-amputation.

3.1.2 Treatment and Control

The first successful report of antibiotic treatment for meningococcal disease was on the use of sulfonamides in 1937 [182]. Penicillin became an effective therapy in the 1940s, followed soon after by chloramphenicol, and most recently the third-generation cephalosporins. Current recommendations are for early empiric treatment with ESCs (cefotaxime or ceftriaxone), followed by 5–7 days of therapy with high-dose penicillin, ampicillin, or cephalosporin once a microbiologic diagnosis is made. For severe penicillin allergy, chloramphenicol is the recommended alternative when available [183]. Chemoprophylaxis with rifampin, ceftriaxone, ciprofloxacin, or azithromycin is indicated for close contacts of patients. Effective and cheap antibiotic treatment is difficult to deliver in the meningitis belt and currently heavy reliance for treatment of individual cases is placed on the use of long-acting chloramphenicol given by intramuscular injection [175]. A trial conducted in Niger has suggested that ceftriaxone, administered as a single 100 mg/kg intramuscular injection, is a suitable alternative to current treatments in terms of efficacy, ease of use, and cost [184].

Control of meningococcal disease has been through the use of vaccines, treatment of identified cases, and prophylaxis of case contacts. Licensed bivalent (A/C) or quadrivalent (ACYW) polysaccharide vaccines have been used in selected "at-risk" populations or in outbreak control. For example, vaccination with a polyvalent ACYW vaccine became mandatory for all pilgrims undergoing the Hajj following a series of outbreaks between the years 1987 and 2001 [185]. Since the induction of compulsory vaccination, the rates of incidence and invasive meningococcal disease decreased in both pilgrims and residents of Mecca and Medina [186]. Until recently, control of epidemic meningococcal disease in sub-Saharan Africa relied on "reactive vaccination" programs utilizing polysaccharide vaccines to interrupt outbreaks, in addition to administration of antibiotic treatment for established cases. Since polysaccharide vaccines fail to induce immunological memory and are less immunogenic in infants and young children, routine preventive vaccination was not utilized, and the overall success was limited by the ability to rapidly identify an outbreak and mount a vaccination response [175].

Unlike polysaccharide vaccines, conjugate vaccines induce immunological memory in children by stimulating T-cell responses that may be boosted upon repeat vaccination and are generally highly immunogenic in infants. The first licensed meningococcal conjugate vaccines were monovalent serogroup C preparations used in universal vaccination campaigns in the UK. Monovalent meningococcal C conjugate vaccines are part of the national immunization programs of several countries in Europe, as well as in Australia and Canada [187–189]. Multivalent conjugate vaccines effective against serogroups A, C, Y, and W have subsequently been licensed, and in the USA routine immunization of adolescents is recommended [183]. The recent development and large-scale administration of a serogroup A conjugate vaccine, MenAfriVac®, in sub-Saharan Africa is bringing about the elimination of epidemic meningitis in that region [190, 191]. Developed in response to an epidemic in the meningitis belt between 1996 and 1997 that resulted in 250,000 cases of disease and 25,000 deaths, MenAfriVac® has since been delivered to more than 217 million people in 15 countries [192, 193]. To date, there have been no cases of serogroup A meningococcal disease in vaccinated individuals. Vaccination campaigns with MenAfriVac® in Chad were undertaken by region. The impact of this vaccine was demonstrated by a 94% reduction in the incidence of meningitis (all cause) in vaccinated regions compared to the unvaccinated regions [194]. This is likely connected to a dramatic reduction in carriage rates which have been determined to remain at low levels years after vaccination [195, 196].

Although the development and use of meningococcal conjugate vaccines has resulted in a marked reduction in disease where universal vaccination programs have been introduced, control of serogroup B outbreaks has been challenging. This is due to the fact that the group B polysaccharide is poorly immunogenic and is chemically identical to material found in the human central nervous system. Thus, formulation of serogroup B vaccines has necessarily relied on the study of non-capsular antigens as vaccine candidates.

Serogroup B meningococci are often of diverse subtypes, but individual subtypes may give rise to epidemic or hyperendemic disease [197]. Preparations of outer membrane vesicles (OMVs) derived from the specific serogroup B strain associated with an outbreak or hyperendemic meningococcal disease have exhibited efficacy in Norway, Cuba, Brazil, Chile, and New Zealand [198–205]. Vaccines for prevention of endemic serogroup B disease caused by antigenically

diverse strains have been the focus of new meningococcal vaccine development, and protein-based serogroup B vaccines have been licensed in parts of Europe, Canada, Australia, and recently the USA. Because disease rates are low, clinical end-point efficacy studies of these vaccines were not possible. Antibodies generated in response to these vaccines have been shown to be bactericidal against selected strains, but additional studies and epidemiologic surveillance following widespread use will provide additional information about their effectiveness [206–210].

3.2 Antimicrobial Resistance in *N. meningitidis*

Fortunately, unlike with the gonococcus, antibiotic resistance has not yet had a major impact on clinical disease management of *N. meningitidis* infections. One explanation for this, at least for the penicillins, has been provided by Antignac et al. who noted differences in the gene coding for PBP-2, *penA*, suggestive of variation arising after an event separating the two species [211]. That is, meningococci and gonococci have evolved differently in regard to their capacity to develop resistance. Nevertheless, meningococcal susceptibility patterns have been changing over the past two decades [212].

3.2.1 *N. meningitidis* Resistance to Agents Used for Treatment

Penicillins

Resistance to penicillin is due in part to development of altered forms of PBP-2, which have decreased affinity for penicillin [211, 213, 214]. Mutations in *penA* have been correlated with decreased susceptibility to β-lactam antibiotics [215], though β-lactamase production is not an important resistance mechanism in meningococci. Decreased membrane permeability [216] and efflux [217] may also contribute to resistance.

Isolates with a decreased susceptibility to penicillin were first identified in Spain in 1985 [218]. Since then, they have been found across much of Europe, North America, Australia, and parts of Africa, though with widely varying rates. While numerous reports show the prevalence of moderately penicillin susceptible strains (MIC 0.125–1 μg/mL) are increasing, the degree of resistance appears stable [212, 219]. Indeed, a 2007 genomic study analyzing the *penA* sequence from 1670 meningococcal isolates collected from 22 countries and spanning 60 years demonstrated the frequent emergence of altered PBP-2 alleles that occurred independent of clonal expansion [220]. A mechanism that explains the deficiency of increased resistance levels has been recently described, as alterations in peptidoglycan modifications arising from *penA* mutation lead to decreased Nod1-dependent inflammatory responses and meningococcal colonization [221]. Thus, *penA* acquisition comes at a fitness cost to the organism.

Chloramphenicol

Chloramphenicol is no longer commonly used in developed nations and has not been standard therapy for meningococcal meningitis in Vietnam since the 1980s. It is used frequently in topical, especially ophthalmologic, preparations, and it remains standard parenteral treatment in many developing countries, particularly in Africa. Despite its widespread use there, a 2001 study of 33 serogroup A isolates from nine countries collected between 1963 and 1998 demonstrated chloramphenicol susceptibility in all cases [222]. Only one of the isolates demonstrated the possible presence of the chloramphenicol acetyltransferase (*catP*) gene, possibly acquired from *Clostridium perfringens*, which mediates chloramphenicol resistance. As sequencing was not conducted and results relied solely upon the performance of the polymerase chain reaction, the authors concluded the presence of *catP* in this isolate to be a likely false positive.

While meningococcal susceptibility to chloramphenicol is common, there have been two reports of isolates verified to exhibit chloramphenicol resistance [223]. In the first, two serogroup B isolates were recovered from patients in Australia in 1994 and 1997. In the second, strains were isolated from the CSF of 12 patients between 1987 and 1996. Eleven of these were epidemiologically unrelated strains from Vietnam, and one was from France from a patient with no history of travel to Southeast Asia. While all 12 strains were serogroup B, they were also genetically diverse. MICs for these strains were 64 mg/l, and disk-agar dilution tests showed them to also be resistant to sulfonamides and streptomycin, but susceptible to penicillins, cephalosporins, tetracyclines, macrolides, rifampin, and quinolones. In the case of both reports, the presence of *catP* gene was confirmed.

3.2.2 *N. meningitidis* Resistance to Agents Used for Prophylaxis

Resistance of meningococci to sulfonamides was identified in the USA as early as 1963 and is now widespread. Although sulfonamides were no longer used for treatment of clinical disease, they were widely prescribed for prophylaxis prior to the identification of resistance [224]. Resistance is due to mutations in the gene for dihydropteroate synthase [225].

Resistance to rifampin has also been identified [226, 227], a result of mutations in the *rpoB* gene and changes in membrane permeability [180, 223, 228]. A 1997 study from the CDC found 3 of 97 isolates to be resistant to rifampin [229]. A larger study from Australia involving 1434 isolates obtained over six years in the 1990s found only eight isolates resistant to rifampin (MIC 1 mg/l) and one with reduced susceptibility to ciprofloxacin (MIC 0.25 mg/l) [228]. A 2003 study in France found only one out of 2167 isolates to be resistant to rifampin and one additional isolate with reduced

susceptibility [180], though three cases of patients infected with a serogroup C rifampin-resistant strain were recently described [230, 231]. Other studies in Europe and Latin America found similar patterns [213, 232, 233]. A 1996 study in the USA showed the development of rifampin resistance during prophylaxis treatment. Oropharyngeal cultures were obtained before and three weeks after prophylaxis treatment was instituted in a middle school in Seattle. No secondary cases occurred, but resistance developed in 12% of the isolates, all of which were group B [234].

There have been several reports of reduced susceptibility to ciprofloxacin, including, among others, a serogroup C strain from a patient with invasive disease in Australia, a group B strain from a carrier in France, and a group B strain isolated from the CSF of a patient in Spain [235, 236]. The first documented cases of ciprofloxacin-resistant meningococci in North America were reported at the northern border between Minnesota and North Dakota between 2007 and 2008 [237]. More recently, a study of 374 isolates in China collected between 1965 and 2013 highlighted the changing patterns of fluoroquinolone resistance in Asia, as the number of isolates that were nonsusceptible to ciprofloxacin increased from 0% in 1965–1985 to 84% in 2005–2013 [102]. This rapidly evolving resistance is a result of the ability of *N. meningitidis* to develop mutations in the *gyrA* and *parC* genes that are similar to the mutations in QRNG [238].

3.3 Clinical Significance of Resistance in *N. meningitidis*

A study from the UK specifically examined the question of a link between reduced susceptibility to penicillin and fatal outcome from meningococcal infection [181]. The authors retrospectively analyzed over 11,000 cases reported between 1993 and 2000 in England and Wales. During this time period, the frequency of penicillin intermediate strains increased from less than 6% to greater than 18% (12.6% overall), with a higher frequency among serogroups C and W135. The overall case-fatality rate was around 8%, and while there was an association between fatal outcome and specific serogroups and serotypes, there was no link with reduced susceptibility to penicillin. In a Spanish study of isolates from 1988 to 1992, 34% of strains (72 of 213) showed decreased susceptibility to penicillin. Higher morbidity/mortality was associated with these strains, even though penicillin was not used for therapy in all cases [239].

Isolated case reports raise the possibility of treatment failure associated with decreased susceptibility to penicillin. A report from the UK describes an 18-year-old with meningococcal meningitis who was treated with IV benzylpenicillin and, after an initial clinical response, remained ill several days later. The CSF culture was positive when repeated. After treatment was changed to chloramphenicol, this patient rapidly improved. The *N. meningitidis* isolated from CSF initially and upon repeat culture had a penicillin MIC of 0.64 (reduced susceptibility). Of note, the dose of penicillin was lower than some use [240]. Another report from Argentina also suggests possible treatment failure of penicillin [241].

Prophylaxis failures associated with rifampin resistance have been reported [226, 242]. In Israel, three small clusters of disease that occurred in the military were examined. In one, the initial case was rifampin sensitive, but two secondary cases occurred among the contacts who had taken rifampin, and the strains were identified to be rifampin resistant. All three strains were group C:NT:P1.2 [227]. In the 1997 CDC study, nine contacts of individuals with rifampin resistant *N. meningitidis* received prophylaxis with rifampin and none developed disease [229].

3.4 Treatment and Infection Control Recommendations

Penicillin G remains the recommended treatment for invasive meningococcal disease in the USA and elsewhere. The dose is 250,000 U/kg per day (up to a maximum of 12 million U/day), divided every 4–6 h. Cefotaxime, ceftriaxone, and ampicillin are acceptable alternatives. Recent data suggest that shorter courses of treatment than the usually accepted 7–10 days of therapy are adequate for management of meningococcal disease [184, 243]. Chloramphenicol is recommended for patients with penicillin allergy characterized by anaphylaxis. For disease that may have been acquired in regions of the world where decreased susceptibility to penicillin is common or resistance has been reported, cefotaxime, ceftriaxone, or chloramphenicol is recommended. Chemoprophylaxis is recommended for persons who have had close contact with infected individuals, for whom the risk of developing invasive disease is increased. This includes household contacts, childcare or nursery school contacts during the seven days prior to disease onset in the index patient, and individuals who have been exposed to the index patient's secretions, such as by kissing or sharing eating utensils during the seven days prior to the onset of illness. In addition, health-care workers who administered mouth-to-mouth resuscitation or were unprotected during endotracheal intubation should receive chemoprophylaxis. The patient should also receive prophylaxis to eliminate carriage unless the infection was treated with ceftriaxone or cefotaxime. Recommended regimens include rifampin, 600 mg (or 10 mg/kg for children over one month of age and 5 mg/kg for infants under one month of age), every 12 h for two days; ceftriaxone, 250 mg intramuscularly as a single dose (125 mg for children less than 15 years of age); or ciprofloxacin, 500 mg as a single oral dose [183].

Secondary cases of meningococcal disease can occur several weeks after onset of disease in an index patient. Therefore, vaccination can be used as an adjunct to chemoprophylaxis.

4 Commensal *Neisseria* Species

N. lactamica, *N. sicca*, *N. subflava* (biovars subflava, flava and perflava), *N. mucosa*, *N. flavescens*, *N. cinerea*, *N. polysaccharea*, and *N. elongata* subspecies *elongata*, *glycolytica*, and *nitroreducens* are human commensal organisms that are rarely associated with disease in a normal host. *N. elongata* subspecies *elongata, N. subflava*, and *N. sicca/perflava* have been occasionally associated with infective endocarditis that occurs on damaged or normal heart valves and in congenital heart disease [244, 245]; *N. sicca* and *N. perflava* have been described in pulmonary and disseminated infections in patients with AIDS [246].

Antibodies to *N. lactamica* developed during carriage are thought to provide immunity to meningococcal disease. Interest in *N. lactamica* has thus been focused mainly on identifying the "immunizing" characteristics and dynamics of carriage of this organism. There are, however, few large studies on antimicrobial resistance in the commensal *Neisseria* sp. derived from these carriage studies.

The commensal *Neisseria* are by their nature longer-term inhabitants of the nasopharynx than the more transient, invasive subtypes of *N. meningitidis.* For this reason, they are exposed more often and for a greater duration to resistance pressures arising from use of antimicrobials, prescribed for any reason. It is therefore reasonable to suggest that the commensal *Neisseria* may harbor a reservoir of resistance genes available for acquisition by the invasive species. Penicillin-binding proteins, encoded by chromosomal *penA* genes, are the target site for the penicillins. It has been shown that mosaic *penA* genes present in the highly transformable commensal *Neisseria* confer intermediate resistance to penicillin. These resistance genes are then transferred to other commensal *Neisseria* and also to *N. meningitidis* by recombination [247, 248].

One report of antibiotic resistance in 286 *N. lactamica* isolates collected in Spain in 1996 and 1998 during studies on meningococcal carriage demonstrated raised penicillin MICs (0.12–1 mg/l) in all isolates tested [249]. Additionally, about 2% of isolates in this study showed decreased quinolone susceptibility many years before its appearance in pathogenic *N. meningitidis* in that country. In another carriage study conducted following the outbreak of fluoroquinolone-resistant meningococci in the USA, *N. lactamica* strains were determined to exhibit the same mutation in *gyrA* that was observed in isolates recovered from infected patients, suggesting occurrence of a horizontal gene transfer event [250]. Likewise, examination of *N. gonorrhoeae* isolates in Japan that had decreased susceptibility to cefixime identified mosaic PBP-2 contained fragments that were identical to the PBP-2 of *N. cinerea* and *N. perflava* [251].

Isolates of *N. elongata* subspecies *elongata, N. subflava*, and *N. sicca/perflava* found in occasional instances of systemic infection often display resistance or decreased susceptibility to penicillins and other agents. Thus, misuse of antibiotics may have profound consequences on the commensal members of this genus in terms of both the emergence and spread of resistant genes. Because the pathogenic *Neisseria* species also occupy the same niche as the commensals, during which time the opportunity for genetic transfer arises, "downstream" effects on both meningococci and gonococci may also be observed.

Mechanisms of Resistance in *Haemophilus influenzae* and *Moraxella catarrhalis*

55

Michael R. Jacobs

1 Introduction

Haemophilus influenzae and *Moraxella catarrhalis* are found as both respiratory tract commensals and respiratory and invasive pathogens. While it is ideal to tailor chemotherapy to a known pathogen with a known drug susceptibility profile, it is often difficult or impractical to isolate the causative agent, and many infections are treated empirically [1]. It is therefore important to know the activity of antimicrobial agents against the pathogens associated with diseases being treated empirically and the effect of resistance mechanisms on in vivo activity. Antimicrobial agents should be used rationally, avoiding overuse, tailoring treatment to identified pathogens as much as possible, and basing empiric treatment on the disease being treated and the susceptibility of the predominant pathogens at breakpoints based on pharmacokinetic (PK) and pharmacodynamic (PD) parameters [2]. The current status of resistance mechanisms found in *Haemophilus influenzae* and *Moraxella catarrhalis* against the antimicrobial agents recommended for empiric and directed treatment of the diseases caused by these pathogens forms the basis of this review.

2 Carriage of *Haemophilus influenzae* and *Moraxella catarrhalis*

Many infections, particularly those of the respiratory tract, are superinfections of inflammatory processes, such as viral infections, by bacteria colonizing the nasopharynx and oropharynx. Bacteria normally residing in the mouth and respiratory tract include streptococcal species, especially *Streptococcus pneumoniae*, *H. influenzae*, *M. catarrhalis*, *Neisseria* species, various anaerobes, and staphylococcal species. Carriage of *S. pneumoniae*, with over 90 serotypes, *H. influenzae*, both encapsulated and nonencapsulated strains, and *M. catarrhalis* changes over time as immunity develops to each strain and different strains are acquired from other persons [3, 4]. Carriage of these species is also influenced by use of protein-conjugated capsular polysaccharide vaccines, *H. influenzae* type b (Hib) and the 7-, 10-, and 13-valent pneumococcal vaccines [5].

3 Major Diseases Caused by *Haemophilus influenzae* and *Moraxella catarrhalis*

The major diseases caused by these pathogens are childhood meningitis and bacteremia, community-acquired pneumonia in adults and children, acute otitis media, acute sinusitis, and acute exacerbations of chronic bronchitis. Empiric and directed antimicrobial therapy of these diseases will be briefly reviewed to establish the range of antimicrobial agents of clinical importance, and therefore where resistance needs to be considered.

3.1 Meningitis

While Hib vaccination has greatly reduced the incidence of Hib meningitis in countries where it is used, meningitis remains a serious problem in children under 7 years of age in areas where the vaccine is not used [6, 7]. Current WHO estimates are that, while Hib vaccine was used in 189 countries by the end of 2013, overall worldwide coverage with three doses of Hib was estimated at 52 % in 2013, being particularly low in the Western Pacific (18 %) and in Southeast Asia (27 %) regions, with 199,000 vaccine-preventable deaths per year [8]. The empiric antimicrobial treatment of meningitis recommended by the Infectious

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_7

Diseases Society of America for this age group is vancomycin plus a third-generation cephalosporin such as cefotaxime or ceftriaxone [9]. If a Gram stain of cerebrospinal fluid shows Gram-negative bacilli presumptively identified as *H. influenzae*, a third-generation cephalosporin alone is recommended. Alternative therapies for *H. influenzae* include chloramphenicol, cefepime, and meropenem. Once the pathogen has been isolated and identified, and susceptibilities are known, the antibiotic choices can be narrowed or changed if necessary. For β-lactamase-negative *H. influenzae*, ampicillin is recommended as standard therapy, with a third-generation cephalosporin, cefepime, or chloramphenicol as alternate regimens. β-Lactamase-positive *H. influenzae* should be treated with a third-generation cephalosporin, with cefepime or chloramphenicol as alternatives. Meningitis caused by *H. influenzae*, usually untypeable strains, can also occur in patients who have suffered basilar skull fractures. These patients should be treated with the same agents discussed above, with the addition of moxifloxacin to the list of alternative agents recommended for adult patients only.

3.2 Childhood Pneumonia and Bacteremia

In regions where protein-conjugated Hib and pneumococcal capsular polysaccharide vaccines are not used, the most common bacterial causes of childhood pneumonia between 6 months and 5 years of age are *S. pneumoniae*, *H. influenzae* type b, and *M. catarrhalis* [10, 11]. *Mycoplasma pneumoniae* and *Chlamydia* (*Chlamydophilia*) *pneumoniae* become more common at school age, with *M. pneumoniae* more common in the 5–10-year-old cohort and *C. pneumoniae* more common after age 10 [12, 13]. Bacteremia with *S. pneumoniae* and *H. influenzae* type b occurs with or without the presence of pneumonia.

High-dose amoxicillin (90 mg/kg/day), either alone or with the addition of clavulanic acid, is the first-line drug of choice for empiric treatment of outpatients with childhood-presumed bacterial pneumonia [14]. If oral antibiotics are not tolerated, daily intramuscular (IM) ceftriaxone has good coverage for the three major bacterial pathogens. In older children with a higher probability of *C. pneumoniae* or *M. pneumoniae*, addition of a macrolide is recommended [13–17]. Oral cephalosporins should be avoided due to a lack of coverage for penicillin-resistant pneumococci. Recommended empiric therapy for inpatients includes ceftriaxone or cefotaxime to provide coverage for penicillin-non-susceptible *S. pneumoniae* and β-lactamase-positive *H. influenzae*. The addition of azithromycin or erythromycin is recommended to provide coverage for atypical pathogens in older children. Vancomycin or clindamycin should be added for life-threatening pulmonary infections in which *Staphylococcus aureus* is a suspected pathogen as virulent, community-acquired, methicillin-resistant strains are increasingly being encountered. Directed parenteral therapy for pneumonia due to *H. influenzae* includes ampicillin for β-lactamase-negative strains and ceftriaxone, cefotaxime, or cefuroxime for β-lactamase-positive strains.

3.3 Community-Acquired Pneumonia (CAP) in Adults

The most common causes of CAP are *S. pneumoniae* (26–60 %), *M. pneumoniae* (10–37 %), untypeable *H. influenzae* (2–12 %), *Legionella pneumophila* (2–6 %), *C. pneumoniae* (5–15 %), and *M. catarrhalis* (2–3 %) [1]. Treatment guidelines for management of CAP in immunocompetent adults have been established by the American Thoracic Society and the Infectious Diseases Society of America [18]. Recommendations for outpatients with no comorbidities include azithromycin, clarithromycin, and doxycycline if no antibiotic therapy had been administered in the past 3 months; if antibiotic therapy had been administered in the past 3 months, recommendations are levofloxacin, gemifloxacin, or moxifloxacin as single agents or combination macrolide-β-lactam therapy [azithromycin or clarithromycin with amoxicillin (3 g/day) or amoxicillin-clavulanate (4 g/250 mg/day)]. Recommendations for outpatients with comorbidities include azithromycin, clarithromycin, levofloxacin, gemifloxacin, or moxifloxacin if no antibiotic therapy had been administered in the past 3 months; if antibiotic therapy had been administered in the past 3 months, recommendations are levofloxacin, gemifloxacin, or moxifloxacin as single agents or combination macrolide-β-lactam therapy [azithromycin or clarithromycin with amoxicillin-clavulanate (4 g/250 mg/day)]. Amoxicillin-clavulanate or clindamycin is recommended for suspected aspiration pneumonia. High-dose amoxicillin, high-dose amoxicillin-clavulanate, cefpodoxime, cefprozil, cefuroxime axetil, levofloxacin, gemifloxacin, or moxifloxacin is recommended for influenza with bacterial superinfection. Recommendations for inpatients in medical wards include levofloxacin, gemifloxacin, or moxifloxacin alone or azithromycin or clarithromycin plus cefotaxime, ceftriaxone, ampicillin-sulbactam, or ertapenem. Recommendations for patients requiring intensive care are the same plus inclusion of an antipseudomonal agent if infection with *Pseudomonas aeruginosa* is a concern. The guidelines emphasize that the infectious etiology be determined whenever possible and that pathogen-directed therapy be used once the organism has been identified. Virulent, community-acquired, methicillin-resistant *S. aureus* (MRSA) are increasingly being encountered, and the addition of vancomycin or other anti-MRSA agents should also be considered [19].

Ceftaroline and tigecycline have recently been approved for the treatment of CAP in adults [20]. Ceftaroline is highly potent against *H. influenzae*, while MICs of tigecycline are close to its susceptibility breakpoint (Figs. 55.8 and 55.10). The efficacy and safety profile of ceftaroline was comparable

to ceftriaxone in patients hospitalized with CAP. Tigecycline is approved for the treatment of CAP but has a safety warning regarding an increased mortality risk compared to other agents used to treat pneumonia.

3.4 Acute Otitis Media (AOM)

AOM is one of the most common pediatric infections, second only to the common cold in prevalence, occurring most often between 6 months and 3 years of age, especially in children with frequent viral upper respiratory infections [29]. The principal bacterial causes of AOM are *S. pneumoniae* (25–50 %), untypeable *H. influenzae* (23–67 %), and *M. catarrhalis* (12–15 %) [30, 31]. In the USA introduction of the conjugate pneumococcal vaccine in children has resulted in untypeable, β-lactamase-producing *H. influenzae*, and ampicillin-resistant serotype 19A *Streptococcus pneumoniae* is becoming more prevalent in patients failing first-line amoxicillin therapy [32–34]. Recent guidelines for empiric treatment of AOM include the following [35]. Amoxicillin (80–90 mg/kg/day) or amoxicillin-clavulanate (90/6.4 mg/kg/day) is recommended as initial therapy, with cefdinir, cefuroxime axetil, cefpodoxime, or ceftriaxone (50 mg/kg/day IM or IV for 1–3 day) as alternatives for patients with penicillin allergy. Amoxicillin-clavulanate (90/6.4 mg/kg/day) or ceftriaxone (50 mg/kg/day IM or IV for 3 days) is recommended for patients not responding to treatment after use of amoxicillin for 48–72 h. Addition of clindamycin and diagnostic tympanocentesis are offered as additional options.

3.5 Acute Sinusitis

Although most cases of acute sinusitis are viral, *S. pneumoniae*, untypeable *H. influenzae*, and *M. catarrhalis* are the predominant pathogens when bacterial superinfection occurs, with *M. catarrhalis* being more common in children [22]. Recommended first-line therapy for adults is amoxicillin-clavulanate (1.5 g/375 mg/day–1.75 g/250 mg/day), while recommended second-line therapy is amoxicillin-clavulanate (4 g/250 mg/day) or doxycycline [36]. Doxycycline, levofloxacin, or moxifloxacin is recommended for β-lactam allergic patients. Ampicillin-sulbactam, levofloxacin, moxifloxacin, ceftriaxone, or cefotaxime is recommended for hospitalized patients. Recommended first-line therapy for children is amoxicillin-clavulanate (45/6.4 mg/kg/day), while recommended second-line therapy is amoxicillin-clavulanate (90/6.4 mg/day). Levofloxacin, clindamycin plus cefixime, or cefpodoxime is recommended for β-lactam allergic children. Ampicillin-sulbactam, levofloxacin, ceftriaxone, or cefotaxime is recommended for hospitalized children.

3.6 Acute Exacerbations of Chronic Bronchitis (AECB)

Acute bacterial exacerbations of chronic bronchitis are predominantly caused by the typical upper respiratory bacteria, untypeable *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*, which make up 85–95 % of cases, with *H. influenzae* usually the most frequent pathogen [37]. In addition, *H. parainfluenzae*, *P. aeruginosa*, *S. aureus*, *M. pneumoniae*, *Legionella pneumophila*, and opportunistic Gram-negative organisms are occasionally implicated, with the latter found principally in severe disease. The presence of a new strain of *H. influenzae*, *S. pneumoniae*, or *M. catarrhalis* from the sputum of a patient with chronic bronchitis increases the relative risk of an exacerbation twofold [4].

Recommendations for treatment of AECB are stratified by the presence of baseline patient factors (pulmonary function, comorbid illnesses, recurrent exacerbations, chronic steroid use, home oxygen use, and hypercapnia) and severity of the exacerbation. Severity of the exacerbation is based on the presence of increased dyspnea, increased sputum volume, and increased sputum purulence. A "mild" exacerbation is one featuring only one of these three symptoms and does not require antibiotic treatment. "Moderate" or "severe" exacerbations require the presence of any two of the three symptoms, and treatment is determined by the severity of baseline patient factors. Recommendations for patients without the baseline risk factors listed above include azithromycin, clarithromycin, doxycycline, cefuroxime axetil, cefpodoxime, and cefdinir. Recommendations for patients with any of the baseline risk factors listed above include amoxicillin/clavulanic acid, levofloxacin, gemifloxacin, and moxifloxacin; ciprofloxacin should be considered if *Pseudomonas aeruginosa* is suspected. Patients with worsening clinical status or inadequate response in 72 h should be reevaluated and have sputum cultures performed [38, 39]. First-line, narrow spectrum antibiotics (amoxicillin, ampicillin, trimethoprim/sulfamethoxazole, and doxycycline) are recommended for elderly patients who are likely to have a low probability of resistant organisms, while second-line, broader spectrum agents (amoxicillin/clavulanic acid, second- or third-generation cephalosporins, and respiratory fluoroquinolones) are suggested for patients with significant risk factors for resistant organisms or who failed initial antibiotic treatment [40].

4 Baseline Susceptibility and Development of Resistance

Every bacterial species typically has a baseline, wild-type population with a defined, usually narrow, range of intrinsic susceptibility to antimicrobial agents at the time of introduction of a new antimicrobial drug class [41]. This defines the

initial spectrum of activity of each antimicrobial agent, and this in turn depends on the dosing regimen and the site of infection. Species can then be studied based on baseline susceptibilities and susceptibilities of strains with decreased susceptibility, should they be present initially or should they develop. Susceptibility breakpoints between susceptibility of baseline, wild-type populations and those of populations with acquired resistance can be used and are referred to as "microbiological breakpoints" [41]. Such breakpoints are very useful but do not necessarily correlate with clinically relevant breakpoints. Unfortunately, many breakpoints in common use for *H. influenzae* are microbiological breakpoints that are of little clinical use, and the current CLSI (formerly NCCLS) interpretation guideline for *H. influenzae* states that results of susceptibility testing using breakpoints provided for the oral β-lactam, macrolide and ketolide agents "are often not useful for the management of individual patients" but "may be appropriate for surveillance or epidemiologic studies" [42].

Clinically relevant susceptibility breakpoints are also typically developed for each agent, enabling isolates to be classified as susceptible, intermediate, or resistant. Such breakpoints should be based on pharmacokinetic and pharmacodynamic (PK/PD) parameters and appropriate clinical studies and should be the same for all species associated with each clinical syndrome, e.g., pneumonia, meningitis, cystitis, otitis, etc. Many breakpoints were developed before these principles were introduced, and some breakpoints in clinical use have been shown not to be appropriate, particularly for oral agents. This is especially the case for *H. influenzae*, as noted earlier, while CLSI does not have breakpoints for *M. catarrhalis*, although other groups such as EUCAST do have these [23]. To overcome this problem, breakpoints based on PK/PD parameters where available, and adequate clinical studies have been developed and will be used in this review to enable meaningful use of the terms clinical susceptibility and clinical resistance [26, 43].

5 Mechanisms of Resistance of *H. influenzae* and *M. catarrhalis*

5.1 β-Lactams

β-Lactams exert an antimicrobial effect by interfering with the formation and maintenance of the peptidoglycan layer of the bacterial cell wall [44, 45]. The cross-linking of stem peptides is facilitated by peptidases, which are located on the extracellular surface of the cell membrane [46]. β-Lactams exert their antimicrobial effect by irreversibly binding to these peptidases, which are frequently referred to as penicillin-binding proteins (PBPs) [47]. Resistance is achieved when genetic alterations result in a PBP that has a reduced affinity for β-lactam antibiotics or when β-lactamases are produced [25, 48, 49]. β-Lactamases are structurally related to PBPs and have a high affinity for β-lactam antibiotics; the interaction between β-lactams and β-lactamases causes a permanent opening of the β-lactam ring, thereby inactivating the antibiotic (Fig. 55.1) [45, 50]. Unlike the interaction between the antibiotic and PBPs, the interaction between β-lactams and β-lactamases does not result in a covalent bond, and the enzyme is free to inactivate other β-lactam molecules.

The predominant mechanism of β-lactam resistance in *H. influenzae* is β-lactamase production, and the genes encoding for β-lactamases in *H. influenzae* are found primarily on plasmids; however, in some cases, these genes are incorporated into the bacterial chromosome [51]. Two distinct β-lactamases are produced by strains of *H. influenzae*: TEM-1 and ROB-1, of which, the TEM-1 β-lactamase is more common [52]. Three β-lactamases are produced by *M. catarrhalis*: BRO-1, BRO-2, and BRO-3, which are structurally similar to each other, but are distinct from the TEM-1 or ROB-1 β-lactamases [53].

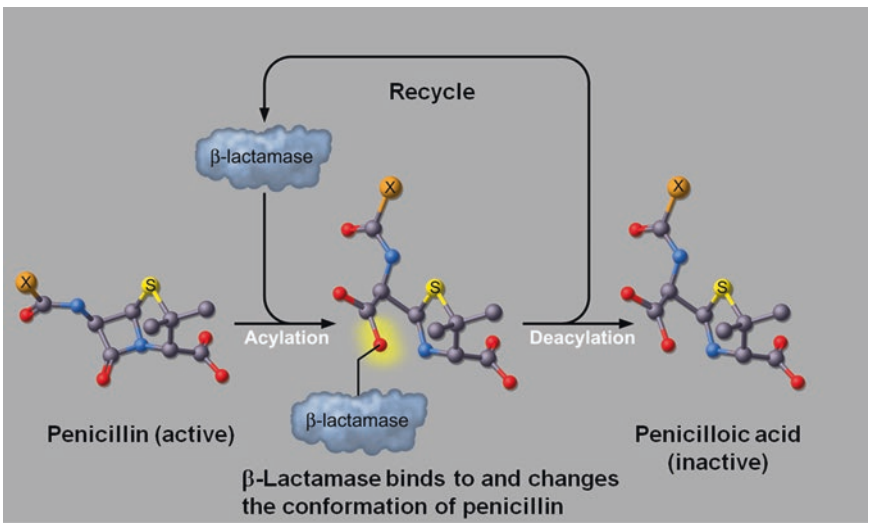

Fig. 55.1 Antibiotic inactivation of penicillins by β-lactamases of *H. influenzae* and *M. catarrhalis*. Copyright Michael R. Jacobs, used with permission

Resistance via β-lactamase production cannot be overcome by increasing the dose of the β-lactam antibiotic (i.e., the concentration at the site of infection) because the β-lactamase enzyme is regenerated following each interaction with—and subsequent inactivation of—an antibiotic. However, this mechanism of resistance can be overcome by using a combination of a β-lactam antibiotic with a β-lactamase inhibitor (e.g., amoxicillin-clavulanate) or by using β-lactam antibiotics that are stable to the actions of β-lactamases (e.g., ceftriaxone, cefuroxime, cefpodoxime, cefixime, provided the pharmacokinetic properties of the agent are adequate). β-Lactamase inhibitors act as "suicide substrates," forming a covalent bond between the enzyme and the β-lactamase inhibitor, inactivating the enzyme, and preventing it from destroying more β-lactam molecules (Fig. 55.2) [54]. β-Lactamase-stable agents evade the action of β-lactamases due to stereochemical blocking of the attachment site of β-lactamases by the side chains of these agents. Extended-spectrum β-lactamase (ESBL) variants of TEM-1 with increased antibiotic resistance to broad-spectrum β-lactam antibiotics and, in some cases, β-lactamase inhibitors (e.g., clavulanic acid) have appeared in *Enterobacteriaceae*, but have not been detected in clinical isolates of *H. influenzae*, although they have been expressed in cloned strains [55]. ESBLs have been reported in two South African isolates of *H. parainfluenzae* that produced a TEM-15 enzyme and had cefotaxime MICs of >16 μg/mL [56].

Non-β-lactamase-mediated resistance to β-lactams due to PBP alterations have occurred in *H. influenzae*, both type b and untypeable strains, mediated via changes in PBP3, which is encoded by the *ftsI* gene [25, 57]. This PBP is made up of an N-terminal hydrophobic region, a central penicillin-binding domain, and a C-terminal domain, and the active site of transpeptidase activity is formed by three conserved amino acid motifs, SXXK, SSN, and KTG (Fig. 55.3). These motifs occur at amino acid positions 326–330, 379–381, 512–514 in PBP3 of *H. influenzae* [28]. Strains with specific

mutations in or around these motifs are referred to as β-lactamase negative, ampicillin resistant (BLNAR) or β-lactamase positive, amoxicillin-clavulanate resistant (BLPACR) if they are also β-lactamase positive [57]. Strains are further divided into low- and high-level resistant: low-level BLNAR strains have ampicillin MICs of 0.5–4 µg/mL (compared to a modal value 0.12 µg/mL for wild-type strains), and high-level BLNAR strains have ampicillin MIC of 1–16 µg/mL (Fig. 55.4). Low-level BLNAR and BLPACR strains have N526K or R517H substitutions close to the KTG motif in the *ftsI* gene, while high-level BLNAR and BLPACR strains additionally have S385T or S385T and L389F substitutions close to the SSN motif (Fig. 55.3) [28, 58, 59]. Horizontal transfer of the *ftsI* gene in *H. influenzae* has been demonstrated within and between *H. influenzae* and *H. haemolyticus* [60]. MICs of all β-lactams are higher against strains with *ftsI* mutations than against wild-type strains, and the clinical significance varies based on the PK/PD breakpoint for each agent (Figs. 55.4 and 55.5).

Low-level BLNAR and BLPACR strains are fairly common in many countries, accounting for up to 10 % of isolates, while high-level BLNAR and BLPACR strains to date are rare in most areas, accounting for fewer than 1 % of isolates [61–63]. However, in Japan low-level BLNAR and BLPACR strains have been reported from 26 % of nonmeningeal and 40 % of meningeal isolates, while high-level BLNAR and BLPACR strains account for 13 % of nonmeningeal and 24 % of meningeal isolates [6, 25]. Similar findings in nasopharyngeal isolates from Japanese children with AOM have also been reported [48]. High-level BLNAR and BLPACR strains have also been reported from Korea and Spain [64–66].

5.2 Protein Synthesis Inhibitors

Several classes of agents inhibit protein synthesis [67]. Although these agents are chemically and structurally distinct, they all exert an antimicrobial effect by binding to the

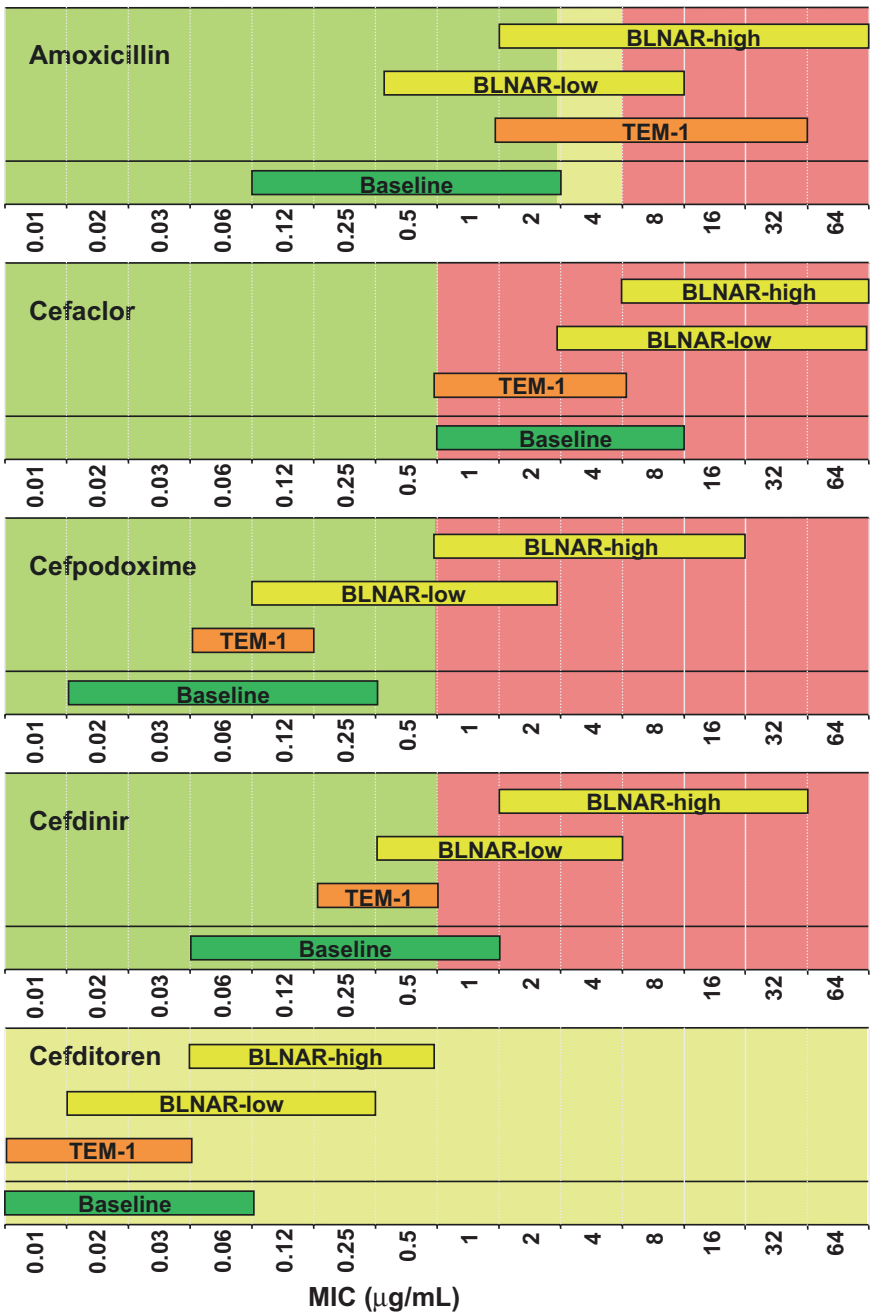

Fig. 55.5 Correlation between β-lactam resistance mechanisms and susceptibility of *H. influenzae* to amoxicillin, cefaclor, cefpodoxime, cefdinir, and cefditoren. Background color indicates susceptibility based on PK/PD parameters: green, susceptible; yellow, intermediate; red, resistant. Adapted from Hasegawa et al. [6] and Sanbongi et al. [59]. Copyright Michael R. Jacobs, used with permission

23S component of the 50S subunit of bacterial ribosomes and disrupting protein synthesis [68]. The number of 70S ribosomes in a typical bacterium ranges from 20,000 to 70,000, each of which consists of two subunits: 50S and 30S. The 50S subunit is comprised of 34 ribosomal proteins and two strands of ribosomal RNA (rRNA; 23S RNA and 5S RNA). The rRNA provides structure to the 50S subunit and determines the position of the ribosomal proteins. Tetracyclines prevent the binding of charged tRNA to the A site of the ribosome; chloramphenicol inhibits the peptidyl transferase reaction of the large subunit of the ribosome; MLS antibiotics, which include macrolides (e.g., erythromycin, clarithromycin), azalides (e.g., azithromycin), lincosamides (e.g., clindamycin), ketolides (e.g., telithromycin), and streptogramins, block the ribosome exit tunnel, thereby preventing movement and release of the nascent peptide.

5.3 MLS Agents and Ketolides

Macrolide resistance mechanisms include efflux pumps, either intrinsic or acquired, ribosomal methylase, and alterations in ribosomal proteins and RNA [69, 70]. *H. influenzae* is intrinsically resistant to MLS agents and ketolides. This is

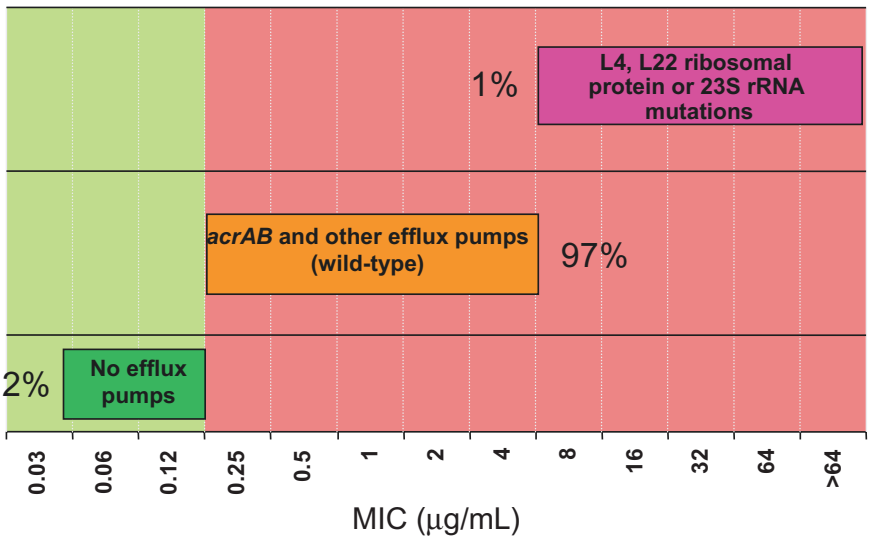

Fig. 55.6 Correlation between azithromycin MICs and resistance mechanisms of *H. influenzae*. Adapted from Peric et al. [74] Copyright Michael R. Jacobs, used with permission

associated with the presence of an *acr*AB efflux pump homologous to this mechanism in *E. coli*, explaining the limited activity of these agents against most wild-type strains of this pathogen [71–73]. Occasional strains of *H. influenzae* lack this efflux pump and have lower MICs than typical wild-type strains, while a few strains have higher MICs associated with mutations in L4 or L22 ribosomal proteins or 23S rRNA (Fig. 55.6).

5.4 Tetracyclines

Tetracyclines exert an antimicrobial effect by binding to the 30S subunit of bacterial ribosomes and preventing tRNA from binding to the A or P sites [75]. Tetracycline resistance in *H. influenzae* is produced by a cell membrane-associated efflux mechanism encoded by the *tet*(B) gene, which is usually located on conjugative plasmids [76, 77]. The efflux protein encoded by the *tet*(B) gene confers resistance to both tetracycline and minocycline, but not glycylcyclines [76]. Tetracycline resistance is often transmitted on conjugative plasmids carrying ampicillin-chloramphenicol-tetracycline-kanamycin resistance genes, which have been described in *H. influenzae* type b isolates in Belgium, Spain, and Cuba [78, 79].

5.5 Quinolones

The quinolones have a broad spectrum of activity and exert an antimicrobial effect by interfering with DNA replication, and subsequently, bacterial reproduction. Two enzymes that are important in the replication process are DNA gyrase and topoisomerase IV, and resistance to quinolones among strains of *H. influenzae* occurs via alterations in the quinolone resistance-determining region (QRDR) of these genes [80, 81]. These alterations can occur via spontaneous mutations or via the acquisition of DNA from other bacteria. The newer quinolones are potent against *H. influenzae*, and the prevalence of resistance among clinical strains is low [49, 63, 82]. However, spontaneous quinolone-resistant mutants are readily selected in vitro by exposure to quinolones, and this has resulted in development of considerable resistance to this drug class in other species [83, 84]. Quinolone-resistant isolates of *H. influenzae* have been shown to have high mutation frequencies [85].

5.6 Chloramphenicol

Chloramphenicol resistance in *H. influenzae* is usually associated with plasmid-mediated production of chloramphenicol acetyltransferase (CAT) encoded by the *cat* gene, with occasional strains having a penetration barrier [86, 87]. The *cat* gene is carried on conjugative plasmids ranging in molecular weight from 34×10^6 to 46×10^6, and these plasmids often carry genes encoding for resistance to tetracycline and ampicillin as well. These conjugative plasmids can also be incorporated into the chromosome [88]. The CAT enzyme produced resembles the type-II CATs produced by enterobacteria. Resistance associated with a permeability barrier is due to the loss of an outer membrane protein [86].

5.7 Folic Acid Metabolism Inhibitors

Trimethoprim and sulfamethoxazole (used alone or in combination) exert an antimicrobial effect by interfering with cellular metabolism and replication by sequentially blocking the production of tetrahydrofolate. During normal cellular metabolism, dihydrofolate is reduced to tetrahydrofolate by

the enzyme dihydrofolate reductase (DHFR) [89]. Tetrahydrofolate is an important cofactor in many cellular reactions, supplying single-carbon moieties for the production of thymidylate, purine nucleotides, methionine, serine, glycine, and other compounds [90]. Inhibiting the production of tetrahydrofolate causes the bacterial cells to die because the lack of thymine prevents DNA replication [91]. Trimethoprim is a substrate analog of dihydrofolate and blocks the reduction of dihydrofolate to tetrahydrofolate by DHFR, whereas sulfamethoxazole is a substrate analog of para-aminobenzoic acid, which is involved in the production of dihydropteroate, a precursor compound of dihydrofolate, blocking the enzyme dihydropteroate synthetase (DHPS) (Fig. 55.7) [89]. Thus, the use of these compounds in combination limits the production of dihydrofolate and prevents the conversion from dihydrofolate to tetrahydrofolate. Both compounds, trimethoprim and sulfamethoxazole, selectively inhibit bacterial metabolism with little toxicity to humans because humans do not synthesize folic acid; rather, the necessary levels of folic acid are obtained from dietary sources.

Resistance to trimethoprim occurs via alteration in the affinity between trimethoprim and DHFR. The decreased affinity is the result of altered genes that encode for DHFR, which often are carried on plasmids or transposons and probably originated from closely related bacteria. Studies have shown that substitutions in the amino acid sequence of DHFR result in resistance to trimethoprim without affecting the affinity of the natural substrates [92–94]. Resistance to trimethoprim-sulfamethoxazole among strains of *H. influenzae* is common and is caused by an increase in the production of DHFR with altered affinity for trimethoprim [95]. Resistance to trimethoprim-sulfamethoxazole also has been noted among strains of *M. catarrhalis*, which is intrinsically resistant to trimethoprim [96–99].

Resistance of *H. influenzae* to sulfonamides is associated with two mechanisms [100]. The first is mediated via the *sul2* gene, a common mediator of acquired sulfonamide resistance in enteric bacteria, which encodes for drug-resistant forms of DHPS. The second is mediated via the mutations in the chromosomal gene encoding DHPS, *folP*, associated with insertion of a 15 bp segment together with other missense mutations.

6 History of Geographical Spread

Bacterial antibiotic resistance results from antibiotic pressure and natural selection and can be spread either through clonal expansion or horizontal transfer, usually through plasmids, phage vectors, or natural transformation systems. The key antimicrobial class to which resistance in *H. influenzae* and *M. catarrhalis* has developed has been the β-lactams, predominantly due to β-lactamase production.

6.1 *Haemophilus influenzae*

Cases of ampicillin treatment failure in *H. influenzae* meningitis were first reported in 1973 [101] and confirmed in 1974 [102, 103] at which time β-lactamase production was identified as the mediating cause [104]. These cases were dispersed throughout the USA, England, and New Zealand. By the late 1970s, ampicillin resistance in *H. influenzae* in the UK was already reported to be at 6.2 %, 92 % of which was β-lactamase mediated [105]. In the early 1980s, BLNAR strains of *H. influenzae* began to be isolated in the USA, the UK, New Zealand, and Japan [105–107]. BLNAR and BLPACR strains are now common in Japan, Korea, and

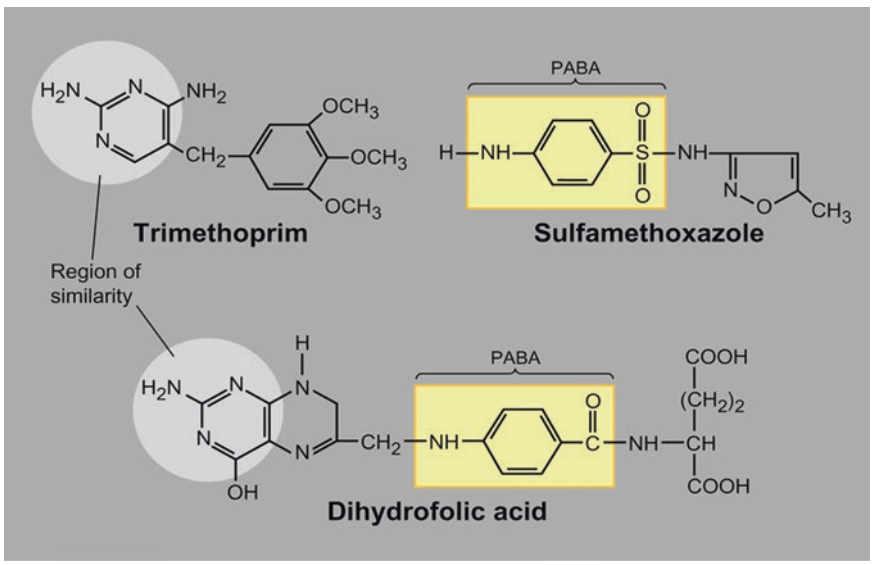

Fig. 55.7 Mechanism of action of trimethoprim and sulfonamides is by mimicry of dihydrofolic acid components, blocking the enzymes involved in conversion of PABA to dihydrofolic acid and dihydrofolic acid to tetrahydropholic acid, the active form of the enzyme. Regions of similarity of trimethoprim and sulfamethoxazole with dihydrofolic acid are highlighted. Copyright Michael R. Jacobs, used with permission

Spain [6, 59, 65, 66]. β-Lactamase production among strains of *H. influenzae* has generally increased from the 1980s, but has been stable for the past two decades [63, 108]. During the early 1980s, the proportion of strains that produced β-lactamases in the USA was approximately 10–15 %, whereas more recent surveillance studies have demonstrated an overall global prevalence of 20 % [63]. Prevalence of β-lactamase production in various countries varied from 4.2 % in Russia to 29.6 % in the USA (Fig. 55.8) [21]. Clonally related, multidrug-resistant *Haemophilus influenzae* PBP3-mediated resistance to broad-spectrum cephalosporins has recently emerged in Norway [109].

The activity of macrolides against *H. influenzae* has remained essentially unchanged throughout the past 30 years, although a few hyper-resistant strains have developed [26, 74]. Resistance to tetracyclines and chloramphenicol has developed, associated with plasmids carrying ampicillin-chloramphenicol-tetracycline-kanamycin resistance genes as noted earlier, predominantly in type b isolates [110]. Resistance to quinolones among clinical isolates of *H. influenzae* is also rare; however, surveillance studies have identified a few clinical strains with increased quinolone MICs, and an outbreak of a highly resistant clone was detected in a long-term care facility [21, 26, 111]. Twelve of 457 isolates

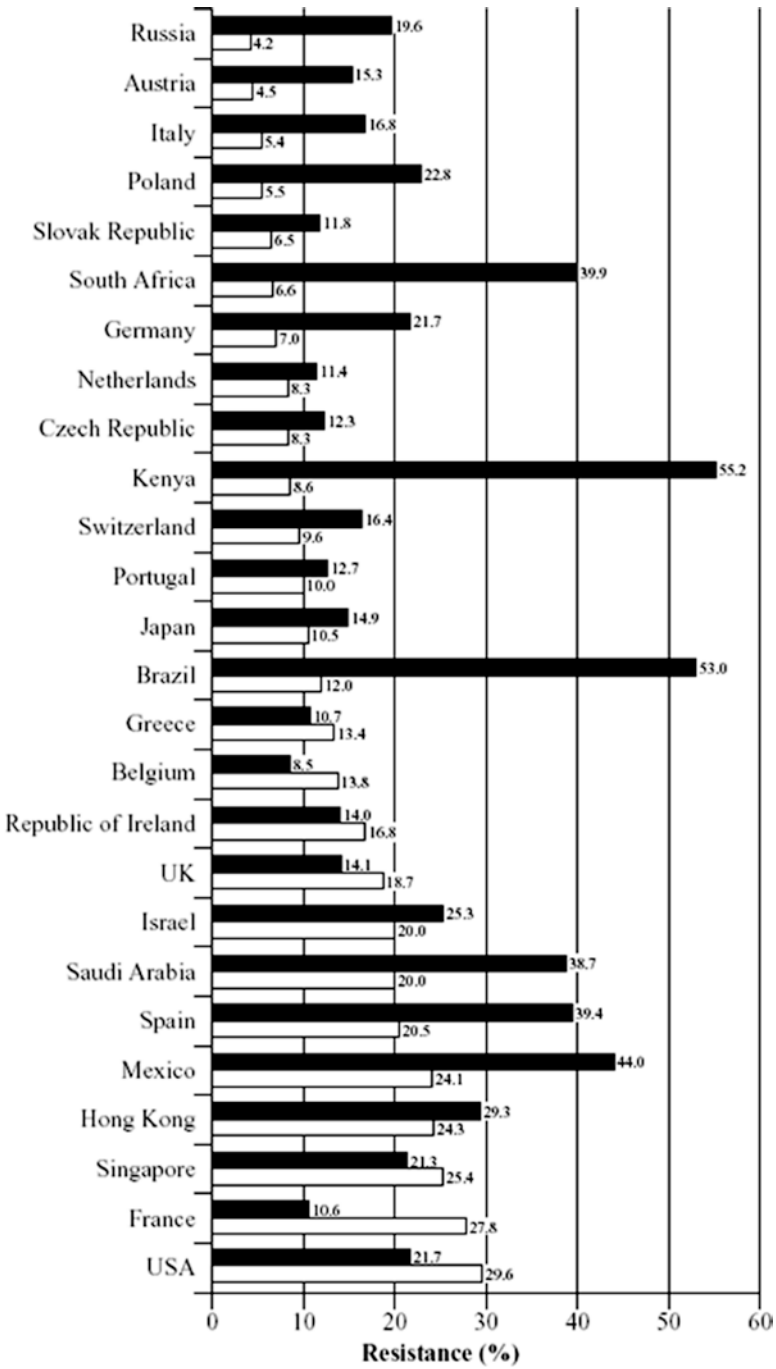

Fig. 55.8 Prevalence of trimethoprim-sulfamethoxazole resistance (MIC ≥ 1 μg/mL) (black bars) and β-lactamase production (white bars) in *H. influenzae*, Alexander Project 1998–2000. Reproduced with permission from Jacobs et al. [21]

(2.6 %) of *H. influenzae* isolated in Hokkaido prefecture, Japan, during 2002–2004, were quinolone resistant, with resistant isolates found only in patients over 58 years of age [82]. In contrast, resistance to trimethoprim-sulfamethoxazole has increased over the past two decades, with resistance varying from a low of 8.5 % in Belgium to a high of 55.2 % in Kenya (Fig. 55.8) [21].

6.2 *Moraxella catarrhalis*

β-Lactamase production among strains of *M. catarrhalis* also is prevalent. β-Lactamase-mediated resistance first appeared in the late 1970s and is now present in at least 90 % of worldwide isolates. Walker and Levy, working from a 10-year veterans administration hospital collection of *M. catarrhalis* isolates, examined the genetic changes that accompanied the transition from less than 30 % to greater than 95 % of isolates being β-lactamase positive in that comparatively brief period [112]. A surveillance study noted that nearly 100 % of strains of *M. catarrhalis* produced β-lactamases [21]. Amoxicillin-clavulanate is active against *M. catarrhalis*, with MICs of 0.12–0.25 μg/mL. β-Lactamase-stable cephalosporins, macrolides, and fluoroquinolones all are active against the majority of strains of *M. catarrhalis*.

7 Clinical Significance

Significant advances have recently been made in understanding the relationships between in vitro susceptibility and in vivo response to infection based on PK/PD correlations. In the absence of human studies or to complement limited human data, susceptibility breakpoints can be established based on animal models and pharmacokinetic parameters. Clinically relevant susceptibility breakpoints can then be derived based on applying these PK/PD parameters to standard dosing regimens. For nonmeningeal infections breakpoints can be derived from nonprotein-bound plasma drug levels present for 25–50 % of the dosing interval for time-dependent agents such as β-lactams and from AUC/MIC ratios exceeding 30 for concentration-dependent agents such as most non-β-lactam agents. These principles have repeatedly been validated in animal models and in bacteriologic outcome in human studies of AOM, AECB, and sinusitis [2, 43, 113–116]. Breakpoints for agents recommended for use against *H. influenzae* and *M. catarrhalis* based on PK/PD parameters, as well as current CLSI and EUCAST breakpoints, are shown in Table 55.1. While PK/PD and EUCAST breakpoints are very similar, many CLSI breakpoints for *H. influenzae* are considerably higher and generally represent microbiological rather than clinical breakpoints as discussed earlier. Susceptibility of worldwide isolates of *H. influenzae* and *M. catarrhalis* to agents recommended for treatment of diseases due to these pathogens is shown in Table 55.2, with regional differences in susceptibility of *H. influenzae* in Table 55.3.

The relationships between MIC distributions and susceptibility breakpoints are important as they determine the clinical activity of agents. MICs of clinically useful agents should be below PK/PD breakpoints, and the greater the difference between MICs and breakpoints, the greater the likelihood that the agent will be successful in clinical use. It is therefore important to examine MIC distributions in relation to breakpoints, and several patterns are found with *H. influenzae* (Figs. 55.9, 55.10, and 55.11) [21, 22, 24–28, 57].

- A unimodal MIC distribution with modal MIC value fourfold (i.e., two doubling dilutions) or more below the breakpoint. This is the case with cefuroxime (parenteral), amoxicillin-clavulanate, cefixime, cefpodoxime, and the quinolones. These agents are therefore highly active against *H. influenzae* and are most suitable for empiric use.
- A unimodal MIC distribution with breakpoint within the MIC distribution, as seen with cefuroxime (oral), cefdinir, cefprozil, and doxycycline. These are agents with limited clinical activity, and their use should be limited to circumstances where other more suitable agents cannot be used.
- A unimodal MIC distribution with breakpoint below the MIC distribution, as seen with cefaclor, erythromycin, azithromycin, clarithromycin, and telithromycin. These agents have intrinsic resistance due to pharmacokinetic limitations and have essentially no clinically useful activity against *H. influenzae*.
- A bimodal MIC distribution with a clearly defined susceptible population below the breakpoint and a clearly defined resistant population, typically with defined resistance mechanisms. This is the case with the ampicillin- and amoxicillin-resistant populations associated with β-lactamase production, tetracycline-resistant population associated with *tetB* gene, trimethoprim-sulfamethoxazole-resistant population associated with mutations in DHFR and DHPS, and chloramphenicol-resistant population associated with *cat* gene. These agents are suitable for directed use against *H. influenzae* and for empiric use where resistance is low, or the consequences of treatment failure are minor, although drug toxicity also needs to be considered.

Comparison of these PK/PD-based susceptibility interpretations with current recommendations for treatment of diseases associated with *H. influenzae* reveal the following:

- **Meningitis.** Current empiric therapy recommendations, vancomycin plus a third-generation cephalosporin such as cefotaxime or ceftriaxone or a third-generation cephalosporin alone if Gram stain enables presumptive pathogen

Table 55.1 Breakpoints (μg/mL) used to determine susceptible (*S*), intermediate (*I*), and resistant (*R*) categories, based on PK/PD, EUCAST, and CLSI interpretative breakpoints [21, 23, 42, 108, 115, 117]. PK/PD breakpoints are applicable to both species

identification as *H. influenzae*, are still valid except in areas where high-level BLNAR and BLPACR strains are prevalent and Hib is not in use [6]. Suggested therapy for areas where high-level BLNAR and BLPACR strains occur is cefotaxime or ceftriaxone plus meropenem based on no additional loss of affinity of meropenem for PBP3 between low and high BLNAR strains (Table 55.4 and Fig. 55.4) [6, 59]. Alternative therapies recommended for *H. influenzae*, chloramphenicol, cefepime and meropenem appear to be valid except in areas where chloramphenicol-resistant strains or high-level BLNAR and BLPACR strains are prevalent. Moxifloxacin is recommended as an alternative agent for adults, which is a valid option as virtually all *H. influenzae* are currently susceptible. The use of quinolones in children should also be considered if other options are contraindicated. Development of susceptibility breakpoints for *H. influenzae* applicable to meningitis would be very worthwhile.

- **Childhood pneumonia and bacteremia.** Current empiric and directed treatment recommendations are valid except for areas where BLNAR and BLPACR strains are prevalent, where the efficacy of oral amoxicillin and amoxicillin-clavulanate against high-level BLNAR strains may be compromised. The efficacy of parenteral cephalosporins and meropenem may also be compromised, but MICs of high-level BLNAR strains are currently below PK/PD breakpoints (Tables 55.4 and 55.5 and Fig. 55.4) [6, 59].
- **CAP in adults.** Recommendation of azithromycin, clarithromycin, or doxycycline for outpatients with no comorbidities and of azithromycin or clarithromycin for outpatients with comorbidities if no antibiotic therapy had been administered in the past 3 months is problematic as these agents have little if any clinical activity against *H. influenzae*, and the activity of these agents against macrolide-resistant pneumococci remains a concern [118]. The remaining recommendations for CAP are valid except for areas where BLNAR and PLPACR *H. influenzae* are found as discussed earlier, in which case respiratory quinolones and meropenem are suitable agents.

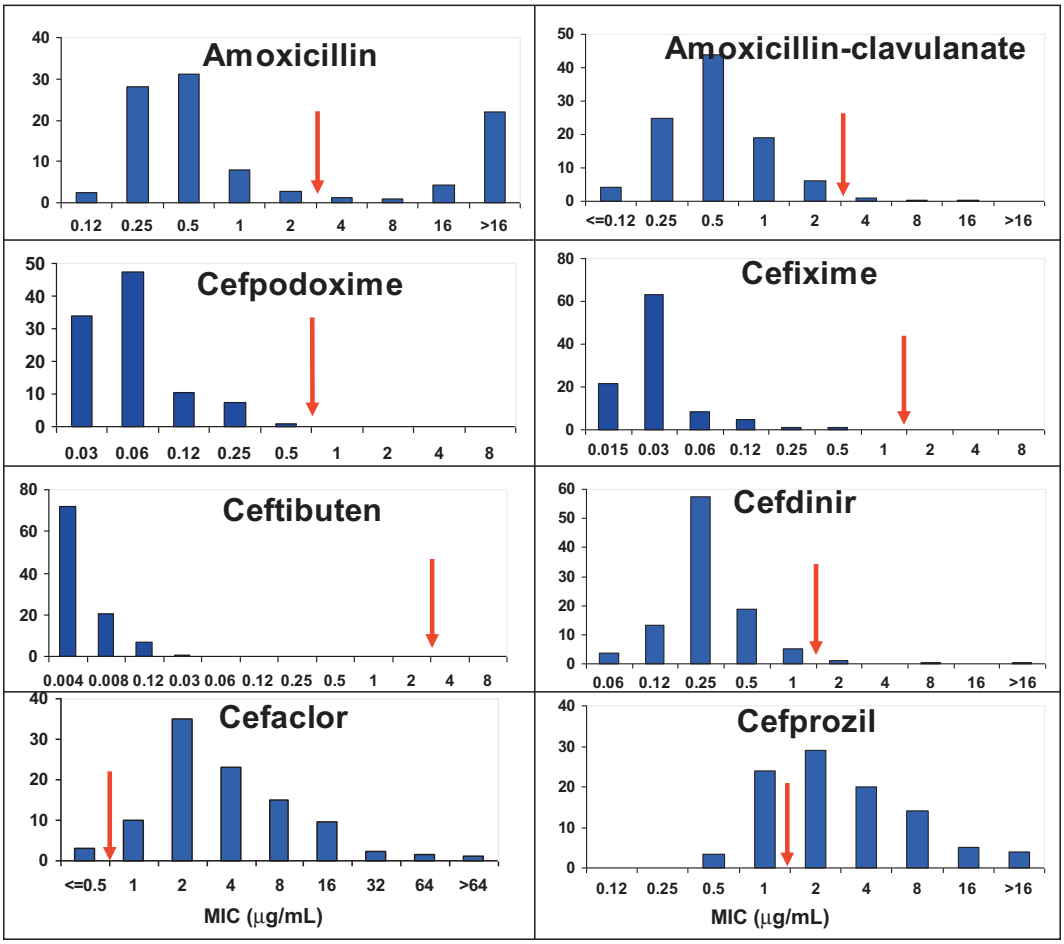

Fig. 55.10 MIC distributions of selected oral β-lactam antimicrobial agents for *H. influenzae*. Arrows indicate PK/PD breakpoints. Data adapted from literature or the databases used to generate these publications [21–28]. Copyright Michael R. Jacobs, used with permission

- **AOM.** Current recommendations are valid with the exception again of areas where BLNAR and PLPACR *H. influenzae* are found, where MIC_{90}s of amoxicillin, cefaclor, cefpodoxime, and cefdinir against high-level BLNAR and PLPACR strains are above PK/PD breakpoints (Table 55.5). The MIC_{90} of cefditoren against high-level BLNAR strains is 0.25 µg/mL; however, the PK/PD breakpoint for this agent has not been established but is likely to be lower than the MIC_{90} value [119, 120]. Cefixime may have clinically useful activity against high-level BLNAR strains, but additional information is needed, and the use of quinolones should be considered [34, 120, 121].
- **Acute sinusitis.** As is the case for AOM, current recommendations for sinusitis are valid with the exception of areas where BLNAR and PLPACR *H. influenzae* are found.
- **AECB.** Recommendations for patients with baseline risk factors, amoxicillin-clavulanate, and respiratory quinolones are valid as *H. influenzae* is the predominant pathogen, and these agents are active based on PK/PD breakpoints. However, of the agents recommended for patients without baseline risk factors, azithromycin, clarithromycin, telithromycin, doxycycline, cefuroxime axetil, cefpodoxime, and cefdinir, only cefpodoxime is active against *H. influenzae* based on PK/PD breakpoints. The rationale for these latter recommendations of agents that will not be effective for the patient group with a high probability of spontaneous resolution is unclear.

8 Laboratory Determination of Susceptibility

8.1 MIC Determination

Susceptibility testing of *H. influenzae* by MIC determination has been well standardized, with CLSI, EUCAST, and other methods generally providing comparable results [42,122]. The main requirements for testing are to ensure that concentrations

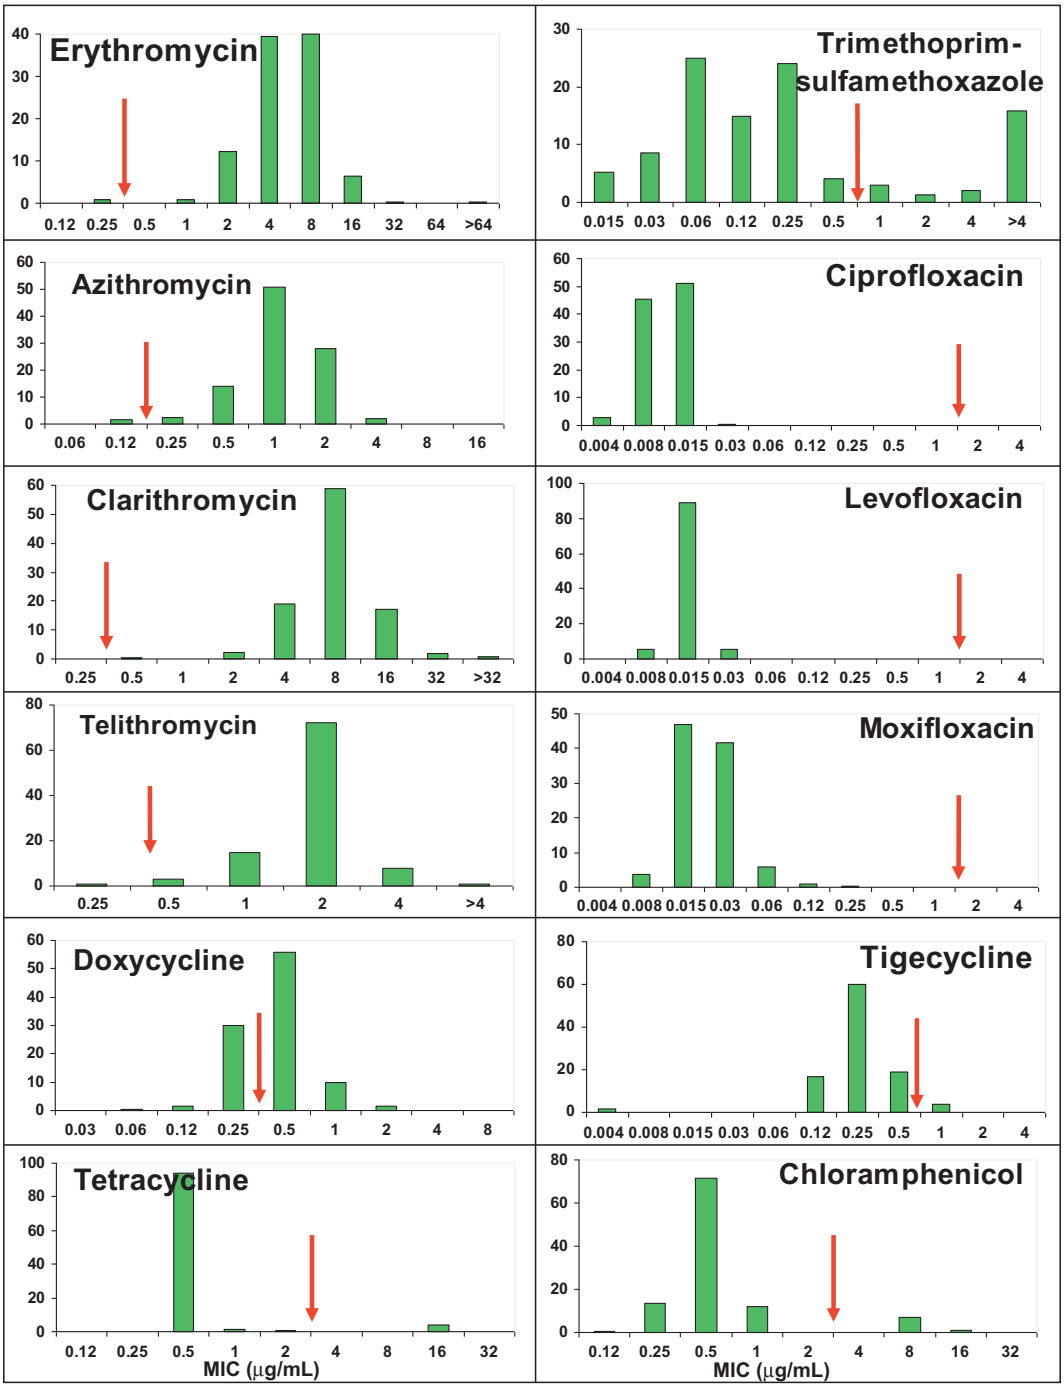

Fig. 55.11 MIC distributions of selected non-β-lactam antimicrobial agents for *H. influenzae*. Arrows indicate PK/PD breakpoints. Data adapted from literature or the databases used to generate these publications [21–28]. Copyright Michael R. Jacobs, used with permission

of hematin, hemoglobin, blood or other iron source, and NAD adequately support growth, that the inoculum size is correct, and that appropriate quality control strains are included in each test batch. The medium specified by CLSI is Haemophilus Test Medium (HTM), which consists of cation-supplemented Mueller-Hinton broth supplemented with 5 mg of yeast extract per mL, 15 µg of NAD per mL, and 15 µg of hematin per mL [42, 123]. The medium specified by BSAC is Iso-sensitest agar or broth supplemented with 5 % horse blood (lysed for the broth formulation) and 20 µg of NAD per mL [124]. Results obtained with these two methods and other variations are comparable [125, 126]. The media containing hematin should be fresh as hematin tends to precipitate out of solution on storage [125]. CLSI specifies susceptibility testing of *M.*

catarrhalis with Mueller-Hinton broth or agar [117]. BSAC recommends Iso-sensitest agar supplemented with 5 % horse blood [124]. EUCAST recommends MH-F medium, consisting of Mueller-Hinton broth supplemented with 5 % lysed horse blood and 20 mg/L β-NAD, for testing *Haemophilus* spp. and *Moraxella catarrhalis* [127]. Agar versions of these media are used for disk and gradient diffusion methods.

8.2 Disk Diffusion Testing

CLSI and EUCAST both show interpretative disk diffusion criteria for a number of agents against *Haemophilus* species [42, 128]. However, most MIC distributions are unimodal, and testing of these agents is best performed by MIC determination rather than disk diffusion. Agents showing bimodal MIC distributions, such as ampicillin, amoxicillin, tetracycline, chloramphenicol, and trimethoprim-sulfamethoxazole, are the most suitable for testing by disk diffusion. EUCAST and CLSI also have some disk diffusion interpretations for *M. catarrhalis* [23, 117]. A major limitation of disk diffusion testing is that interpretative criteria for many agents are based on microbiological rather than PK/PD breakpoints, so their clinical relevance is limited.

8.3 Gradient Diffusion (E-Test)

This method has been widely used and is generally comparable to standard MIC methods for testing *H. influenzae* [129]. MICs of macrolides, ketolides, and quinolones are generally twofold higher by E-test with incubation in a 5–10 % CO_2

atmosphere, so this needs to be considered when interpreting and comparing results [130, 131]. The accuracy of E-test for differentiation of BLNAR and BLPACR strains from baseline strains has not been adequately established [57].

8.4 β-Lactamase Detection

This is best determined by the chromogenic cephalosporin method using nitrocefin, which is converted from a yellow to a pink compound when hydrolized by β-lactamases, or other comparable agents [132].

9 Infection Control Measures

Prior to the introduction of the Hib vaccine, *H. influenzae* type b was the most common cause of bacterial meningitis in children between the ages of 2 months and 5 years. Prevention, through widespread use of the Hib vaccine, has been highly effective. In areas where the vaccine is unavailable or in unvaccinated children, *H. influenzae* type b meningitis remains a childhood threat [8, 133]. The disease remains communicable as long as the organism is present in the nasopharynx and until 24–48 h after beginning effective antibiotic treatment. Contacts, particularly those under 6 years of age, should receive prophylactic treatment with rifampin (20 mg/kg in children and 600 mg in adults, once daily, by mouth for 4 days).

Prevention of AOM due to untypeable *H. influenzae* using a novel vaccine containing polysaccharides from 11 *S. pneumoniae* serotypes each conjugated to *H. influenzae*-derived protein D has been demonstrated [134]. In addition to protection against pneumococcal AOM, efficacy of this vaccine was also shown by a 35.5 % reduction in episodes of AOM caused by untypeable *H. influenzae*.

10 Conclusions

H. influenzae and *M. catarrhalis* are major pathogens associated with common respiratory tract infections, and *H. influenzae* type b is an invasive pathogen of unimmunized children. Treatment of these infections is limited by both intrinsic and acquired resistance, and mechanisms of resistance continue to evolve in these pathogens. Application of PK/PD principles to these pathogens is essential to understand the clinical relationship between in vitro susceptibility and in vivo response. Judicious use of antimicrobial agents is the key to preserving the activity of these agents and to prevent further development of resistance.

Enterobacteriaceae

56

David L. Paterson and Yohei Doi

1 Introduction

Gram-negative bacteria of the Enterobacteriaceae family are important causes of urinary tract infections (UTIs), bloodstream infections, hospital- and healthcare-associated pneumonias, and various intra-abdominal infections. Within this family, *Escherichia coli* is a frequent cause of UTIs, species of *Klebsiella* and *Enterobacter* are important causes of pneumonia, and all of the Enterobacteriaceae have been implicated in bloodstream infections and in peritonitis, cholangitis, and other intra-abdominal infections. Additionally, organisms such as *Salmonella* produce gastroenteritis and, subsequently, in some patients, invasive infection. Emerging resistance in Enterobacteriaceae is a significant problem. Resistance related to production of extended-spectrum beta-lactamases (ESBLs) and carbapenemases is a major problem in the management of infections with the Enterobacteriaceae. The emergence of carbapenemases in Enterobacteriaceae is of particular concern since these organisms often present with extensive drug resistance (XDR) and sometimes even pan-drug resistance (PDR).

2 Overview of Resistance Trends

Approximately 50–60 % of *E. coli* isolates are resistant to ampicillin [1, 2]. This resistance is mediated by broad-spectrum (but not extended-spectrum) beta-lactamases such as TEM-1 [3]. The addition of beta-lactamase inhibitors, such as clavulanic acid, can protect penicillins from hydrolysis by TEM-1. Thus, rates of resistance of *E. coli* to amoxicillin-clavulanate are only approximately 5 % [3, 4]. When all Enterobacteriaceae are considered, almost one quarter of isolates are resistant to amoxicillin-clavulanate [4]. This is likely because of production of beta-lactamases, such as AmpC beta-lactamases, by organisms such as *Enterobacter cloacae,* that are not inhibited by clavulanate.

The third-generation cephalosporins were developed, in part, because of the advent of broad-spectrum beta-lactamases such as TEM-1. The most frequent acquired mechanism of third-generation cephalosporin resistance in Enterobacteriaceae is production of extended-spectrum beta-lactamases (ESBLs). In the United States, the Centers for Disease Control and Prevention (CDC) has ranked ESBL-producing Enterobacteriaceae as a serious threat with an estimated 26,000 cases occurring annually with 1,700 subsequent deaths. In the most recent report by the CDC-coordinated National Healthcare Safety Network (NHSN) System (comprising 2009–2010 data), 28.8 % of *Klebsiella* spp. isolates implicated in central line-associated bloodstream infections (CLABSI) in the United States were resistant to third-generation cephalosporins [5]. This number remained stable compared with the prior period (2007–2008). Resistance to third-generation cephalosporins was observed in 37.4 % of *Enterobacter* species, which also remained stable. Notably, however, the third-generation cephalosporin resistance rate in *E. coli* increased substantially from 12.3 to 19.0 % between these periods. In some countries in Europe, even higher rates of invasive *K. pneumoniae* isolates resistant to third-generation cephalosporins (up to 74.8 % in Bulgaria) have been reported for the year of 2012 (http://www.ecdc.europa.eu/en/publications/Publications/antimicrobial-resistance-surveillance-europe-2012.pdf).

Rates of resistance to fluoroquinolones are on the rise as well, especially in *E. coli*, increasing from 37.7 % in 2007–2008 to 41.8 % in 2009–2010 in the aforementioned NHSN survey [5]. In Europe, the rates of fluoroquinolone resistance range from 9.7 % in Iceland to 42.0 % in Cyprus

and Italy in 2012. Non-susceptibility rates to fluoroquinolones in species other than Enterobacteriaceae are generally lower at 9.7 % in *K. pneumoniae*, 10.1 % in *Enterobacter cloacae*, 17.0 % in *Citrobacter freundii*, and 4.3 % in *Serratia marcescens*, among inpatient urinary tract infection isolates in the United States between 2009 and 2011.

Rates of ciprofloxacin resistance in *Salmonella* spp. are increasing as well, going from just 0.4 % in 1996 to 2.4 % in 2009 according to the CDC's National Antimicrobial Resistance Monitoring System (NARMS) data [6].

Aminoglycosides have maintained good activity against Enterobacteriaceae. Rates of amikacin non-susceptibility were 1.3 % in *E. coli*, 5.5 % in *K. pneumoniae*, and 1.0 % in *E. cloacae* among inpatient UTI isolates in the United States between 2009 and 2011 [7]. Gentamicin non-susceptibility was 16.8 % in *E. coli*, 22.4 % in *K. pneumoniae*, and 7.0 % in *Enterobacter* spp. among pneumonia isolates from the United States and Europe in 2012 [8]. Methylation of 16S ribosomal RNA is emerging as a mechanism of high-level resistance to aminoglycosides across the board (amikacin, gentamicin, and tobramycin) in Enterobacteriaceae [9]. However, this mechanism likely accounts for just a small percentage of aminoglycoside-resistant isolates at the present time.

Carbapenem resistance in Enterobacteriaceae used to be extremely rare, but this has changed dramatically in the last decade. In the most recent report by the NHSN comprising 2009–2010 data, 12.8 % of *Klebsiella* spp. isolates implicated in central line-associated bloodstream infections in the United States were resistant to carbapenems [5]. Unfortunately more recent national surveillance data from the United States is not available. However, in the recent report on antibiotic resistance threats, carbapenem-resistant Enterobacteriaceae (CRE) were ranked one of the three "urgent" threats. It was estimated that 9,300 cases occur annually with 610 deaths. High rates of carbapenem-resistant *K. pneumoniae* have been reported in some countries in Europe, reaching 60.5 % in Greece and 28.8 % in Italy (http://www.ecdc.europa.eu/en/publications/Publications/antimicrobial-resistance-surveillance-europe-2012.pdf). Carbapenem resistance in species other than *Klebsiella* spp. remains less common, with 1.9 % for *E. coli* asnd 4.0 % for *Enterobacter* spp. showing resistance to this class among CLABSI isolates in the United States [5].

Acquired resistance to tigecycline and polymyxins is uncommon but has been reported in association with the use of these agents [10–13]. Of note, tigecycline lacks activity against *Proteus* spp., *Providencia* spp., and *Morganella morganii*, and polymyxins are not active against *Proteus* spp., *Providencia* spp., and *Serratia marcescens* [14, 15].

3 ESBL-Producing Enterobacteriaceae

3.1 General Issues and Nomenclature

Infections caused by ESBL-producing Enterobacteriaceae are serious concerns in the current environment. Some ESBLs represent enzymes that have evolved from broad-spectrum (but non-ESBL) beta-lactamases such as TEM-1, TEM-2, and SHV-1. The CTX-M-type ESBLs appear to be derived from chromosomally encoded beta-lactamases produced by *Kluyvera* spp. [3]. ESBLs can hydrolyze most cephalosporins and penicillins. However, ESBLs are typically not active against cephamycins (e.g., cefotetan, cefoxitin, or cefmetazole) or carbapenems (doripenem, imipenem, ertapenem, and meropenem) and can generally be inhibited by beta-lactamase inhibitors, such as clavulanate, sulbactam, or tazobactam. Unlike most ESBLs that have been found in *E. coli*, *K. pneumoniae*, and other Enterobacteriaceae, OXA-type ESBLs have been found mainly in *Pseudomonas aeruginosa* and only rarely in Enterobacteriaceae [16].

ESBLs should be distinguished from other beta-lactamases capable of hydrolyzing extended-spectrum cephalosporins and penicillins. Examples include AmpC-type beta-lactamases and carbapenemases. Carbapenemases may be further grouped as either metallo-beta-lactamases (class B) or serine carbapenemases (classes A and D). Like ESBLs, AmpC beta-lactamases hydrolyze third-generation or expanded-spectrum cephalosporins, but unlike ESBLs, they are also active against cephamycins and are resistant to inhibition by clavulanate or other beta-lactamase inhibitors [17, 18]. In addition, AmpC beta-lactamases do not efficiently hydrolyze fourth-generation cephalosporins such as cefepime and cefpirome. Carbapenemases generally have broader-range activity, inactivating carbapenems as well as expanded-spectrum cephalosporins [17, 19].

3.2 In Vitro Susceptibility Profiles and Clinical Outcomes

Rates of resistance of ESBL-producing Enterobacteriaceae to the cephalosporins should be reviewed with caution. In general, a much greater proportion of Enterobacteriaceae used to be genotypically defined as ESBL producers than would be suggested by examining resistance rates to third-generation cephalosporins according to the Clinical and Laboratory Standards Institute (CLSI) criteria prior to 2010 [20]. This had clinical relevance. In a study of patients with ESBL-producing *K. pneumoniae* bacteremia, 54 % of patients receiving treatment with a susceptible cephalosporin, as determined by old CLSI criteria, experienced clinical failure [20]. These results

were consistent with those from a variety of observational studies, which show rates of clinical failure of >90 %, approximately 67 %, and <30 % with cephalosporin MICs of 8, 4, and ≤2 μg/mL, respectively, when third-generation cephalosporins were used to treat ESBL producers [21, 22]. To address this problem, the CLSI has lowered the susceptibility break points for key cephalosporins in clinical use. Under these revised break points, detection of ESBL is considered optional. This is based on the consideration that the use of cephalosporins will be avoided for most ESBL-producing Enterobacteriaceae by the treating providers since they would report as resistant to them. Still, nearly 40 % of ESBL-producing Enterobacteriaceae are reported as susceptible to ceftazidime due to the low catalytic efficiency of CTX-M-type ESBLs toward this agent [23]. The clinical significance of this phenomenon has not been established.

3.3 Treatment of ESBL Producers

The presence of ESBL-producing Enterobacteriaceae complicates therapy, especially since these organisms are often multidrug resistant. When isolates from a patient indicate an ESBL-producing organism, the first thing to consider is whether the patient has a true infection versus colonization. Patients with positive isolates from urine or perhaps the respiratory tract may be only colonized, and, clearly, there is no indication for treatment in those situations. Assuming the patient has a serious infection due to ESBL-producing Enterobacteriaceae, the choice of empirical therapy is made difficult by the likelihood of multidrug resistance and the fact that there are no data from large, randomized, controlled trials (RCTs) designed to compare one antibiotic therapy with another for infections caused by ESBL-producing organisms. One such RCT is underway (the "MERINO" trial; NCT02176122), but results are not expected until 2017. The major controversy is whether piperacillin/tazobactam can be used for serious infections due to ESBL producers and whether outcomes with this beta-lactam/beta-lactamase inhibitor combination (BLBLIs) are as good as those observed with carbapenem therapy.

Proponents of meropenem superiority point to a number of lines of evidence. Firstly, carbapenems are not typically hydrolyzed by ESBLs nor do they undergo a significant inoculum effect. Several clinical studies have shown a clinical benefit of carbapenem therapy. A prospective, observational, international study of patients with *K. pneumonia* bacteremia reported an all-cause 14-day mortality rate of 3.7 % (1 out of 27) with the use of a carbapenem alone, compared with rates of 36.3 and 44 % with fluoroquinolone and non-carbapenem beta-lactam monotherapy, respectively [22]. For patients infected with ESBL-producing *K. pneumoniae*, the corresponding 14-day mortality rates were 4.8 % (2 out of 42) among patients receiving carbapenem monotherapy or combination therapy and 27.6 % (8 out of 29) among those receiving treatment with a non-carbapenem antibiotic. A number of other studies showed similar results, and a meta-analysis of these published in 2012 found a superiority of carbapenems over non-carbapenem regimens, including BLBLIs [24]. Two subsequent observational studies have also shown superiority of carbapenems over piperacillin/tazobactam [25, 26].

On the contrary side, by definition, ESBLs are inhibited by beta-lactamase inhibitors such as tazobactam [3]. However, *E. coli* or *Klebsiella* may produce multiple beta-lactamase types some of which are resistant to inhibition by tazobactam. Additionally, in some cases outer membrane protein loss may contribute to resistance to tazobactam [27]. Despite these limitations, observational studies suggest that piperacillin/tazobactam may have a role in the treatment of ESBL-producing organisms. The largest observational studies with an analysis by treatment outcome were published in February 2012 by Rodriguez-Bano and colleagues [28] and in October 2012 by Peralta et al. [29]. Rodriguez-Bano performed a post hoc analysis of six published cohorts of patients with bacteremia due to ESBL-producing *E. coli*. In all cohorts, analysis was restricted only to those infections with an organism susceptible to the antibiotic analyzed. In this study, carbapenems (such as meropenem) were not superior to beta-lactam/beta-lactamase inhibitor combinations (such as piperacillin/tazobactam). Specifically, in the definitive therapy cohort, mortality rates at 30 days were not significantly different: 9.3 % for those who received a beta-lactam/beta-lactamase combination (such as piperacillin/tazobactam) and 16.7 % for those who received a carbapenem ($p > 0.20$) [28]. Peralta et al. reviewed the outcome of 387 patients with ESBL-producing *E. coli* or *Klebsiella* infections. Overall inpatient mortality was 20.9–18.2 % for those receiving piperacillin/tazobactam and 25.7 % for those receiving a carbapenem [29]. Again, no superiority was seen when the outcome of those treated with a carbapenem was compared to piperacillin/tazobactam. A recently completed retrospective international cohort study (the "INCREMENT" study) comparing patients receiving definitive therapy with a BLBLI versus carbapenems should add further to the debate on the use of non-carbapenems for ESBL producers.

While ESBLs do not effectively hydrolyze cephamycins (such as cefoxitin or cefotetan), Enterobacteriaceae may exhibit resistance to those agents due to plasmid-mediated expression [30] or overexpression [31] of AmpC beta-lactamases. The development of porin-deficient mutants may also contribute to resistance to cephamycins [32]. Such occurrences have argued against the use of cephamycins in patients with serious infections due to ESBL-producing Enterobacteriaceae. ESBL-producing organisms may be susceptible to cefepime. Subgroup analysis from a randomized,

evaluator-blind trial comparing cefepime with imipenem in patients with nosocomial pneumonia showed that 100 % of patients (10 out of 10) receiving imipenem for pneumonia caused by an ESBL producer experienced a positive clinical response compared with only 69 % of patients (9 out of 13) treated with cefepime [33]. In a retrospective study of 145 patients with bloodstream infections due to ESBL-producing organisms, multivariate analysis showed that empirical therapy with cefepime for BSI due to an ESBL-producing pathogen was associated with a trend toward an increased mortality risk and empirical carbapenem therapy was associated with a trend toward decreased mortality risk [34].

Similarly, fluoroquinolones, aminoglycosides, and trimethoprim-sulfamethoxazole (TMP-SMX) are generally not appropriate initial therapeutic choices for serious infections caused by ESBL-producing Enterobacteriaceae because ESBL producers are often resistant to these drugs as well [35–37]. With fluoroquinolones, even in the presence of apparent susceptibility, there may be a substantial failure rate. In the international study discussed earlier, 36.4 % of patients who received treatment with a fluoroquinolone for bacteria caused by ESBL-producing *K. pneumoniae* died within 14 days [22], and a recent meta-analysis of non-randomized studies suggested that non-carbapenem, non-beta-lactamase beta-lactamase inhibitor agents (such as fluoroquinolones) were associated with higher mortality compared with carbapenems for definitive treatment of ESBL-producing Enterobacteriaceae infections [24].

3.4 Community-Acquired ESBLs

ESBL-producing Enterobacteriaceae are prevalent in the hospital setting, and there is now evidence that they, in particular ESBL-producing *E. coli*, are emerging and spreading in the community as well [38]. Most cases of ESBL-producing organisms in the community have been reported internationally although reports from the United States are also emerging [39, 40]. Most commonly, the cases of community-acquired ESBL producers involve urinary tract infections (UTIs), although gastrointestinal infections in the community may also be important. A population-based laboratory surveillance study of ESBL-producing *E. coli* bacteremia in the Calgary Health Region of Canada reported that 76 % of patients had community-onset disease [41]. The study did not address whether the ESBL-producing *E. coli* were necessarily acquired in the community, but the data do speak to the high prevalence of infections associated with ESBL-producing species in the community [38]. The most common ESBL type in *E. coli* isolated from patients with community-onset infections is of the CTX-M type, in particular CTX-M-14 and CTX-M-15, many of which are produced by a single clonal lineage of *E. coli* belonging to sequence type (ST) 131 and the sublineage *H*30 within ST131 [42–44].

The typical clinical picture for community-associated infection involving ESBLs is UTI (sometimes associated with bacteremia) due to CTX-M-producing *E. coli*, with elderly women being most commonly affected. Isolates are resistant to typical first-line agents for UTI, such as ciprofloxacin, TMP-SMX, gentamicin, and ceftriaxone. So there is now the very real risk that treatment of community-acquired infections with *E. coli* may be compromised because of multidrug resistance. In a study conducted at hospitals in Michigan between 2010 and 2011, 16 and 18 % of ESBL-producing *E. coli* cases were community associated [45]. The healthcare community needs to be aware of this emerging problem of community-acquired ESBL producers, especially now that detection of ESBL is not always performed by microbiology laboratories.

ESBL-producing pathogens may also be involved in gastrointestinal infections acquired in the community. Bacterial species that have been reported to produce ESBLs leading to drug-resistant gastroenteritis include *Salmonella* species, *Shigella*, and Shiga toxin-producing *E. coli* [46–50]. The possible emergence and spread of *Salmonella* strains resistant to antibiotics commonly used as treatment are concerns, because those infections can be invasive. TEM-, SHV-, and CTX-M-type ESBLs, as well as AmpC beta-lactamases, have been identified in infection-causing *Salmonella* [46, 47, 51]. Within the United States, the mechanism of *Salmonella* resistance to third-generation cephalosporins has been linked to production of AmpC beta-lactamases [52–54]. In particular, resistance has been associated with the plasmid-mediated AmpC beta-lactamase known as CMY-2. More recently, *Salmonella*-producing ESBL has been reported among both human and animal isolates in the United States as well [55, 56]. Resistant to third-generation cephalosporins is of concern because (1) ceftriaxone and, secondarily, fluoroquinolones are the drugs of choice for invasive *Salmonella* disease and (2) fluoroquinolones are not indicated for use in children. Fortunately, ceftriaxone-resistant *Salmonella* are currently rare in the United States, but they represent an area that bears further watching.

4 Antibiotic Resistance in *Enterobacter* Species

Enterobacter species are significant causes of nosocomial infection and are intrinsically resistant to aminopenicillins, cefazolin, and cefoxitin due to production of constitutive chromosomal AmpC beta-lactamases [57]. Moreover, beta-lactam exposure is capable of inducing expression of AmpC beta-lactamases in *Enterobacter* species—with consequent resistance to third-generation cephalosporins. Furthermore, mutations can result in permanent hyperproduction and persistent resistance. Treatment of *Enterobacter* infections with third-generation cephalosporins may select for mutant strains

associated with hyperproduction of AmpC beta-lactamase. The prevalence of *Enterobacter* species resistant to third-generation cephalosporins has increased since the introduction and common use of these antibiotics. For example, in one study, resistance to third-generation cephalosporins emerged in approximately 20 % of patients during treatment for *Enterobacter* bacteremia [58]. Multidrug-resistant *Enterobacter* species in initial positive blood cultures were significantly more prevalent ($P < 0.001$) among patients who had previously received third-generation cephalosporins than among patients who had previously received other antibiotic treatments, and they were associated with higher mortality rates [58].

Third-generation cephalosporins should be avoided as treatment for serious infection with *Enterobacter* species because their use in such situations results in selection of derepressed mutants which hyperproduce AmpC. In contrast, cefepime is comparatively stable to AmpC beta-lactamases and therefore has been regarded as a suitable option for treatment of *Enterobacter* infections [57]. However, ESBL-producing *Enterobacter* species, particularly *E. cloacae*, have been identified in the United States [59–62], Europe [63], and Asia [64–66]. Those producing CTX-M- and SHV-type ESBLs may have elevated cefepime MICs which compromise the activity of the antibiotic [67].

5 Fluoroquinolone Resistance

Fluoroquinolones have been used widely for the treatment of serious *E. coli* UTIs and may also be used to treat other infections caused by other members of the Enterobacteriaceae family [68, 69]. Hence, fluoroquinolone resistance in Enterobacteriaceae may lead to treatment failures and is a significant concern, as is the emergence of plasmid-mediated resistance to fluoroquinolones. In the early 2000s, means of 7.3 and 8.2 % of *E. coli* isolates were fluoroquinolone resistant from patients in ICUs and non-ICU areas of US hospitals, respectively [70]. By 2010, 36.5 and 47.1 % of *E. coli* CLABSI isolates from patients in ICUs and non-ICU areas were resistant to fluoroquinolones, respectively [5]. Prior receipt of a fluoroquinolone has been shown to be an independent risk factor for fluoroquinolone resistance [71].

Quinolone resistance in Enterobacteriaceae is usually due to alterations in target enzymes (DNA gyrase and/or topoisomerase IV) or to impaired access to the target enzymes, occurring either because of changes in porin expression or because of efflux mechanisms [72]. Both of these principal means of resistance are caused by chromosomal mutations. The recent deterioration of fluoroquinolone susceptibility in *E. coli* has coincided with worldwide dissemination of *E. coli* ST131 *H*30, which is resistant to fluoroquinolones due to DNA gyrase and topoisomerase IV alterations. Plasmid-mediated fluoroquinolone resistance has also emerged in *K. pneumoniae* and *E. coli*. The first case of plasmid-mediated resistance to fluoroquinolones in *K. pneumoniae* was reported in the United States in 1998 and was from a strain isolated at the University of Alabama in 1994 [71]. The plasmid, pMG252, confers multidrug resistance and was shown to greatly increase fluoroquinolone resistance when transferred to strains of *K. pneumoniae* deficient in outer membrane porins. The gene associated with that resistance has been designated *qnr*. Fluoroquinolone resistance associated with *qnr*-containing plasmids has now emerged in *E. coli* and *K. pneumoniae* strains [73–75]. A study in the United States reported that 11.1 % of *K. pneumoniae* strains from six states exhibited plasmid-mediated fluoroquinolone resistance associated with the *qnr* gene, although none of the *E. coli* strains examined contained *qnr* [76]. Some of the strains contained the original pMG252 plasmid, but *qnr* was carried on different plasmids for others. The mechanism of fluoroquinolone resistance associated with *qnr*-containing plasmids involves inhibition of fluoroquinolone binding with DNA gyrase [77]. Other mechanisms of plasmid-mediated fluoroquinolone resistance in Enterobacteriaceae include acetylation by AAC(6')-lb-cr, a variant of the gene encoding the aminoglycoside acetyltransferase AAC(6')-lb [78], and efflux pump QepA1 [79, 80].

The emergence of this new plasmid-mediated mechanism of fluoroquinolone resistance is particularly worrisome because it provides a mechanism for the rapid development and spread of fluoroquinolone and multidrug resistance to important members of the Enterobacteriaceae family.

5.1 Carbapenem Resistance

The emergence and spread of carbapenem-resistant Enterobacteriaceae (CRE) is one of the most recent and worrisome developments in antimicrobial resistance. The problem is most acute with *K. pneumoniae*. While resistance to carbapenems may involve several combined mechanisms including modifications to outer membrane permeability and upregulation of efflux systems, the recent surge in CRE is mostly mediated by production of carbapenemases. Among various carbapenemases, the most frequently encountered one in the United States and Europe is KPC. In the United States, carbapenem resistance has been observed in strains of *K. pneumoniae*-producing class A carbapenemases, mostly KPC-2 or KPC-3 [81–88]. These enzymes are apparently obtained via plasmid conjugation and are capable of hydrolyzing and inactivating all carbapenems. KPC-producing strains have generally been shown to exhibit multidrug resistance that includes piperacillin-tazobactam, third- and fourth-generation cephalosporins, fluoroquinolones, and aminoglycosides, as well as carbapenems [88]. Loss of outer membrane proteins appears to be a required cofactor for high-level resistance in KPC-2- and KPC-3-producing

strains [83, 84, 89]. The spread of KPC-producing *K. pneumoniae* is understood as a highly clonal process, where most isolates found in the United States as well as worldwide belong to a single lineage ST258 or related STs [90]. As with metallo-beta-lactamase-producing Enterobacteriaceae, susceptibility testing may falsely indicate the clinical susceptibility of KPC-producing *K. pneumoniae* due to an inoculum effect [81, 86, 87].

On a global scale, other emerging carbapenemases of concern include NDM-1 and OXA-48. NDM-1 was initially described in 2009 as a novel metallo-beta-lactamase produced by *K. pneumoniae* and *E. coli* isolates in a patient who returned from India to Sweden [91]. Subsequently, NDM-1-producing Enterobacteriaceae has been found to be highly prevalent in the Indian subcontinent [92, 93] and has spread worldwide in a matter of several years [94]. OXA-48 is a class D serine carbapenemase that was initially reported in *K. pneumoniae* in Turkey [95]. Detection of OXA-48-producing Enterobacteriaceae poses a challenge since, unlike other carbapenemases, OXA-48 hydrolyzes penicillins and carbapenems but not cephalosporins. This means that some OXA-48 producers are susceptible to cephalosporins and may be easily missed unless the carbapenem MICs are high enough for them to be classified as resistant to carbapenems. Nonetheless, it is becoming clear that OXA-48-producing Enterobacteriaceae have a broad geographic distribution, covering North Africa, the Middle East, Turkey, and India [96].

5.1.1 Treatment of Carbapenemase Producers

Options for treating patients infected with carbapenem-resistant *K. pneumoniae* are limited as they are typically resistant to all beta-lactam agents including carbapenems, but some strains remain susceptible to gentamicin, and most remain susceptible to tigecycline and colistin. Agents consistently shown to have in vitro activity against KPC-producing *K. pneumoniae* include tigecycline (65–100 % susceptible), colistin (73–93 %), aminoglycosides (gentamicin 30–63 %, amikacin 6–77 %), and tetracyclines (32–67 %) [81, 88, 97–99].

Colistin is a cationic cyclic polypeptide linked to a fatty acid chain and is often the only agent against carbapenemase-producing Enterobacteriaceae that achieves adequate serum levels exceeding the MICs. However, it has to be administered as a microbiologically inactive prodrug, and due to this unique pharmacokinetic property as well as potential for nephrotoxicity limiting the dosing range, it is often given in combination with another agent as part of combination therapy.

Among 889 patients included in a systematic review of treatment outcome of carbapenemase-producing *K. pneumoniae* infections, 441 received combination therapy and 346 received monotherapy [100]. The mortality rates were 27.4 % for combination therapy and 38.7 % for monotherapy ($p < 0.001$). The mortality rates within monotherapy were 40.1 % for carbapenem, 41.1 % for tigecycline, and 42.8 % for colistin. The mortality rates for combination therapy were 30.7 % for carbapenem-sparing combinations and 18.8 % for carbapenem-containing combinations, suggesting that adding a carbapenem in the combination may provide survival benefit. A large proportion of patients in this analysis were derived from four studies conducted in the United States, Greece, and Italy addressing the clinical outcome of carbapenemase-producing *K. pneumoniae* bacteremia, most of which were due to KPC-producing isolates. These data support the use of combination therapy that includes colistin and/or tigecycline along with carbapenem in the therapy of invasive infections due to carbapenem-resistant *K. pneumoniae*. On the other hand, patients may fare well regardless of therapy for noninvasive infections such as uncomplicated urinary tract infection. In a retrospective study examining the clinical outcome of 21 patients with urinary tract infection due to carbapenem-resistant *K. pneumoniae*, 90 % of them had clinical success regardless of therapy given, and the overall 30-day mortality was low at 6 % [101].

There are several new agents with activity against CRE which have been recently approved or are in late clinical development that merit mention. Avibactam is a non-beta-lactam beta-lactamase inhibitor that is active against known Ambler class A and C beta-lactamases with activity against some Ambler class D enzymes as well [102]. It is not active against MBLs (e.g., NDM, VIM, IMP) due to the absence of the active site serine residue in these enzymes [103, 104]. Of note, avibactam has a potent inhibitory activity against KPC that is substantially greater than that of clavulanate and tazobactam [105]. Ceftazidime-avibactam is FDA approved for the treatment of complicated intra-abdominal infections and complicated urinary tract infections. It may play a role in the empirical monotherapy of invasive infections suspected to be caused by resistant Enterobacteriaceae pathogens and also potentially definitive therapy of KPC-producing Enterobacteriaceae infection.

Plazomicin is a novel aminoglycoside that is designed to resist most clinically relevant aminoglycoside-modifying enzymes and holds promise for the treatment of infections caused by CRE, including KPC-producing *K. pneumoniae* [106]. It is currently undergoing a phase 3 superiority trial targeting CRE bacteremia and pneumonia, where plazomicin-based regimens will be compared with colistin-based regimens. It is however not active against most NDM-producing isolates due to the coproduction of 16S ribosomal RNA methyltransferase.

6 Conclusions

Enterobacteriaceae are significant causes of serious infections, and many of the most important members of this family are becoming increasingly resistant to currently available antibiotics. It is a troubling trend and one that requires vigilance

and intensified measures to control the further spread of resistance by these important Gram-negative pathogens. It should be emphasized that improvements in infection control and antibiotic stewardship are necessary if the steady rise in ESBL-producing and carbapenemase-producing Enterobacteriaceae and in other forms of resistance in these species is to be slowed or stopped.

Infection control is a key aspect in restriction of the emergence and spread of resistant Enterobacteriaceae. With regard to ESBL and KPC producers, there is ample evidence of person-to-person spread. Combining reductions in third-generation cephalosporin use with traditional infection control measures—such as the use of gloves, gowns, and hand hygiene in the care of colonized or infected patients—has been reported to control the hospital spread of multidrug-resistant *K. pneumoniae*. As the list of antibiotics with potential activity against those strains continues to shrink, measures that prevent and slow the spread of multidrug-resistant Enterobacteriaceae strains throughout the world need to be put in action.

Pseudomonas

57

Kamilia Abdelraouf and Vincent H. Tam

1 Introduction

Pseudomonas species are non-fermentative Gram-negative bacteria that are ubiquitous in diverse environments. *Pseudomonas aeruginosa* is an opportunistic pathogen for humans, and is a major cause of infections among hospitalized patients, especially those with impaired immune function. It is a common cause of hospital-acquired pneumonia, bloodstream, and urinary tract infections. Owing to its low outer membrane permeability, and the expression of several multidrug efflux pumps and chromosomal β-lactamase, *P. aeruginosa* is intrinsically resistant to many antimicrobial agents. Moreover, it has a remarkable capability to acquire additional drug resistance through several pathways, such as the horizontal transfer of resistance determinants and the acquisition of resistance mutations that alter the expression and/or function of chromosomally encoded resistance mechanisms. Multidrug-resistant *P. aeruginosa* in intensive care units have severely limited our therapeutic options. Thus, the increasing emergence of multidrug-resistant *P. aeruginosa* isolates in hospital settings should be regarded as a serious health hazard. A concerted effort is urgently needed to curtail the spread of resistance. The objective of this chapter is to review the current knowledge on *P. aeruginosa* with an emphasis on its antibiotic resistance mechanisms, including intrinsic, acquired, and adaptive mechanisms. Key strategies for prevention and management of *P. aeruginosa* resistance are also discussed.

2 Overview: Pseudomonas spp.

Pseudomonas bacteria are Gram-negative aerobes that belong to the family Pseudomonadaceae [1]. These bacteria are abundant in the environment. The number of organisms belonging to pseudomonas genus has increased steadily over the years to more than 200 species [2].

Several strains of pseudomonas genus have been identified as human pathogens. For example *P. oryzihabitans* (previously known as *Flavimonas oryzihabitans*) is an emerging pathogen that could cause infections in humans such as bacteremia, urinary tract, and catheter-associated infections [3–6]. *P. fluorescens* is a widespread bacterium that is found in a variety of environments such as refrigerated food and water [7]. It has also been suggested to play a role in Crohn's disease [8, 9] and associated with several outbreaks of bacteremia among hospitalized patients [10, 11]. *P. putida* has been infrequently associated with infections in humans such as bacteremia, urinary tract infections, and pneumonia [12, 13]. Antibiotic resistance in some of these pseudomonas species has been reported [6, 14, 15]. However, these species are generally considered of low virulence and of little clinical significance compared with *P. aeruginosa*, the most important human pathogen belonging to the pseudomonas genus.

P. aeruginosa was first isolated in 1882 by Gessard from green pus [16]. The majority of *P. aeruginosa* clinical isolates produce the green-blue pigment pyocyanin, which is responsible for their characteristic green color [17]. *P. aeruginosa* is very versatile biochemically and could inhabit different environments such as soil and water. It can also adapt efficiently to hospital environment; *P. aeruginosa* was found in cultures of samples taken from hospital sinks, drains, bathtubs, ventilators, and, occasionally, the hands of clinical staff [18]. *P. aeruginosa* also has the capability to tolerate hostile environmental conditions that are deemed inhospitable to the majority of other microorganisms, which makes this bacterium very difficult to eradicate [19].

P. aeruginosa is an opportunistic pathogen that is commonly associated with nosocomial infections, especially

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_9

among immunocompromised patients [20]. Chronic lung infection due to *P. aeruginosa* is very common among cystic fibrosis patients and is considered to be the leading cause of mortality in these patients [21]. *P. aeruginosa* is also an important cause of urinary tract infections, community- and hospital-acquired pneumonia, bacteremia, and soft-tissue infections [22]. A wide array of virulence factors mediate the pathogenicity of this bacterium such as production of proteases, endotoxin A, lipases, phospholipases, and pyocyanin [23]. Additionally, a major virulence determinant is the expression of the type III secretion system (T3SS). By means of T3SS needlelike appendages, effector proteins are translocated from the bacterium into the host cells. Four effectors have been identified in *P. aeruginosa*: ExoY, ExoS, ExoT, and ExoU. These effectors are believed to promote cell injury and antagonize wound healing. Thus, infections due to T3SS-expressing phenotypes are usually invasive and associated with increased mortality [23].

P. aeruginosa infections are generally more challenging to treat; thus, they are associated with high morbidity and mortality [24, 25]. This is attributed to *P. aeruginosa* remarkable capability to resist antimicrobial chemotherapy. In fact, the majority of the known mechanisms of antibiotic resistance, including enzymatic and mutational mechanisms, could be seen in this bacterium [26]. *P. aeruginosa* is intrinsically resistant to a variety of structurally unrelated antimicrobial agents. The complete genome sequencing of the wild-type strain PAO1, achieved in 2000, has provided valuable information on the molecular aspects of this inherent property [19]. Intrinsic resistance in *P. aeruginosa* is attributed primarily to its outer membrane impermeability and the activity of several multidrug efflux pumps [27]. Moreover, *P. aeruginosa* could readily develop additional resistance during treatment through horizontal transfer of resistance determinants and/or resistance mutations. Acquired resistance has been reported to all classes of antipseudomonal drugs: penicillins, cephalosporins, carbapenems, monobactams, fluoroquinolones, aminoglycosides, and polymyxins. Mechanisms of acquired resistance in *P. aeruginosa* include the production of drug-inactivating enzymes, overexpression of drug efflux pumps, alterations in target site, or further reduction in outer membrane permeability. These mechanisms could also present simultaneously resulting in multidrug resistance, which could significantly compromise treatment and adversely affect clinical outcomes [28].

3 Epidemiology of *P. aeruginosa* Infections

3.1 Respiratory Tract Infections

P. aeruginosa is responsible for several pneumonia syndromes. Community-acquired pneumonia (CAP) due to *P. aeruginosa* is rare. However, reported cases of CAP due to *P. aeruginosa* are usually very rapidly progressive and fatal even among previously healthy subjects [29, 30]. Risk factors include lung diseases, especially chronic obstructive pulmonary disease, smoking, HIV infection, previous hospitalization, and intubation [31]. On the other hand, hospital-acquired pneumonia (HAP) due to *P. aeruginosa* is very common, especially in intensive care units (ICUs) and among immunocompromised patients. In fact, *P. aeruginosa* is the leading cause of nosocomial pneumonia and the most frequently isolated bacterium from respiratory tract in the ICUs [32]. *P. aeruginosa* is an established causative pathogen of bronchoscope-associated pneumonia (BAP) through the use of contaminated bronchoscopes [33] and healthcare-associated pneumonia (HCAP) [34]. According to a recent surveillance study, *P. aeruginosa* was the most common cause of ventilator-associated pneumonia (VAP) in different geographic regions, accounting for approximately 26 % of all VAP cases [35]. Duration of hospital stay was identified as a possible risk factor for VAP due to *P. aeruginosa* [36]. Even with appropriate antibiotic therapy, mortality due to *P. aeruginosa* VAP could exceed 40 % [31, 37].

In addition, *P. aeruginosa* is commonly associated with chronic lung infections in cystic fibrosis patients. Chronic lung infection due to *P. aeruginosa* is seen in approximately 80 % of adult cystic fibrosis patients and accounts for the majority of the attributed mortality in these patients [38]. Chronic *P. aeruginosa* lung infections are also common among patients with chronic bronchiectasis and chronic obstructive pulmonary disease [23].

3.2 Urinary Tract Infections (UTIs)

UTIs are the most frequent infections acquired by hospitalized adult patients with an estimated prevalence of 30–40 % of all nosocomial infections. The incidence of nosocomial UTI in critically ill patients ranges between 7 and 31 %. Gram-negative bacteria account for approximately 71 % of UTIs [39]. The organisms most frequently implicated in nosocomial UTIs are *Escherichia coli*, *Proteus mirabilis*, *P. aeruginosa*, *Klebsiella pneumoniae*, and *Enterococcus faecalis* [40]. *P. aeruginosa* is the third most common cause of urinary tract infection [38]. UTIs due to *P. aeruginosa* are more common among ICUs and patients with indwelling urinary catheters [22].

3.3 Skin and Soft-Tissue Infections (SSTIs)

SSTIs include necrotizing infection, infections associated with bites and animal contact, diabetic foot infections, surgical site infections, and burn infections [41, 42]. Risk factors for SSTIs include diabetes, renal failure, cirrhosis, and conditions that impair the immune function such as glucocorticoid use, chronic immunosuppressive therapy, and HIV infection [43].

Infections due to Gram-negative aerobes such as *P. aeruginosa* are frequently reported. *P. aeruginosa* is often identified as the most frequent bacterial pathogen in burn units. *P. aeruginosa* is also the fourth most common cause of surgical site infection following gastrointestinal surgery [38].

3.4 Bacteremia

Bacteremia is a serious and potentially life-threatening medical condition. Although the majority of bacterial bloodstream infections are caused by Gram-positive strains [44], *P. aeruginosa* is also an important causative agent of bacteremia. *P. aeruginosa* bacteremia is associated with high mortality. Reported crude mortality rates due to *P. aeruginosa* bacteremia in ICUs are higher than 50 % among immunosuppressed patients [45]. Immunocompromised patients and patients with malignancy or neutropenia are also at high risk of *P. aeruginosa* bacteremia. Risk factors for mortality in patients with *P. aeruginosa* bacteremia include septic shock, pneumonia, having a severe underlying disease, neutropenia, inappropriate empirical therapy, delay in starting effective antimicrobial therapy, and multidrug resistance [45–48].

4 Intrinsic Resistance Mechanisms

A major challenge in the treatment of *P. aeruginosa* infections is that this bacterium is intrinsically resistant to many structurally unrelated antimicrobial agents [27]. This could be attributed in part to its low outer membrane permeability, owing to its naturally incompetent porin systems, which selectively restricts antibiotic uptake [49]. Porins are trans-outer-membrane proteins that form water-filled channels through which hydrophilic molecules diffuse into the bacterium. Several important families of porins have been identified in *P. aeruginosa* [19]. OprF porins are the most abundantly expressed on the outer membrane of *P. aeruginosa*. Unlike other porin proteins, OprF porins are nonspecific, allowing the diffusion of large as well as small molecules, with an exclusion limit estimated at 3000 Da [50]. Therefore, they are regarded as general-diffusion porins. OprF porins are formed mostly of small channels and a few large channels, which promote the uptake of larger substrates. However, owing to the limited number of large channels, the uptake capacity of large substrates, including antimicrobial drugs, is somewhat restricted. Therefore, the significance of their contribution to antibiotic permeability through the outer membrane of *P. aeruginosa* is debatable [51, 52]. In addition to the nonspecific OprF family, several specific porins have been identified. OprB porins are carbohydrate-selective porins that are primarily responsible for glucose and other sugars uptake such as fructose, mannitol, and xylose [53, 54]. Some evidence suggests that they might also play a role in the uptake of tobramycin [55]. OprD porins promote the uptake of basic amino acids and small peptides [56]. They also play a role in the uptake of carbapenems, in particular imipenem [57–59]. OprD porins are moderately expressed on the outer membrane of *P. aeruginosa*, so mutations that result in deletion of these porins contribute considerably to the reduced susceptibility of this bacterium to carbapenems [60]. Other porin families have not been shown to play a significant role in susceptibility of *P. aeruginosa* to antibiotics [61].

Although poor outer membrane permeability plays a significant role in the reduced susceptibility of *P. aeruginosa*, it does not solely account for its high level of intrinsic antibiotic resistance. Several studies that involved the use of inhibitors or *P. aeruginosa* knockout mutants suggested that the expulsion of antibiotics by energy-dependent multidrug efflux systems constitutes the most important mechanism of intrinsic resistance [62]. The efflux pumps that are associated with clinically significant intrinsic resistance are those belonging to the resistance-nodulation-cell division (RND) family. Whole-genome sequence information suggested the presence of more than ten RND family multidrug efflux pumps in *P. aeruginosa* [19]. Members of RND family that are expressed at basal levels by *P. aeruginosa* wild-type strains and have been shown to confer intrinsic multidrug resistance are MexAB–OprM and MexXY–OprM. The former was the first system to be identified. It is a tripartite system, consisting of an inner membrane drug-proton antiporter (MexB), an outer membrane channel-forming component (OprM), and a periplasmic membrane linker protein (MexA) [63, 64]. It plays a role in the intrinsic resistance to a wide range of antibiotics including fluoroquinolones, some β-lactams such as carbenicillin, tetracycline, macrolides, chloramphenicol, novobiocin, trimethoprim, and some sulfonamides [65–69]. MexAB-OprM expression is regulated by the repressor protein MexR, which is responsible for the negative downregulation of expression [67, 70]. The other efflux system, MexXY-OprM, has the ability to efflux aminoglycosides, tetracycline, and erythromycin [71–73]. However, it appears that their activity is contingent upon the induction of MexXY expression by wild-type strains in the presence of certain antimicrobial agents [72]. Similar to MexAB-OprM, the MexXY-OprM system also utilizes OprM as its outer membrane component [71, 72, 74]. MexZ protein appears to repress the expression of mexXY [73].

In addition to the previously mentioned mechanisms, some strains of *P. aeruginosa* constitutively produce chromosomal AmpC β-lactamase, which hydrolyzes β-lactams by cleaving the amide bond of β-lactam ring [75, 76]. Wild-type strains of *P. aeruginosa* produce insignificant levels of AmpC β-lactamase and are, therefore, susceptible to penicillins, cephalosporins, and carbapenems. Induction of β-lactamase

expression occurs upon exposure to some β-lactams, resulting in reduced susceptibility to β-lactams including the inducing agent [77].

It is worth mentioning that these resistance mechanisms do not appear to function independently; collaboration takes place between different mechanisms resulting in very low susceptibility to antimicrobials. For instance, interplay takes place between poor outer membrane permeability of *P. aeruginosa* and AmpC β-lactamase overproduction, resulting in significant elevation in β-lactams MIC [61, 78]. Another study also suggested that interplay could also take place between efflux and AmpC β-lactamase activity [75]. Therefore, it seems that each mechanism acts to facilitate the function of another mechanism, resulting in the substantial intrinsic resistance observed for this bacterium. Moreover, the intrinsic resistance of *P. aeruginosa* could be further potentiated via target-site mutations.

5 Acquired Resistance Mechanisms

Although the inherent intrinsic resistance is always a concern, the biggest problem with *P. aeruginosa* is its extraordinary ability to acquire additional resistance via several pathways. Segments of DNA, such as plasmids, integrons, or phages that carry antibiotic resistance genes, can rapidly spread resistance among bacterial strains. This mechanism is known as "horizontal transfer of resistance determinants." This type of resistance was demonstrated against several classes of antipseudomonal drugs including aminoglycosides and β-lactams [79–81]. For example, genes encoding aminoglycoside-modifying enzymes, extended-spectrum β-lactamase (ESBLs), metallo-β-lactamases (MBLs), and 16S rRNA methylases could be transferred among *P. aeruginosa* strains through this mechanism [81–86]. Horizontal transfer is particularly critical because it is associated with rapid and broad dissemination of resistant determinants among bacterial populations.

Another important mechanism is acquisition of resistance mutations that have the capability to alter the expression and/or function of chromosomally encoded mechanisms. For example, mutations that compromise the expression of efflux repressor genes *mexR* or *mexZ* could result in overproduction of MexAB-OprM or MexXY-OprM efflux systems, respectively, resulting in reduced susceptibility to their antibiotic substrates [67, 87–90]. Other mutations could result in the induction of MexCD-OprJ and MexEF-OprN [91–94]. These are multidrug efflux systems that are not naturally produced by wild-type *P. aeruginosa* stains. Their expression in response to mutations in *nfxB* and *nfxC* genes results in considerable resistance to a variety of antimicrobial agents [65, 69, 93, 95–97].

Several other resistance mutations such as those resulting in reduced outer membrane permeability via the alteration of porins or mutations in antibiotic-binding sites have been reported in the literature [98, 99]. Such mutational resistance pathways are commonly associated with considerable clinical resistance. Furthermore, it was also suggested that synergistic interplay between different resistance mutations in *P. aeruginosa* could result in high-level resistance [100, 101].

In addition to these pathways, several low-level resistance mutations have been recently described for *P.* aeruginosa [102–105]. Although these mutations were not individually associated with a significant increase in the level of resistance, accumulation of several of these mutations could result in stepwise evolution of high-level resistance. This phenomenon was termed "creeping baselines" [27, 106] and was precisely demonstrated by El'Garch et al. Using a set of generated double-, triple-, and quadruple-PAO1 mutants in their study, they were able to demonstrate the cumulative effects of different nonenzymatic mutations on aminoglycoside resistance, with MICs increasing from 2-fold for the double mutants to 64-fold in the quadruple mutant compared with the wild-type strain PAO1 [107]. This phenomenon has also been shown to affect the susceptibility of *P. aeruginosa* to other classes of antibiotics [106]. Therefore, the gradual accumulation of several low-impact mutations in *P. aeruginosa* genome, as seen with isolates obtained from patients with cystic fibrosis, could ultimately give rise to clinically significant resistance.

Certain types of mutational resistance have been suggested to elicit dramatic modifications in *P. aeruginosa* phenotype. Mutations that inactivate the DNA mismatch repair system (MMR), which is responsible for the maintenance of the genetic material by repairing DNA replication errors, result in rapid increase in the bacterial mutation frequency [108]. These strains are known as hypermutable strains or "mutators," and they are highly prevalent among cystic fibrosis patients who are chronically colonized with *P. aeruginosa* [109]. Mutations in *mutS*, *mutL*, or *mutU* (also known as *uvrD*) are primarily responsible for hypermutation [110]. Mutators have the capability to acquire resistance and multidrug resistance to β-lactams, aminoglycosides, and fluoroquinolones [111–115]. Furthermore, some evidence suggests that mutators acquire additional resistance mechanisms much more rapidly than non-mutator strains [112, 116].

Specific mechanisms of acquired resistance to different antibiotic classes are further discussed later in this chapter.

6 Adaptive Resistance Mechanisms

Adaptive resistance is a set of resistance mechanisms to one or more antimicrobial agents that are induced in response to drastic environmental conditions or the exposure to a certain triggering agent [117]. In contrast to acquired resistance, this class of resistance is characterized by being non-mutational, not

inheritable, and of transient nature (i.e., upon removal of the triggering factor, the MICs gradually revert to near-baseline level). Adaptive resistance was first discovered in the 1960s, but owing to its transient nature, this class of resistance has been overlooked for decades. It is now being increasingly recognized as an important contributor to the poor clinical outcome of *P. aeruginosa* infections along with intrinsic and acquired resistance mechanisms.

Triggering factors for adaptive resistance include subinhibitory concentrations of antibiotics as well as some environmental signals such as pH, anaerobiosis, cation levels, and formation of biofilms [106]. These triggering signals appear to cause the dysregulation of one or more resistance genes, resulting in alteration in function of efflux systems, the outer membrane permeability, and/or the enzymatic activity. Several mechanisms of adaptive resistance have been identified in *P. aeruginosa*. For example, induction of *ampC* gene-encoded β-lactamases in response to exposure to some β-lactams has been previously described [118]. Overexpression of gene encoding the transporter MexY of the MexXY-OprM efflux system has also been observed following exposure to aminoglycosides [119]. However, since adaptive resistance has gained attention only recently, the majority of the molecular mechanisms involved in this type of resistance are still not completely understood.

7 Mechanisms of Resistance to Important Antipseudomonal Drugs

7.1 Resistance to β-Lactams/Carbapenems

β-lactams act by inhibiting the synthesis of bacterial cell wall via blocking the action of transpeptidases, also known as penicillin-binding proteins (PBPs) [120]. This class includes penicillins, cephalosporins, carbapenems, monobactams, as well as β-lactam/β-lactamase-inhibitor combinations [121]. Wild-type strains of *P. aeruginosa* are intrinsically resistant to penicillin G, aminopenicillins, as well as first- and second-generation cephalosporins. They are otherwise susceptible to the majority of the remaining β-lactams such as carboxypenicillins, ureidopenicillins, aztreonam, some third- and fourth-generation cephalosporins, and group 2 carbapenems [122]. *P. aeruginosa* could additionally acquire resistance to β-lactams through the production of β-lactamases, overexpression of several efflux systems, alteration of outer membrane permeability, and/or alteration of PBP (target site) [26].

7.1.1 Production of β-Lactamases

β-Lactamases are enzymes that disrupt the amide bond of β-lactam ring and thus inactivate them. Production of β-lactamases is the most important mechanism of resistance to β-lactams in *P. aeruginosa* [123]. Hundreds of β-lactamases have been reported; they are commonly categorized based on substrate specificity or proteomic homology. Four major classes of β-lactamases belonging to Ambler's molecular classification system have been identified in *P. aeruginosa*: A–D [124, 125]. Class A, C, and D β-lactamases inactivate the β-lactam ring via a catalytically active serine residue [126]. Class B metallo-β-lactamases (MBLs) operate through a different mechanism. They are characterized by having divalent cations, usually zinc, as metal cofactors in their active centers [127].

Carbenicillin-Hydrolyzing β-Lactamases (CARBs)

These enzymes belong to class A of β-lactamases. Four types have been identified in *P. aeruginosa*: CARB-1 (PSE-4), CARB-2 (PSE-1), CARB-3, and CARB-4 [128]. These enzymes can hydrolyze carboxypenicillins, ureidopenicillins, and cefsulodine but not caftazidime or carbapenems. Their activity is inhibited by commercially available β-lactamase inhibitors such as clavulanic acid, tazobactam, and sulbactam [129].

AmpC β-Lactamase (Cephalosporinase)

AmpC β-lactamase belongs to molecular class C of β-lactamases. This enzyme is encoded by the gene *ampC*, which is expressed by wild-type *P. aeruginosa* in low quantities [130, 131]. However, induction of *ampC* expression could occur in the presence of some β-lactams, such as imipenem, resulting in increased enzymatic activity (up to thousandfold). Increased production of AmpC β-lactamase in *P. aeruginosa* confers resistance to third-generation cephalosporins and is a common finding in clinical isolates [132–135]. Although imipenem is an excellent inducer of *ampC*, its resistance to hydrolysis preserves its efficacy against *P. aeruginosa* strains that overexpress AmpC [136, 137]. However, *ampC* overexpression, alone or in combination with OprD inactivation, is correlated with reduced susceptibility to doripenem and meropenem, resulting in two- to four-fold increase in MICs [137]. Additionally, extended-spectrum AmpC, which has the ability to inactivate imipenem as well as oxyiminocephalosporins, has been reported in clinical *P. aeruginosa* isolates [138]. The activity of AmpC β-lactamase is not inhibited by commercially available β-lactamase inhibitors except avibactam [127, 139]. Plasmid-mediated transfer of AmpC β-lactamase has not been detected in *P. aeruginosa*.

Oxacillinases

They are also known as OXA-type enzymes. They belong to class D of β-lactamases. Classical oxacillinases (not belonging to extended-spectrum β-lactamases) include OXA-1, OXA-2, and OXA-10 types and they hydrolyze carboxypenicillins and ureidopenicillins [26, 140, 141]. OXA-50 type, which is chromosomally encoded in *P. aeruginosa*, has been shown to exhibit weak hydrolytic activity against imipenem and, to a much lesser extent, meropenem.

The activity of OXA-50 is weakly inhibited by tazobactam and clavulanic acid [142].

Extended-Spectrum β-Lactamases (ESBLs)

These are a group of β-lactamases that can hydrolyze a wide range of β-lactams including penicillins, narrow- and extended-spectrum cephalosporins, and aztreonam. However, they do not hydrolyze cephamycins and carbapenems [127, 143]. Transfer of ESBL-encoding genes in *P. aeruginosa* is plasmid or integron mediated [141,143]. Several ESBLs have been detected in *P. aeruginosa*, which belong to molecular classes A and D [144].

Class A ESBLs: Seven types have been detected in *P. aeruginosa*: TEM, SHV, PER, VEB, GES/IBC, BEL, and PME [145–152]. Class A ESBLs confer resistance to carboxypenicillins, ureidopenicillins, aztreonam, and extended-spectrum cephalosporins such as ceftazidime, cefepime, and cefpirome. However, they do not confer resistance to carbapenems [144]. Their activity can be inhibited by β-lactamase inhibitors such as clavulanic acid and tazobactam [152, 153].

Class D ESBLs: They are also known as OXA-type ESBLs. OXA-11 was the first OXA-type ESBL to be discovered in *P. aeruginosa* [154]. These enzymes confer resistance to cefotaxime, ceftazidime, cefipime, cefpirome, moxalactam, meropenem, and aztreonam [142, 155]. They are not inhibited by β-lactamase inhibitors such as clavulanic acid or tazobactam except for OXA-18 and OXA-45 [125, 127, 143].

Class B Metallo-β-Lactamases (MBLs)

MBLs are considered to be ESBLs as they have the capability to hydrolyze all β-lactams including the carbapenems (imipenem, meropenem, and doripenem) except for aztreonam. Owing to their carbapenem-hydrolyzing capability, they are often referred to as carbapenamases [156]. MBLs are not inhibited by commercially available β-lactamase inhibitors; however, they are susceptible to inhibition by metal ion chelators such as EDTA [157]. Transfer of class B MBL-encoding genes in *P. aeruginosa* is plasmid or integron mediated [85]. The types of MBLs that have been identified in *P. aeruginosa* are IMP, VIM, SPM, GIM, NDM, AIM, and FIM [158–164].

7.1.2 Efflux

MexAB-OprM efflux system contributes to the intrinsic resistance of wild-type *P. aeruginosa* strains to the majority of β-lactams [165]. Moreover, overexpression of MexAB-OprM, which occurs primarily through mutations in *mexR*, *nalC*, *nalB*, or *nalD* genes, is associated with further reduction in susceptibility to β-lactams [67, 70, 166, 167]. Overproduction of MexAB-OprM reduces *P. aeruginosa* susceptibility to penicillins, cephalosporins, monobactams, and meropenem but not to other carbapenems (imipenem or panipenem) [58]. Overexpression of MexCD-OprJ system, due to mutations in the *nfxB* gene, confers resistance to cefepime and cefpirome [168, 169]. MexXY-OprM expression is associated with resistance to cefepime [170]. Mutations in the *nfxC* gene resulting in overexpression of MexEF-OprN pumps confer resistance to carbapenems, especially imipenem. However, this resistance appears to be attributed to the decreased expression of OprD porin observed in *nfxC* mutants [171].

7.1.3 Alteration in Outer Membrane Permeability

Clinical *P. aeruginosa* strains that lack OprD porins due to mutations in *oprD* gene show increased resistance to imipenem but not to other β-lactams [58, 171, 172]. Inactivation of *oprD* is also associated with reduced susceptibility to meropenem and doripenem. However, clinical resistance to these carbapenems appears to be contingent upon the presence of additional mechanisms such as the overproduction of AmpC or MexAB-OprM in the *oprD* mutants [137].

7.1.4 Alteration of Target Site

Production of modified PBP with low affinity to β-lactams by *P. aeruginosa* or reduced transcription of *pbp* is associated with increased resistance to β-lactams [173–175]. Alteration of PBP1a/b pattern has been linked to β-lactam resistance in *P. aeruginosa* clinical isolates [176]. Downregulation of *pbp3* has also been shown to play a role in carbapenem resistance [177]. However, the presence of other underlying resistance mechanisms in the clinical isolates examined makes it difficult to draw a definite conclusion on the relative contribution of such mechanism to the observed resistance.

7.2 Resistance to Aminoglycosides

Aminoglycosides are polycationic molecules that exhibit bactericidal activity against *P. aeruginosa.* These agents act primarily by binding to the bacterial 30S ribosomal subunit, and thus impairing bacterial protein synthesis [178]. The most important mechanism of *P. aeruginosa* resistance to aminoglycosides is through the synthesis of aminoglycoside-modifying enzymes (AMEs). Other important resistance mechanisms include active efflux as well as modification of target site [179].

7.2.1 Aminoglycoside-Modifying Enzymes (AMEs)

AMEs inactivate aminoglycosides by attaching a functional group to the antibiotic molecules, and thus compromising

drug binding to the target site (the bacterial 30S ribosomal subunit) [178, 180]. AME-encoding genes are horizontally transferred through mobile genetic elements such as plasmids and integrons [179]. Three classes of AME have been identified in *P. aeruginosa*:

Aminoglycoside Acetyltransferases (AACs)
They are responsible for acetylation of aminoglycosides. They confer resistance to gentamicin, tobramycin, netilmicin, amikacin, and arbekacin [179, 181–183].

Aminoglycoside Nucleotidyltransferases (ANTs)
They are also known as aminoglycoside adenyltransferases (AADs). They act by adenylation of aminoglycosides such as gentamicin, tobramycin, isepamicin, amikacin, and streptomycin [179, 184].

Aminoglycoside Phosphotransferases (APHs)
They are responsible for phosphorylation of aminoglycosides. They confer resistance to gentamicin, kanamycin, neomycin, streptomycin, isepamicin, tobramycin, and amikacin [179, 185, 186].

7.2.2 Efflux and Alteration in Outer Membrane Permeability

Several studies published in the 1970s and 1980s suggested that reduction in *P. aeruginosa* outer membrane permeability could result in reduced intracellular concentration of aminoglycosides, and thus reduced susceptibility to all aminoglycosides. Impermeability was believed to be the most common resistance mechanism among isolates from cystic fibrosis patients [187–190]. However, it is now known that reduced intracellular accumulation is attributed to active aminoglycoside efflux rather than reduced uptake [73, 191, 192]. Exposure to aminoglycosides has been shown to induce the expression of MexXY-OprM efflux system resulting in reduced susceptibility to aminoglycoside [192]. This induction is attributed to overexpression of the gene encoding the transporter MexY [73, 119, 191], mutations in the repressor *mexZ* gene [193, 194], or other mutations [195]. It has also been suggested that the novel outer membrane protein OpmG and its closely related paralog OpmI are involved in aminoglycoside efflux [196].

7.2.3 Alteration of Target Site

Mutations resulting in alterations in bacterial ribosomes have been associated with high-level resistance to aminoglycosides. Acquisition of the *rmtA* gene, which encodes 16S rRNA methylase, via mobile genetic elements is associated with high-level pan-aminoglycoside resistance [86]. Similarly, acquisition of *rmtD* or *armA* gene, which encodes novel 16S rRNA methylases, confers pan-aminoglycoside resistance [197–199].

7.3 Resistance to Quinolones/ Fluoroquinolones

Quinolones and fluoroquinolones are bactericidal agents that interact with two enzymes that are essential for bacterial DNA replication, transcription, recombination, and repair: DNA gyrase (topoisomerase II) and topoisomerase IV [200]. This interaction results in inhibition of bacterial DNA synthesis as well as RNA synthesis at higher drug concentrations [201]. The two major mechanisms of *P. aeruginosa* resistance to quinolones are the alteration of target enzyme and active efflux.

7.3.1 Alteration of Target Site

Fluoroquinolone resistance mutations occur most commonly in the quinolone resistance determining regions (QRDRs) of the genes encoding DNA gyrase and/or topoisomerase IV. Mutations in *gyrA/gyrB* genes, which encode DNA gyrase, result in production of modified enzyme with reduced affinity to quinolones. This mechanism is associated with a dramatic reduction in the susceptibility of *P. aeruginosa* to ciprofloxacin as well as other quinolones [98, 202, 203]. Mutations in *parC/parE* genes, which encode topoisomerase IV, are also associated with reduced susceptibility to quinolones [92]. Multiple mutations in *gyrA* and/or *parC* gene are associated with high-level resistance [203–205].

7.3.2 Efflux

Quinolones are substrates for all four major efflux pumps identified in *P. aeruginosa*: MexAB-OprM, MexXY-OprM, MexEF-OprN, and MexCD-OprJ. Therefore, mutations resulting in overexpression of any of these pumps generally result in an increase in quinolone MICs, including ciprofloxacin. Active efflux appears to be the most prevalent mechanism of fluoroquinolone resistance among cystic fibrosis isolates [92, 169, 206–209]. A study has also provided evidence that MexVW-OprM system (a newly identified member of the RND family) could be involved in resistance to fluoroquinolones [210].

Although alteration of target enzyme and active efflux are commonly regarded as the only two mechanisms contributing to resistance, a recent study suggested that additional unidentified mechanism(s) may contribute to the high-level fluoroquinolone resistance observed in clinical isolates [211]. In this study, mutations in the QRDRs were introduced into the susceptible *P. aeruginosa* reference strain PA14 and the efflux regulator-encoding genes were inactivated generating mutants that overexpress the MexCD-OprJ,

MexAB-OprM, MexXY, and MexEFOprN efflux pumps. The results indicated that these two mechanisms might not be sufficient to explain the level of fluoroquinolone resistance observed in clinical *P. aeruginosa* isolates. Further studies are needed to corroborate these findings.

7.4 Resistance to Polymyxins

The primary mode of action of polymyxins is through the interaction with lipid A component of the bacterial outer membrane lipopolysaccharide, resulting in alteration in permeability and disruption of cell homeostasis [212]. *P. aeruginosa* can develop resistance to polymyxin as well as other cationic antimicrobial peptides via the modification of lipid A with 4-amino-L-arabinose, which interferes with polymyxin interaction with the outer membrane. Genes in the *arnBCADTEF-pmrE* operon (also known as *pmrHFIJKLME* [PA3552-59]) encode enzymes responsible for the synthesis and the addition of 4-amino-L-arabinose to lipid A [213, 214]. Transcription of *arnBCADTEF-pmrE* operon is stimulated in response to antimicrobial peptide exposure through three two-component regularity systems, PmrAB, PhoPQ, and ParRS [215–217]. Mutations in *pmrB*, *phoQ*, or *parR* genes that result in the activation of this mechanism have been associated with low- to moderate-level polymyxin resistance in clinical *P. aeruginosa* strains [218–220]. Recently, two additional two-component regulatory systems, CprRS and ColRS, have been found to play a role in polymyxins and other cationic antimicrobial peptide resistance in *P. aeruginosa* [221, 222].

8 Biofilm Resistance and Nonreplicating Persisters

Biofilms are populations of one or more types of bacteria that are attached to surfaces and enclosed in exopolysaccharide matrices [223]. Biofilms can grow on medical implants, central venous catheters, urinary catheters, endotracheal tubes, and prosthetic heart valves leading to serious nosocomial infections [224, 225]. Several bacterial species have been shown to grow in biofilms including *P. aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, *and Staphylococcus aureus* [226]. Chronic lung infections in cystic fibrosis patients are commonly associated with *P. aeruginosa* biofilms [227].

Formation of biofilms is regarded as a form of adaptive resistance [106]. It has been established that when bacteria are enclosed in biofilms, they become between 10 and 1000 times more resistant to antimicrobials compared with planktonic (free-living) bacteria [228]. This is particularly problematic for cystic fibrosis patients and could explain, at least in part, why in vitro susceptibility testing fails to accurately predict the in vivo efficacy of therapy for infections due to *P. aeruginosa* [229].

Several mechanisms are responsible for *P. aeruginosa* biofilm resistance. It has been suggested that the exopolysaccharide matrix acts as a physical and chemical barrier to the diffusion of antimicrobial agents through the biofilm. Using different in vitro models, it has been shown that the biofilm matrix could limit the interaction between the bacteria and the antimicrobial agent [230, 231]. The growth rate of bacterial cells in biofilm could also contribute to resistance. *P. aeruginosa* cells are metabolically less active and grow at a slower rate in biofilms compared with planktonic cells. This is generally accompanied by increased resistance to antimicrobial agents that target metabolically active cells [232, 233]. The slow growth of bacteria in biofilms could be attributed to slow diffusion of nutrients through the matrix resulting in nutrient deficiency as well as waste product accumulation.

It was also suggested that the high bacterial cell density within biofilm could trigger a general stress response [234]. Two alternative sigma factors, RpoS and AlgT, are known to protect the cell against environmental stresses. These two factors are highly expressed in *P. aeruginosa* cells within biofilm. These two factors have also been shown to increase the resistance of *P. aeruginosa* cells to oxidative biocides and thus they contribute to the observed biofilm resistance [235]. Furthermore, some studies have shown that a population of bacteria within a biofilm does not react uniformly to the action of antimicrobials. Depending on the availability of nutrients, cells that are closer to the exposed side of the biofilm grow at a faster rate compared with cells that are deeply embedded within the matrix. Thus, the location of the bacterial cells within the biofilms seems to play a role in their physiological response to antimicrobials [236, 237]. It has also been suggested that *P. aeruginosa* biofilm cells display particular phenotypes that are profoundly different from planktonic cells and have the ability to combat the damaging effects of antimicrobial agents [238, 239]. For example, a novel ABC-family efflux system that is preferentially expressed in biofilm cells has been shown to confer resistance to aminoglycosides [240].

In addition to the previously mentioned resistance mechanisms, nonreplicating persister cells represent another challenge in the eradication of *P. aeruginosa* biofilms [241]. Persister cells are a group of multidrug-tolerant bacterial cells that constitute a small subpopulation within the bacterial community. These cells can withstand therapeutic concentrations of antibiotics and are able to replicate after the antibiotic pressure is withdrawn, resulting in recurrence and relapse [241]. Persisters are present in substantial numbers in *P. aeruginosa* biofilms and they are increasingly recognized as an important factor in biofilm resistance [242, 243]. The

key difference between persistent cells and drug-resistant cells is that upon regrowth of persisters, the proliferated population will exhibit similar sensitivity to the original bacterial population. On the other hand, acquired resistance mechanisms alter the bacterial genome permanently and are inheritable upon regrowth [241].

Recalcitrant chronic infections with *P. aeruginosa* in cystic fibrosis patients are strongly linked to persisters. Using a longitudinal study design, Mulcahy et al. compared persistence between isolates collected from 15 cystic fibrosis patients at the onset of the chronic infection with *P. aeruginosa* and after 96 months. They were able to demonstrate that formation of persisters increased dramatically for the late isolates without significant increase in drug resistance, which suggested that persisters played a significant role in recalcitrant cystic fibrosis infection [227].

9 Multidrug Resistance

Multidrug resistance among *P. aeruginosa* isolates is an emerging threat that severely limits our therapeutic options, especially in the ICUs [244]. The prevalence of these multidrug-resistant isolates is increasing worldwide at an alarming rate. Clinicians are obligated to adopt more aggressive treatment strategies, such as prolonged and continuous infusion of β-lactam antibiotics, or the use of older antibiotics such as polymyxins, despite their toxicity [245, 246].

A major problem appears when attempting to assess the problem of multidrug resistance in *P. aeruginosa*; a consensus of the definition of multidrug resistance is lacking, which hinders the direct comparison of the findings from different studies. Multidrug resistance in *P. aeruginosa* has been arbitrarily defined in the literature as resistance to at least two, three, four, or eight antipseudomonal drugs [247]. Similarly, many definitions of extensive-drug resistance and pan-drug resistance are being used in the medical literature. Recently, a joint initiative by the European Centre for Disease Prevention and Control (ECDC) and the Centers for Disease Control and Prevention (CDC) led to the creation of a standardized international terminology to describe acquired resistance profiles in all the bacteria that are prone to multidrug resistance: Multidrug resistance was defined as acquired non-susceptibility to at least one agent in three or more antimicrobial classes, while extensive-drug resistance was defined as non-susceptibility to at least one agent in all but one or two antimicrobial classes. Pan-drug resistance should be reserved for isolates that are resistant to all available therapeutic options [248].

Several surveillance studies have attempted to elucidate the specific mechanism(s) of multidrug resistance in *P. aeruginosa*. Multidrug-resistant phenotypes were generally attributed to multiple sequential resistance mutations or acquisition of resistance genes via horizontal transfer, each conferring resistance to one class of antibiotics. It could also be mediated via a single mechanism such as overexpression of multidrug efflux pumps(s). Overexpression of the efflux pump(s) of the RND family was a common finding among multidrug-resistant clinical isolates. In particular, overexpression of MexB of the MexAB-OprM system, which confers resistance to a broad spectrum of antimicrobial agents, was frequently detected in clinical isolates [133, 135, 249, 250]. Overexpression of MexXY-OprM was also highly prevalent (up to 72 % in some series) [135, 166, 249–252]. Loss of outer membrane porin OprD, which confers resistance to carbapenems, was frequently detected in up to 100 % of the isolates [135, 249, 250, 252]. Mutations in QRDR of *gyrA* and *parC* were common in multidrug-resistant isolates [133, 249]. Finally, overexpression of chromosomal AmpC β-lactamase [135, 249, 253] as well as acquisition of MBL (e.g., VIM-2, and VIM-4) [133, 249, 254], ESBLs [250, 253], and OXA-type β-lactamases [249, 250] were also reported.

Several risk factors for the isolation of multidrug-resistant *P. aeruginosa* in clinical settings have been identified recently. Prior exposure to antibiotics, especially quinolones, was an important risk factor for nosocomial infections with multidrug-resistant isolates in several studies [255–260]. Prior exposure to β-lactam antibiotics or aminoglycosides was also associated with increased risk for isolation of multidrug-resistant phenotypes [25, 244, 256, 260, 261]. Other risk factors included ICU stay [244, 262], being bedridden, the use of invasive devices [244], a history of *P. aeruginosa* infection during the preceding year, a history of chronic obstructive pulmonary disease [261], corticosteroid therapy [260], and mechanical ventilation [25].

10 Effect of Antibiotic Resistance on Fitness and Virulence

Whether different resistance mutations are associated with a cost in *P. aeruginosa* fitness and virulence is debatable. Several studies have suggested that resistance mutations come at a physiological cost to the bacterium, which compromises its ability to develop stress adaptation mechanisms. This cost is manifested by the reduced bacterial survival under suboptimal growth conditions such as in an animal host or in a nutrient-limited environment [263–267]. For example, resistant mutants that overexpress one or more efflux system are usually less fit compared with their wild-type counterparts [263, 267]. Thus, in the absence of an antibiotic selective pressure, resistant phenotypes were less capable of competing with their susceptible counterparts coexisting in the environment. However, bacterial adaptation through the acquisition of compensatory mutations could act to restore the bacterial fitness without a significant reduction

in bacterial resistance [268, 269]. Metabolic compensation of fitness costs without acquiring compensatory mutations was also recently reported [270]. Thus, the notion that resistant isolates are usually less fit compared with their wild-type counterparts remains controversial.

Although infections resulting from resistant isolates are generally associated with worse clinical outcomes [244, 271, 272], several reports suggested that some multidrug-resistant *P. aeruginosa* isolates were less pathogenic than nonresistant isolates, as reflected by reduced production of virulence determinants and higher bacterial clearance rates [62, 266, 273, 274]. Thus the adverse outcomes in patients infected with resistant isolates could be attributed, at least in part, to factors other than virulence such as decreased effectiveness of second-line antibiotics or a delay in the initiation of appropriate antimicrobial therapy. However, some reports observed that certain multidrug-resistant *P. aeruginosa* genotypes displayed a highly virulent phenotype; isolates harboring the *exoU* gene of the T3SS were rapidly cytotoxic and had the greatest impact on disease severity compared with the exoS genotype [275, 276]. Additionally, some resistance mutations have been shown to enhance virulence. For example, *P. aeruginosa* strains that lacked OprD porin were more pathogenic compared with strains expressing this porin [277]. Therefore, it seems that a detailed phenotypic analysis is essential in order to accurately predict the fitness and virulence of the clinical isolates.

11 Prevalence of Resistance and Multidrug Resistance

Resistant *P. aeruginosa* isolates are highly prevalent worldwide. Resistance is particularly a problem in ICUs and among cystic fibrosis patients; aminoglycoside resistance is common among isolates from cystic fibrosis patients, while resistance to β-lactams and fluoroquinolones is highly prevalent among ICU isolates.

The trends in the incidence of resistance among clinical *P. aeruginosa* isolates are somewhat controversial. A national surveillance of the resistance rates among *P. aeruginosa* isolates obtained from ICU patients in the USA between 1993 and 2002 revealed a significant decline in susceptibility to all antipseudomonal drugs over the years [278]. The most significant increase in resistance rate was observed for ciprofloxacin (15–32 %), imipenem (15–23 %), and tobramycin (9–16 %). The rate of multidrug resistance, defined as resistance to ≥3 of the following drugs, ceftazidime, ciprofloxacin, tobramycin, and imipenem, also increased steadily over the 10-year period (4–14 %). The resistance rates to different antipseudomonal agents for isolates from 2002 are shown in Table 57.1. On the other hand, another national surveillance for *P. aeruginosa* isolates from US ICUs between 1993 and 2004 failed to demonstrate an increasing trend in emergence of resistance for the majority of the tested antipseudomonal drugs, except for ciprofloxacin (11.2–28.9 %), imipenem (10.6–14.5 %), and tobramycin (7.8–13.7 %) [279]. Nevertheless, a significant increase in the rate of multidrug resistance, defined as resistance to at least one extended-spectrum cephalosporin, one aminoglycoside, and ciprofloxacin, was observed over the 12-year period (1.7–9.3 %). The resistance rates among isolates collected between 2002 and 2004 from the latter study are reported in Table 57.1. Likewise, a summary of antimicrobial resistance patterns for healthcare-associated infections reported to the National Healthcare Safety Network (NHSN) at the CDC in 2009 and 2010 revealed that the proportion of resistant *P. aeruginosa* isolates did not change significantly from that in the previous 2 years [310]. It also showed that the resistance rates did not significantly differ by critical care location status. Interestingly, the reported resistance rates to different antipseudomonal agents were comparable to those observed in 2002 by Obritch et al. as shown in Table 57.1. This suggests that the resistance rates in the USA were mostly consistent over the past decade.

In Europe, the reported trends in resistance rates were also not consistent. Similar to the inference drawn by Obritch et al., the annual report of the European antimicrobial resistance surveillance network (EARS-Net) revealed a steady increase in the rate of *P. aeruginosa* resistance to all antipseudomonal drug classes between 2008 and 2011 in several countries [280]. For example, a significantly increasing trend in resistance to piperacillin, ceftazidime, fluoroquinolones, aminoglycosides, and carbapenems was observed in France. A significantly increasing trend in multidrug resistance, defined as resistance to ≥3 antibiotic classes, was also observed. However, the observations from another study that assessed the trends in *P. aeruginosa* resistance using isolates collected from six French hospitals between 2001 and 2011 contradicted those reported by the EARS-Net [282]. Slekovec et al. observed a significantly increasing trend in resistance to carbapenems only. Moreover, they observed a significantly decreasing trend in resistance to fluoroquinolones, aminoglycosides, and aztreonam. The discrepancy in the observed resistance trends between the two studies could be attributed, at least in part, to the difference in the resistance definitions; Slekovec et al. used a constant definition of resistance in accordance with the EUCAST 2013 breakpoints while the susceptibility testing results in EARS-Net report were based on the clinical breakpoint criteria used by the local laboratories of the reporting countries. Therefore, the lack of consensus in resistance definitions makes the direct comparison of the findings from different studies difficult [248].

The first national prospective surveillance study to assess antimicrobial resistance in Canada was performed in 2008 and included 373 *P. aeruginosa* isolates from patients in 10

Table 57.1 Reported rates of antimicrobial resistance among *P. aeruginosa* isolates

different hospitals [281]. The reported resistance rates were generally lower than those reported in the studies from the USA and Europe (Table 57.1). Based on hospital ward location, the resistance rates were the highest among isolates from cystic fibrosis clinics and ICUs. The rate of multidrug resistance, defined as resistance to ≥3 of the following, cefepime, piperacillin/tazobactam, meropenem, amikacin or gentamicin, and ciprofloxacin, was 5.9 %. The lower rate of multidrug resistance compared with that reported in the studies from the USA and Europe could be attributed in part to the slightly more restrictive definition of multidrug resistance used in this study. Thus, in the absence of a standard definition for the multidrug-resistant phenotype, the prevalence of multidrug-resistant *P. aeruginosa* might not be easily compared across different studies that used different definitions.

The increasing prevalence of multidrug-resistant *P. aeruginosa* is particularly concerning because infections due to these isolates are generally associated with less favorable clinical outcomes [28]. A study to examine the impact of multidrug-resistant *P. aeruginosa* bacteremia on patient outcomes revealed that multidrug resistance was independently associated with 30-day mortality [odds ratio (OR): 6.8]. Furthermore, the time to mortality was significantly shorter among patients with multidrug-resistant *P. aeruginosa* bacteremia (p = 0.011) [45]. Another study that evaluated the clinical outcomes among patients with *P. aeruginosa* bloodstream infections in two Italian university hospitals revealed

that multidrug resistance and inadequate initial antimicrobial therapy were independently associated with 21-day mortality (OR: 3.31 and 2.73, respectively) [260]. In addition to increased mortality, infections due to multidrug-resistant *P. aeruginosa* were also associated with increased morbidity. Isolation of multidrug-resistant *P. aeruginosa* was associated with a higher incidence of surgery (i.e., surgical removal of infection source), increased number of invasive procedures such as bronchoscopy or catheter implantation, increased length of hospital stay, and increased frequency of patient discharge to chronic care facility [244]. However, it is worth mentioning that the adverse outcomes in patients infected with resistant isolates are not always attributed to enhanced virulence of these strains compared with their susceptible counterparts (as discussed earlier under "Effect of antibiotic resistance on fitness and virulence"). Other factors, such as decreased antibiotic effectiveness or a delay in the initiation of appropriate antimicrobial therapy, could also contribute to the clinical outcome of these infections.

A few studies have addressed the economical burden of multidrug-resistant *P. aeruginosa* infections. These studies generally suggested that these infections were associated with increased hospital charges as well as length of stay [28]. For example, a case series that included 22 patients hospitalized between August 1994 and December 1997 aimed to examine the economic outcome of infections due to multidrug-resistant *P. aeruginosa.* They found that multidrug resistance was associated with significantly higher mean hospitalization charges compared with susceptible *P. aeruginosa* infections. This was attributed in part to the need for surgery to remove infection source among patients with multidrug-resistant infections, which increased both hospitalization costs and length of stay [283]. A more recent retrospective study of all hospital admissions between January 1, 2005, and December 31, 2006, was carried out in a tertiary-care teaching hospital in Spain to assess the hospital costs of nosocomial multidrug-resistant *P. aeruginosa* acquisition. The study included 402 *P. aeruginosa*-positive cultures. Compared with nonresistant isolates, resistant and multidrug-resistant isolates were independently associated with an increased hospital total cost (more than 70 % increase per admission) [284]. Thus, finding appropriate strategies to curb the emergence and spread of multidrug-resistant infections are essential to not only improve the clinical outcomes but also limit the heavy economic burden associated with the management of these patients.

12 Strategies for Prevention and Management of Resistance

Effective prevention and management of antibacterial resistance require coordination of different strategies for prompt detection, infection control, and effective treatment.

12.1 Development of Reliable Clinical Prediction Tools

Identifying patients at risk for adverse outcomes resulting from *P. aeruginosa* infection, such as development of drug resistance or death, is very important. Development of validated tools predicting these adverse outcomes can improve medical decision making. For example, clinical prediction tools could be derived to quantify the risk of resistant *P. aeruginosa* for a given subject with *P. aeruginosa* infection. Using factors predictive of multidrug resistance among patients with *P. aeruginosa* respiratory tract infections, Lodise et al. developed an institution-specific tool to estimate the probability of multidrug resistance among this patient group [285]. This model could assist clinicians in their empirical decision-making process and thus improve the therapeutic outcome. Similarly, several models have been developed to predict mortality among patients with *P. aeruginosa* bacteremia [286, 287]. Such models could be valuable to clinicians in the identification of patients at high risk of mortality and, thus, implementation of patient-targeted monitoring/interventions to decrease mortality.

12.2 Early Detection and Isolation

Patients at increased risk for acquiring nosocomial *P. aeruginosa* infections, such as immunocompromised patients or those requiring mechanical ventilator, should be recognized and monitored closely for any signs of infection. The delay in the detection of *P. aeruginosa* infections could potentially result in the loss of an opportunity to initiate early appropriate antibiotic therapy, which could result in poor prognosis. Novel techniques for the rapid detection of *P. aeruginosa* include quantitative PCR (qPCR), peptide nucleic acid fluorescence in situ hybridization (PNA FISH), and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Several studies have suggested that qPCR and MALDI-TOF MS were highly sensitive and specific tools for early detection of *P. aeruginosa* compared with specimen culture [288, 289]. Similarly, a recent study that assessed the utility of PNA FISH for rapid detection of *P. aeruginosa* showed that this technique offered a sensitivity and specificity of 100 % and 95 %, respectively, for *P. aeruginosa* clinical isolates [290]. However, these methods cannot reliably predict the antibiotic susceptibility when used alone. Clinical *P. aeruginosa* isolates exhibit diverse resistance mechanisms and antimicrobial susceptibilities. Thus, in vitro susceptibility testing remains important to guide the selection of appropriate chemotherapy. Specimens for culture and susceptibility testing should still be collected promptly, preferably before administration of any antibiotics.

12.3 Infection Control and Transmission Reduction

Since *P. aeruginosa* is primarily associated with nosocomial infections, strict compliance with infection control practices is critical to avoid hospital outbreaks. This may include policies for contact isolation of patients colonized or infected with multidrug-resistant isolates, to minimize the risk of patient-to-patient transmission [291]. Other measures include frequent hand washing, sterile insertion techniques for intravascular catheters, and cleaning and disinfecting devices such as the stethoscope's diaphragm.

12.4 Implementation of Antibiotic Stewardship Programs (ASPs)

ASPs are sets of coordinated hospital-based strategies dedicated to improving antibiotic use by enhancing the patients' outcomes, minimizing resistance development, and avoiding unnecessary treatment costs. The core element of a successful hospital ASP is to implement interventions that could improve antibiotic use such as antibiotic "time-outs," dose adjustment and optimization, tracking and reporting antibiotic use, and evaluation of patients' outcomes. Other important ASP elements include leadership support and continuous staff education by providing regular updates on the most recent local antibiotic resistance trends, antibiotic prescribing, and strategies for infectious disease management that address both national and local problems.

There is substantial amount of evidence that demonstrated the success of ASPs in improving the quality of patient care, reducing treatment failures, and minimizing antibiotic resistance. Regal et al. compared *P. aeruginosa* susceptibility patterns before and after reduction in β-lactam use as part of an ASP. They reported an increase in *P. aeruginosa* susceptibility to ceftazidime, piperacillin, imipenem, and aztreonam [292]. A significant increase in *P. aeruginosa* susceptibility to imipenem was also observed by Goldstein et al. after starting ertapenem use in a community teaching hospital [293]. In view of the benefits of ASPs and the pressing need to improve antibiotic use in hospitals, in 2014 the CDC recommended that all acute-care hospitals implement these programs [294].

12.5 Appropriate Empiric Therapy

Once an infection due to *P. aeruginosa* is diagnosed, prompt administration of appropriate empiric therapy is critical to clinical outcome. For uncomplicated lower urinary tract infections, antibiotic monotherapy is recommended except in case of neutropenic patients or when bacteremia is suspected. Combination therapy with two or more antipseudomonal agents is commonly used for severe infections such as bacteremia and hospital-acquired pneumonia [295]. The rationales for administration of combination therapy are to increase the probability of appropriate empirical coverage, minimize selection of resistant mutants, and achieve synergetic antibacterial effect. A combination of one aminoglycoside and one β-lactam is commonly used for treatment of bacteremia due to *P. aeruginosa*. Several studies reported an advantage for appropriate empirical combination therapy over appropriate empirical monotherapy [296–298]. However, some recent studies provided additional insights into this claim. Bowers et al. compared the outcomes of patients receiving appropriate empirical combination versus monotherapy for *P. aeruginosa* bacteremia. After adjusting for baseline APACHE II scores and lengths of hospital stay prior to the onset of bacteremia, they found no statistical differences in 30-day mortality, hospital mortality, or time to mortality following appropriate empirical combination versus monotherapy [24]. Pena et al. also reported similar results; they found that treatment with combination antimicrobial therapy did not reduce the mortality risk compared with single-drug therapy for *P. aeruginosa* bloodstream infections after adjustment for the potential confounders [299]. A comprehensive review that analyzed data from 18 studies including 426 nonneutropenic patients with *P. aeruginosa* sepsis compared all-cause mortality following the use of β-lactam/aminoglycoside combinations versus β-lactam monotherapy. They observed no significant differences between the study groups. Additionally, they observed that the adverse events, particularly the nephrotoxicity, occurred significantly more frequently in the combination study group [300]. Thus, as long as the empiric therapy was appropriate, no advantage to antipseudomonal combination therapy over monotherapy was observed in terms of clinical outcomes. Furthermore, several studies showed that the β-lactam/aminoglycoside combination therapy was not superior in suppressing resistance emergence compared with β-lactam monotherapy [301]. Large, prospective, randomized, controlled trials are needed to further evaluate the validity of the empirical combination therapy for treatment of *P. aeruginosa* infections in different patient populations.

12.6 Alternative Routes of Drug Administration

In case of difficult-to-treat *P. aeruginosa* infections, alternative routes of antibiotic administration might be considered as adjunct therapy. For example, inhaled aminoglycosides such as tobramycin are used to eradicate *P. aeruginosa* in cystic fibrosis patients as well as lung infections in non-cystic fibrosis patients with bronchiectasis [302]. Inhaled

aminoglycosides or colistin could also be beneficial in the treatment of ventilator-associated pneumonia due to multidrug-resistant *P. aeruginosa* [303]. Topical polymyxin B is also used in conjugation with systemic antibiotics for the treatment of clinically infected wounds [304]. Piperacillin/tazobactam combination is used for treatment of endophthalmitis due to multidrug-resistant *P. aeruginosa* via intravitreal instillation [305]. Intrathecal colistin has been successfully used to treat central nervous system infections post-neurosurgery due to multidrug-resistant *P. aeruginosa* such as meningitis and ventriculoperitoneal shunt infections [306–308]. In addition to the direct antibiotic delivery to the infection site, these routes of administration reduce the drug systemic exposure and consequently minimize the adverse effects.

13 Conclusions

P. aeruginosa is a major cause of nosocomial infections and a challenging pathogen to combat in healthcare settings. Resistance to all classes of antipseudomonal drugs is increasingly reported. Unfortunately, only very few new antibiotics for the treatment of drug-resistant *P. aeruginosa* strains are expected to become commercially available within the next decade [309]. Thus, it appears that *P. aeruginosa* infections will continue to be a problem for many years to come. High standards of infection control and judicious antimicrobial use are crucial to prevent the situation from deteriorating.

Acinetobacter baumannii and *Acinetobacter* spp.

58

Federico Perez and Robert A. Bonomo

1 Introduction: Challenges in Microbiology and Classification

Acinetobacter baumannii is a bacterial pathogen increasingly identified in the clinical microbiology laboratory as a cause of infection in humans. Upon microscopic examination, *A. baumannii* appears as a Gram-negative coccobacillus, and it produces clear colonies when grown on MacConkey agar, indicating its inability to ferment lactose. The taxonomy of *Acinetobacter* genus, part of the γ subclass of the *Proteobacteria* phylum, is complex and currently comprises 43 species (http://www.bacterio.net/acinetobacter.html), defined mostly by genomic DNA–DNA hybridization.

The original description of *A. baumannii* dates back to 1986 (Bouvet and Grimont). Although *A. baumannii* is the most frequently identified nosocomial pathogen in the genus *Acinetobacter*, several other species are becoming increasingly important in the clinic as occasional causes of infections and outbreaks in humans. These include *A. nosocomialis* and *A. pittii*, which are phenotypically similar to *A. baumannii* and therefore very difficult to distinguish in the clinical microbiology laboratory by traditional biochemical methods. This limitation can be partially overcome when "state-of-the art" technologies such as matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry or PCR/electrospray ionization mass spectrometry (PCR/ESI-MS) and nucleic acid sequencing are employed. With considerable less frequency, *A. ursingii*, *A. haemolyticus*, *A. lwoffii*, *A. parvus*, and *A. junnii*, among others, are also found as a cause of infection in humans. The most recently identified species of the genus is *A. seifertii*, found among clinical isolates from as early as the 1990s. The taxonomic effort that led to the recognition of the new species *A. seifertii* required a multifaceted analysis, which included similarities in the sequence of housekeeping genes, as well as the determination of a sufficiently low (<95 %) average nucleotide identity (AIN) relative to the whole genome sequence of other *Acinetobacter* species. Also, in order to differentiate *A. seifertii*, proteomic analysis with whole cell MALDI-TOF mass spectroscopy has been employed, as well as metabolic and physiologic testing and sequencing [1–8]

2 Insights from Genomic Analysis of *Acinetobacter baumannii*

With advances in genomic tools, several analyses have focused on *A. baumannii* and other representatives of the genus and revealed insights into its genetic diversity and evolutionary dynamics. A more comprehensive analysis of various genomes of *Acinetobacter* spp. has also been carried out, with the goal of covering the entire range of diversity of the species. In the case of *A. baumannii*, various genotypes defined by multilocus sequence typing (MLST) were also included. The analysis revealed that the average genome had a size of 3.87 Mb (ranging from 2.7 to 4.9 Mb). For *A. baumannii*, the core genome had 1590 orthologous protein families, which correspond to 44 % of the size of the smallest *A. baumannii* and with a gene repertoire

relatedness of only 78 %, therefore indicating the great genetic variability within the species and suggesting frequent horizontal gene transfer. Also, genomic analysis reveals that the genus of *Acinetobacter* is very ancient, approximately 5 million years old, based on the differences in the sequence between *A. baumannii* and the most distant species of the genus [8–15].

There are various mechanisms that make it possible for *A. baumannii* to accumulate such genetic diversity. Among these, one of the most important are integrons of the *intI1* class. Such integrons demonstrate tremendous abundance in *A. baumannii*, as revealed by genomic analysis. Insertion sequences (IS) have also been implicated in genetic diversity and especially in the regulation of antibiotic resistance. Diverse IS are frequently found in the genome of *A. baumannii*. In this regard, the role of IS*Aba1* serving as a promoter determining the expression of carbapenemase genes located downstream has achieved special recognition [16]. Although not established as widely, the process of natural transformation among *Acinetobacter* spp. is also known to occur [9, 17, 18].

Horizontal transfer of genetic material in *Acinetobacter*, including antibiotic resistance determinants, may also be facilitated by transduction with phages. Comparative genomic analysis reveals the frequent presence of phage sequences in *A. baumannii.* Similarly, there is evidence from the genomic analysis of the predominance of mobilizable small elements over large conjugative elements. Similarly, the conservation of the genetic machinery required for transformation in the majority of *Acinetobacter* genomes suggests that most members of the genus are naturally transformable given certain conditions (see above). In order to preserve their genome from "infection" with transmissible genetic elements such as plasmid and viruses, bacteria possess clustered regularly interspaced short palindromic repeats (CRISPR), which, in conjunction with other sequences (such as the *cas* genes and Cas proteins), form the CRISPR-Cas, an adaptive immune system. Within *A. baumannii*, most CRISPR-Cas systems are of type I-Fb, indicating that this may serve as a target for genetic fingerprinting [19]. CRISPR-Cas systems are likely to have an important role in the dynamics of the genomic transformation and in particular in controlling the transfer of conjugative elements. Acquisition of antibiotic resistance often results from the transfer of a mobile element encoding several resistance genes. A classical example is the genomic island (AbaR1) that contains dozens of antibiotic resistance determinants from diverse bacterial origins [10].

Genetic insertion and deletions occur in particular areas of the genome, deemed "hotspot" regions. According to a detailed comparative genomic analysis, it appears that approximately 80 "hotspot" regions only comprise 5 % of all possible loci and yet include 66 % of the accessory genome. Thus, it appears that a great deal of genetic diversity occurs in a few "hotspot" locations in the genome of *A. baumannii* [8]. Other mechanisms of genetic diversity are also at play in *A. baumannii*. Diversification can also result from allelic exchange by homologous recombination in the core genome. In *A. baumannii*, this process is estimated to affect up to a third of core gene families. Lastly, the emergence of genetic diversity within *A. baumannii* can also be due to point mutations; resistance to antibiotics can clearly result in such instances. Bacteria may undergo hypermutagenesis due to activation of error-prone DNA polymerases that can accelerate the dynamics of adaptation due to the mechanism of point mutations. These mutations in turn can affect two-component regulatory systems leading to efflux pump overexpression [20].

3 Determining Virulence, an Elusive Target in *A. baumannii*

Establishing the attributes of virulence that make *A. baumannii* such a successful human pathogen has been elusive. On the one hand, the systematic analysis of virulence has failed to distinguish a particular virulence factor distinctly linked to epidemiological and clinical outcomes. On the other hand, the complicated microbiology and nomenclature of the *Acinetobacter* spp. family make it very difficult to interpret the literature and to establish the attributes of *A. baumannii* versus other species of *Acinetobacter*. Even nonclinical isolates of *Acinetobacter* harbor some of the same virulence machinery that is found among clinical isolates of *A. baumannii*. Interestingly, although the name *Acinetobacter* is derived from the Greek term indicating "no movement," it appears that this is a misnomer. In particular, *A. baumannii* spreads rapidly over surfaces perhaps as the result of twitching motility [21].

A well-known and distinguishing characteristic of *A. baumannii* is its ability to survive in the environment; as reviewed below, this attribute also likely contributes to its dissemination [22]. Therefore, factors that permit its survival in biotic and abiotic surfaces can be considered as important attributes of virulence. *A. baumannii* is able to form highly structured microbial communities called biofilms. The factors that contribute to biofilm formation include, among others, the Csu pili [23], two-component regulatory systems such as BfmRS, and quorum-sensing systems [24, 25]. Similarly, adherence to host cells and tissues is a crucial initial stage of colonization and subsequent infection. Surface proteins such as Bap, the exopolysaccharide poly-β-1,6 *N*-acetylglucosamine, PNAG, and the autotransporter Ata play an important role in this regard [26–28]. There also is an O-glycosylation system that appears to be important for biofilm formation and virulence. Similarly, an outer membrane protein Omp 38 or ompA is involved in adhesion and in subsequent stages of cell invasion and apoptosis [29]. Paradoxically, *A. baumannii* strains

that demonstrate adherence to human epithelial cells may elicit a poor inflammatory response allowing bacteria to evade the host immune system and lead to persistence of *A. baumannii* [30].

Like any other Gram-negative bacteria, the outer membrane of *A. baumannii* contains lipopolysaccharide (LPS), a component important in the development of septic shock once *A. baumannii* enters the bloodstream. Most *Acinetobacter* LPS molecules contain an O-polysaccharide chain (O-antigen), involved in the pathogenic activity of other Gram-negative bacteria. Endotoxins of *A. baumannii* stimulate an inflammatory signal in monocytes, and responses to *A. baumannii* are dependent on Toll-like receptors, TLR2 and TLR4. Indeed, blocking the production of LPS in mice, for instance, with the use of the LPS synthesis inhibitor LPCx, effectively silences the effects of LPS on the host's immune system and facilitates the elimination of *A. baumannii* through opsonophagocytic killing, leading to improved survival [31–33].

Another component of the cell envelope of *A. baumannii*, the capsular polysaccharide, also can play a role in virulence, given its importance in mediating resistance to complement killing [34]. *A. baumannii*, similar to other Gram-negative bacteria, secrete outer membrane vesicles (OMVs) during various stages of bacterial growth and while stressed. OMVs are spherical nanovesicles composed of LPS, OMPs, lipids, select periplasmic proteins, and nucleic acids. More recently, OXA and metallo-β-lactamases were found in OMVs. Virulence factors such as OmpA have been associated with OMVs in *A. baumannii*, inducing apoptosis [35]. Other proteins considered as potential virulence determinants in *A. baumannii* include also phospholipase D and phospholipase C [36]. An interesting observation in *A. baumannii* is that ethanol may promote bacterial growth and stimulate metabolic pathways that are related to virulence [37].

4 Antibiotic Resistance in *A. baumannii*

The emergence of resistance to multiple classes of antibiotics in *A. baumannii* represents a veritable threat to public health. Because of this phenomenon, there are often only a few, at best, effective antibiotic options to treat infections caused *by A. baumannii*. In order to understand better and compare data regarding resistance to multiple classes of antibiotics, it is useful to understand the terminology commonly used to designate whether *A. baumannii* is "multidrug resistant" (MDR), "extensively drug resistant" (XDR), or "pandrug resistant" (PDR). The relevant classes of antibiotics that offer activity *against A. baumannii* but that may be inactive due to acquisition of mechanisms of resistance are aminoglycosides, carbapenems, beta-lactam/beta-lactamase inhibitor combinations (with ampicillin/sulbactam as a special category), expanded-spectrum cephalosporins, fluoroquinolones, polymyxins, folate inhibitors, and tetracyclines. When resistance or non-susceptibility occurs to more than one or more agents from three or more antibiotic categories, the organism is termed MDR; resistance or non-susceptibility to one or more agents to all but two or less categories is termed XDR; resistance or non-susceptibility to all agents in all categories is called PDR [38].

4.1 Mechanisms of Resistance to β-Lactams

The mechanisms that are implicated in the development of resistance to β-lactams in *A. baumannii* include β-lactamases and modifications in the permeability of the bacterial membrane through changes in outer membrane proteins (OMPs) or expression of efflux pumps [39].

Among the β-lactamases found in *Acinetobacter* spp., AmpC enzymes, or class C β-lactamases in the Ambler classification, are known for their ability to hydrolyze penicillins and cephalosporins and to be impervious to β-lactam–β--lactamase inhibitors such as clavulanic acid, sulbactam, and tazobactam. This family of enzymes is designated as *Acinetobacter*-derived cephalosporinases or ADCs [40]. The presence of an insertion sequence (IS) such as IS*AbaI* acts as a promoter for the expression of the gene coding for ADCs.

Another group of β-lactamases of considerable clinical importance in *A. baumannii* are Ambler class D enzymes, also known as oxacillinases (OXAs). OXAs receive that designation because prototype representatives of the enzyme are able to hydrolyze oxacillin. Within *A. baumannii*, however, OXAs are characterized by their carbapenemase activity and are designated as carbapenem-hydrolyzing class D β-lactamases or CHDLs. There are five groups of OXAs relevant to *A. baumannii*: OXA-51, OXA-23, OXA-24/40, OXA-58, and OXA-143. In the case of OXA-51, its role as a resistance determinant against carbapenems and cephalosporins is greatly conditioned by the presence of insertion sequences (typically IS*Aba1*) that promotes their expression [41].

Class B metallo-β-lactamases (MBLs) are an additional group of β-lactamases of clinical relevance in *A. baumannii*. The common characteristic of MBL enzymes is that they render bacteria resistant to all β-lactams, with the exception of the monobactam aztreonam. The key feature of MBLs is the presence of a zinc moiety, which can be chelated by EDTA to inactivate the enzyme. The MBLs present in *A. baumannii* include IMP, VIM, SIM, and NDM. Interestingly, IMP and VIM enzymes, although found in *A. baumannii*, really originated in *Pseudomonas aeruginosa* from Japan and Italy, respectively. SIM, on the other hand, is a MBL native to *A. baumannii* identified originally in Korea. More

recently, NDM was identified in *Enterobacteriaceae* from travelers returning from the Indian subcontinent. Various reports have identified bla_{NDM} genes in *A. baumannii* isolates from India, Egypt, China, Germany, the Balkans, the USA, and Israel. The genetic context of bla_{NDM} in *Acinetobacter* suggests this MBL arose in this genus [42, 43]. Carbapenem resistance can occur in *A. baumannii* even in the absence of any known carbapenemase through the loss of certain outer membrane proteins, such as CarO. Other outer membrane proteins have been involved in carbapenem resistance, especially in conjunction with the expression of class C and D enzymes.

4.2 Mechanisms of Resistance to Aminoglycosides

The main mechanism of resistance to aminoglycosides among *A. baumannii* is through the expression of aminoglycoside-modifying enzymes (AMEs), such as aminoglycoside acetyltransferases, nucleotidyltransferases, and phosphotransferases. A study that analyzed *A. baumannii* isolates from a military facility in the USA uncovered the presence of the following genes coding for AMEs: *aphA6*, *aadA1*, *aadB*, *aacC1*, and *aacC2* [3]. There is an important association of AMEs with mobile genetic elements such as plasmids and class I integrons that largely accounts for their widespread dissemination [44].

Other types of AMEs have been described in *A. baumannii* from the Far East; for instance, amikacin resistance was mediated in Japan by a novel type of AME, encoded by *aac(6′)-Iad*. Similarly, *armA* has been implicated in methylation of 16S rRNA in *A. baumannii*, also resulting in resistance to amikacin, as well as gentamicin and tobramycin [45, 46]. Additionally, in *A. baumannii* aminoglycoside resistance can be mediated by expression of the AdeABC efflux pump, which is also implicated as a mechanism of resistance against fluoroquinolones, among other antibiotics [47].

4.3 Mechanisms of Resistance to Fluoroquinolones

Resistance of *A. baumannii* to fluoroquinolones is often caused by modifications in the structure of DNA gyrase secondary to mutations in the quinolone resistance-determining regions (QRDR), including the *gyrA* and *parC* genes coding for DNA gyrase and DNA topoisomerase IV. These changes result in a lower affinity for the binding of the quinolone to the enzyme–DNA complex. As mentioned, another important mechanism of resistance to fluoro quinolones is mediated by efflux systems that decrease intracellular drug accumulation. In contrast to *Enterobacteriaceae* where it is fairly prevalent, plasmid-mediated quinolone resistance (*qnr* genes) is rarely found in *A. baumannii*, with the exception of the sporadic detection of *qnrA* in Algerian and Chinese isolates [48, 49].

4.4 Mechanisms of Resistance to Polymyxins

Increasing resistance to antibiotics, especially carbapenems, has prompted the widespread use of polymyxin B and colistin as therapeutic agents to treat infections caused by *A. baumannii*. Although the majority of *A. baumannii* retain susceptibility to polymyxins, the occurrence of resistance is not rare.

The common pathway leading to resistance to polymyxins in Gram-negative bacteria is the neutralization of the negative charges of the outer membrane through lipid A modifications. The two-component regulatory system pmrA/pmrAB, upon activation, leads to lipid A modifications through the addition of phosphoethanolamine. A more drastic mechanism of polymyxin resistance in *A. baumannii* is the loss of lipopolysaccharide through mutations affecting key genes involved in the biosynthesis of lipid A, such as *lpxA*, *lpxC*, or *lpxD*. These latter changes in the structure of the outer membrane lead to profound alterations in the physiology of *A. baumannii*, leading to increased susceptibility to other classes of antibiotics and to loss of biological fitness. Heteroresistance, or subpopulations of genetically identical subclones that are more resistant than the original parent clone, also has been observed in *A. baumannii* as a result of the selective pressure exerted by polymyxins [50–55].

4.5 Mechanisms of Resistance to Tetracyclines and Tigecycline

The resistance to tetracyclines in *A. baumannii* is due to the effect of either efflux pumps or a ribosomal protection protein. There are two transposon-mediated efflux pumps: TetB facilitates the efflux of both tetracycline and minocycline, whereas TetA does not have minocycline as its substrate but only tetracycline. The ribosomal protection protein, encoded by the *tet(M)* gene, shields the ribosome from the action of tetracycline, doxycycline, and minocycline. None of the abovementioned mechanisms interfere with the activity of tigecycline, which, although related to tetracyclines, is in its own glycylcycline class [18, 56].

The role of the AdeABC efflux pump as a mechanism of resistance to tigecycline is well established. The overexpression of the *adeABC* locus correlated with an increase in the tigecycline MIC in *A. baumannii* strains. This pump confers broad substrate specificity, including tigecycline, gentamicin, levofloxacin,

and chloramphenicol. A two-component regulatory system, sensor AdeS and regulator AdeR proteins, regulates the pump and can be disrupted by the insertion sequence IS*Aba1*, among other possible mutations and insertions [18, 20, 57].

5 Infections Caused by *A. baumannii*

Infection and colonization with *A. baumannii* infections mostly affect immunosuppressed patients or those with serious underlying diseases, who are subjected to invasive procedures and treated with broad-spectrum antibiotics. Infection and colonization with *A. baumannii* are therefore more frequently found among hospitalized patients, especially those in intensive care units (ICUs) and in long-term care facilities (LTCFs).

The most common syndromes associated with *A. baumannii* are pneumonia, including hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP), and bloodstream infections associated with catheters, or from various other sources. These may include urinary tract infections, complicated skin and soft tissue infections, intra-abdominal infections, and central nervous system infections often associated with neurosurgical procedures and intracranial shunts. HAP and VAP in particular are associated with poor outcomes that are likely related to the severity of underlying illness and inappropriate initial antibiotic regimens conditioned by extensive antibiotic resistance.

There has been an ongoing controversy over whether colonization and infection with *A. baumannii* are associated with increased morbidity and mortality or if poor outcomes are due to the underlying host characteristics, the virulence of the pathogen, or the antibiotic treatment. The systematic evaluation of the available literature suggests a statistically significantly higher mortality in patients who have acquired *A. baumannii* (even colonization) [58]. Another important study indicates that infections with MDR *A. baumannii* are independently associated with prolonged hospital and ICU lengths of stay compared with the outcomes for uninfected patients and those infected with drug-susceptible *A. baumannii*. However, in this analysis, there was no difference in mortality between the groups [59]. A meta-analysis identified studies comparing mortality in patients with carbapenem-resistant *A. baumannii* vs. carbapenem-susceptible *A. baumannii*. Patients with carbapenem-resistant *A. baumannii* had a significantly higher risk of mortality, with an odds ratio of 2.2. In this analysis, patients with carbapenem-resistant *A. baumannii* were more likely to have severe underlying illness and also to receive inappropriate empirical antimicrobial treatment, which increases the risk of mortality [60].

Infections caused by *A. baumannii* play a growing role among patients with cancer. A case-control study demonstrated that acquisition of MDR *A. baumannii* among cancer patients is associated with nosocomial factors, rather than characteristics of the underlying cancer. Furthermore, *A. baumannii* in cancer patients is associated with prolonged hospitalization and increased mortality [61]. Instances of bacteremia with XDR *A. baumannii* in patients with hematological malignancy and neutropenia, however, are associated with a staggering mortality rate at 30 days of 83 % and are especially high in patients who do not receive appropriate antibiotic therapy because of the XDR phenotype [62].

Patients with solid organ transplants who become infected with *A. baumannii* that is resistant to carbapenems suffer from prolonged hospitalization, infection with other MDR organisms, allograft dysfunction and loss, and high overall infection-related mortality [63]. Especially important are VAP and other respiratory infections, which are associated with frequent recurrence in recipients of cardiothoracic transplants [64]. Their increased net state of immune suppression and exposure to healthcare may predispose patients with solid organ transplants to unusual presentations of *A. baumannii* infection. For instance, fulminant sepsis caused by carbapenem-resistant *A. baumannii* harboring the $bla_{\text{OXA-23}}$ carbapenemase gene led to the death of a patient 6 days after simultaneous kidney–pancreas transplantation. Autopsy findings revealed disseminated infection with acute mitral valve endocarditis, myocarditis, splenic and renal emboli, peritonitis, and pneumonia [65].

Although only a few cases have been described in the literature, it appears that HIV-associated *Acinetobacter* infections are associated with significant morbidity, especially when a low CD4+ cell count, neutropenia, and hospitalization are present [66]. Examination of records of patients with *A. baumannii* acquisition in an ICU in Cape Town, South Africa, revealed that patients with HIV and AIDS were more likely to have bacteremia and had higher mortality rates than non-HIV-infected patients [67]. It is interesting that similar clinical patterns of HIV-associated *A. baumannii* bacteremia are not observed in the USA.

A. baumannii became well known as a major pathogen found in personnel participating in military operations in the Middle East as part of the Global War on Terrorism, after September 11, 2001. Initially, increasing numbers of *A. baumannii* bloodstream infections were reported in patients at military medical facilities in which service members are injured in the Iraq/Kuwait region during Operation Iraqi Freedom (OIF) and in Afghanistan during Operation Enduring Freedom (OEF). Most of the cases were initially treated at Landstuhl Regional Medical Center in Germany and Walter Reed Army Medical Center (WRAMC) in the District of Columbia and later at the US Navy hospital ship Comfort, National Naval Medical Center, and Brooke Army Medical Center. Noteworthy was the high level of antimicrobial resistance [68].

Among military personnel, *A. baumannii*-associated skin and soft tissue infections presented as cellulitis, which often progressed to necrotizing infection with bullae [69]. A systematic investigation of the outbreak of *A. baumannii* among military personnel suggested that environmental contamination of field hospitals and infection transmission within healthcare facilities played a major role in the dissemination of the pathogen [70]. A detailed molecular characterization of antimicrobial resistance in *Acinetobacter* spp. from WRAMC revealed a complex genetic background, including PER-1 as well as the carbapenemases OXA-58 and OXA-23 [3].

Similarly, *Acinetobacter* has been identified as a common cause of infection among victims of natural disasters. One of the most recognized examples is the presence of MDR *Acinetobacter* among the victims of the 2005 Indian Ocean earthquake and tsunami that caused several hundred thousand fatalities. Upon evacuation to European medical centers, some of the victims were noted to have soft tissue wounds and other instances of traumatic injury where *Pseudomonas* and enterobacteria were prominently involved, as well as *Acinetobacter* [71]. The ICUs of hospitals in Turkey also saw the emergence of *Acinetobacter* infection in victims of the violent earthquake of Marmara in 1998 [72].

Of particular interest, and in contrast with its standing as a nosocomial pathogen, *A. baumannii* has been found as the cause of serious infections among community dwellers particularly in Australia and Southeast Asia. Clinical presentations are distinctly severe and include pneumonia and bacteremia complicated with acute respiratory distress syndrome and disseminated intravascular coagulopathy. Cigarette smoking, alcoholism, chronic obstructive airway disease, and diabetes mellitus are underlying factors that lead to high mortality [73, 74].

6 Epidemiology of *A. baumannii*

There is an interesting association between colonization and infection with *A. baumannii* and temperate climates. The analysis of a large database of more than 200,000 blood cultures obtained from 132 hospitals through 7 years (1999–2006) revealed that there were 51.8 % (95 % CI 41.1–63.2) more infections caused by *A. baumannii* in the summer months than in the winter months. Similarly, there is a 10 % increase in the incidence of *A. baumannii* infections for every 10 °F increase in temperature. Of note, these variations according to temperature and season exceeded those that were observed for other Gram-positive and Gram-negative pathogens [75]. The reasons behind these observations remain unclear. It has been speculated that higher temperature may facilitate growth of bacteria in the environment and increase colonization in humans.

As mentioned previously, perhaps one of the most remarkable characteristics of *A. baumannii* is its ability to survive in the environment, including hospital surfaces. This feature, together with the presence of determinants of resistance to multiple antimicrobial agents, is thought to largely explain its success as a nosocomial pathogen. Investigations exploring desiccation tolerance in *A. baumannii* demonstrated a survival of up to 27 days in simulated hospital conditions. Strain-dependent variations have been observed, but there is necessarily not an advantage among outbreak-related strains [76, 77].

There is a critical interplay between environmental contamination and patient colonization with *A. baumannii*: even when colonization is remote, the surrounding environment is frequently contaminated [78]. Conversely, patients exposed to a contaminated hospital environment have 2.77 times higher risk of acquiring *A. baumannii* than unexposed patients [79]. It is thought that patient colonization with *A. baumannii* is both an important risk factor for subsequent infection and transmission. For instance, the presence of carbapenem-resistant *A. baumannii* on surveillance cultures is associated with an eightfold higher risk of subsequent development of carbapenem-resistant *A. baumannii* infections in the ICU setting [80]. It is recognized that hospitalized patients can serve as long-term carriers of *A. baumannii*. Unfortunately, the overall sensitivity of surveillance cultures from a single site is low (30 %), and it remains so even when up to six anatomical sites are sampled (55 %). Interestingly, the mean duration of *A. baumannii* isolation has been reported to be as long as 20 months [81]. Furthermore, it is possible that aerosolization of *A. baumannii* can occur, especially linked to rectal colonization, and contribute to the transmission of this pathogen [82, 83].

The profile of patients (e.g., severe underlying comorbidities) and the types of infections (e.g., VAP) associated with *A. baumannii* means that its transmission is mostly restricted to intensive care units. Especially in the USA, however, patients residing in LTCFs demonstrate particular vulnerability to colonization and infection caused by *A. baumannii*. Therefore, LTCFs represent a new frontier in the epidemiology of this important healthcare-associated pathogen [84, 85].

Given these characteristics, the prevention and control of infections caused by *A. baumannii* becomes a particular challenge. *A. baumannii* is recognized for its ability to cause outbreaks in different healthcare settings. Outbreaks of *A. baumannii* involving closely related strains, as revealed by various discriminatory typing methods, have often been described. A common environmental reservoir may be identified as the source of such outbreaks [86]. In one particular outbreak, transmission of clonal strain of *A. baumannii* was apparently caused by dissemination during the pulsatile lavage of wounds, likely resulting in environmental

contamination [87]. In another clonal outbreak, cultures from a wound care cart, environmental and clinical cultures, were all genetically related. In this instance, patient isolation, elimination of the wound care cart, and decontamination with vaporized hydrogen peroxide resulted in effective decontamination. However, when patients colonized with *A. baumannii* reoccupied rooms, environmental contamination recurred [88].

In many other instances, the epidemiology of *A. baumannii* is much more complex and difficult to decipher. This is due to the coexistence of sporadic and epidemic clones, as well as the fluid reservoir of *A. baumannii* in patients and the environment, and therefore presents a unique challenge to the prescription and implementation of effective infection control measures. In certain locales, *A. baumannii* can attain endemic status, characterized by the presence of multiple strain types and sustained high prevalence. In order to respond to such a situation, a long-term multifaceted "bundle" approach was implemented in a Spanish hospital. The program consisted of staff education, optimization of hand hygiene, contact precautions and patient isolation, environmental cleaning, and active surveillance in select areas and periods. This bundle of interventions resulted in sustained decrease in rates of *A. baumannii* colonization and infection [89].

Understanding the transmission dynamics of MDR and XDR, *A. baumannii* requires the application of molecular tools to determine their genetic type and mechanisms of antibiotic resistance. Similarly, this information can serve to describe the temporal evolution of *A. baumannii.* Typing of DNA digests using a standardized protocol of pulsed field gel electrophoresis (PFGE) has enhanced the epidemiological investigation of outbreaks by demonstrating highly related or indistinguishable isolates, suggesting transmission from a common source or from patient to patient [90]. Additionally, the combination of PFGE, ribotyping, and amplified fragment length polymorphism (AFLP) led to the identification of certain European clones of *A. baumannii* that have also been found globally [91, 92]. MLST has permitted further characterization of the population structure, genetic diversity, and distinctness of those clones of *A. baumannii* [93]. An automated repetitive-sequence-based PCR (rep-PCR) has also been employed to type *A. baumannii* to study outbreaks and has also served to identify global clones [84, 94].

Interestingly, the application of molecular epidemiology tools to *A. baumannii* demonstrates the temporal pattern of strain replacement leading to the global predominance of three lineages, especially the erstwhile European and now international clone II, usually associated with carbapenemases OXA-23 and OXA-24/40. Due to the combination of a MDR phenotype with its successful global dissemination, *A. baumannii* belonging to these groups of strains have been designated as a "high-risk clone" [95].

7 Treatment of Infections Caused by *A. baumannii*

The treatment of infections caused by *A. baumannii* is complicated by the increasing occurrence of MDR, XDR, and PDR strains. Furthermore, clinical data of the highest quality, such as randomized controlled trials, are usually not available to support recommendations for the treatment of *A. baumannii*. Therefore, decisions regarding the antibiotic treatment of *A. baumannii* are largely based on observational studies, which are often not controlled and have selection bias as an inherent limitation. Similarly, information derived from antimicrobial susceptibility surveys is often used to guide the use of antibiotics.

The presence of cephalosporinases of the AmpC type, or ADCs, makes the choice of cephalosporins perilous. Therefore, most clinicians when confronted with a seriously ill patient infected with *A. baumannii* usually rely on a carbapenem. Imipenem as a rule demonstrates higher potency (a lower MIC) than meropenem or doripenem and therefore is the preferred carbapenem for the treatment of *A. baumannii* infections. A clinical series of 63 patients with VAP caused by *Acinetobacter* demonstrated effective treatment with imipenem in 83 % of patients. The same study also highlights ampicillin/sulbactam as an excellent alternative to imipenem with similar efficacy, albeit in a smaller number of patients [96].

In the case of infections caused by *A. baumannii*, sulbactam is considered the active beta-lactam that binds to penicillin-binding proteins (PBP2), as opposed to other situations where it serves as an inhibitor of beta-lactamases. Other combinations containing sulbactam, such as cefoperazone/sulbactam, are also used where available. In an observational study, a favorable clinical outcome occurred in 77 % of patients treated cefoperazone/sulbactam vs. 75 % in patients treated with imipenem. A small meta-analysis of four studies suggested that sulbactam-based therapies are similarly efficacious to various comparator drugs (e.g., fluoroquinolones, tetracyclines, polymyxins, carbapenems) [97, 98]. Given all these observations, sulbactam, when active, is the preferred option to treat carbapenem-resistant *A. baumannii*. Even in cases where *A. baumannii* retains susceptibility to beta-lactams, sulbactam may serve as a carbapenem-sparing alternative. Unfortunately, as MDR *A. baumannii* has disseminated widely due to the success of "high-risk clones," and a substantial fraction of carbapenem-resistant strains are also resistant to sulbactam [94].

Polymyxins are an alternative frequently relied upon for the treatment of carbapenem and sulbactam-resistant *A. baumannii*. Polymyxins have indeed become the antibiotics of "last resort" to treat infections caused by XDR *A. baumannii.* Polymyxin B and polymyxin E, better known as colistin, differ slightly in their amino acid composition, where polymyxin B features phenylalanine in place of the

D-leucine present in colistin. Polymyxins were initially developed in the 1950s, later abandoned, and then "rediscovered" in the last two decades with the emergence of MDR and XDR *A. baumannii*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*. Considerable progress has been made to fill gaps in the understanding of their mechanism of action, their pharmacokinetic and pharmacodynamic characteristics, and their clinical efficacy. In this regard, the critical comparison of polymyxin B and colistin has led to the notion that the former is actually a better antibiotic agent for most uses, except the treatment of urinary tract infections [99].

In the case of colistin, which is administered as the prodrug colistimethate, there is a very narrow therapeutic window, where an average concentration at steady state of 2 μg/mL is needed to achieve therapeutic targets but where a concentration of approximately 2.5 μg/mL correlates with renal toxicity [100]. Usual dosing regimens do not appear to result in sufficient initial concentrations of colistin to achieve bacterial killing, especially among patients with intact renal function (CrCl >80 mg/min) [101], and a loading dose of colistin is required to more rapidly achieve concentrations that correlate with therapeutic targets. Further caution is required with colistin monotherapy due to suboptimal exposure and the potential for the emergence of resistance [102].

These limitations support the direct coadministration of colistin for the treatment of infections occurring in certain anatomic compartments, in addition to IV therapy. For instance, the supplemental use of aerosolized colistin may offer benefit in the treatment of pneumonia, and intrathecal and intraventricular colistin may be advantageous for the treatment of central nervous system infections. A meta-analysis of observational studies describing the outcomes of patients treated with intravenous and aerosolized forms of colistin for the treatment of VAP demonstrated similar hospital mortality and nephrotoxicity in patients treated with either colistin or comparator drugs [99]. A meta-analysis and systematic review of observational studies evaluated the safety and efficacy of aerosolized colistin as an adjunctive to intravenous antimicrobials and suggested improved outcome with the additional use of aerosolized colistin [103]. Similarly, a review of the experience treating MDR and XDR *A. baumannii* ventriculitis and meningitis with intraventricular and intrathecal colistin suggests frequent successful outcomes (89 %), at the expense of not infrequent (11 %) but reversible chemical ventriculitis/meningitis [104].

An interesting opportunity to observe the utility of colistin for the treatment of *A. baumannii* bacteremia was afforded by the experience in Korea, where colistin only became available in 2006. Monotherapy with colistin was associated with similar mortality (35.5 %) than therapy with non-active drugs (38.5 %) [105]. In general, there is concern about the efficacy of colistin used as monotherapy for the treatment of bloodstream infections, and therefore combination therapy has been proposed; however, there is no consensus about its benefit. Evidence supporting combination therapy is only available from observational studies. A high-quality prospective observational study conducted in 28 Spanish hospitals did not find an association of combination therapy with improved mortality in infections caused by *A. baumannii* [106]. Unfortunately, the multiple combinations proposed and the variations in the quality of the studies preclude firm conclusions. Systematic reviews of the evidence are not definite about the merits of combination therapy with colistin and even suggest similar safety and efficacy of colistin monotherapy when compared to standard antibiotics [107, 108].

Treatment of serious infections caused by XDR *A. baumannii* with colistin monotherapy has been compared with combination therapy with colistin and rifampin in a multicenter, open-label, clinical randomized controlled trial. Although there was a significant increase in microbiologic eradication with the additional use of rifampin, no difference was observed for infection-related death (43 %) and length of hospitalization [109]. Another small study comparing colistin monotherapy with colistin and rifampin for the treatment of *A. baumannii* reported similar results [110]. It has been suggested that rifampin perhaps was not the best partner for a combination therapy regime including colistin [111].

Two randomized controlled trials are in progress to evaluate the use of colistin monotherapy vs. colistin and meropenem in combination for the treatment of *A. baumannii*, among other XDR Gram-negative bacteria (NCT01597973 and NCT0173250). Interestingly, the preliminary results of a randomized controlled trial comparing colistin versus colistin plus intravenous fosfomycin (not potent enough to be used as monotherapy) for the treatment of carbapenem-resistant *A. baumannii* infection demonstrated a significantly more favorable microbiological response, but no significant difference in important clinical outcomes such as survival, in patients who received combination therapy [112]. In contrast, a prospective multicenter observational study identified increased mortality associated with a colistin–tigecycline combination (when the MIC of tigecycline exceeded 2 mg/L) compared to the colistin–carbapenem combination [113].

Tigecycline has been used for the treatment of infections caused by carbapenem-resistant *A. baumannii*, in cases where other alternatives do not exist and to avoid the nephrotoxicity associated with the use of polymyxins. Worldwide surveillance of the in vitro activity of tigecycline against carbapenem-resistant *A. baumannii* revealed that, in 2011, 35 % of isolates displayed an MIC of 2 μg/mL or higher. Overall resistance rates to tigecycline in Latin America, among other regions, have increased [114]. Tigecycline only achieves a maximal concentration in serum of 0.6 μg/mL, raising concerns about the ability of this drug to meet the requisite PK/PD parameters to effectively treat bloodstream infections. [18]. There are only limited data supporting the

role of tigecycline to treat serious infections caused by carbapenem-resistant *A. baumannii* such as bloodstream infection or VAP [115]. An analysis of the clinical outcomes of patients with infections caused by MDR *A. baumannii* who were treated with tigecycline alone or in combination with other antibiotics, or with imipenem and sulbactam, revealed that among 386 patients, 120 patients were treated with imipenem or sulbactam, and 266 received tigecycline. Of these, 108 were treated with tigecycline alone and 158 were treated with tigecycline in combination with other agents. There were no significant differences in survival rates between the groups. However, the patients in the tigecycline group were less ill and received other agents in addition to tigecycline, whereas the patients in the non-tigecycline group were not on any agents with demonstrated activity against *A. baumannii* [116]. Clinicians may see a clearer role for tigecycline in the treatment of skin and soft tissue infections and intra-abdominal infections where carbapenem-resistant *A. baumannii* is documented as a pathogen. However, it is difficult to find clinical data supporting this choice. In general, other antibiotic options, if available, should be given as preference to treat serious infections caused by XDR *A. baumannii.*

Minocycline has received attention as a possible option for the treatment of infections caused by XDR *A. baumannii*. This representative of the tetracycline class of antibiotics displays in vitro activity against approximately 80 % of *A. baumannii* strains from a global collection [117]. Therefore, given its availability in the USA as an intravenous formulation, minocycline has been used to treat carbapenem-resistant *A. baumannii.* Clinical and microbiologic responses, according to uncontrolled observational studies, have been good. Minocycline has been administered both as monotherapy and in combination with other antimicrobials and demonstrates an acceptable side effect profile [118, 119].

8 Conclusion

We have summarized some of the major aspects of the classification, microbiology, genomics, virulence, antibiotic resistance, infection control, and therapy of *A. baumannii*, with some mention of other *Acinetobacter* species as deemed relevant. As we advance in our understanding of *A. baumannii*, we appreciate that challenges will be ever present. In the next few years, more knowledge will be uncovered revealing the complexity of *A. baumannii*, especially as the role of genetic elements such as CRISPR-Cas, siRNAs, and bacteria network theory is elucidated. We anticipate that novel therapeutic approaches such as vaccines, immunomodulators, and modification of endolysins to create artilysins that are able to pass the outer membrane and become active against *Acinetobacter* may someday be used [33, 120, 121].

Antimicrobial Resistance in *Stenotrophomonas maltophilia*: Mechanisms and Clinical Implications

59

Xian-Zhi Li and Jennifer Li

1 Introduction

Previously known as *Pseudomonas maltophilia* [1] and *Xanthomonas maltophilia* [2], *Stenotrophomonas maltophilia* belongs to a member of the Gammaproteobacteria and is one of eight species in the genus of *Stenotrophomonas* [3, 4]. An aerobic, nonfermentative Gram-negative bacterium ubiquitous in nature, *S. maltophilia* has increasingly emerged as a global opportunistic pathogen, particularly among life-threatening infections in immunocompromised patients [5–11]. Remarkably, this microbe features high-level intrinsic resistance to a variety of antimicrobial agents, including β-lactams (even carbapenems), aminoglycosides, quinolones, macrolides, and tetracyclines regardless of its clinical and/or environmental sources [7, 10, 12]. Acquired multidrug resistance (MDR) can be readily derived after exposure of *S. maltophilia* to different antimicrobials and is rapidly emerging in clinical isolates [13]. This species possesses various molecular and biochemical mechanisms of resistance, which include the production of Ambler class A and B β-lactamases, several aminoglycoside-modifying enzymes, Qnr quinolone target protection proteins, and multidrug efflux transporters. Together with virulence factors, the MDR phenotype poses a major hurdle for therapeutic development. Trimethoprim-sulfamethoxazole and other antimicrobial combination regimes remain as the dominant therapeutics within the limited drugs available against *S. maltophilia*. However, in addition to a global emergence of resistance to trimethoprim-sulfonamides, the remaining options for combination therapies are often only based on *in vitro* antimicrobial synergy testing and/or case reports. This chapter provides an overview of the features, mechanisms, and clinical implications of antimicrobial resistance in *S. maltophilia* with an emphasis on the genetic and biochemical mechanisms of resistance.

2 *S. maltophilia*, a Global Opportunistic Pathogen

S. *maltophilia* exists in numerous aquatic and humid environments which include animals, plants, foods, and water [4, 14]. Though originally regarded as an emerging nosocomial pathogen restricted mainly to hospital settings [7], it has now expanded globally to be associated with both hospital-associated and community-acquired infections [14–16]. Its high-level MDR and propensity to colonize poses a challenge for hospital infection control practices. Risk factors for colonization and infection with this organism often include previous exposure to antimicrobial agents, intensive care unit stay, malignancy, prolonged hospitalization, mechanical ventilation, and the use of intravascular devices [7, 14, 17, 18].

Unsurprisingly, a major predisposing factor for *S. maltophilia* infection is prior antimicrobial usage, particularly the use of broad-spectrum agents [17, 18]. On the contrary, studies have also associated a decreased risk of *S. maltophilia* infections in cystic fibrosis patients using oral antimicrobials to maintain lung functions [19]. This organism is an especially obtrusive opportunistic pathogen in immunocompromised individuals, particularly those with cystic fibrosis and underlying malignancies [7, 9, 10]. A recent epidemiological study reported that *S. maltophilia* was found to be isolated in up to 9.4 % of bloodstream infection samples obtained from cancer patients [20]. Detection of *S. maltophilia* (e.g., within airways and the gastrointestinal tract) does not necessarily suggest active infection; however, a variety of infections can be caused by this organism,

and these include, for example, respiratory tract infections, bacteremia, endocarditis, urinary tract infections, skin and soft tissue infections, bone and joint infections, gastrointestinal infections, and meningitis [7, 10, 14, 21]. *S. maltophilia* possesses numerous virulence factors [21] with strong versatility and adaption characteristics and can be part of polymicrobial infections [4, 7, 10, 14]. A systematic review of the literature indicates that the attributable mortality from *S. maltophilia* infections should not be underestimated [22]. Indeed, *S. maltophilia* was the eighth-most isolated Gram-negative organism (4.3 % [3217/74,394]) from intensive care unit patients in the USA during the period of 1993–2004 [23]. Another study ranked it as the sixth (4.4 %) and ninth (3.2 %) most frequent organism isolated from patients hospitalized with pneumonia (2009–2012) in the USA and the European/Mediterranean regions, respectively [24]. Extensively drug-resistant strains were also reported to have a strong association with higher mortality rates in patients [25]. Additionally, *S. maltophilia* is able to form biofilms, which again poses a significant challenge for effective therapeutic intervention [26, 27].

3 High-Level Intrinsic Multidrug Resistance and Emergence of Acquired Resistance

S. maltophilia is intrinsically resistant to multiple antibiotics and disinfectants [7], and both clinical and environmental isolates often display high-level MDR [6, 10, 12, 28, 29]. For instance, *S. maltophilia* isolates are resistant to nearly all β-lactams (including carbapenems) and aminoglycosides, with many isolates also showing resistance toward fluoroquinolones and tetracyclines [10, 30–33]. These characteristics further constrain the already limited therapeutic options in the treatment of *S. maltophilia* infections. Even drug combinations such as ciprofloxacin with β-lactams or aminoglycosides show limited synergistic interaction or no activity against *S. maltophilia* [34].

Table 59.1 provides antimicrobial susceptibility data available in literature [10, 32, 35, 36] as well as the drugs to which intrinsic resistance has been defined for *S. maltophilia* by the Clinical and Laboratory Standards Institute (CLSI)[37]. The strain ULA-511 included in Table 59.1 was a clinical isolate

from a collection at the University of L'Aquila in Italy [38] and has been used as a laboratory reference strain for studying antimicrobial resistance for over two decades [32, 35, 36, 39, 40]. It is important to note that multidrug-resistant strains can be readily selected from the exposure of susceptible *S. maltophilia* to a variety of structurally unrelated antimicrobial agents in the laboratory [32, 41, 42] or recovered from patients receiving antimicrobials, e.g., β-lactams, aminoglycosides,

fluoroquinolones, or trimethoprim-sulfamethoxazole (co-trimoxazole) [13, 43, 44]. Although trimethoprim-sulfamethoxazole is still generally the drug of choice (both used alone or in combination) to treat *S. maltophilia* infection [10], global emergence of acquired trimethoprim-sulfamethoxazole resistance has been reported [45–49]. A 2001 study [50] has shown that resistant *S. maltophilia* strains were frequently associated with pulmonary infections, independent of the geographic regions assessed (Asia Pacific, Canada, Europe, Latin America, and the USA). The rates of resistance to trimethoprim-sulfamethoxazole for 842 *S. maltophilia* isolates (1997–1999) were 2 % in Canada and Latin America and 10 % in Europe, while resistance rates to ciprofloxacin, gatifloxacin, and trovafloxacin ranged from 21 to 49 %, 2 to 15 %, and 2 to 13 %, respectively. Ceftazidime and ticarcillin-clavulanate showed higher resistance with rates ranging from 25 to 53 % and 10 to 29 %, respectively [50]. An independent German study following chronically colonized cystic fibrosis patients detected resistance rates of 17 % for trimethoprim-sulfamethoxazole, 3 % for tigecycline, 30 % for levofloxacin and moxifloaxcin, 54 % for ceftazidime, and 58 % for colistin [51]. Considering the threat from multidrug-resistant Gram-negative bacterial infections such as *Acinetobacter baumannii* and *Pseudomonas aeruginosa* implicated in ventilator-associated pneumonia or in cystic fibrosis patients [52–55], it is necessary to highlight a possible important issue regarding the selection or enrichment of *S. maltophilia* (in addition to the targeting pathogens) through carbapenem or polymyxin therapy of other Gram-negative infections because *S. maltophilia* are intrinsically resistant to carbapenems and show variable susceptibilities (in many cases, resistance) to polymyxins [56–58]. Together, the intrinsic resistance and the feature of readily acquired high-level MDR in *S. maltophilia* undoubtedly pose a major concern regarding anti-stenotrophomonal chemotherapy.

4 Molecular and Biochemical Mechanisms of Resistance

4.1 Genomic Analysis of Antimicrobial Resistance Determinants

The current massively available bacterial genomic data allow us to readily assess the presence and distribution of genetic determinants for antimicrobial resistance among bacterial species. The first whole-genome sequence data of *S. maltophilia* became available in 2008 for strain K279a, which can be considered as a wild-type strain (also used as a model laboratory organism) and has a genome size of 4.85 Mb with an average G+C content of 66 % [59]. In comparison with other high-level intrinsically resistant pathogens, this genome size is smaller than that of *P. aeruginosa* (6.3 Mb) [60] but larger than that of *A. baumannii* (3.2–3.9 Mb) [61]. Subsequent whole-genome sequencing has also ascertained several other strains including those with acquired MDR [62–65].

Genomic data provide insightful clues to the genomic features and genetic elements of resistance for *S. maltophilia*. Firstly, *S. maltophilia* strains display significant genetic heterogeneity [66, 67]. Secondly, a large number of resistance genes are identified in the genomes of *S. maltophilia*; these include genes encoding for β-lactamases, aminoglycoside-modifying enzymes, and multiple drug efflux transporters (Table 59.2; see below for details). *S. maltophilia* also contains a chromosomal *qnr* gene termed Sm *qnr* [59, 64, 68], which usually occurs on plasmids of other bacterial species [69, 70]. Mobile genetic elements such as class I integrons are also identified in the genome of multidrug-resistant isolates with similar arrangements to resistance gene cassettes [65, 71, 72]. Antimicrobial resistance genomic islands have been identified in various bacterial species such as *A. baumannii* [73] and *Salmonella* spp. [74]. A similar genomic island of ca. 40 kb was also observed in *S. maltophilia* that contained six resistance determinants (including *tetR-tetA*(A), *strA/strB*, *sul1*, *aadA2*, and *floR* genes) and conferred an MDR phenotype [75]. As expected, this island region possessed mobile genetic elements such as integrons and insertion sequences [75]. Thirdly, comparative genomic analyses between the pathogenic multidrug-resistant *S. maltophilia* and plant-associated *S. maltophilia* and *Stenotrophomonas rhizophila* strains have revealed an overall high degree of sequence similarity including genes involved in antimicrobial resistance [64] as well as strain-specific pathogenicity islands [76]. Lastly, several plasmid-borne insertion sequence common region (IS*CR*) elements, which serve as gene-capturing systems, are also found in close relation with genes conferring resistance to trimethoprim-sulfamethoxazole in *S. maltophilia* [46, 77].

4.2 β-Lactam Resistance

β-Lactamases represent the most important mechanism of β-lactam resistance in Gram-negative bacteria and hydrolyze the four-membered β-lactam ring of β-lactams [78]. There are more than 1000 naturally occurring β-lactamases reported to date, and these enzymes are divided into four classes (Ambler A, B, C, and D) on the basis of their primary amino acid sequences and catalytic mechanisms [79]. Class A, C, and D β-lactamases are serine-dependent enzymes, while class B β-lactamases are metalloenzymes [78]. As for *S. maltophilia*, two types of β-lactamases were initially reported in the early 1980s [80] and are currently known as the L1 (Ambler class B) and L2 (Ambler class A) β-lactamases, which are both constitutively produced and can be further induced [67, 81–83]. These two β-lactamases together confer resistance to virtually all β-lactam agents including carbapenems (except for several β-lactams such

Table 59.2 Biochemical mechanisms of antimicrobial resistance in *S. maltophilia*

Antibiotic class	Drug-inactivating enzymes	Drug target alteration/ protection/by-passing	Drug efflux pump/outer membrane permeability
β-Lactams	Class B metallo L1 and Class A L2 β-lactamases, and other β-lactamases (TEM-2, CTX-M, and NDM-1)		RND pumps SmeABC and SmeDEF; outer membrane permeability
Aminoglycosides	*N*-acetyltransferases: AAC(6′)-Iam, AAC(6′)-Iak, AAC(6′)-Iz and AAC(2′) *O*-nucleotidyltransferase: ANT(3′′) *O*-phosphotransferase: APH(3′)-IIc, StrA/StrB		Lipopolysaccharide alteration; ABC pump MacABC; RND SmeOP-TolC and SmeYZ
Chloramphenicol	Chloramphenicol acetyltransferase		RND pumps SmeDEF and SmeVWX; MFS pumps FloR and MfsA
Fluoroquinolones		Alterations of DNA gyrase and topoisomerase IV (although remained to be fully confirmed); Qnr pentapeptide family proteins	RND pumps SmeABC, SmeDEF, SmeIJK, and SmeVWX; ABC pump SmrA; MFS pump MfsA
Fusaric acid			ABC pump FuaABC
Macrolides	Macrolide phosphotransferase		RND pumps SmeABC, SmeDEF, and SmeOP-TolC; ABC pump MacABC; MFS pump MfsA
Polymyxins			Lipopolysaccharide alteration; ABC pump MacABC
Sulfonamides		Dihydropteroate synthase (encoded by *sul1* and *sul2*)	RND pump SmeDEF
Trimethoprim		Dihydrofolate reductase (encoded by *dhfr* or *dfrA* genes)	RND pump SmeDEF
Tetracyclines			RND pumps SmeABC, SmeDEF, SmeIJK, SmeOP-TolC, and SmeVWX; ABC pump SmrA; MFS pumps TetA, TcrA and MfsA
Tigecycline			RND pumps SmeABC and SmeDEF

as ceftazidime and ticarcillin-clavulanate which may still be active, when viewed from a clinical resistance breakpoint perspective) (Table 59.1) [13, 30, 84]. The differential contribution of these two β-lactamases toward β-lactam resistance was determined for the first time in mutants carrying chromosomal deletions of *blaL1* and/or *blaL2* genes [32]. Clinical isolates with diverse L1/L2 β-lactamases have been reported [81, 85]; yet the majority of isolates from different geographic regions showed similar profiles of β-lactamase production and phenotypes of β-lactam resistance [86]. In spite of the chromosomally encoded nature of L1 and L2 enzymes, a mega-plasmid carrying both L1 and L2 genes was also reported [87]. Additionally, low outer membrane (OM) permeability and multidrug efflux pumps also play a role in β-lactam resistance [36, 88, 89], but can be masked in detection when in the presence of L1 and/or L2 enzymes.

L1 β-lactamase. This metalloenzyme, encoded by the *blaL1* gene (also known as *blaS* gene) on the chromosome [90], belongs to class B in Ambler's classification and group 3b in functional classification [78, 91]. With an isoelectric point of ca. 7 and a monomeric molecular mass of ca. 28 kDa, this enzyme requires a divalent metal ion to exert its catalytic activity [39, 82, 92]. Divalent chelators such as ethylenediaminetetraacetic acid inhibit L1 enzyme activity. L1 β-lactamase has a broad substrate profile and hydrolyzes most β-lactams, although it still preferentially hydrolyzes carbapenems over other types of β-lactams [93]. As previously mentioned, genetic studies have identified molecular heterogeneity of the L1 enzyme among various *S. maltophilia* strains, which is largely due to amino acid sequence variation [67, 85]. This variance has led to subclassification of the L1 enzymes [87] into three sub-enzymes. Alignment of the L1 β-lactamase and class B metallo-β-lactamases with those of other bacteria has identified conserved regions within class B β-lactamases [94]. The enzyme exists as a tetramer and displays αβ/βα folding observed only in the metallo-β-lactamases [95]. Simulated binding of the substrates ampicillin, ceftazidime, and imipenem reveals direct interactions between the β-lactam carbonyl oxygen and nitrogen with zinc ions and of the β-lactam carboxylate with Ser187. Ullah et al. [95] have proposed that the catalytic mechanism of the L1 enzyme includes a nucleophilic attack

of the bridging water on the β-lactam carbonyl carbon, electrostatic stabilization of a negatively charged tetrahedral transition state, and protonation of the β-lactam nitrogen by a second water molecule coordinated by zinc ions. The direct metal-substrate interaction provides a substantial contribution to substrate binding and may explain the lack of specificity of class B β-lactamases. Therefore, it is not surprising that the L1 β-lactamase makes *S. maltophilia* highly resistant to carbapenems as well as most other β-lactams [32, 93].

The L1 enzyme, unlike the L2 enzyme (see below), is not susceptible to clinically available β-lactamase inhibitors such as clavulanate, sulbactam, and tazobactam, indicating little application of these inhibitors against L1 β-lactamase. However, inhibition studies against the L1 β-lactamase have shown that thiol ester derivatives of mercaptoacetic acid are able to inhibit the L1 enzyme as well as other metallo-β-lactamases [40, 96–98]. A carbapenem compound with a benzothienylthio moiety at the C-2 position of 1-methylcarbapenem was shown to be a potent inhibitor of class B β-lactamases (with very low *Ki* values) including L1 enzyme [99, 100]. The flavonoids galangin and quercetin were also noted to inhibit the L1 enzyme, though the effect was not reversible by the addition of $ZnCl_2$ [101]. Two thiol-containing compounds, *N*-(2′-mercaptoethyl)-2-phenylacetamide and *N*-benzylacetyl-D-alanylthioacetic acid, were found to be competitive inhibitors of the L1 enzyme [97]. Furthermore, a peptide with a consensus sequence (i.e., Cys-Val-His-Ser-Pro-Asn-Arg-Glu-Cys) was also reported to be a specific inhibitor of the L1 enzyme [102].

L2 β-lactamase. This enzyme belongs to Ambler class A β-lactamase and Bush group 2e [78]. With a molecular mass of ca. 30 kDa and an isoelectric point of 8.4, it exists as a dimeric form [103]. The crystal structure of the L2 enzyme is also available (*doi:10.2210/pdb1o7e/pdb*). The L2 enzyme is closely related to the TEM β-lactamases with a serine active site, but it displays unusual cephalosporinase activity in which the enzyme preferentially hydrolyzes cephalosporins, including cefotaxime, but not carbapenems [104]. Consistent with class A enzymes, L2 enzymes are more sensitive to clavulanate (with IC_{50} values of <0.1 μM) than sulbactam and tazobactam (IC_{50} values are mostly >0.1–2 μM) [105]. Indeed, ticarcillin-clavulanate is among the very limited β-lactam agents active against *S. maltophilia* (Table 59.1) [106].

Regulation of L1 and L2 β-lactamase expression. β-Lactamase induction in Gram-negative bacteria is intimately linked to cell wall peptidoglycan recycling with an involvement of a complex network [107, 108]. A similar regulatory network also exists in *S. maltophilia* as detailed in this section. First, there is constitutive basal expression of both L1 and L2 enzymes, which contributes almost equally to nitrocefin hydrolysis [32]. Yet, the production of these two enzymes can be further stimulated by inducers such as various β-lactam agents (in particular by cefoxitin and imipenem, two classic AmpC β-lactamase inducers) [109]. An early study isolated three types of mutants including one with (a) constitutive overexpression of the L1 enzyme and inducible expression of the L2 enzyme, (b) overexpression of the L2 enzyme and inducible expression of the L1, and (c) constitutive overexpression of both L1 and L2 enzymes, which together suggested a possible overlapping regulatory mechanism toward L1 and 2 expression [110]. Subsequent studies have revealed the involvement of multiple gene products, AmpR, $AmpD_I$, AmpN, AmpG, MrcA, and NagZ, in the regulation of L1 and L2 expression (Fig. 59.1) [111–115].

A regulatory gene, *ampR*, is transcribed divergently from the L2 gene and encodes a LysR-type regulator (AmpR), which upon binding to anhydro-*N*-acetylmuramyl-peptides (anhMurNAc-peptides, inducing peptides) activates the expression of L1 and L2 genes (e.g., in response to β-lactam challenge) [111]. In contrast, the binding of AmpR to UDP-*N*-acetylmuramic acid pentapeptide (suppressing peptides) causes a conformation that represses β-lactamase expression. Disruption of the *ampR* gene significantly increases the susceptibility to β-lactams [111]. Degraded peptide products from cell wall peptidoglycans such as *N*-acetylglucosaminyl-1,6-anhydro-*N*-acetylmuramyl-peptides (GlcNAc-anhMurNAc-peptides), including GlcNAc-anhMurNAc-tripeptide, GlcNAc-anhMurNAc-tetrapeptide, and GlcNAc-anhMurNAc-pentapeptide, are transported by AmpG permease across the inner (cytoplasmic) membrane into the cytosol. AmpG is encoded from an operon comprised of *ampNG*, which is essential for induction of both L1 and L2 β-lactamases (*ampN* is a putative endonuclease gene) [113]. Inactivation of either AmpG or AmpN increases β-lactam susceptibility. Thus, mutants that do not express AmpG are unable to recycle cell wall peptides and cannot be induced by a β-lactam. AmpD, a cytosolic anhydro-*N*-acetylmuramyl-L-alanine amidase, acts as a key enzyme in balancing the concentrations of GlcNAc-anhMurNAc-peptide and UDP-*N*-acetylmuramic acid-pentapeptide within the cytosol. AmpD mutations result in the accumulation of high-level anhMurNAc-peptides even in the absence of β-lactam induction and cause β-lactamase overproduction [112]. Mutations in one of the two AmpD homologs, $AmpD_I$, are found to be involved in β-lactamase hyperexpression [112, 116]. Inactivation of another gene, *mrcA* (predicted to encode penicillin-binding protein PBP1a), causes an increase of basal L1/L2 β-lactamase activity by 100-fold [114]. Lastly, another β-lactamase expression regulatory pathway is linked to the *nagZ* gene that encodes β-*N*-acetylglucosamidase and is constitutively expressed in *S. maltophilia* [115]. NagZ produces anhydro-MurNAc-peptides and is critical for basal expression of β-lactamases [115]. Its inactivation decreases basal β-lactamase activity by 20 %; however, there are likely both NagZ-dependent and NagZ-independent pathways for the induction of β-lactamase activities. NagZ inactivation reduces cefuroxime- and piperacillin-induced β-lactamase activity but does not affect the induction by aztreonam, carbenicillin, and cefoxitin [115].

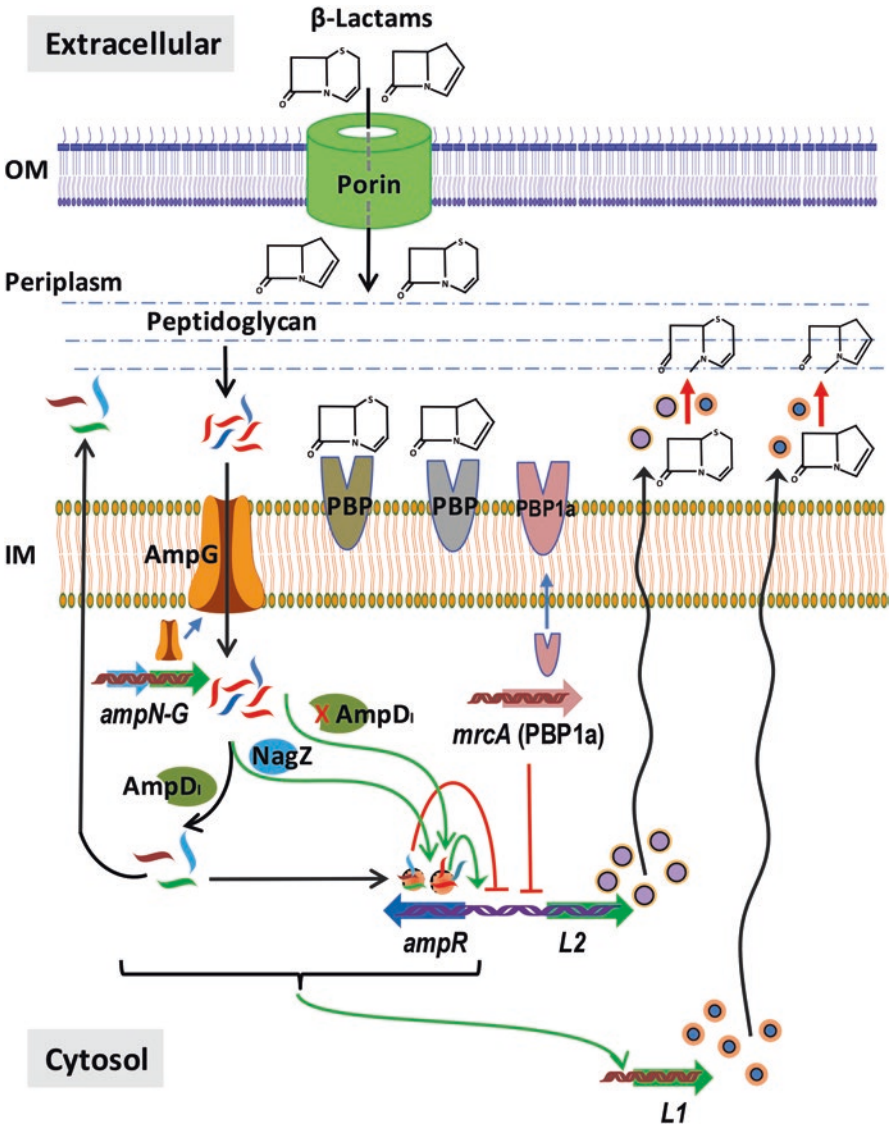

Fig. 59.1 Mechanisms involved in regulating L1 and L2 β-lactamase expression in *S. maltophilia*. There is a basal constitutive expression of *blaL1* and *blaL2* genes in wild-type strains even in the absence of β-lactams. Under normal cell wall recycling, *N*-acetylglucosaminyl-1,6-anhydro-*N*-acetylmuramyl-peptides are removed from the cell wall and transported into the cytoplasm via the AmpG permease. These GlcNAc-anhMurNAc-peptides are cleaved by $AmpD_I$ to generate free peptides, which are later converted into UDP-MurNAc-pentapeptides. These pentapeptides in turn interact with AmpR bound to the *ampR-blaL2* intergenic region to represses transcription of *blaL2* gene and to allow basal production of L2 β-lactamase. In the presence of β-lactam induction, β-lactams (e.g., cefoxitin and imipenem) cross the outer membrane (OM) through porins, enter the periplasm, and interact with the inner membrane (IM)-associated target penicillin-binding proteins (PBPs). There is an increase in 1,6-anhydromuropeptides, which, when bound to AmpR, convert it into a transcriptional activator to increase *blaL2* expression. Mutations in *ampDI* can inactivate $AmpD_I$ and lead to the derepression of *blaL2* expression. Expression of *nagZ* (encodes β-*N*-acetylglucosamidase) and inactivation of *mrcA* (encodes PBP1a) also enhance *blaL2* expression. Similar *blaL1* gene expression is also observed but detailed mechanisms remain to be further studied

Other β-lactamases. Due to the heterogeneity of the L1 and L2 enzymes in *S. maltophilia* [117], it was difficult to determine whether *S. maltophilia* produced additional chromosome-encoding β-lactamase(s) before its sequenced genome became available [82]. With the available L1- and L2-deficient double mutant [32], an attempt to identify additional β-lactamases via a biochemical means and to select β-lactam resistant mutants was unsuccessful (X.-Z. Li, unpublished). It is now known that there are no additional β-lactamase-encoding genes identified in the genomes of several *S. maltophilia* strains sequenced to date [59, 62–65]. Nevertheless, a gene encoding a TEM-2 β-lactamase was identified within a novel Tn*1*-/Tn*3*-type transposon in the genome of a clinical isolate. The gene was almost identical to the *blaTEM*-2 gene, representing the first example of a TEM in *S. maltophilia* [118]. Class A extended-spectrum β-lactamases of CTX-M type (e.g., CTX-M-1 and CTX-M-15) were also observed in *S. maltophilia* [119, 120]. An isolate containing *blaNDM-1* gene (that encodes another class B metallo-β-lactamase) was also reported [83, 121].

4.3 Aminoglycoside Resistance

The production of aminoglycoside-modifying enzymes represents the major mechanisms responsible for aminoglycoside resistance [122–124]. Indeed, *S. maltophilia* genome encodes multiple known and putative aminoglycoside-modifying enzymes (such as 2′ or 6′ *N*-aminoglycoside acetyltransferases [AAC; e.g., AAC(6′)-Iam] and 3′-phosphotransferases [APH]) (Table 59.2) [59], which render strains highly resistant to virtually all aminoglycosides (Table 59.1). It also contains a gene for a putative spectinomycin phosphotransferase, which explains the high-level resistance to aminocyclitol agents [59, 75]. King et al. initially demonstrated the presence of AAC(6′) [122]. Subsequently, the *aac(6′)-Iz* gene was reported to be widely distributed in *S. maltophilia* [125], and its inactivation led to an increased susceptibility to amikacin, gentamicin, netilmicin, sisomicin, and tobramycin (2- to 128-fold decrease in MIC values) [29]. Another new AAC(6′)-Iak shows 86 % identity to AAC(6′)-Iz and can acetylate amikacin, arbekacin, dibekacin, isepamicin, kanamycin, neomycin, netilmicin,

sisomicin, and tobramycin [126]. Both AAC(6′)-Iz and AAC(6′)-Iak enzymes share a similar substrate profile [126]. Disruption of the gene encoding APH(3′)-IIc increased the susceptibility to butirosin, kanamycin, neomycin, and paromomycin (4- to 32-fold MIC reduction) [127]. *S. maltophilia* was also noted to produce an *O*-nucleotidyltransferase, ANT(3″), which modifies streptomycin and spectinomycin [128].

Additionally, growth temperature can affect the compositions of the OM lipids including lipopolysaccharide (LPS), thus subsequently aminoglycoside susceptibilities (e.g., cells grown at 37 °C become more susceptible to aminoglycosides than those at 30 °C) [129–131]. In this regard, *S. maltophilia* was seen to survive exposure to aerosolized tobramycin at 16,000 μg/mL in cystic fibrosis patients; this survival was enhanced at lower temperatures [132]. Aminoglycosides are polycationic agents, and thus anionic binding sites of LPS affect the entry of aminoglycosides [128]. Inactivation of the *spgM* gene (which encodes phosphoglucomutase) results in shorter O-polysaccharide chains and a modest increase in susceptibility to gentamicin, colistin (polymyxin E), and polymyxin B [133]. Lastly, several multidrug efflux pumps MacABC, SmeOP-TolC, and SmeYZ are also involved in aminoglycoside resistance (Table 59.2) (see Sect. 4.10) [134–137]. The observation of the reduction of amikacin and gentamicin MIC values by 128-fold in SmeYZ-deficient mutants [137] shows the significance of the SmeYZ pump in aminoglycoside resistance. However, considering the presence of native aminoglycoside-modifying enzymes, we think of a need to investigate whether the genetic inactivation of *smeYZ* could affect expression of any aminoglycoside-modifying enzymes. Additionally, overproduction of SmeDEF results a fourfold reduction of the kanamycin MIC value [36].

4.4 Fluoroquinolone Resistance

S. maltophilia also exhibits high-level resistance to fluoroquinolones, though newer agents (e.g., clindafloxacin and moxifloxacin) exhibit higher activity than older compounds (Table 59.1) [31, 35, 42]. Unexpectedly, unlike many other Gram-negative bacteria, the target proteins of fluoroquinolones, topoisomerases II (also called DNA gyrase, encoded by *gyrAB*) and IV (*parCE*), are not considered as the primary targets responsible for fluoroquinolone resistance in *S. maltophilia*. For example, although sequence changes occurred in quinolone resistance-determining regions (QRDRs) of *gyrAB* and *parCE* genes of *S. maltophilia*, they were not consistently related to changes of the ciprofloxacin MIC values [138]. Additionally, no alterations in *gyrA* or *parC* were observed in other clinical isolates of varied ciprofloxacin susceptibilities [139]. A study comparing isogenic ciprofloxacin-susceptible (MICs of 0.5–4 μg/mL) and ciprofloxacin-resistant mutants (MICs of 16–128 μg/mL) did not find sequence alterations in QRDRs [140]. Instead, these aforementioned studies suggested the contribution from drug efflux pumps to fluoroquinolone resistance. SmeABC, SmeDEF, and SmeVWX pumps are, for instance, known to confer fluoroquinolone resistance in clinical isolates with high-level fluoroquinolone resistance [36, 71, 141, 142] (see Sect. 4.10). These pumps are also heavily involved in the emergence of quinolone resistance [143].

Plasmid-borne *qnr* genes are widely distributed in *Enterobacteriaceae* and encode a pentapeptide repeat family product that protects DNA gyrase and confers low-level resistance to fluoroquinolones (reviewed in Refs. [69, 70]). SmQnr, a Qnr homolog, encoded by *S. maltophilia* chromosome consists of 219 amino acid residues [68, 144] and indeed contributes to low-level intrinsic resistance to quinolones [145]. To date, approximately 60 variants of the SmQnr family have been identified in numerous isolates of varying regions [49, 146–148]. Chromosomal *qnr* genes are also present in the genomes of >90 bacteria species [69, 70]. Together, these chromosomal sources of the *qnr* genes may serve as a reservoir of plasmid-borne *qnr* genes observed in Enterobacteriaceae. Nevertheless, plasmid-borne Sm*qnr* appears unstable in *Escherichia coli* in comparison with the widely distributed plasmid-borne *qnrA* gene [149, 150]. Expression of SmQnr is negatively controlled by a transcriptional repressor, SmQnrR, whose encoding gene forms an operon with a major facilitator superfamily transporter gene (Sm*tcrA*). SmQnrR can also repress its own expression as well as Sm*tcrA* expression [151].

4.5 Resistance to Amphenicols

A gene encoding a putative chloramphenicol acetyltransferase exists within the genome of *S. maltophilia* and likely provides a mechanism of resistance to amphenicols [59]. Moreover, the amphenicol efflux exporter *floR* gene has also been identified in resistant *S. maltophilia* [46, 75]. Additional multidrug efflux pumps such as SmeDEF and SmeVWX are also involved in chloramphenicol resistance [36, 141].

4.6 Resistance to Macrolides

Though macrolide antimicrobials are mostly active against Gram-positive bacteria, certain agents (e.g., azithromycin) also possess activity toward Gram-negative bacteria [152]. However, *S. maltophilia* strains are intrinsically resistant to macrolides, a characteristic that is attributable to multiple mechanisms. Macrolides are large hydrophobic molecules and cannot effectively cross the OM barrier [153]. Their physical-chemical properties also make them good substrates of multidrug efflux pumps [36, 135, 153]. Moreover, the

S. maltophilia genome carries a gene that encodes a macrolide-inactivating enzyme, macrolide phosphotransferase [59].

4.7 Resistance to Polymyxins

Polymyxins are large (>1100 Da), cationic lipopeptide antibiotics (with a net positive charge of 4 and a fatty acid tail for polymyxin B). They target the OM of the Gram-negative bacteria by competitively displacing the divalent cations (Mg^{2+} and Ca^{2+}) from the negative-charged LPS molecules, resulting in destabilized OM membrane barrier [154]. Thus, polymyxins are strong OM perturbants and exhibit activities against many Gram-negative bacteria including nonfermentative bacilli. Their unique mode of action also explains the role of polymyxins or derivatives (e.g., polymyxin B nonapeptide) in increasing the activity of a range of anti-Gram-positive agents against Gram-negative bacteria [155]. Although the mechanisms about the variable polymyxin susceptibilities of *S. maltophilia* remain to be investigated, resistance to polymyxins in Gram-negative bacteria takes several forms, often due to the alterations in the OM. First, adaptive resistance to polymyxins occurs as a non-mutational, transient phenomenon in response to the inducing conditions as observed in *Salmonella* and *P. aeruginosa* [156]. For instance, two-component regulatory systems, PhoPQ and PmrAB, can be activated independently under magnesium starvation, leading to LPS modifications that reduce the negative charge of anionic lipid A and electrostatic attraction to polymyxins [156]. Second, mutation-mediated acquired resistance can also develop [157]. Mutations affecting PhoPQ, PmrAB, and another two-component regulatory system, ParRS, contribute to the LPS alterations and result in polymyxin resistance. For example, ParRS in *P. aeruginosa* affects expression of the LPS modification *arn* operon and of *mexXY* efflux pump gene and confers resistance to polymyxins and aminoglycosides [158]. Capsular polysaccharides can also reduce the interaction between the OM and polymyxins, producing polymyxin resistance as observed in *Klebsiella pneumoniae* [157]. In *A. baumannii*, mutations in one of several lipid A biosynthesis genes lead to the complete loss of the LPS production and yield polymyxin resistance with a >128-fold increase in MIC values of colistin and polymyxin B (as expected, with increased susceptibility to other agents including azithromycin, cefepime, and teicoplanin because of the disruption of the OM permeability barrier) [159]. In *S. maltophilia*, the LPS integrity also plays an important role against the action of polymyxins since disruption of an LPS-related gene *spgM* generates an increased susceptibility to polymyxins [133]. Moreover, the effect of growth temperature on LPS profiles in *S. maltophilia* produces a modest effect on polymyxin susceptibility (a twofold MIC decrease at 37 °C than 30 °C which is, however, in contrast to the immense effect on aminoglycoside susceptibility) [130]. Efflux pumps such as MacABC also contribute to polymyxin resistance in *S. maltophilia* [59, 135] with a four- to eightfold decrease of colistin and polymyxin B MIC values for the *macAB*-disrupted mutant [135]. Although it is speculated that the known mechanisms of polymyxin resistance in other bacteria are likely applicable to *S. maltophilia*, elucidation of polymyxin resistance in *S. maltophilia* remains an important area of research.

4.8 Resistance to Tetracyclines and Tigecycline

Tetracycline resistance in Gram-negative bacteria is mostly mediated by plasmid-encoded tetracycline-specific efflux transporters (i.e., Tet proteins) and ribosome target modifications and protection mechanisms [160]. Tigecycline, a 9-*t*-butylglycylamido derivative of minocycline (belonging to the glycylcycline class), was developed to overcome the presence of Tet pumps [161] but is still subjected to efflux by multidrug efflux transporters [153]. Although *tet(A)* is found in a genomic island containing a resistance gene cassette in *S. maltophilia* [75], the multidrug efflux pumps encoded by the chromosome are predominantly responsible for high-level intrinsic and acquired resistance to tetracyclines and tigecycline. Inactivation of multidrug efflux pump SmeDEF in a wild-type strain reduces the susceptibility to tetracyclines (tetracycline, doxycycline, and minocycline) and tigecycline (two- to fourfold MIC reduction). SmeDEF overproduction confers increased resistance to these tetracycline agents (two- to eightfold MIC increase), and its inactivation renders the mutant stain more susceptible than the wild-type strain [36]. Inactivation of another multidrug efflux pump, SmeIJK, in a mutant overproducing the SmeIJK system results in increased susceptibility to tetracycline and minocycline (fourfold MIC decrease) [134]. The TcrA pump is also involved in resistance to tetracyclines [151].

4.9 Resistance to Sulfonamides and Trimethoprim

Resistance to sulfonamides and trimethoprim is mediated by dihydropteroate synthase (encoded by a *sul* gene) and dihydrofolate reductase (encoded by a *dhfr* or *dfrA* gene), respectively, and each of these enzymes is comprised of different variants [162]. Resistance gene cassettes or genomic islands containing integrons and several resistance genes including *sul* and/or *dhfr* have increasingly been found in *S. maltophilia* strains [47, 48, 71, 163, 164], and this phenomenon explains the increasing global emergence of resistance to sulfonamides and trimethoprim in *S. maltophilia* [45, 46, 48]. In one study

from China, nearly 50 % of the 442 tested isolates were resistant to this combination agent [49]. In a report analyzing isolates from various global sources [46], 17 out 25 sulfonamide-trimethoprim-resistant isolates (MICs of >32 μg/mL) carried the *sul1* gene and a class 1 integron, while susceptible isolates (MICs of 0.5–2 μg/mL) were *sul1*-negative. Moreover, the *sul2* gene and several IS*CR* variants were also present in plasmids from the resistant isolates [46]. A recent study conducted in Korea showed the presence of *sul1*, *dfrA*, integrons, and/or IS*CR* elements in resistant isolates, and 72 % (23/32) isolates with high-level resistance to trimethoprim-sulfamethoxazole were *sul1*-positive [48]. Interestingly, epigallocatechin gallate, a component of green tea, displays activity against *S. maltophilia* (with an MIC range of 4–250 μg/mL for 18 isolates tested) due to its inhibition of dihydrofolate reductase from trimethoprim-susceptible *S. maltophilia*, and it also shows a synergistic effect with sulfamethoxazole [165]. SmeDEF overproduction yields a four- to eightfold increase of the MIC values of trimethoprim and trimethoprim-sulfamethoxazole [36, 166], suggesting a non-antifolate mechanism of resistance to sulfonamides and trimethoprim, which are also substrates of *P. aeruginosa* Mex efflux pumps [167]. Although overproduction of SmeABC results in an enhanced susceptibility to trimethoprim, the OM component SmeC may provide a function to the yet-unidentified efflux pump(s) involved in trimethoprim resistance as *smeC* inactivation has a four- to eightfold reduction of the trimethoprim MIC values [89]. Inactivation of SmeYZ decreases the MIC of trimethoprim-sulfamethoxazole by 16-fold [137].

4.10 Multidrug Resistance

The OM permeability barrier and multidrug efflux pumps interact to contribute to intrinsic and acquired MDR of *S. maltophilia* [153]. The OM consists of a LPS-containing lipid bilayer region and functions as an effective barrier in reducing influx of toxic agents including antimicrobials. Small hydrophilic agents like β-lactams may cross the OM via the water-filled porin channels, and large or hydrophobic agents require the penetration OM lipid bilayer [153]. Agents that increase OM permeability can sensitize the activity of many anti-Gram-positive agents against Gram-negative bacteria. Polymyxins act on the OM and thus increase the access of various agents to their cellular targets. In one study, polymyxin B at 0.1 μg/mL was able to enhance activities of trimethoprim-sulfamethoxazole against all 30 multidrug-resistant *S. maltophilia* isolates tested [168], consistent with the role of the OM barrier in resistance. Lactoferrin can damage the OM and increases rifampin susceptibility (with rifampin MIC values reduced by 3- to 16-fold in the presence of lactoferrin) [169]. A fragment of a cationic frog peptide, esculentin-1b, was also expected to act on bacterial membranes and was able to sensitize the activities of amikacin and colistin against *S. maltophilia* strains [170]. Additionally, alterations in OM proteins were observed in fluoroquinolone- and multidrug-resistant isolates [171]; this may contribute to reduced OM permeability and/or increased drug efflux.

On the other hand, *S. maltophilia* possesses various drug exporters (Table 59.2) that belong to one of the following superfamilies: the (1) ATP-binding cassette (ABC) superfamily, (2) drug/metabolite transporter superfamily (which includes the small multidrug resistance [SMR] family), (3) major facilitator superfamily (MFS), and (4) resistance-nodulation-cell division (RND) superfamily [153]. However, no reports have described the multidrug/oligosaccharide-lipid/polysaccharide export superfamily (that includes the drug resistance-related multidrug and toxic compound extrusion [MATE] family) in *S. maltophilia*. These drug exporters may have either a broad (polyspecific) or narrow substrate profile and actively extrude relevant drug substrate(s) out of the cell. In particular, the RND-type multicomponent efflux pumps play important roles in MDR in Gram-negative bacteria, especially in the nonfermentative bacilli including *S. maltophilia* where the OM permeability barrier is already quite effective [153].

RND pumps. Eight RND-type Sme systems and several other types of drug exporters are encoded in the chromosome of *S. maltophilia* [59]. An RND pump complex typically comprises of three components, a pump located in the inner membrane, an OM channel protein, and an accessory protein (periplasmic adaptor protein) linking the first two components [153]. Figure 59.2 shows the genetic organization of the eight RND systems including their possible regulatory genes. Each system is encoded by an operon that contains two or three genes. For several RND systems, although a gene for an OM component is absent (i.e., with *smeGH*, *smeIJK*, *smeMN*, and *smeYZ* operons), an OM channel protein encoded by other operons or genes may provide the structural part required for a functional multicomponent efflux machinery [36, 89], similar to the role of *E. coli* TolC and *P. aeruginosa* OprM in multiple RND pumps [153]. Some RND pump operons are constitutively expressed (e.g., *smeDEF*) and are responsible for intrinsic resistance. Acquired resistant mutants with RND pump overexpression can be readily selected by antibiotics (e.g., chloramphenicol, fluoroquinolones, and tetracyclines) or biocides (e.g., triclosan) [32, 141, 143, 172, 173]. The first RND pump identified in *S. maltophilia*, SmeABC, contributes to acquired MDR including resistance to trimethoprim-sulfamethoxazole [71, 89, 174]. Another RND pump, SmeDEF, is the most important RND pump with respect to its role in both intrinsic and acquired MDR [35, 36, 71, 166, 175, 176]. Inactivation of SmeDEF mostly leads to a two- to

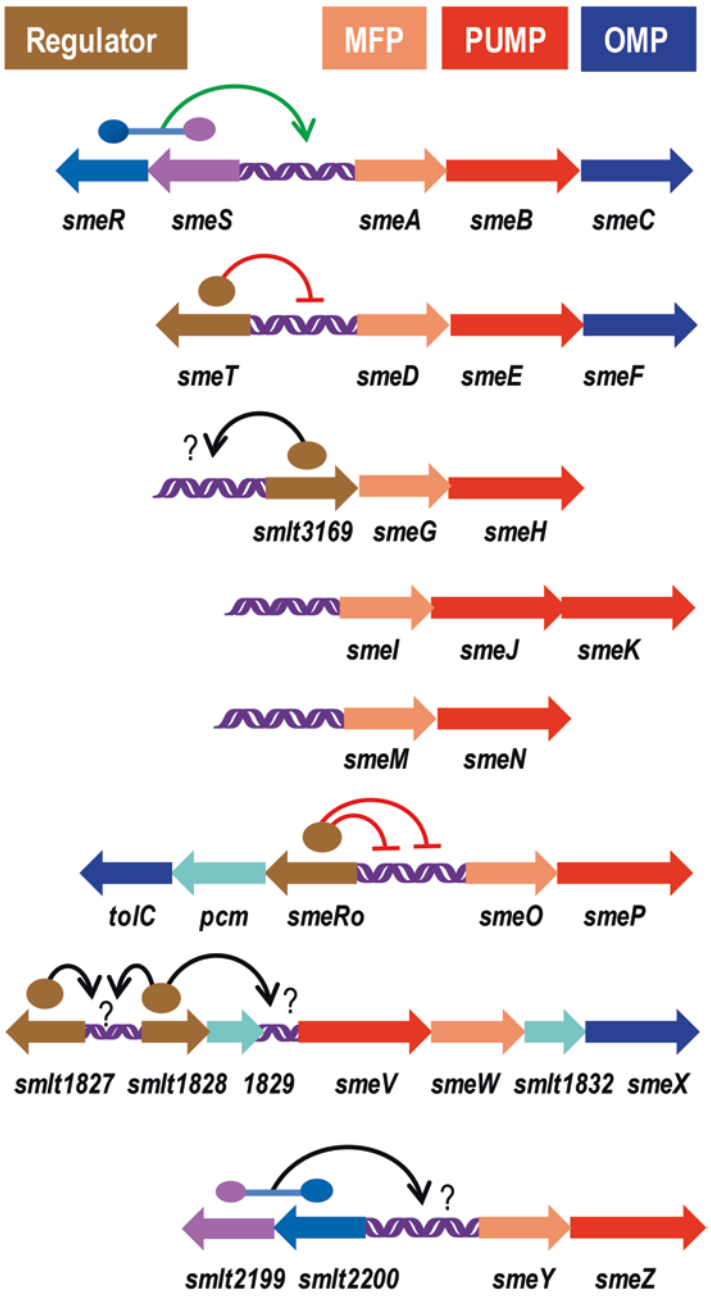

Fig. 59.2 Regulation of RND multidrug efflux system expression in *S. maltophilia*. Eight RND pump operons identified in this organism are presented (mostly in the right) with arrows showing gene transcriptional directions. The three different colors (*orange*, *red*, and *blue*) correspond to their roles as a membrane fusion protein (MFP; also called periplasmic adaptor protein)), a pump, or an outer membrane protein (OMP), respectively. Genes encoding the proven or putative regulators are shown on the left with their gene transcriptional directions indicated by arrows. While the green arrow from SmeSR represents positive regulation of *smeABC* expression, the inhibitory red lines show repression of relevant gene transcription by repressors. The role of putative regulators of relevant RND pump expression (indicated with a brown oval with a black arrow and question mark) remains to be investigated

eightfold reduction of the MIC values of fluoroquinolones, tetracyclines, tigecycline, trimethoprim-sulfamethoxazole, macrolides, chloramphenicol, novobiocin, β-lactams (in the absence of L1 and L2 β-lactamases), dyes, and detergents [36, 166]. Moreover, the SmeOP-TolC efflux system provides resistance to several antibiotics (amikacin, gentamicin, erythromycin, leucomycin, and doxycycline), carbonyl cyanide 3-chlorophenylhydrazone (a proton conductor), dyes, and detergents [136]. SmeYZ is involved in resistance to aminoglycosides and trimethoprim-sulfamethoxazole [137]. Overexpression of SmeVWX enhances resistance to chloramphenicol, quinolones, and tetracyclines but also susceptibility to aminoglycosides [141]. A simultaneous hyperexpression of SmeJK (paired pumps that form one exporter) and SmeZ pumps increases the substrate profile in clinical isolates and plays a role in resistance to ciprofloxacin and tetracyclines as well as resistance to aminoglycosides [134]. Additionally, although several efflux inhibitors including phenylalanine-arginine-β-naphthylamide (PAβN) show strong inhibitory activity against RND pumps of *E. coli* and *P. aeruginosa* [153], PAβN does not affect SmeDEF pump activity [177].

Non-RND pumps. Three ABC-type exporters are demonstrated for their involvement in resistance: (1) the

tripartite FuaABC system confers fusaric acid-inducible resistance to fusaric acid [178]; (2) MacABC provides intrinsic resistance to aminoglycosides, macrolides, and polymyxins as its inactivation yields a two- to eightfold MIC decrease [59, 135]; (3) the SmrA is linked to resistance to fluoroquinolones, tetracyclines, doxorubicin, and dyes when expressed in *E. coli* [179]. Additionally, an MFS-type pump, EmrCAB, is involved in extrusion of hydrophobic toxic agents but is not well expressed intrinsically [180]. A recent study described the induction by redox cycling agents and the activation by SoxS of another MFS-type exporter, MfsA, which mediates resistance to paraquat [181]. Lastly, a gene encoding an SMR protein was also reported [71].

Role of efflux pumps beyond drug resistance. The drug efflux pumps may also have physiological functions that go beyond drug resistance [153]. Colonization of plant roots is considered to be an original function of SmeDEF pump [182]. Native expression level of SmeDEF may provide an optimal physiological role since its overproduction results a virulence cost [183]. Inactivation of SmeIJK produces slow growth and also increases the sensitivity to membrane-damaging agents and activation of cell envelope stress response [184]. SmeYZ contributes to oxidative stress response and virulence [137]. MacABC is involved in tolerance to both oxidative and cell envelope stresses as well as biofilm formation [135].

Regulation of efflux pump expression. The presence and multiple functions of multidrug efflux transporters require a well-regulated expression of these exporters. Indeed, five of the eight RND-type pumps have regulatory genes located adjacent to the structural genes as shown in Fig. 59.2. The operons for SmeABC and SmeYZ systems are linked to two-component regulatory systems, SmeSR and Smlt2200-Smlt2199, respectively [59, 89]. SmeSR positively controls the expression of SmeABC and L2 β-lactamase [89]. A TetR family repressor [185] is each found for SmeDEF, SmeGH, and SmeOP [186, 187]. The SmeT repressor of the SmeDEF pump is the most-characterized pump regulator in *S. maltophilia*. An overlapping promoter region exists between *smeDEF* and *smeT* genes. Functioning as a dimer [187], SmeT negatively controls the expression of both *smeDEF* and *smeT*. Mutations in *smeT* such as a Leu166Gln substitution in SmeT yield an elevated production of *smeDEF* and *smeT* [186]. An *IS*1246-like element in the *smeDEF* promoter where SmeT acts was found to be responsible for SmeDEF overproduction in clinical isolates [176]. Natural flavonoids also bind to SmeT and thus derepress SmeDEF expression [182]. Additionally, the local regulator, FuaR, positively influences the expression of the fusaric acid-inducible FuaABC pump [178], and the EmrR repressor inhibits production of the EmrCAB pump [180].

4.11 Tolerance to Heavy Metals

Silver ions can affect multiple cellular processes including increased OM permeability and thus show activity against Gram-negative bacteria including *S. maltophilia* [188, 189]. A cluster of genes related to antibiotic and heavy metal resistance were observed in a clinical isolate, and these genes include *mphBM* (for a macrolide phosphotransferase) and the *cadCA* operon (that encodes a CadC regulator and CadA cadmium efflux pump) [190]. The *S. maltophilia* genome contains several heavy metal resistance genes related to arsenic, copper, and mercury resistance [59]. Indeed, attention should be paid to the high-level tolerance of *S. maltophilia* against various heavy metal salts such as cadmium, cobalt, copper, lead, selenite, tellurite, uranyl, and zinc [191]. An isolate obtained as a culture contaminant was able to grow in the presence of 500 μM $CdCl_2$, 20 mM tellurite, or 50 mM selenite or the presence of 20 μM $AgNO_3$, 50 μM $HgCl_2$, and other heavy metals. Two mechanisms were revealed, which involved the reduction of oxyanions to nontoxic elemental ions and detoxification of Cd into CdS [191]. In this case, susceptibility of *S. maltophilia* to $AgNO_3$ is comparable to the level of $AgNO_3$ susceptibility of *E. coli* [192], consistent with possible role of silver agents against multidrug-resistant Gram-negative bacteria [189].

5 Antimicrobial Therapy for *S. maltophilia* Infections

High-level intrinsic MDR poses a major challenge for the treatment of *S. maltophilia* infections, and the choice of drugs is indeed very limited. Despite the emergence of global resistance to sulfonamides/trimethoprim, the antifolate sulfonamide/trimethoprim combination regimen still constitutes the major active antimicrobial against *S. maltophilia* [9, 10, 193]. Susceptibility to other agents may likely be unpredictable [9]. The drugs currently recommended from the CLSI [37] for antimicrobial susceptibility testing only include trimethoprim-sulfamethoxazole, ceftazidime, ticarcillin-clavulanate, chloramphenicol, levofloxacin, and minocycline (Table 59.1). Thus, even though susceptibility testing conducted with other antimicrobial agents, the lack of their interpretative criteria may not provide sufficient guidance for the selection of drugs against *S. maltophilia*. In this regard, the understanding of pharmacodynamics and pharmacokinetics of relevant antimicrobial agents under specific administration routes and dosages will be important for guiding the selection of the antimicrobials.

In clinical settings, antimicrobial combination therapies are often considered for treating *S. maltophilia* infections. However, in many cases, data are often generated from *in vitro* antimicrobial synergy studies, and their clinical efficacy

remains to be fully investigated via clinical trials. Trimethoprim-sulfamethoxazole remains the empirical or the first-line choice for *S. maltophilia* infections [7, 14, 193–195]. This combinational agent is also used together with other agents. For instance, the combination of trimethoprim-sulfamethoxazole and ciprofloxacin was able to cure a case of pediatric *S. maltophilia* meningitis [196].

Ticarcillin-clavulanate combination was another major choice of the therapy [10, 14, 195] but is not commercially available (discontinued by the manufacturer in the late 2014). Certain other β-lactam-β-lactamases inhibitor combinations including aztreonam-clavulanate, ticarcillin-sulbactam, piperacillin-tazobactam, ampicillin-sulbactam, ceftazidime-clavulanate, cefoperazone-sulbactam, cefepime-clavulanate, and ceftolozane-tazobactam do not show a good activity against *S. maltophilia* [194, 197]. It is noted that many of these combinations are, however, not commercially available. Additionally, an attention should be paid to carbapenems to which *S. maltophilia* are intrinsically resistant (Table 59.1), and carbapenems are not suitable for treating *S. maltophilia* infections [56].

Fluoroquinolones have been a drug option. A study showed that the therapy with levofloxacin, ciprofloxacin, or trimethoprim-sulfamethoxazole for *S. maltophilia* infections (mostly pulmonary) produced similar effectiveness results (with 52–61 % clinical success rates) [44]. Based on the 30-day mortality rates and adverse drug events, a retrospective study suggested levofloxacin as an alternative regimen to trimethoprim-sulfamethoxazole in treating *S. maltophilia* bacteremia [43]. Another retrospective study confirmed the use of fluoroquinolone agents in combination with trimethoprim-sulfamethoxazole [198]. Moxifloxacin or levofloxacin is suggested as second-line treatment options [195]. Subinhibitory concentrations of moxifloxacin and other fluoroquinolones decrease adhesion and biofilm formation of *S. maltophilia* [26, 199].

Minocycline has a good activity against *S. maltophilia* (Table 59.1). Similarly, tigecycline is a candidate for clinical investigations with respect to *S. maltophilia* infections (Table 59.1) [200, 201]. The MIC_{50} and MIC_{90} values of tigecycline for 120 isolates were, respectively, 0.5 and 1.5 μg/mL in a study conducted in Spain [200]. Another study reported tigecycline MIC_{50} and MIC_{90} values of 2 and 4 μg/mL, respectively, for 903 isolates from 2006 to 2010 in Taiwan (with an MIC range of 0.03–16 μg/mL) [202]. Yet, a French study showed higher MIC_{50} and MIC_{90} values of 2 and 8 μg/mL, respectively, for 72 isolates [203]. This agent was compared with trimethoprim-sulfamethoxazole in treating *S. maltophilia* infections with no significant differences in mortality and clinical response rates between the two treatment regimens [204]. A high doubled tigecycline dosage regimen was reported to be successful in treating *S. maltophilia* bacteremia [205].

Despite the high rates of insusceptibility to numerous agents overall, the literature has provided various examples of assessing antimicrobial combinations against multidrug-resistant isolates. A review article published in 2008 conducted a literature analysis of therapeutic options for *S. maltophilia* infections beyond trimethoprim-sulfamethoxazole [206]. This study found that: (1) 20 of 49 cases (41 %) were treated with ciprofloxacin alone or in combination with other antibiotics (with a cure/improvement rate of 90 %); (2) 12 of 49 cases (25 %) were treated with ceftriaxone- or ceftazidime-based regimens (with a cure/improvement rate of 75 %); (3) 6 of 49 cases (12 %) were treated with ticarcillin- or ticarcillin-clavulanate-based regimens (with a cure/improvement rate of 67 %). Other 11 patients received various antimicrobials including aminoglycoside-based regimens, carbapenems, levofloxacin, chloramphenicol, aztreonam, minocycline, and other β-lactams [206]. This study also indicated the lack of clinical trials for these therapeutic combination options as a major limitation. Another study [207] describes the *in vitro* testing of 517 combinations which included levofloxacin, ceftazidime, ticarcillin-clavulanate, piperacillin-tazobactam, aztreonam, chloramphenicol, minocycline, tobramycin, and trimethoprim-sulfamethoxazole for their activities against 80 respiratory isolates from cystic fibrosis patients, showing that the most synergistic combination was ticarcillin-clavulanate plus aztreonam (92 % synergistic), followed by ticarcillin-clavulanate plus colistin (40 %), and ticarcillin-clavulanate plus levofloxacin (19 %). A case report revealed that chloramphenicol and rifampin were the only agents active against an isolate which was recovered from the urinary device of a patient with myelofibrosis, and this patient had been exposed to treatments with levofloxacin, amoxicillin-clavulanate, ceftazidime, and piperacillin-tazobactam [208].

Polymyxins are among the limited "last-resort" antibiotics for treating multidrug-resistant Gram-negative infections such as those caused by multidrug-/carbapenem-resistant *A. baumannii*, *P. aeruginosa*, and *Enterobacteriaceae* [53, 209]. However, *S. maltophilia* isolates display variable susceptibility to polymyxins, rendering the challenge for using colistin in treating *S. maltophilia* infections. In one study, the colistin MIC range, MIC_{50}, and MIC_{90} values of 0.01–32, 2, and 32 μg/mL, respectively, were reported for 72 isolates that were from France in 2008–2009 [203]. In another study, all 17 tested isolates from Singapore in 2004 were resistant to colistin with MIC_{50} of 128 μg/mL [210]. A case report showed an extensively drug-resistant isolate from a burnt, septicemia patient to be only susceptible to colistin [211]. Although colistin is not an agent for *in vitro* susceptibility testing of *S. maltophilia* [37], colistin has, nevertheless, been tested in combination with other agents for activity against *S. maltophilia*. Colistin in combination with trimethoprim-sulfamethoxazole, tigecycline, or rifampin showed a synergistic effect against *S. maltophilia* [168, 212]. However,

little information is available on intravenous administration of colistin for therapy of *S. maltophilia* infections. There were only a few retrospective studies that described the limited numbers of *S. maltophilia* isolates in colistin therapy of infections associated with multidrug-resistant Gram-negative bacteria [213, 214]. A report suggests using the combination regimens that include colistin, fluoroquinolones, or tigecycline [215]. A case study described the successful treatment of recurrent *S. maltophilia* ventilator-associated pneumonia with intravenous doxycycline and aerosolized colistin [216].

Additionally, azithromycin-trovafloxacin combinations did not show a measurable activity against *S. maltophilia* [217]. However, azithromycin-trimethoprim-sulfamethoxazole, azithromycin-ceftazidime, or clarithromycin-ceftazidime combination produced *in vitro* synergistic or additive effects [218]. The lipoglycopeptide telavancin plus colistin was also synergistic against colistin-susceptible *S. maltophilia* [219]. A triple combination comprising of a siderophore monobactam (BAL19764), a class C β-lactamase inhibitor (a monobactam), and a clavulanate had a BAL19764 MIC_{90} value of 2 μg/mL against 12 isolates [220]. To recapitulate, despite extensive *in vitro* combination testing and retrospective clinical case reports, well-designed clinical trials including microbiological and clinical outcomes are often lacking for the combinatorial therapeutic options.

6 Conclusions

S. maltophilia is an important nosocomial opportunistic pathogen that poses a great challenge for antimicrobial therapy due to its high-level broad intrinsic resistance. This resistance phenotype can be explained by the available genome data and various biochemical studies, which show the presence of resistance determinants against major clinically relevant antimicrobial agents. The intrinsic resistance feature is further complicated by the global emergence of resistance to the primary choice of drugs, trimethoprim-sulfamethoxazole, as well as to other agents. Susceptibility/resistance phenotype of clinical isolates can be unpredictable; thus, it is important to conduct antimicrobial susceptibility testing with suspected *S. maltophilia* infections. Nevertheless, the interpretative susceptibility breakpoints for *S. maltophilia* are only available for a limited number of agents. Therapeutic options often require a combination of agents which display variable activities against *S. maltophilia*. It is worrisome that there is a lack of data from clinical trials since most therapeutic recommendations are only generated from *in vitro* antimicrobial synergy data and clinical case reports. Additionally, the characteristic of *S. maltophilia* with intrinsic resistance to carbapenems and variable susceptibilities to polymyxins requires clinical investigation of the effect of these "last-resort" antibiotics on the emergence of *S. maltophilia* infections during their therapy of infections associated with other multidrug-resistant Gram-negative bacteria. Given the nosocomial, opportunistic nature of *S. maltophilia* (especially affecting immunocompromised patients), hospital infection control and hygiene practices play an important role in minimizing bacterial infections and should not be underestimated. Intervention measures should focus on preventing transmission of *S. maltophilia* within healthcare facilities and reducing the predisposing risk factors that enhance *S. maltophilia* colonization in patients, particularly with at-risk populations.

7 Addendum in Proof

Outer membrane vesicles from *S. maltophilia* were shown to contain both L1 and L2 β-lactamases and to increase β-lactam resistance in *S. maltophilia* as well as in *P. aeruginosa* and *Burkholderia cenocepacia* [223]. Regulation of Sm*qnr* expression by SmQnrR was suggested to be strain-specific [224]. Genetic inactivation of *smlt2199-smlt2200-encoded* two-component regulatory system ($SmeS_yR_y$) yielded an increased susceptibility to aminoglycosides but a decreased susceptibility to multiple antibiotics including chloramphenicol, ciprofloxacin, macrolides, and tetracycline [225]. This differential susceptibility phenotype is attributable to the reduced expression of SmeYZ pump and elevated expression of SmeDEF pump [225]. Two-component regulatory system PhoPQ also affects antimicrobial susceptibility with a PhoP mutant showing increased membrane permeability and reduced expression of SmeZ pump [226]. Disruption of the MFS-type efflux pump, MfsA, led to increased susceptibility to aminoglycosides, chloramphenicol, erythromycin, fluoroquinolones, rifampicin, tetracycline, and two first-generation β-lactam agents (4- to 16-fold decrease in MIC values) [227]. Increased prevalence (39%) of resistance to trimethoprim-sulfamethoxazole in *S. maltophilia* has been reported [228], highlighting the importance of antimicrobial susceptibility testing in selection of antimicrobials against *S. maltophilia* infections. A genetic assay named loop-mediated isothermal amplification (LAMP) was recently shown to provide a helpful tool for monitoring the spread of sulfonamide resistance genes, dihydropteroate synthase *sul1* and *sul2* genes [229]. Finally, a new clinical case study from the USA discussed several potential antimicrobial combinations for the treatment of a renal transplant patient with blooddstream *S. maltophilia* infection by showing the utility of a novel drug combination, ceftazidime-avibactam and aztreonam, although the latter remains to be further studied for its safety and efficacy [230].

Antimicrobial Resistance of *Shigella* spp., Typhoid *Salmonella*, and Non-typhoid *Salmonella*

60

Herbert L. DuPont and Jean M. Whichard

1 Introduction

At the end of the nineteenth century, the two great forms of dysentery were identified: sporadically occurring amoebic dysentery (amebiasis) and bacillary dysentery (shigellosis) that tended to produce outbreaks of diarrheal disease. Since first identified, *Shigella* spp. have been shown to be important causes of morbidity worldwide and for epidemic strains of *S. dysenteriae* type 1 (Shiga bacillus) major causes of mortality in tropical endemic regions.

Enteric or typhoid fever is a striking syndrome of fever with abdominal symptoms and signs associated with bacteremic salmonellosis. If untreated, typhoid fever may progress to life-threatening complications in the second week of illness including perforated intestine and intestinal hemorrhage. The serotypes of *Salmonella* responsible for typhoidal illness are Typhi, Paratyphi A, Paratyphi B, and Paratyphi C.

Non-typhoidal strains of *Salmonella* are important causes of usually self-limiting foodborne gastroenteritis in healthy children and adults, although at extremes of age and when infection occurs in certain very susceptible hosts, illness is complicated by the presence of fever and systemic toxicity due to systemic or bacteremic infection which may be associated with disease complications.

Humans and primates are the reservoir for shigellosis and typhoid *Salmonella* infections, and the widespread use of antibacterial drugs in human medicine is most relevant for emergence of antibacterial resistance among those diseases. In these cases, self-medication and purchase of antibacterial drugs without a prescription are commonly practiced in many areas of the developing world. In industrialized regions, antibiotic use for viral infections and other conditions for which antibiotics are not indicated contribute to a rising rates of resistance. For non-typhoid *Salmonella* strains, animals serve as the major microbial reservoir, and the use of antibiotics in animals provides selective pressure that contributes to selection of antibacterial-resistant strains that can infect humans that come into contact with animals or food animal products.

This review looks at the current state of antibacterial resistance among shigellae and salmonellae and focuses on current guidelines of antimicrobial therapy in the setting of changing resistance.

2 Burden and Importance of *Shigella* and *Salmonella*

2.1 *Shigella*

The annual number of *Shigella* diarrhea and dysentery cases has been estimated to be 165 million leading to approximately one million deaths in the developing world [1]. *S. dysenteriae* 1 (the Shiga bacillus) characteristically has a more severe outcome and can produce widespread and severe epidemics. In the USA, it is estimated that we have approximately 500,000 cases of shigellosis each year, but only very few cases caused by *S. dysenteriae* 1 [2]. *Shigella* strains continue to be important causes of travelers' diarrhea in international visitors and military populations [3, 4]. Shigellosis is uniquely pathogenic among bacterial pathogens resulting in common person-to-person spread because of low dose required for illness [5]. Infection results from oral exposure to human feces containing *Shigella*, directly or in the form of contaminated food or water or exposure to contaminated recreational waters. Shigellosis can spread among young children in daycare, in settings where hand hygiene is inadequate, and outbreaks have occurred in men

who have sex with men (CDC [6] *Shigella*—Shigellosis. 29 Sept 2014). Strains of *Shigella* should be suspected as a potential etiologic agent in patients with sporadically occurring dysentery where many stools of small volume are passed that contain gross blood and mucus. The illness tends to be clinically striking and may persist for a week or longer if untreated.

2.2 Typhoid *Salmonella*

Buckle et al. estimated that there were approximately 26.9 million cases of typhoid fever in the world in 2010 [7]. Crump et al. [8] have estimated a conservative case fatality rate of 1 % among patients suffering from typhoid fever The infectious dose of typhoid *Salmonella* is moderately high [9] explaining the rarity of person-to-person spread and the need for a food or water vehicle for disease transmission. Typhoid fever is particularly endemic in the Indian subcontinent, Southeast Asia, Africa, and South America. The disease is striking, and patients with typhoid fever often present themselves to medical centers for evaluation. It is one of the most important febrile conditions among international travelers to endemic areas. Blood cultures should always be obtained in travelers with fever following return from endemic tropical regions to evaluate for the presence of typhoid fever.

2.3 Non-typhoid *Salmonella*

Non-typhoid salmonellosis causes approximately 1.0 million cases of domestically acquired foodborne disease in the USA leading to an estimated 19,000 hospitalizations and nearly 400 deaths [2, 10]. A surprisingly high incidence of the organism is seen in young infants less than 1 year of age. This appears to be related to a reduced number of organisms needed for development of gastroenteritis in this age group plus household exposure to the organism from common in-home cross contamination.

3 Patterns of Susceptibility of *Shigella* spp. by Geography

The first antibiotic shown to be effective in shortening shigellosis was ampicillin [11]. In children with severe shigellosis, orally absorbable ampicillin was shown to be superior to orally administered nonabsorbable neomycin with both drugs showing similar levels of in vitro susceptibility. This study provided indirect evidence that drug absorption was required for mucosally invasive shigellosis. With the subsequent widespread use of ampicillin for therapy of bacterial diarrhea in the 1970s and 1980s, ampicillin resistance occurred widely [12] leading to the search for other drugs to treat this severe form of diarrhea and dysentery. Nelson et al. [13] demonstrated that trimethoprim-sulfamethoxazole (TMP/SMX) was active in vitro and showed that the drug shortened clinical shigellosis in infected children. Soon after this study in pediatric shigellosis, adults with endemic shigellosis were shown to have improvement in their clinical disease by administration of the drug [14], and DuPont et al. [15] showed TMP/SMX was active in shortening the duration of travelers' diarrhea due to strains of *Shigella* during short-term stay in Mexico. During the 1980s, TMP/SMX remained active against isolated strains of *Shigella* in the USA, Europe, Latin America, and Asia [12], while in the 1990s identified enteric bacterial pathogens including strains of *Shigella* began to lose their susceptibility to TMP/SMX with rates of resistance reaching 50–94 % throughout the world. In the USA, we initially found TMP/SMX resistance among persons returning from international travel after visiting regions showing resistance [16]. The National Antimicrobial Resistance Monitoring System (NARMS) found that 43.3 % of the *Shigella* isolates tested from patients in the USA in 2012 were resistant to TMP/SMX [17].

One of the first drugs to be successfully used to treat TMP-/SMX-resistant shigellosis was nalidixic acid, a quinolone available in pediatric suspension form and with in vitro activity against enteric bacterial pathogens [16]. The drug possessed a potential for quinolone toxicity in children limiting widespread use. Mecillinam (pivamdinicillin) was further evaluated and found to have value in the treatment of shigellosis in Bangladesh [18] for susceptible and more resistant forms of *Shigella*. Resistance to nalidixic acid became common, presumably through general use, particularly with strains of *S. dysenteriae* 1 [19]. With the availability of the newer fluoroquinolones, beginning with norfloxacin (NF) followed by ciprofloxacin (CF) and levofloxacin (LF), the outcome of treatment of shigellosis in adults was immediately improved.

In the USA, 4.5 % of the *Shigella* tested by NARMS in 2012 were resistant to nalidixic acid, and 2.0 % were resistant to the fluoroquinolone (FQ) ciprofloxacin [17]. *Shigella* that are nalidixic acid resistant usually show resistance or decreased susceptibility to fluoroquinolones because the main mechanism of resistance, topoisomerase mutations, affects efficacy of fluoroquinolones as well as nalidixic acid. However, mechanisms that confer resistance to fluoroquinolones but not nalidixic acid have also been identified [20]. In recent years in Asia, nalidixic acid resistance has reached very high levels for *S. flexneri* and *S. dysenteriae* strains with these strains typically showing fluoroquinolone resistance [21, 22]. A clonal epidemic of antimicrobial susceptible strain of *S. dysenteriae* 2 has been seen in Bangladesh [23].

Antimicrobial susceptibility of strains of *Shigella* has related to the general use of antimicrobials in the population, as well as by the pathogen species causing illness. *S. flexneri*

Table 60.1 Changing susceptibility of *Shigella* spp.

Region	Amp	TMP/SMX	Nalidixic acid	Fluoroquinolone	Azithromycin	References
USA	18 → 26	0 → 43	Low → 5	Low → 2	4	[17]
Europe, Middle East	18 → 10–77	6 → 64–95	Low → 0–49	Low → 0–4	4	[29–34]
Latin America	15 → 43–100	0 → 27–100	0	0 → 0	Low → ?	[35–38]
Asia	10 → 43–100	10 → 63–98	Low → 59–100	0 → 12–82	Low → 17–49	[39–47]
Africa	37 → 12–60	6 → 25–99	Low → 0–7	Low → 0–7	?	[48–51]

Initially from 1970s to 1980s until the 2000s–2010s by Region of the World
[a]Antimicrobial resistance is currently highest for strains of *S. dysenteriae* 1 with high rates also seen in strains of *S. flexneri* and low rates for *S. sonnei* isolates

showed greater resistance to prevalent drugs than *S. sonnei* [24], and *S. dysenteriae* 1 showed the highest degree of resistance compared with other serotypes [16]. Over time in endemic areas such as Bangladesh, nalidixic acid resistance has become clinically important with the drug no longer being helpful in the management of Shiga dysentery [16].

Given the high levels of resistance to traditional antimicrobial agents, physicians have turned to azithromycin (AZ) for treatment of shigellosis. Early reports of azithromycin-resistant *Shigella* surfaced in the late 1990s in Vietnam and Thailand [25]. Azithromycin treatment failure in a pediatric outbreak of *Shigella sonnei* in France in 2007 was attributed to a plasmid-borne macrolide phosphotransferase gene, *mphA* [26]. This gene was first found in *Shigella sonnei* isolated from patients in the USA in 2005 [27]. It has also since been found in *Shigella flexneri* and occasionally *Shigella boydii*. Outbreaks have occurred in men who have sex with men, and a 2014 study found a high proportion of HIV coinfection among men infected with *Shigella* that showed decreased susceptibility to azithromycin [28]. Clinical interpretive criteria for azithromycin are lacking for *Shigella*, and more data on the clinical implications of *Shigella* that show azithromycin non-susceptibility are necessary before CLSI can establish those clinical interpretive criteria.

In Table 60.1 a world region summary of antimicrobial susceptibility data for isolated *Shigella* strains in various published studies is provided.

4 Enteric Fever Due to Strains of *Salmonella* Typhi and *S.* Paratyphoid

Since the 1940s typhoid fever has been managed in the developing world with chloramphenicol. The drug was inexpensive and effective in shortening the illness. In the 1970s, chloramphenicol resistance among typhoid *Salmonella* strains emerged in the Indian subcontinent and in Mexico [52] leading to the successful evaluation of other antimicrobial agents, including ampicillin and then trimethoprim-sulfamethoxazole for therapy of typhoid fever [53]. Beginning with the 1980s, multidrug-resistant strains of typhoid *Salmonella* emerged in Asia and Europe. The plasmid-encoded resistance identified not only was directed to chloramphenicol but to ampicillin and trimethoprim-sulfamethoxazole complicating therapy and leading to increased mortality [54]. Worldwide occurrence of *Salmonella* Typhi resistance to chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole has continued to increase.

Nalidixic acid resistance among enteric *S.* Typhi strains was shown to be an important predictor of intermediate resistance for the fluoroquinolone and represented an indication to administer higher doses of fluoroquinolones for successful treatment [55]. Fluoroquinolone resistance has been documented among isolated strains of typhoid *Salmonella* [56, 57], although it has not yet become important or widespread [55, 58]. Most fluoroquinolone-resistant *S.* Typhi strains have been shown to have point mutations in the genes encoding DNA gyrase or DNA topoisomerase IV enzymes located within bacterial chromosomes [59]. Fluoroquinolones act on *GyrA* and at higher concentrations on *ParC*, with point mutations leading to reduced susceptibility to ofloxacin, ciprofloxacin, and to gatifloxacin [60]. A few years ago, the Clinical and Laboratory Standards Institute updated clinical interpretation of resistance among invasive strains of *Salmonella* based on more recent clinical outcomes and microbiological data. The updated definition of clinical resistance captures isolates with lower minimum inhibitory concentration results (≥1 μg/mL) or disk diffusion zone diameters (≤20 mm) [61].

In the USA where most cases of typhoid fever occur secondarily to international travel, particularly to the Indian subcontinent, multidrug resistance rates rose from <1 % to >10 % in the 1990s [62, 63]. Resistance to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole rose to 18.6 % in 2006 and subsequently declined. In 2012, 9.2 % of the *Salmonella* Typhi isolates obtained from patients in the USA were resistant to all three of these drugs [17].

In Europe, multiresistance became even more common in recent years with nearly one third of isolates showing reduced fluoroquinolone susceptibility indicating a need for higher doses when treated with this class of drugs [64]. Of relevance, in some areas with an increasing resistance of

S. Typhi strains to fluoroquinolones, a concomitant decrease in resistance to chloramphenicol has been found [65], which could influence future treatment recommendations in developing countries where the cost differential between fluoroquinolones and chloramphenicol is great. In a study carried out in Nepal, multiresistant and extended-spectrum β-lactamase producing enteric fever strains were more commonly classified in the laboratory as Paratyphi A than Typhi [66]. A study of Paratyphi isolates from India also demonstrated nalidixic acid resistance and a reduced susceptibility to ciprofloxacin [67]. Almost all *Salmonella* Paratyphi A isolates obtained from humans in the USA are resistant to nalidixic acid [17], and infection has been associated with travel to South Asia [68]. Susceptibility testing of isolated typhoid and paratyphoid *Salmonella* is important in managing enteric fever patients to identify the optimal therapy and to prevent delayed recovery and treatment failures.

5 Gastroenteritis due to Non-typhoid *Salmonella*

During the 1970s and 1980s, strains of non-typhoid *Salmonella* were shown to have variable susceptibility to ampicillin, tetracycline, and TMP/SMX [12]. In more recent years, resistance to ampicillin, TMP/SMX, chloramphenicol, aminoglycosides, chloramphenicol, and sulfonamides has become widespread throughout the world related at least in part to the potential of these bacterial pathogens for horizontal transfer of resistance mediated by plasmids, transposons, or integron cassettes. Just as with other enteric pathogens, the use of traditional antimicrobial agents for treatment of invasive salmonellosis has largely been replaced by other drugs, in this case fluoroquinolones and extended-spectrum cephalosporins. Extended-spectrum cephalosporins are particularly important for treating pediatric infections.

There is evidence for the non-typhoid *Salmonella* that dissemination of multidrug resistance is secondary to both local antimicrobial use with local selection of resistance strains as well as by more widespread dissemination of resistant clones of *Salmonella* amplified within livestock and other animal populations [69–71]. Resistant *Salmonella enterica* serovars isolated from different institutions may show the same genetic lineage supporting the concept of clonal spread [72]. Retail meats can be shown to harbor antibacterial-resistant strains of *Salmonella* supporting current recommendations that national surveillance for antimicrobial-resistant *Salmonella* should include the monitoring of retail foods and that restrictions of the use of antibiotics important in human medicine should be imposed for all food animals [73].

Rates of fluoroquinolone resistance among strains of non-typhoid *Salmonella* were shown to increase between 1995 and 1999 in travelers returning to the USA. Ciprofloxacin resistance increased from 4 % to 24 % for various travel destinations, while for those returning from Thailand, the increase was even greater with increase in resistance rates being shown to rise from 6 % to 50 % [74].

Resistant *Salmonella enterica* serovars may be isolated from poultry [75], and shell eggs have been found to harbor resistant *Salmonella*, including strains resistant to nalidixic acid, with the resistance pattern showing serotype dependence [76]. Isolation of quinolone-resistant *Salmonella* from retail meats purchased in the USA has been very rare, and among the four food animals (cattle, chickens, swine, and turkeys) under surveillance at slaughter by NARMS, cattle have been the most frequent source of nalidixic acid-resistant *Salmonella* (between 1 % and 3 % from 2009 to 2011) [77]. Enteritidis is the most frequent serotype of quinolone-resistant *Salmonella* isolated from humans in the USA [17], and quinolone-resistant infections in humans in the USA are associated with foreign travel [78].

Of the many serotypes of *Salmonella*, serovar Typhimurium is the most resistant to antibacterial drugs. Multidrug-resistant definitive type (DT) 104 *S.* Typhimurium has emerged worldwide and has appeared in the USA, DT 104 strains are responsible for about one third of infections in the USA. They are characteristically resistant to ampicillin, chloramphenicol, tetracycline, streptomycin, sulfamethoxazole, and kanamycin [79]. Bacteriophage typing can identify various DT 104 types belonging to multiple serotypes but with similar mechanisms of integron gene resistance that may confer resistance to aminoglycosides, trimethoprim, and β-lactam drugs [73]. *Salmonella* phage type DT104 harbors a genomic island called *Salmonella* genomic island 1 (SGI-1) containing an antibiotic gene cluster conferring multidrug resistance [80]. The CDC-sponsored FoodNet program demonstrated that human acquisition of DT 104 in the USA was related to prior receipt of an antimicrobial agent during the 4 weeks preceding illness onset [79].

Between 1998 and 2002, multidrug-resistant *Salmonella* Newport emerged as an important public health problem in the USA [81]. This strain is particularly important because it is not only resistant to the drugs seen with DT 104 strains, but it is resistant to the third-generation cephalosporin, ceftriaxone, which is the treatment of choice for systemic pediatric salmonellosis. Instead of the chromosomal multidrug resistance seen in *Salmonella* Typhimurium DT104, this multidrug resistance in *Salmonella* Newport is attributed to a plasmid that carries several resistance genes including one or more copies of the bla_{CMY-2}β-lactamase gene [82, 83]. Resistance in these strains appears to be encouraged by the use of antibacterial drugs in livestock with resultant spread to humans [81, 84]. The spread from bovine sources to humans may also be facilitated by human use of antibacterial drugs [85]. Currently, *S.* Newport is the third most common *Salmonella* serotype in the USA [17] having increased in importance fivefold from 1998 to 2001 [81].

Ceftriaxone-resistant *Salmonella* Heidelberg emerged more recently in the USA. Ceftriaxone resistance among this serotype isolated from humans in the USA rose to over 20 % in 2009 [17], but this emergence has been smaller in magnitude than the increase in serotype Newport because Heidelberg is a less frequently isolated serotype in humans than Newport [86]. Infections are mainly associated with poultry, a common reservoir for this serotype. Unlike cephalosporin-resistant *Salmonella* Newport, cephalosporin-resistant members of this serotype generally do not exhibit the other non-β-lactam resistances because the types of plasmids circulating in these two serotypes are different.

Ciprofloxacin-resistant *Salmonella* Kentucky was isolated from French patients who had traveled to northeast and eastern Africa in the early 2000s [87]. This was also seen in England and Wales and Denmark in travelers returning from African countries or the Middle East [88], and most of the isolates were resistant to several other drugs. The global spread of the predominant sequence type (ST) of ciprofloxacin-resistant *Salmonella* Kentucky, ST 198, was described in 2013 [89]. These strains contain *gyrA* mutations; most contain SGI1 or variants of SGI1, many contain β-lactamase genes including those that confer resistance to extended-spectrum cephalosporins, and a few contained genes associated with resistance or decreased susceptibility to carbapenems ($bla_{\text{VIM-2}}$ and $bla_{\text{OXA-48}}$). Poultry are the main reservoir, but these strains have also been isolated from contaminated meats, seafood, and spices and from other animals [89].

When compared with susceptible strains, multidrug-resistant strains of *Salmonella* are more likely to produce severe infection and mortality [90] and to lead to hospitalization [91]. There is evidence that antimicrobial-resistant *Salmonella* are not only able to resist the effect of antibiotics to which they show low susceptibility, but they may be more virulent than susceptible strains causing more prolonged and more severe illness than their antibiotic-susceptible counterparts [92]. Comorbid conditions of the host may affect susceptibility to salmonellosis and influence outcome. In one study in Ethiopia, the *Salmonella* isolates from patients with HIV infection showed greater resistance to antimicrobials than those from HIV negative controls [93]. It will be important to monitor the incidence of antimicrobial-resistant *Salmonella* in human populations as well as the food supply to help predict the evolution of antimicrobial resistance in human infections [94, 95].

6 Current Therapeutic Recommendations

In Table 60.2, recommendations for therapy of the various bacterial enteric infections considered herein are summarized.

6.1 *Shigella*

The fluoroquinolones have become the mainstay of therapy for adult patients with shigellosis. Most cases should be treated with antibacterial drugs for 3 full days, although for many persons with milder forms of shigellosis caused by species other than *S. dysenteriae* type 1, single-dose treatment may be effective [96, 97]. Single-dose therapy with azithromycin appears to be effective in treating many forms of shigellosis [98]. Azithromycin or one of the third-generation cephalosporins should currently be considered the drug of choice for treatment of pediatric shigellosis. Strains of *S. sonnei* resistant to third-generation cephalosporins have been encountered [99]. While azithromycin is an important form of therapy for shigellosis, there may be challenges with the interpretation of in vitro susceptibility testing of *Shigella* isolates using Etest and disk diffusion [100].

Table 60.2 Recommended therapy of shigellosis and salmonellosis based on current susceptibility patterns

Condition	Children		Adults	
Shigellosis	Azithromycin[b]	5 mg/kg/day for 3 days	Norfloxacin (NF), or ciprofloxacin (CF), or levofloxacin (LF), or azithromycin (AZ)	NF 400 mg bid, CF 500 mg bid, or LV 500 qd for 3 days or AZ 1000 mg in a single dose
Typhoid fever	Ceftriaxone	50 mg/kg/day in two IV doses/day for 7–10 days	CF, LF, or other fluoroquinolone (FQ) or azithromycin (AZ)	FQ given in full doses for 7–10 days
				AZ 500 mg qd for 7 days
Salmonellosis (a febrile, nontoxic condition in healthy host)	Fluid therapy and observation		Fluid therapy and observation	
Salmonellosis (When a febrile, or toxic condition, or in special host[a])	Treat for bacteremia as typhoid fever or with azithromycin (AZ) for cephalosporin-resistant strains	See above for ceftriaxone dosing, AZ 10 mg/kg/day in single daily dose for 7 days	Treat for bacteremia as typhoid fever[c]	

[a]Extremes of age (<3 months, >65 years of age), sickle cell anemia, inflammatory bowel disease, hemodialysis, receiving systemic corticosteroids or anticancer or anti-immunity drugs, AIDS (for AIDS or immunocompromised, continue therapy for at least 2 weeks)
[b]Ciprofloxacin can be safely given for 3 days to older children, although not approved for bacterial diarrhea
[c]Immunocompromised patients may need prolonged treatment

One concern in the therapy of Shiga dysentery due to *S. dysenteriae* 1 is the development of hemolytic uremic syndrome (HUS), an association which has been reported [101]. The relationship of antimicrobial therapy to the development of HUS in Shiga dysentery was studied by Bennish and coworkers [102] who found in one small study that treatment of Shiga *Bacillus* dysentery did not predispose to HUS and stools in treated subjects showed a reduction of Shiga toxin.

6.2 Typhoid Fever

While the drug of choice for three decades, chloramphenicol, has been used more sparingly in recent years due to the emergence of resistance, high relapse rate, and failure to eradicate intestinal carriage of the organism [9]. Resistance to chloramphenicol, ampicillin, and TMP/SMX has been seen worldwide for strains of *Salmonella* Typhi. Fluoroquinolones remain active in vitro, render high concentrations in bile and macrophages, and can also be given for shorter courses. For adults in regions where it is not prohibitively expensive, the fluoroquinolones represent the current treatment of choice [58, 63]. The recommended duration of fluoroquinolone use in adults with typhoid fever is 7–10 days, and the drug should be given orally as soon as oral medications can be taken. Ceftriaxone (1–2 g per day) for 7–10 days is effective in adults with typhoid fever, and the third-generation cephalosporins represent the treatment of choice for pediatric typhoid fever [103]. Oral cefixime and oral azithromycin remain alternatives for resistant strains [104].

6.3 Non-typhoid Salmonellosis

Over the years multidrug-resistant strains of non-typhoid *Salmonella* have emerged producing dilemmas in therapy of human infections. Fortunately, most cases of non-typhoid salmonellosis represent mild to moderate self-limiting gastroenteritis. In a subset of patients, bacteremia or other systemic infection including meningitis may occur which explains the nearly 600 deaths in the USA each year associated with intestinal salmonellosis. In conditions in which *Salmonella* bacteremia and systemic infection should be suspected and where antimicrobial therapy should be initiated empirically, it must include patients with *Salmonella* gastroenteritis in the following patient groups: (1) extremes of age (<3 months and >65 years of age); (2) undergoing regular hemodialysis; (3) receiving high-dose steroids; (4) with the presence of AIDS or cancer or receipt of anticancer drugs that alter immunocompetence; (5) and with the presence of inflammatory bowel disease or sickle cell disease. In these cases antibiotics are given for 7–10 days to treat bacteremic disease rather than a localized enteric infection. In immunocompromised persons with cancer or AIDS and possible systemic salmonellosis, the antibiotics are given for at least 2 weeks with some needing therapy even longer. The antimicrobials given to patients with bacteremic disease or possible bacteremic disease do not shorten nonsystemic intestinal disease and may encourage the emergence of resistant forms with transient shedding [105] without decreasing post-diarrhea shedding of *Salmonella* [106].

The treatment of choice for therapy of systemic non-typhoid *Salmonella* infection in adults is a fluoroquinolone, given orally when it can be taken by that route. The fluoroquinolones remain active against strains of *Salmonella* encountered in the USA [94]. For children, parenteral third-generation cephalosporins should ordinarily be used for systemic salmonellosis. With the occurrence of cephalosporin-resistant non-typhoid *Salmonella* from animal populations, new treatments are needed for children.

Since most non-typhoid *Salmonella* strains now are multidrug resistant, in vitro susceptibility testing should routinely be performed with isolated strains while empirically employed.

7 General Comments in regard to Enteric Pathogen Resistance

Non-*Salmonella enterica* pathogens, including *Shigella*, typhoid *Salmonella*, and *Campylobacter jejuni*, characteristically develop polyclonal resistance in response to local antibiotic use patterns. The occurrence of important clonal spread of non-typhoid *Salmonella* strains has facilitated widespread distribution of antimicrobial resistance resembling the problem of methicillin-resistant *Staphylococcus aureus*, which has spread within the community from a hospital reservoir. In studying clonal spread of non-typhoid *Salmonella*, multiple genetic typing procedures may be needed for epidemiologic study as single gene characterization may give an incomplete epidemiologic picture [107]. Although less important from a public health standpoint, multiclonal spread can occur for *Salmonella enterica* strains [108].

Antimicrobial Resistance in *Vibrio*

61

Michael L. Bennish, Wasif A Khan, and Sabeena Ahmed

1 Introduction

This chapter addresses antimicrobial resistance in a genus—*Vibrio*—that contains over 100 species, of which at most 15 are known to be pathogenic in man [1, 2]. *Vibrio* species are facultative anaerobic gram-negative bacilli. With the exception of *Vibrio cholerae,* all are halophilic (salt loving) [1]. Several *Vibrio* species that were only rarely associated with human disease have recently, based on phylogenetic analysis, been reclassified into other genera and will not be considered in this chapter [3, 4].

Pathogenic vibrios cause both intestinal and extraintestinal illnesses. The best known and most common of these intestinal illnesses is cholera. *Vibrio* infections, potentially requiring antimicrobial therapy, fall into three distinct clinical syndromes: cholera caused by either *Vibrio cholerae* O1 or O139 and rarely other *V. cholerae* serogroups; less severe non-cholera diarrhea caused by non-O1 or O139 *V. cholerae* or other *Vibrio* species; and soft tissue infections and sepsis caused by halophilic, marine vibrios. Infections with *V. cholerae* O1 or the currently much less frequently identified O139 serogroup, both of which can produce the secretagogue cholera toxin, occur almost exclusively in poor countries where access to clean water and proper sanitation is uncommon.

Vibrio cholerae serogroups in addition to *V. cholerae* O1 and O139 have been associated with intestinal infection and diarrhea [5–7], as have other *Vibrio* species, including *Vibrio parahaemolyticus* [8–10] and *Vibrio mimicus* [11, 12]. Occasionally, these other *V. cholerae* serogroups and *Vibrio* species may have the genetic capacity for the elaboration and production of cholera toxin [7, 13, 14] and thus can cause a cholera-like illness. More commonly, they cause less severe diarrhea. These occur wherever marine or seafood exposure takes place. Cholera and non-cholera diarrhea occur in otherwise healthy hosts, and most commonly in children in endemic areas.

Skin and soft tissue infections, including necrotizing fasciitis and sepsis, are the other clinical syndromes caused by vibrios [15]. These are most common in immunocompromised hosts, especially those with hepatic impairment. The most common pathogen associated with soft tissue infections and septicemia is *Vibrio vulnificus* [16–19]. *V. vulnificus* is also the *Vibrio* infection with by far the highest associated mortality rate [1, 17].

The primary reservoir for all vibrios is marine or estuarine waters—usually in tropical and subtropical areas, but occasionally in temperate regions as well [20]. *V. cholerae,* because it is not halophilic, may also inhabit freshwater (or at least non-saline waters). These inland waters are often heavily polluted with human waste that may serve as the nidus for outbreaks of cholera [21]. Thus, the frequent occurrence of cholera outbreaks inland from ocean coasts or estuaries. Infections can occur from exposure to "fresh" water, food containing *V. cholerae*, or from person-to-person transmission.

Vibrios replicate best in water temperatures between 20 and 30 °C [22]. Global warming has changed both the geographic distribution and seasonality of coastal marine water temperatures in the 20–30 °C interval. These changes in ocean temperatures, rather than simply better case ascertainment, are believed to be partially responsible for the increases in *Vibrio* infections, especially with non-cholera vibrios, which have been observed in recent years in the United States and Europe [1, 17, 23, 24].

The pathogenesis and epidemiology of these three distinct clinical syndromes caused by vibrios—cholera, non-cholera diarrhea, or wound infection and sepsis—differ substantially and affect the need for antimicrobial therapy and the development of antimicrobial resistance.

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_13

Acquired multidrug resistance to *V. cholerae* O1 and O139 is now common and firmly established wherever infections occur. Acquired resistance in *V. cholerae* O1and O139 is primarily from acquisition of transmissible genetic elements, including conjugative plasmids, integrons, or integrative conjugative elements that carry genes encoding resistance. Circulating strains can both gain and lose resistance during the course of an epidemic, and surveillance of resistance patterns is essential. Because onset of disease is rapid, and disease can be rapidly fatal without appropriate fluid and antimicrobial therapy, antimicrobials should be administered empirically to patients with clinical cholera based on the known prevalence of resistance. In addition, cholera is usually treated in settings where isolation of the infecting organism and susceptibility testing are not routinely available. Thus surveillance programs that monitor resistance and report to peripheral clinics where cholera patients are cared for, are essential for the management of this disease.

Resistance is not as common in halophilic vibrios as it is in *V. cholerae*. Although there are a number of agents that remain active in vitro against these organisms, because of the relative rarity of infections, and the absence of clinical trials, choice of therapy is predicated upon in vitro and animal studies, and limited clinical experience.

Cholera caused by infection with *V. cholerae* O1 or O139 is by far the most common of all illnesses resulting from infection with vibrios. Cholera results from ingestion of water or food contaminated with *V. cholerae* O1 or O139. Infection is confined to the intestinal lumen where the elaboration of cholera toxin results in a profound watery diarrhea.

Cholera is a voluminous diarrhea that occurs in pandemics (there have been seven pandemics to date), can be periodically epidemic, and is endemic in its historic cradle in the Ganges Delta and elsewhere in the Indian subcontinent. Cholera is often fatal if rapid access to effective therapy is not available [25]. There are an estimated 1.3 billion persons at risk of infection in 69 countries where cholera is endemic [26]. Infections are almost entirely confined to poor countries lacking basic hygiene, good sanitation, and access to potable water. Both endemic disease and epidemics that can affect tens or hundreds of thousands of persons in previously non-endemic areas (particularly refugee camps) occur [27, 28]. Infections occur in all ages, but in endemic areas infections disproportionately affect the young [29, 30].

The most recent (2014) annual worldwide summary of cholera from the World Health Organization (WHO) reported 190,549 cases of cholera and 2231 deaths from cholera in 42 countries [31]. These numbers are clearly a gross underestimate of the actual burden of disease. For instance, research institutes in India and Bangladesh that extensively study cholera (and publish results in the international scientific literature) do not report any cases of cholera to the WHO and have not done so for many years. A more accurate estimate is that there are approximately 20 times more cholera cases than what is reported to the WHO (thus 2,800,000 actual cases) and that deaths are approximately 45 times greater than what is reported (91,000 actual deaths) [26].

Because of the large number of *V. cholerae* O1 or O139 infections and its distinctive clinical presentation, it has been possible to conduct numerous randomized controlled trials to identify agents effective in its treatment. This has provided a solid base of evidence for determining optimal antimicrobial therapy [32–42]. The large number of infected persons has also provided extensive information on resistance patterns, usually obtained as part of systematic longitudinal surveys at research centers devoted to the study of enteric infections, or during outbreak investigations [43–84] (Table 61.1).

Diarrhea resulting from infections with *V. cholerae* serogroups other than O1 or O139 or with other *Vibrio* species (most commonly *Vibrio parahaemolyticus*) is, unlike cholera, indistinct enough clinically, and sufficiently sporadic, that it has precluded randomized clinical trials of antimicrobial therapy [1, 8–10, 85–87]. Thus, the efficacy of antimicrobial therapy for non-cholera diarrhea caused by vibrios other than *V. cholerae* O1 or O139 is uncertain.

Most cholera infections occur in isolated areas of developing countries that lack access to basic diagnostic microbiologic facilities. For most patients with cholera, the infecting organism is not isolated, and antimicrobial susceptibility is not determined. In any case, antimicrobial treatment is required early in the course of illness if it is to be useful and cannot await the 48–72 h required to isolate the infecting organism and to determine its in vitro susceptibility. Cholera is a disease that strikes rapidly (patients can purge a volume of water equal to their body weight in 24 h). By the time the organism is isolated and antimicrobial susceptibility determined, the patient will be either dead or in better health. Antimicrobial treatment thus has to be empiric, based upon the known prevalence of resistance in circulating strains of *V. cholerae* O1 or O139.

In contrast, *Vibrio* infections causing fasciitis, tissue necrosis, or sepsis result from ingestion of contaminated seafood or inoculation through the skin by injury while in contaminated waters or while handling seafood [1, 2, 11, 17, 19, 22, 88], are locally and systemically invasive [16, 89, 90], generally occur sporadically and in relatively small numbers [90–92], and disproportionately affect the elderly and the immunocompromised, especially those with cirrhosis [19, 90, 92, 93]. Infections are most commonly reported from rich and medium-income countries, perhaps because ascertainment is difficult in poor countries. As with non-cholera *Vibrio* species causing diarrhea, there have been no randomized trials that define the best antimicrobial therapy, and reports on patterns of resistance are based upon small numbers of clinical isolates or surveys of environmental isolates

[94–101]. In contrast to cholera patients, patients with invasive vibrio infections are more likely to be cared for in hospital settings where a definitive microbiologic diagnosis and ascertainment of antimicrobial resistance can be done [16].

This chapter will discuss each of these clinical syndromes—cholera, non-cholera diarrhea, and wound infection and sepsis—in turn.

2 Cholera Caused by *V. cholerae* O1 or O139

2.1 Geographic Spread and Epidemiology of Resistance

Tetracycline was the first antimicrobial agent systematically evaluated for the treatment of cholera [40–42]. It soon established itself as the drug of choice for treating this disease. For the first two decades of its use—until the late 1970s—reported resistance to tetracycline was rare [102]. Resistance to other agents used for cholera treatment—including ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole—was also infrequent. In a report on 1109 isolates of *V. cholerae* O1 obtained from patients in the Philippines in 1969, only 11 (1.0%) demonstrated resistance to drugs in use for treatment [103]. In a report of 1156 strains from Asia, Africa, and Europe reported on in 1976, only 27 (2.7%) were resistant to one of the drugs tested—tetracycline, ampicillin, chloramphenicol, or a sulfa agent—all drugs then used to treat cholera [102].

By the end of the 1970s, however, plasmid-mediated multiple drug resistance to tetracycline, ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole was being commonly reported from *V. cholerae* O1 strains isolated in Asia and Africa [104–107]. The conjugative group C plasmid acquired by *V. cholerae* contained genes encoding for type II dihydrofolate reductase, a ß-lactamase, and other resistance mechanisms.

Since then multiple antimicrobial resistance has been a characteristic feature of *V. cholerae* O1 worldwide, from Africa [44, 70, 74, 78, 79, 83, 84, 108–110], Asia [48–50, 52, 53, 56, 58–60, 63, 64, 66, 71, 72, 80, 82, 111–114], Europe [115, 116], South and Central America and the Caribbean [47, 117–119], and Oceania [77] (Table 61.1). The spread of resistance was facilitated by the transfer of the resistance plasmid between circulating strains of *V. cholerae* and from other *Enterobacteriaceae*.

V. cholerae O139 was first identified as a cause of clinical cholera in 1992, when it caused large epidemics of severe diarrhea in Bangladesh and subsequently in other Asian countries [120]. This was the first non-O1 serogroup of *V. cholerae* to produce cholera toxin and to cause epidemic cholera. The epidemic strain evolved from a *V. cholerae* El Tor O1 strain that had acquired the O139 antigen-encoding genes following horizontal gene transfer from a donor strain and recombination with the El Tor O1 chromosome [121, 122]. The O139 epidemic strain also differed from endemic O1 strains by its resistance to trimethoprim-sulfamethoxazole, streptomycin, and furazolidone. Resistance to these agents was conferred by a novel transmissible genetic element—the SXT "constin." Constin was an acronym of its properties—conjugative, self-transmissible, and integrating. And SXT because the constin incorporated genes conferring resistance to sulfamethoxazole and trimethoprim [123, 124]. This SXT constin, or variants thereof with different resistance genes, has now been found in *V. cholerae* O1 and other organisms [81]. After rapid spread in the decade after its identification as a cause of cholera, *V. cholera* O139 has largely disappeared, with only scattered cases in Asia, having been reported since 2000 [51, 125].

Resistance in both *V. cholerae* O1 and O139 is not easily predictable in advance of a cholera outbreak. In endemic areas there may be multiple clones of either *V. cholerae* O1 or O139 circulating simultaneously, and these different clones may have differing antimicrobial susceptibilities [126–130]. In non-endemic areas, outbreaks usually result from introduction of a single strain of *V. cholerae* O1 or O139 [131], and most initial infections will be due to organisms with identical antimicrobial resistance profiles [131]. Over time, however, these epidemic strains may acquire (or lose) antimicrobial resistance. Isolates obtained from patients later in the epidemic may differ in antimicrobial resistance when compared to initial isolates [44, 132–135]. One report suggests that in endemic areas, screening environmental isolates using selective enrichment with a combination of antibiotics helps identify *V. cholerae* strains with new antibiotic resistance profiles that are likely to become epidemic [136]. But this hypothesis has yet to be confirmed with sequential observations.

Antimicrobial resistance in *V. cholerae* O1 and O139 is encoded by a number of mobile genetic elements [137]—plasmids [44, 106, 116, 132, 138–141], integrons [116, 134, 135, 141–145], and integrative conjugative elements or constin [123, 124, 143–146]—which can be acquired from other *V. cholerae*, including non-O1 or O139 serogroups which are in the aquatic environment where *V. cholerae* O1 and O139 reside, and from other gram-negative bacteria in the gut [117] (Table 61.2). These mobile elements are not stable [124]. With changing antimicrobial pressure and other ecological changes, resistance can be acquired and resistant strains quickly propagate, or resistance genes can be lost and susceptibility reestablished. Such ecological pressure also enhances the selection of isolates with chromosomal mutational changes in antimicrobial gene targets or antimicrobial efflux pump mechanisms [147, 148]—such as *V. cholerae* O1 isolates with diminished susceptibility, and clinical resistance, to the fluoroquinolones [36, 62, 149–152] (Table 61.2).

Table 61.1 Recent reports of resistance of *V. cholerae* O1 and O139 clinical isolates to antimicrobial agents potentially useful in the treatment of cholera

Abbreviation for antimicrobial agents: *AMP* ampicillin; *AMX* amoxicillin; *AZM* azithromycin; *CEP* cephalosporin agent, including cefepime, cefixime, cefotaxime, ceftazidime, ceftriaxone, or cefalothin; *CHL* chloramphenicol; *CIP* ciprofloxacin; *DOX* doxycycline; *ERY* erythromycin; *FUR* furazolidone; *NAL* nalidixic acid; *NOR* norfloxacin; *SXT* trimethoprim-sulfamethoxazole; *TET* tetracycline

Norfloxacin was the fluoroquinolone agent used for susceptibility testing by Wang, Mwansa, Rajeshwari; all others used ciprofloxacin as one of the fluoroquinolone agents evaluated

Dual values in a cell indicate resistant/intermediate susceptibility

All studies included in the table used the agar disc-diffusion method to determine susceptibility, with the exception of the studies by Wang, Rahmani, and Borkakoty which used broth-dilution MIC testing and studies by Smith, Islam, Ismail, and Quilici, which used the Etest

Acquisition and loss of resistance genes have been clearly illustrated by the experience with *V. cholerae* O139 infections in Asia. After the initial epidemics of cholera caused by *V. cholerae* O139 in the first half of the 1990s, this pathogen largely disappeared as a cause of diarrhea. When infections again reappeared in the latter part of the decade, the organism had lost its resistance to trimethoprim-sulfamethoxazole, one of its original defining characteristics [43, 126, 153–155]. This was as a result of the antibiotic resistance gene cluster in the SXT constin having been deleted [124]. Paradoxically, the clones of *V. cholerae* O1 that emerged after the *V. cholerae* O139 epidemic had subsided (*V. cholerae* O1 as a cause of cholera virtually disappeared during the height of the O139 epidemic in the Indian subcontinent) were resistant to trimethoprim-sulfamethoxazole as a result of acquisition of the SXT constin encoding resistance to trimethoprim-sulfamethoxazole [124]. Multidrug-resistant isolates of *V. cholerae* O1 containing the SXT element have now spread widely to other continents [134]. The most dramatic (and the most highly publicized) example of this spread is the introduction of *V. cholerae* O1 with multiple drug resistance into Haiti by UN staff from South Asia [156]. Within 2 years of the inadvertent introduction of this multiple resistant strain of *V. cholerae* O1, more than 600,000 persons had developed cholera, and more than 7000 had died from cholera [27]. This was in a country with a population of approximately 10,000,000.

What is the current status of antimicrobial resistance in *V. cholerae* O1 and O139*?* Making broad generalizations is difficult. Resistance patterns vary geographically because circulating strains in any area are likely to have evolved from parent strains that may have been the source of the initial epidemics, either acquiring or losing resistance genes. This results in a great variety of resistance phenotypes in areas where cholera is endemic or epidemic, as seen in Table 61.1, which summarizes recent reports from more than 20 countries of the resistance profile of *V. cholerae* O1 or O139.

There is no easily available and up-to-date source tracking resistance patterns. The published literature presents findings that even at the time of publication are likely to be—because of the time required for data collation, manuscript writing, and the publication process (even assuming electronic publication)—2 or more years old. In addition, reports are likely to be weighted to reporting resistance, which is presumably more publication worthy, than reporting the absence of resistance, thus providing a skewed picture of actual resistance patterns. The Weekly Epidemiological Record published by the World Health Organization is the one publication that regularly contains updates on cholera outbreaks as part of its "outbreak news" feature, but these reports most often do not contain information on antimicrobial susceptibility patterns.

In the first edition of this chapter 10 years ago, we noted that there was no available online source where resistance patterns for V. *cholerae* can be reported and the results obtained in a timely fashion. We remain unaware of such a resource currently. There have been efforts to coordinate activities for cholera prevention, control, and treatment. One such example is the Africa Cholera Surveillance Network—Africhol (http://africhol.org/)—funded by the Gates Foundation, which has published continent-wide reports of resistance [84]. But despite the increase in electronic communication in cholera-endemic sub-Saharan Africa—where the population of almost 1 billion persons has 500 million cell phone subscriptions (a 25-fold increase in the last 15 years)—access to contemporaneous information on resistance is not easily available, especially in rural areas. Even in Bangladesh, where cholera remains endemic and annually epidemic and the International Centre for Diarrhoeal Disease Research (icddr,b) treatment center maintains routine surveillance of resistance patterns of diarrheal pathogens isolated from patients, access to this information by healthcare workers in primary care settings remains problematic.

The current picture of resistance in *V. cholerae* O1 remains disconcerting (Table 61.1). Multidrug-resistant *V. cholerae* O1 is now commonplace in all areas where cholera is endemic. At the icddr,b treatment center, where approximately 12,000 patients with cholera caused by *V. cholerae* O1 and 450 with *V. cholerae* O139 were provided care in 2015 (relatively low numbers by historical standards [159]), virtually all isolates were resistant in vitro to trimethoprim-sulfamethoxazole and to tetracycline. Most had only intermediate susceptibility to erythromycin (and presumably to azithromycin as well), and virtually all isolates had diminished susceptibility and diminished clinical response to the fluoroquinolones [33, 160].

Fluoroquinolone in vitro susceptibility does not always equate to clinical efficacy. All *V. cholerae* O1 isolates at the icddr,b appear to be susceptible to fluoroquinolones when tested by either the disc-diffusion method (zone of inhibition >21 mm) or the agar dilution method (minimum inhibitory concentrations below the threshold level of <1 μg/mL that is used for defining resistance) [33, 161]. Globally, most *V. cholerae* O1 isolates remains susceptible to the fluoroquinolones when using these standard threshold levels (Table 61.1) with only occasional resistance being reported [60, 64].

From 1994 to 2012, however, the MIC [90] to ciprofloxacin of *V. cholerae* O1 increased 20-fold, from 0.012 to 0.250 μg/mL [33, 36]. At the same time isolates became frankly resistant to nalidixic acid, an earlier quinolone, with the MIC [90] for nalidixic acid increasing from 32 to ≥256 μg/mL. Isolates resistant to nalidixic acid by disc diffusion had a median ciprofloxacin MIC of 0.190 μg/mL compared to 0.002 μg/mL for nalidixic acid-susceptible isolates. Importantly, the rate of clinical success of single-dose

ciprofloxacin treatment of patients infected with nalidixic acid-resistant isolates was only 18 %, compared to 94 % for the treatment of patients with nalidixic acid-susceptible isolates [33]. Clearly, as with *Salmonella* [162] and *Neisseria gonorrhoeae* [163], applying the in vitro susceptibility breakpoints for the fluoroquinolones for *V. cholerae* O1 does not predict in vivo response to these agents during cholera.

In vitro susceptibility thresholds are derived in part from expected tissue and serum concentration of the antimicrobial agent and the relationship between those concentrations and the MIC for the pathogen under consideration. For cholera, the important determinant of efficacy is concentration in the gut lumen—which is the site of infection. Given high fluid volumes during cholera, gut concentrations of drug are quickly diluted. With single-dose therapy, concentrations of ciprofloxacin in the gut lumen can fall below the MIC of strains of *V. cholerae* with diminished susceptibility within 24 h of ciprofloxacin administration, thus explaining the relative lack of efficacy of single-dose therapy in these patients. Three-day therapy regimens with ciprofloxacin may be more effective than single-dose regimens in patients infected with strains of *V. cholerae* with diminished susceptibility, but clinical response is still not optimal [33, 164].

The decreased susceptibility to the fluoroquinolones among *V. cholerae* is invariably associated with frank resistance to nalidixic acid, and results from a single mutation in the *gyr*A gene coding the enzyme—DNA gyrase—which is the target for the quinolones [165]. Further mutations can then lead to frank resistance among the fluoroquinolones.

Resistance is not fixed. With diminished antimicrobial pressure, there is hope that susceptible isolates may again establish themselves, as both resistance plasmids and resistance genes within the SXT element are unstable [67]. In addition to the example of loss of resistance genotypes in *V. cholerae* O139, the experience at the icddr,b is that resistance to tetracycline fluctuates. Resistance rates among *V. cholerae* O1 reached over 80 % in the early 1990s, disappeared by the latter part of that decade, only to return in 2004, and then fluctuated greatly from year to year [81, 160]. All of the *V. cholerae* O1 isolates from 2006 to 2011 contained the SXT element, presumably still harboring sulfamethoxazole and trimethoprim resistance genes, thus accounting for their continued resistance to those two drugs. Fluctuations in tetracycline resistance were then due either to the loss of the tetracycline resistance genes from the SXT element or the transfer and then loss of the plasmid coding for tetracycline resistance.

The picture is not entirely grim. As can be seen in Table 61.1, in Africa most isolates remain susceptible to erythromycin [84], though it is not clear if they have diminished susceptibility to this agent and to azithromycin given that susceptibility thresholds for erythromycin in *V. cholerae* infections have not been well established [161]. Virtually all African isolates were susceptible to ampicillin, though there is very limited data on the efficacy of ampicillin in the treatment of cholera [32, 166]. The gut luminal concentration of ampicillin in relation to the MIC of *V. cholerae* O1 is not likely to be very high, which does not augur well for efficacy. Many isolates remain susceptible to chloramphenicol, but there is reluctance to reintroducing this drug into routine use given its known (if rare) hematopoietic toxicity.

But in some locations, the problem of resistance is exceedingly grim. In Mozambique, isolates from 2012 and 2013 were almost uniformly resistant to ampicillin, ceftriaxone, chloramphenicol, nalidixic acid, and sulfamethoxazole-trimethoprim. Half were resistant to tetracycline. This leaves only azithromycin as a known effective agent, or using a fluoroquinolone despite its lesser activity and poorer clinical response when used to treat strains that are resistant to nalidixic acid (Table 61.3). In a four-site study from 2010 to 2011 in Bangladesh, virtually all *V. cholerae* isolates were resistant to erythromycin and sulfamethoxazole-trimethoprim, a third were resistant to tetracycline, and a quarter were resistant to azithromycin (the latter based upon susceptibility breakpoints for *Staphylococcus*—breakpoints for azithromycin versus *V. cholerae* have not been established) [161]. Only 1 % were overtly resistant to ciprofloxacin, and though neither nalidixic acid susceptibility testing nor fluoroquinolone MICs determination was done, these isolates most likely had diminished susceptibility to the fluoroquinolones (Table 61.2).

2.2 Clinical Significance

Antimicrobial use in cholera is adjunctive therapy, rather than essential for cure. Because *V. cholerae* O1 and O139 are noninvasive and self-limited infections, the infectious process is in itself not lethal, i.e., there are no infection-induced inflammatory changes leading to cell death and tissue destruction. The lethal consequence of *V. cholerae* O1 and O139 is related to cholera toxin production and the intestinal fluid loss resulting from the effect of toxin and the effects of hypovolemia and shock on organ function. Replacement of fluids—either orally (for patients with mild disease) or both orally and intravenously (for patients with more severe cholera)—is lifesaving [185].

Antimicrobials can, however, reduce the volume of diarrhea by half to two-thirds, and duration of diarrhea by half or more [37, 185, 186] (Table 61.3). Without antimicrobial therapy, patients severely ill with cholera will purge approximately 750 mL per kg body weight after presenting for care; with effective antimicrobial therapy fluid loss can be reduced to 250 mL per kg body weight [37, 41, 42, 186]. In a 50 kg person, a 500 mL per kg difference amounts to 25 l during the course of their stay for treatment. With effective antimi-

Table 61.2 Mechanisms of resistance to antimicrobial agents commonly used in the treatment of *V. cholerae* O1 or O139

Agent	Period when resistance first commonly emerged	Genetic determinants and mechanism of resistance	Comment
Ampicillin and other ß-lactams	1970s	Conjugative plasmids, integrons, or integrative conjugative elements (ICEs) expressing ß-lactamases, including extended-spectrum ß-lactamases [167]	Although strains of *V. cholerae* resistant to ampicillin have waxed and waned in prevalence over the years, and limited surveys suggest that resistant strains are currently uncommon (Table 61.1), ampicillin is not routinely used for the treatment of cholera. Often surveys of resistance, and clinical laboratories that test *V. cholerae* from cholera patients, do not routinely include determination of ampicillin susceptibility, thereby lessening the likelihood that it will be used in clinical practice. It is also not one of the agents recommended by the World Health Organization for treatment of cholera [168]
Macrolides—erythromycin and azithromycin	1990s and 2000s	Multidrug efflux systems [169, 170] carried on conjugative plasmids, integrons, or integrative conjugative elements (ICEs)	Azithromycin, because of its higher concentrations at the site of infection and its inherently greater activity against the bacterial target, may retain activity even when there is diminished susceptibility to erythromycin. Resistance thresholds for these agents have not been well defined when used to treat *V. cholerae* O1 or O139 infections
Nalidixic acid	1990s	The presence of a single mutation in the quinolone resistance-determining region of *gyrA* which encodes the quinolone target enzyme DNA gyrase usually results in high-level resistance to nalidixic acid. Such a change can confer diminished susceptibility, but not frank resistance, in the fluoroquinolones [171]. High levels of resistance to fluoroquinolones require additional mutations—either in *gyrA* or *parC,* which also encodes a fluoroquinolone target enzyme, DNA topoisomerase	Resistance to nalidixic acid can be used as a screening test for identifying isolates with diminished susceptibility, but not frank resistance, to fluoroquinolones [33]. Infection with such isolates usually results in diminished clinical response to treatment with a fluoroquinolone [33]
Fluoroquinolones	1990s	Chromosomal mutations in genes *gyrA* and *parC* that encode the fluoroquinolone target enzymes DNA gyrase and DNA topoisomerase, respectively. Sequential mutations in these genes can incrementally decrease susceptibility to the fluoroquinolones [165]. These mutations can increase the MIC [50] by 100-fold, while isolates still remain susceptible using current threshold definitions (growth inhibited by ≤1 μg/mL of the fluoroquinolone) [33], or they can code for frank resistance (growth inhibited by <4 μg/mL). The transferable genetic element *qnrVC3* facilitates the selection of higher-level resistance mutations [172].The role of efflux pumps in resistance in O1 and O139 serogroups is uncertain [147]	Unlike with other antimicrobial agents, the direction of resistance in the fluoroquinolones has been a one-way street—only getting worse. To date, there has not been a reversion to increased susceptibility in areas where strains of *V. cholerae* O1 with diminished susceptibility have been identified. Of note is that strains with diminished susceptibility to fluoroquinolones but that are still considered susceptible using the threshold criteria of the Clinical Laboratory Standard Institute for either disc-diffusion or broth-dilution testing methods [161] are clinically resistant to fluoroquinolones, especially if used in a single dose [33]

Tetracycline	1970s	Conjugative plasmids that contain genes for multidrug resistance efflux pumps [173]	Tetracycline resistance was one of the first commonly identified occurrences of resistance in *V. cholerae* O1 [104, 105]. This is in large part because it had been the first antimicrobial agent commonly used for the treatment of cholera [174], and presumably ecological pressure resulted in selection of resistant strains. Tetracycline resistance is unstable, and susceptible strains can reemerge following periods when resistant strains have predominated
Trimethoprim-sulfamethoxazole	1970s	Conjugative plasmids, integrons, or integrative conjugative elements (ICEs) [104, 106, 124, 175, 176]. These transferable elements contain genes encoding variants of the dihydropteroate synthase or dihydrofolate reductase enzymes that are essential for bacterial folic acid synthesis. These variants are resistant to the effects of sulfamethoxazole and trimethoprim [177, 178]	As with other resistance determinants that are carried on transmissible elements, the carriage of these elements in *V. cholerae* is unstable. Thus resistance is not fixed. Susceptible strains can arise after resistant strains have emerged and have, for a period, become the predominant circulating strains

Table 61.3 Options for antimicrobial treatment of cholera in adults and children

Drug	Dose	Adult dose	Pediatric dose
Ampicillin	Multiple	Not evaluated	12.5 mg/kg body weight every 6 h for 3 days [166]
	Single	Not evaluated	Not evaluated
Azithromycin	Multiple	Not evaluated	10 mg/kg body weight daily for 3 days [179]
	Single	1 g [36]	20 mg/kg body weight [35]
Ciprofloxacin	Multiple	500 mg every 24 h for 3 days [180, 181]	Not evaluated
	Single	1 g [34]	20 mg/kg body weight [37]
Doxycycline	Multiple	100 mg twice (q 12 h) on day 1, then 100 mg once on days 2 and 3 [39]	2 mg/kg body weight twice (q 12 h) on day 1, then 100 mg once on days 2 and 3 [39]
	Single	300 mg [38]	4 mg/kg body weight [38, 39]
Erythromycin	Multiple	500 mg every 6 h for 3 days [180]	12.5 mg/kg body weight every 6 h for 3 days [182]
	Single	Not evaluated	Not evaluated
Tetracycline	Multiple	500 mg every 6 h for 3 days [180]	12.5 mg/kg body weight every 6 h for 3 days [166]
	Single	1 g [183]	Not evaluated
Trimethoprim-sulfamethoxazole	Multiple	160 mg of trimethoprim and 800 mg of sulfamethoxazole every 12 h for 3 days [184]	10 mg/kg trimethoprim and 50 mg/kg sulfamethoxazole per kg body weight every 12 h×3 days [182]
	Single	Not evaluated	Not evaluated

Resistance to all of the agents listed in the table is common. Selection of an agent for treatment of cholera depends on knowing the contemporaneous susceptibility pattern of *V. cholerae* in the locale where the infection occurred

crobial therapy, the duration of diarrhea is reduced from a mean of slightly less than 4 days to slightly less than 2 days.

The reduction in fluid losses, and the consequent reduction in fluid replacement needs, has important consequences for management of patients. In inexperienced hands, management of fluid replacement in severely dehydrated cholera patients can be problematic, with health care providers often not giving sufficient fluids, resulting in unnecessary mortality. In experienced hands, mortality in cholera should be 0.2 % or less [46]. Cholera mortality, overall, however, remains much higher than that [31, 187]. During epidemics, especially at the beginning of epidemics, mortality rates can be very high. Mortality was almost 50 % during a large outbreak of multiple drug-resistant *V. cholerae* O1 infection in Rwandan refugee camps [28]. At the beginning of the cholera epidemic following the earthquake in Haiti in 2010, the mortality rate exceeded 5 % [188], subsequently reducing to 1 % as international assistance came from the United States (a 2-h flight away) and other donor countries [27].

Inexperienced or overwhelmed staffs have difficulty judging the magnitude of fluid replacement required, most often underestimating the volume needed. Operational constraints—too many patients, too few staff, few if any trained staff, and lack of supplies—are also major impediments to successful treatment of patients with cholera. These problems are exacerbated by the fact that cholera is most common where capacity is most limited. By reducing fluid requirements and duration of illness, effective antimicrobial therapy can greatly reduce the logistic constraints of treating patients with severe cholera. In the end, effective antimicrobial therapy reduces not only the cost of treatment, but can substantially affect mortality.

Successful treatment of cholera has been complicated by the acquisition by the El Tor (named after the quarantine camp for returning Hajis in Egypt where it was first identified in 1905) biotype of *V. cholerae* O1 of genes coding for cholera toxin of the classical biotype of *V. cholerae* [189]. The El Tor biotype is the cause of the seventh pandemic of cholera, which began in 1961 in Indonesia and subsequently spread to all continents except Antarctica and continues to the current day (by definition—the beginning and ending of pandemics having somewhat more arbitrary bookends than even economic recessions). El Tor infection was less likely to produce severe dehydrating diarrhea than infection with the classical biotype—presumably because of lesser expression and lower virulence of the El Tor cholera toxin [190]. With the acquisition of cholera toxin of the classical biotype, infections with this variant El Tor strains are now producing more severe disease, with a higher fatality rate [110, 191]. This variant *V. cholerae* O1 El Tor biotype has now spread from Bangladesh, where it was first identified [189], to other parts of Asia [58, 192, 193], Africa [110, 194], and the Americas [195].

Treatment of cholera is empiric. In cholera-endemic areas or during cholera outbreaks, any adult with severe watery diarrhea is assumed to have cholera [185]. Standard therapy is replacement of fluids—orally if the patient is not dehydrated or intravenously if the patient is severely dehydrated

or has a high rate of purging (>5 mL/kg body weight/h) [196]. All patients with dehydration or a high purging rate should also be treated with an antimicrobial, with the choice of agent guided by preexisting knowledge of the susceptibility pattern of circulating strains [196, 197] (Table 61.3).

2.3 Laboratory Diagnosis of Resistance

Laboratory diagnosis of resistance in individual patients for the purposes of selecting an antimicrobial agent is not useful. The benefit of antimicrobial treatment is evinced when treatment is provided early in the course of illness, rather than after the 48–72 h required for isolation and susceptibility testing of the infecting strain of *V. cholerae* O1 and O139. Thus, the choice of antibiotic for treatment must be based on the knowledge of the pattern of resistance of circulating strains. Susceptibility testing should be used to determine the resistance profile at the beginning of a cholera outbreak and to monitor the resistance profile of circulating strains as part of surveillance of endemic or epidemic disease [198].

Disc-diffusion testing on agar plates is the most commonly used means for determining susceptibility [161, 198–200]. Disc-diffusion testing has the advantage of simplicity, low cost, and reproducibility, all crucial concerns when conducting antimicrobial susceptibility testing in the impoverished settings where cholera occurs. These settings often lack even the most basic diagnostic capacity, and field laboratories usually have to be established during epidemics so that isolation and susceptibility testing can be conducted, or the samples are sent to regional laboratories. These conditions preclude the use of more sophisticated automated systems, no matter how reliable they might be in other settings [161, 198, 201]. In any case, none of these automated systems is approved for use in *V. cholerae*. And although there have been numerous initiatives to develop a rapid diagnostic test for cholera, including point-of-care tests, none have attempted to identify antimicrobial resistance [202].

There are limitations to the use of the disc-diffusion method. The Clinical and Laboratory Standards Institute's (CLSI) interpretive standards for testing of *V. cholerae* are based on limited clinical information and often derived from other organisms [161]. Disc-diffusion testing of doxycycline does not accurately predict clinical response [34]. Patients infected with *V. cholerae* strains that are susceptible to doxycycline in vitro but resistant to tetracycline will not respond to doxycycline administration [34]. Therefore, tetracycline susceptibility testing, rather than doxycycline susceptibility testing, should be used when doxycycline is being considered for treatment of *V. cholerae* O1 or O139 infections. Disc-diffusion and broth-dilution susceptibility standards for testing of erythromycin or azithromycin are extrapolated from activity against *Staphylococcus* [161]. It is important, therefore, to determine clinical response when the macrolides are used for treatment, rather than solely relying on interpretive breakpoints, and adjust treatment protocols accordingly. The latter is easier said than done, as systematic evaluation of clinical response is difficult during the tumult and chaos surrounding a cholera epidemic, or even in endemic settings where cholera is treated.

Disc-diffusion breakpoints for fluoroquinolones are based upon activity against other *Enterobacteriaceae,* with a proposed zone of inhibition for susceptible organisms of ≥21 mm for ciprofloxacin [161]. The zone of inhibition is equivalent to an MIC of <1 μg/mL [161]. These in vitro definitions of susceptibility do not correlate with clinical response. Patients infected with *V. cholerae* O1 strains that were susceptible to ciprofloxacin using the proposed ciprofloxacin susceptibility disc-diffusion breakpoint, but that had ciprofloxacin MICs of 0.250 μg/mL when determined using the Etest, did not respond to ciprofloxacin treatment [33, 36]. Thus ciprofloxacin disc-diffusion results cannot be used for determining susceptibility in *V. cholerae* O1 and O139. And treatment with a fluoroquinolone of infections caused by organisms that have intermediate susceptibility to ciprofloxacin—defined as a zone of inhibition of 18–20 mm, or an MIC of 2 μg/mL [161]—will commonly result in clinical failure, even if a multidose, rather than single dose, therapy regimen is used [33].

Because fluoroquinolones are an important option for treatment of cholera and other enteric infections, it is important to have some method of determining susceptibility that is predictive of clinical response. One option is to use nalidixic acid susceptibilities—and consider all isolates resistant to nalidixic acid in disc-diffusion testing to also be clinically resistant to the fluoroquinolones [33]. The current CLSI guidelines do not contain interpretive standards for nalidixic acid activity against *V. cholerae*, but the CDC and WHO suggest that a zone of inhibition of <19 mm denotes resistance [198, 203].

Another option for determining fluoroquinolone susceptibility is to use the Etest to determine MICs. The Etest, though more expensive than disc-diffusion testing, has the same advantages as disc-diffusion testing of simplicity and reliability for use in developing country settings. Strains with an MIC to ciprofloxacin of ≥0.250 μg/mL should be considered clinically resistant [36]; strains with an MIC 0.002–0.025 μg/mL, though most commonly resistant to nalidixic acid by the disc-diffusion method, will have at least an intermediate clinical response to ciprofloxacin [33, 37, 204]; strains with a ciprofloxacin Etest MIC of ≤0.002 μg/mL will be susceptible to nalidixic acid by disc-diffusion testing and will be fully responsive to ciprofloxacin therapy.

Although the CLSI standards susceptibility testing of *V. cholerae* to erythromycin or azithromycin are based on experience with *Staphylococcus* [161], our experience is that isolates with an Etest MIC of ≤0.750 μg/mL to erythromycin

or an azithromycin Etest MIC of ≤0.125 μg/mL are clinically responsive to these agents [35, 36]. The erythromycin Etest for *V. cholerae* has shown good correlation with agar diffusion testing [205], but the in vitro susceptibility threshold suggested in that study—16 μg/mL—is in excess of the level at which a clinical response could be expected [205].

2.4 Treatment Alternatives

Most circulating strains of *V. cholerae* O1 remain susceptible to at least one antimicrobial agent known to be effective in the treatment of cholera (Table 61.3). Having no alternative agent in hand, however, is not a comfortable position to be in. The last new agent evaluated for the treatment of cholera is azithromycin, which we evaluated in 1999 [35]. Since then, there have not to our knowledge been any new antimicrobial agents identified for the treatment of cholera, nor could we identify any ongoing studies of antimicrobial agents on registers of clinical trials (www.clinicaltrials.gov). A drug to be useful in cholera must be active in vitro, attain high-concentrations in the gut lumen, be orally administered, be safe for use in children, and be inexpensive. No class of antimicrobial agents not already evaluated for use for treating cholera meets those criteria—even if cost is not considered.

Agents that appeared promising when we wrote the previous version of this chapter a decade ago—the nonabsorbable antimicrobial agent rifaximin [206], virstatin, a transcriptional regulator governing expression of cholera toxin and toxin-coregulated pilus [207, 208]—have not panned out.

There are suggestions that drugs that show in vitro resistance may still be effective when used clinically. A nonrandomized study of tetracycline showed some efficacy even in patients whose isolates were resistant in vitro [209]. Although single-dose ciprofloxacin was ineffective in the treatment of *V. cholerae* O1 infections with an increased MIC to ciprofloxacin [36], retrospective observations suggest that multiple-dose therapy may have some efficacy [33].

In one study supplemental zinc provided a very modest reduction in diarrhea duration and volume [210]. This is a somewhat surprising finding because zinc has most often not proved beneficial in the treatment of diarrhea of other etiologies [211] and because the biologic plausibility for such an immediate effect of zinc (within 48 h in a disease that does not involved tissue destruction) is problematic.

The mainstay of cholera treatment remains fluid replacement. If infections occur with strains that have become resistant to all currently known effective agents (a realistic possibility), there will be a commensurate increase in the need for intravenous fluids for patients with cholera. Given the immense logistic challenges that already occur in treating cholera, this will add an additional burden that may, for some patients, result in death.

2.5 Infection Control Measures

The most effective means of avoiding the problem of antimicrobial resistance in *V. cholerae* is to prevent cholera by the provision of potable water and improved sanitation [212]. Unfortunately, the majority of the world still lacks access to clean and safe water, and 1/3 of the global population lack basic sanitation facilities [213]. Both of course should be considered an essential human right, but investment in water and sanitation provision—both by local governments and international and binational funding agencies—remains inadequate [213].

Efforts for the provision of potable water from central water reticulation systems have proved problematic in rural areas of developing countries. There have been substantial efforts to dig tube wells, but maintenance and unintended consequences (high levels of arsenic in some tube wells in the Indian subcontinent, for instance) have proven to be stumbling blocks to these programs [214].

An alternative, or supplemental, solution for the provision of potable water has been efforts to sterilize water after it is collected but before it is ingested. These efforts have included using locally available materials—such as the cloth that is used for making *saris*—to filter out the copepods and other marine life that carry *V. cholerae* [215]. Other methods include the use of narrow-mouth (to prevent continued contamination) water containers to which chlorine is added [216] or the use of ceramic water filters [217]. All such methods recognize that centralized systems to provide potable water remain a distant aspiration for much of the world's population, especially those living in rural areas of poor countries. And the reality that methods for providing safe drinking water have to be inexpensive (for instance boiling water is too expensive for most persons lacking clean water) and adapted to poor, rural conditions.

The continued development and increased utilization of cholera vaccines are perhaps the most promising advances in cholera control since the previous edition of this chapter. Cholera vaccines have been under development and study for more than 100 years [204]. There have been incremental advances in their efficacy and in their simplicity of administration and storage, making them more appropriate for use in the poor regions of the world where cholera most often occurs. Both the level and duration of protection provided are less than ideal [218, 219]. Currently they are mostly used during epidemics in emergency situations—such as refugee camps or after natural disasters. A stockpile of cholera vaccine has been developed for use in emergencies [220], and this may ameliorate the severity of some of the worst cholera outbreaks during disasters and civil strife, such as the epidemics that occurred in Rwanda and Haiti [27, 28]. The routine use of vaccines where cholera is endemic probably awaits development of vaccines that provide longer-lasting immunity.

There are suggestions (but as of yet little empiric evidence) that antimicrobial therapy of patients with cholera might reduce cholera incidence by reducing secondary cases. Recent studies have suggested that *V. cholerae* organisms shed by patients with cholera are "hyper-infective" (have a much lower ID_{50}) when compared to environmental isolates [221]. Such transient hyper-infectivity of *V. cholerae* shed by patients may help explain the predilection of *V. cholerae* to cause explosive epidemics [222]. Modeling suggests that antimicrobial treatment of all patients with moderate or severe disease—who are shedding large volumes of cholera stool (which contains 10^{12} organisms per liter)—may itself reduce cholera death by 12% by reducing the number and severity of secondary cases [223]. When provided along with clean water and cholera vaccines, the combined effect on reducing the number of persons infected and dying during epidemics would be even greater [223].

But it remains unclear how the provision of expanded antimicrobial treatment would actually work to reduce secondary cases of cholera. Patients with moderate or severe cholera seeking care are usually kept at treatment centers or hospitals until their diarrhea has abated—whether or not they have received antimicrobials. The greatest risk for secondary transmission is likely to be before they have come to a facility for care, and it is unclear how antimicrobial treatment would be provided at home. Hospitals themselves can be a nidus of infection—either through nosocomial transmission [224, 225] or by untreated waste from medical facilities leading to exposure in surrounding communities [226, 227]. Presumably more comprehensive antimicrobial treatment of patients in treatment facilities might lessen the risk of secondary transmission occurring in or adjacent to these facilities. But the more obvious (but not always attainable) approach to these problems would be to enhance infection control and treatment of waste.

Because of the high rate of secondary cases in households (up to 50% of household contacts of a person with cholera also become infected), it has also been suggested that prophylactic antimicrobial therapy be administered to household members. A number of studies of this approach have reached varied conclusions: that multidose, multiday prophylaxis, but not short-course antimicrobial prophylaxis, can reduce transmission and secondary cases [228]; that excretion of *V. cholerae* in household contacts can be reduced [229]; that prophylaxis reduces the severity but not the incidence of secondary infections [230]; that prophylaxis transiently delays but does not prevent excretion in household contacts [231]; or that prophylaxis has minimal effect on secondary infections [232]. It is difficult to directly compare the results of these studies because they were conducted under different conditions using different drug regimens. Current guidelines do not recommend the use of antimicrobials for prophylaxis, considering the evidence to support their use is too weak [197, 233]. And the analyses to date—either for increasing the spectrum of patients treated or for prophylactic use—have not accounted for the potential impact of the expanded use of antimicrobials on selecting for resistant *Vibrio cholerae* (or other pathogens for that matter) [223].

3 Diarrheal Disease Caused by Vibrios Other Than *V. Cholerae* O1 or O139

3.1 Geographic Spread and Epidemiology of Resistance

Even more so than for *V. cholerae* O1 or O139, there is no systematic reporting or surveillance for resistance among vibrios causing non-cholera diarrhea.

Vibrio parahaemolyticus is the most common cause of non-cholera *Vibrio*-associated diarrhea, and reports on resistance are most common for this species. This includes a spate of reports on a recent increase in cases due to a distinct serotype that has spread globally [234]. Reports are especially common from Asia, perhaps because ingestion of raw or undercooked seafood can be a cultural norm, general levels of sanitation are poor, and the disease is more common there [9, 10, 85, 87, 235–237]. Infections can occur, however, wherever exposure to marine environments and seafood occur [8, 17, 18, 86]. Ampicillin and streptomycin resistance appears to be a common feature of most recently isolated strains of *V. parahaemolyticus* globally, with most strains remaining susceptible to trimethoprim-sulfamethoxazole, tetracycline, and the quinolones [9, 85, 86, 235, 238].

Diarrhea has been less commonly associated with infection with other *Vibrio* species, including *Vibrio vulnificus*, *Vibrio fluvialis*, *Vibrio mimicus*, and non-O1, non-O139 serogroups of *V. cholerae* [1]. The latter can rarely have virulence attributes—such as the capacity to produce cholera toxin—most commonly associated with *V. cholerae* O1 and O139, and result in clinical cholera [7]. Reports on resistance of these organisms are very sporadic, with many reports including environmental isolates, which may or may not be representative of isolates from patients [5, 101, 239–241].

3.2 Clinical Significance

With the exception of the uncommon non-O1, non-O139 *V. cholerae* isolate that produces cholera toxin, the self-limited diarrhea produced by these vibrios is modest in comparison to cholera. Infection with these organisms does not produce a clinical syndrome that would distinguish it from many other causes of diarrhea not requiring antimicrobial therapy, including viral infections. In the absence of a rapid diagnostic test that would allow for identification of the cause of

diarrhea as a non-cholera vibrio, empiric therapy would result in the overtreatment of many patients with diarrhea caused by organisms that do not require antimicrobial therapy. The only exception may be in foodborne outbreaks, where identification of an outbreak strain may allow presumptive treatment of subsequent infections. But even if infection with a non-cholera vibrio could be assumed or presumed, there have been no controlled studies demonstrating the benefit of antimicrobial therapy in diarrhea caused by non-cholera vibrios.

3.3 Laboratory Diagnosis of Resistance

The most recent (2015) CSLI guidelines for susceptibility testing of infrequently identified bacteria include guidelines for testing of non-cholera *Vibrio* species [161]. Both broth-dilution MIC and disc-diffusion testing are now considered appropriate and acceptable for determining susceptibility of these organisms, using standard media (cation-adjusted Mueller-Hinton broth or Mueller-Hinton agar, respectively) [161]. But as with *V. cholerae* O1 or O139, the scarcity of information on the clinical and bacteriologic response to antimicrobial agents means that the thresholds for susceptibility for these agents are often extrapolated from other organisms. The new guidelines continue to rely on extrapolation from other *Enterobacteriaceae* or *Staphylococcus* in the case of azithromycin. The use of derived breakpoints for these "orphan" organisms recognizes that because of their infrequent isolation, it was not possible to adhere to all the rigorous requirements for establishing breakpoints, especially correlation of the breakpoints with clinical response [242].

3.4 Treatment Alternatives

As with most watery diarrheas, the mainstay of treatment remains the replacement of fluids—orally for most patients or intravenously if dehydration is severe.

3.5 Infection Control Measures

Most infections are associated with poor food hygiene—either ingestion of undercooked seafood, lack of adequate hygienic measures to ensure that other foods are not fecally contaminated by a person with infection, or fecal-oral transmission from person to person. Standard hygienic practices could prevent most infections. But as noted in the section above on cholera, the absence of access to clean water and adequate sanitation continues to remain an obstacle to good hygienic practices in poor countries. In rich countries the emphasis has to be on limiting the risk from seafood that is improperly handled or consumed. This often boils (literally) down to the competing demands of the gourmand and sportsman versus the pesky (and often resented and ineffective) nagging of public health authorities.

4 Tissue-Invasive Disease and Septicemia Caused by Vibrios Other Than *V. cholerae* O1 or O139

4.1 Geographic Spread and Epidemiology of Resistance

Summarizing resistance patterns for vibrios causing invasive disease or septicemia is complicated by a number of factors. These include the relative rarity of their isolation from humans, the equal rarity of reports in the literature on susceptibility, the scarcity of reports on mechanisms of resistance, the diversity of geographic sites in which they are isolated, the absence for the most part of human-to-human spread and therefore the absence of a single strain causing multiple infections, and the absence until recently of standardized methods for susceptibility testing.

Tissue-invasive infections with non-cholera vibrios—especially *Vibrio vulnificus*, the *Vibrio* species most commonly causing tissue-invasive disease—are of greater concern than gastrointestinal infections with non-cholera vibrios because tissue-invasive infections are often lethal without effective antimicrobial therapy. Although the clinical syndromes of soft tissue infection and sepsis with these organisms may include diarrhea in the constellation of symptoms these patients have, it is the former (tissue invasions and sepsis) rather than the latter (diarrhea) that is the concerning feature of this illness.

Unlike *V. cholerae* O1 or 139, where acquired resistance is now widespread, resistance among halophilic (non-cholera) tissue-invasive vibrios appears to be less common. Most reports suggest that *V. vulnificus* is usually susceptible to the fluoroquinolones [89, 94–96, 100, 238, 243, 244], cefotaxime and other third-generation cephalosporins [89, 95, 96, 100, 238, 244, 245], trimethoprim-sulfamethoxazole [96, 100, 238, 243], tetracycline or minocycline [89, 95, 96, 100, 238, 244, 245], and imipenem [89, 96, 238]. Resistance to ampicillin was common at the time the clinical syndromes with these organisms were first characterized in detail [98, 99, 243, 246]. Resistance or intermediate susceptibility (MIC ≥ 1 μg/mL) to ampicillin remains common, as it does to first- or second-generation cephalosporins [89, 96, 100, 244, 245]. The addition of clavulanate to ampicillin or amoxicillin reduces the MIC of strains that are frankly resistant to the β-lactam, but only to an MIC [90] of 4 μg/mL [96]. Gentamicin has also shown at best intermediate activity against *V. vulnificus*, with a reported MIC [50] of 2 μg/mL

and MIC [90] of 4 μg/mL in two studies [89, 95], and MIC values double that in an earlier study [243].

Studies have also reported on the susceptibility of *V. alginolyticus*. For the most part the pattern of resistance is similar for that reported for *V. vulnificus* [96, 100, 247]. Reports on other tissue-invasive *Vibrio* species are even scarcer.

4.2 Clinical Significance

Unlike the noninvasive diarrheal disease caused by *V. cholerae* O1 and O139 or non-cholera vibrios, antimicrobial therapy is essential for survival in tissue-invasive *Vibrio* infections.

There are, as far as we are aware, no controlled studies of antimicrobial therapy for tissue-invasive *Vibrio* disease. Choice of therapy, therefore, is based upon relatively small series of patients, clinical experience, and extrapolation from in vitro or animal studies [89, 94, 95, 245, 248–250].

Because patients with invasive disease caused by non-cholera vibrios are often immunocompromised, and the disease can fulminate (illness onset within 36 h of exposure, 50 % or higher fatality rate in most series), antimicrobial therapy must be started when infection is first suspected based upon clinical presentation and epidemiologic profile (marine exposure in a patient with liver disease or is otherwise immunocompromised), and then adjusted based on subsequent laboratory findings. Drug regimens suggested based upon in vitro and animal studies include ciprofloxacin and cefotaxime [95], single-agent treatment with tetracycline [248], single-agent fluoroquinolone therapy [94], and a combination of cefotaxime and minocycline, which was synergistic in vitro [251, 252].

In recent years the largest series of patients reported in the literature have come from Taiwan. In general, the approach has been to treat with two drugs which are known to have good in vitro activity against non-cholera vibrios. One series reporting on 93 patients who received a variety of antimicrobial regimens suggested that the lowest fatality rate was achieved with a combination of a third-generation cephalosporin and tetracycline or a congener [16]. Patients treated with a first- or second-generation cephalosporin and an aminoglycoside did noticeably worse [16]. Another retrospective report of 89 patients with necrotizing fasciitis caused by *V. vulnificus* found that a combination of a third-generation cephalosporin and minocycline, or a fluoroquinolone and minocycline, did better than patients who received only a third-generation cephalosporin [253]. These studies, like all uncontrolled retrospective studies, are subject to the limitations inherent to such studies—selection of treatment regimens by severity of illness, changing antimicrobial regimens over time, and differences in provider care.

The current CDC treatment recommendations are doxycycline (100 mg PO/IV twice a day for 7–14 days) combined with a third-generation cephalosporin (e.g., ceftazidime 1–2 g intravenously or intramuscularly every 8 h), or a fluoroquinolone as a single agent [250]. Because of concerns about the putative toxicity of fluoroquinolones and doxycycline in children, the CDC recommends trimethoprim-sulfamethoxazole plus an aminoglycoside for this age group. Given the severity of the disease, the recommendation seems misplaced. Fluoroquinolones appear to be safe when used for limited periods in children, and tooth staining with tetracyclines in children is both not inevitable and not resulting in substantial long-term morbidity. Given the lethal nature of tissue-invasive *Vibrio* infections, the risk-benefit ratio for the use of these agents tilts heavily to benefit. In any case, invasive *Vibrio* infections in children are even more infrequent than they are in adults.

4.3 Laboratory Diagnosis of Resistance

As with *V. cholerae* O1 or O139 and non-cholera vibrios causing diarrhea, more complete recommendations for both disc-diffusion and agar dilution MIC testing now exist for tissue-invasive vibrios [161]. And as with *V. cholerae*, the susceptibility breakpoints are in large part extrapolated from the experience with other organisms.

4.4 Treatment Alternatives

Surgical treatment (incision and drainage, debridement of necrotic tissue, fasciotomies, or amputations) when required is an important adjunct to antimicrobial therapy in tissue-invasive disease [16, 88, 89, 249]. Other crucial supportive measures include maintenance of blood pressure (septic shock is a common manifestation of infection, especially in immunocompromised hosts) and measures to control disseminated intravascular coagulation.

4.5 Infection Control Measures

Patients with liver disease are at high risk for *V. vulnificus* septicemia. In the United States, raw seafood, especially oysters, is the most common vehicle of transmission [97]. Efforts should be made to warn all persons who are at high risk of disease to avoid eating raw or undercooked seafood. Posted warnings in restaurants or seafood shops are often not noticed by those at risk, either because they are not conspicuous or they are in a language that is not understood by the person at risk (English language signs for high-risk Hispanic persons with liver disease in the United States, for instance) [254].

In at least one report from Japan, many healthcare providers in endemic areas were also unaware of the risk to persons with hepatic disease from eating raw or undercooked seafood [255]. Thus, in addition to warnings in restaurants and food shops, it is important that the healthcare workers provide advice to patients who would be at increased risk of contracting invasive *Vibrio* infections. Other precautions include the use of gloves for all persons handling seafood commercially and warnings for sports fisherman or others involved in marine activities of the risk of infection if they have an open wound or abrasion or have a penetrating injury (such as with a fishhook). Given the ubiquity of such risk when fishing, it may be best to advise all persons with liver disease or who are immunocompromised to avoid such activities.

Antimicrobial Resistance in *Helicobacter* and *Campylobacter*

62

Patrick F. McDermott and Francis Mégraud

1 Introduction

Helicobacter and *Campylobacter* are Gram-negative spiral flagellated bacteria that inhabit and cause diseases of the gastrointestinal tract. Despite early microscopic observations of "*Vibrio*-like" organisms in blood, stool, and gastric contents, the role of these two genera in infectious disease was established in relatively recent times.

Campylobacter was first generally accepted as an important fecal pathogen in the 1970s, when improvements in culture methods made it feasible to systematically study the role of *Campylobacter* in diarrheal diseases [1]. Today, it is recognized as one of the leading causes of foodborne gastroenteritis in the USA and worldwide, with *Campylobacter jejuni* and *Campylobacter coli* being the most commonly isolated species [2]. It is also the most common antecedent microbial infection associated with Guillain-Barré syndrome [3]. *Campylobacter* are enteric commensals in several animal hosts, which include various avian and mammalian species from which most human infections are thought to originate.

Helicobacters can also be found in the intestinal tract of animals and humans, but the most important species, *Helicobacter pylori*, is essentially present in the stomach of humans where it induces gastritis [4]. Despite the fact that they commonly persist in the human stomach asymptomatically, infection by *Helicobacter pylori* is the most important risk factor for peptic ulcers and gastric MALT lymphoma in some subjects as well as for gastric adenocarcinoma [5].

Other gastric Helicobacters have been described in various animal species. The recognition of the importance of *Campylobacter* and *Helicobacter* in human illness has sparked intense research over the past 30 years into the epidemiology, microbiology, and treatment of diseases caused by these organisms. Each pathogen presents unique and fascinating challenges for intervention and control. While we await future advances in vaccines and other preventive measures, the clinical management of both pathogens relies on the availability of effective antimicrobial agents.

2 *Helicobacter pylori*

Approximately 80 % of adults in developing countries are infected with *H. pylori*, whereas fewer than 30 % are infected in industrialized countries [6]. Poor socioeconomic status is the major risk factor for infection [6]. Large families, small houses, lack of hygiene facilities, and poor education can favor transmission. Although the mode of transmission of *H. pylori* is not definitely proven, oral-oral or fecal-oral are the most probable routes of transmission and occur primarily in early childhood [7]. Family members, and particularly mothers [8, 9], play an important role in transmitting this infection. There is very little evidence for existence of viable sources of *H. pylori* outside the human host.

The standard clarithromycin-based triple therapy used to eradicate *H. pylori* in patients with symptoms is comprised of two antibiotics, most often clarithromycin (Cla) and amoxicillin (Amx), and a proton pump inhibitor (PPI) [10]. It was originally successful in 80–90 % of patients [11], but Cla resistance emerged and is currently the first cause of treatment failure [12]. Antibiotic resistance of *H. pylori* varies widely by geographic regions and among subpopulations within a region. As a result, alternative treatment regimens have been developed. Other antibiotics also used in combination include levofloxacin (Lvf) (as a fluoroquinolone) [13] or rifabutin (Rif) (as a rifampin) [14] or nitrofurans [15, 16]. The current recommendations for treatment [17] include

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_14

bismuth-based quadruple therapy, sequential therapy [18], and non-bismuth quadruple therapy [19].

Relapses of *H. pylori* infection are lower in developed than developing countries, with averages of 2.7 and 13 %, respectively, according to a meta-analysis of studies where the patients were followed for 24–60 months [20]. In developed countries, these relapses occur most often during the first year following eradication treatment and have been found to be essentially recurrences of the original infection. In contrast, during the following years, reinfections are mostly identified based on molecular typing. However, it is difficult to differentiate recurrence from reinfection, since some individuals may harbor genotypically different strains of *H. pylori* simultaneously. In addition, one could be reinfected by the same strain from the same source.

There is no "gold standard" for *H. pylori* diagnosis. The test most commonly used is histopathology which has the added value of showing the status of the gastric mucosa, but this technique is very much dependent on the expertise of the pathologist and on the quality of the biopsy specimen. Among the other invasive tests used, rapid urease test allows a quick and simple diagnosis but lacks sensitivity, and culture has the important advantage of allowing susceptibility testing of all antibiotics but is demanding for transport and for lab procedures. Molecular methods have been developed using PCR, real-time PCR, and FISH. These methods allow, in particular, the detection of point mutations associated with clarithromycin resistance. The noninvasive tests most often used are the urea breath test, serology, and stool antigen tests [21].

2.1 In Vitro Antimicrobial Susceptibility Testing and Interpretive Criteria for *H. pylori*

In the USA, the Clinical and Laboratory Standards Institute (CLSI) recognizes only the agar dilution susceptibility testing method for *H. pylori* [22]. This method requires a cell suspension equivalent to a 2.0 McFarland standard, Mueller-Hinton plates containing 5 % aged (>2 months) sheep blood, and incubation for 72 h in a microaerobic atmosphere at 35 °C ± 2 °C. *H. pylori* ATCC 43504 is the quality control (QC) strain. Currently, there are QC ranges for Amx, Cla, metronidazole (Mtz), and tetracycline (Tet), but interpretive criteria are established only for Cla (resistant breakpoint ≥ 1 μg/mL) [22]. While reproducible, this method is labor intensive and not amenable to regular testing of small numbers of clinical isolates. There is a need for a more rapid and affordable method for routine laboratory use.

In Europe, the European Committee for Antimicrobial Susceptibility Testing (EUCAST) also validated an agar dilution method with a few differences. Mueller-Hinton plates contain 10 % horse blood, the suspension has an opacity equivalent to a McFarland 4 standard, and the QC strains are CCUG 38770, 38771, and 38772 for Amx, Cla, and Mtz, respectively. The interpretative criteria for resistance are Cla, >0.5 mg/L; Amx, 0.12 mg/L; Tet, Lvf, and Rif, 1 mg/L; and Mtz, 8 mg/L (Table 62.1 [23]).

A variety of other methods have been examined for their suitability for testing antimicrobial susceptibility of *H. pylori*. These include a simplified version of the agar dilution method which tests only an antibiotic concentration equivalent to the resistant breakpoint, disk diffusion, the Epsilometer test (Etest, AB bioMérieux, Solna, Sweden), and broth dilution. Disk diffusion is generally not considered a good choice for slow-growing organisms such as *H. pylori,* since the antibiotic gradient decays over time. However, a study in France showed a good correlation between disk diffusion and agar dilution for testing macrolides, given the important MIC differences between susceptible and resistant strains. The cutoff value was established at 22 mm for Cla [24].

There are now other methods derived from the disk diffusion methods such as the Etest which was the pioneer, but others have followed, e.g., Minimum Inhibitory Concentration Evaluators (M.I.C.E.™, Oxoid, Basingstoke, Hants, UK). Etest uses a predefined stable gradient of 15 antibiotic concentrations on a plastic strip using dry chemistry technology.

Table 62.1 Proposed breakpoints for *Helicobacter* susceptibility testing

Antimicrobial agent	Organization	MIC (μg/mL)		
		S	*I*	*R*
Amoxicillin[a]	EUCAST	≤0.12	–	>0.12
Clarithromycin[a,b]	CLSI	–	–	≥1
	EUCAST	≤0.25	–	>0.5
Metronidazole[a]	EUCAST	≤8	–	>8
Rifampicin	EUCAST	≤1	–	≥1
Tetracycline[a]	EUCAST	≤1	–	≥1
Levofloxacin	EUCAST	≤1	–	≥1

[a]Standardized testing methods with quality control ranges available for *H. pylori* ATCC43504
[b]Only breakpoint validated by clinical outcome data. All others are based on ECOFFs and/or the presence of known resistance determinants

While Etest is relatively expensive in comparison to other susceptibility testing methods, it is much simpler than agar dilution and thus is often preferred in clinical settings. Several studies have evaluated the Etest relative to the agar dilution reference method for testing *H. pylori*. These studies suggest that, in general, the Etest correlates well with agar dilution except for Mtz for which the Etest generates higher MIC values [25]. Even when using agar dilution, Mtz susceptibility testing results have shown a lack of reproducibility including intra-laboratory testing [25]. The reason has not been clearly established but it may be linked to the lack of control of the redox potential. Other reasons could be the existence of hetero-resistant subpopulations [26] or infection by multiple strains which may occur in 15–20 % of patients in developed countries [27]. Broth dilution has the advantage of being adapted to automatization, the limitation being the difficulty to grow *H. pylori* in a liquid medium.

The limit of phenotypic methods lies essentially in the need to culture *H. pylori* which requires specific conditions to maintain its viability during transport, and takes time, a minimum of 3 days but up to 8–10 days if few bacteria are present. For these reasons, molecular methods detecting specific mutations associated with resistance have been developed, essentially for Cla for which *H. pylori* resistance was the main factor of failures of the triple therapy recommended all over the world since 1997 [28]. Another resistance important to detect is to fluoroquinolones, which can also be determined by molecular methods [29, 30]. The strong points are that gastric biopsies can be transported without specific requirements and that the test can be performed in a few hours. Details of these methods will be provided after a description of the resistance mechanisms.

2.2 Resistance to Specific Antimicrobials

Below we shall consider the different mechanisms of resistance to specific antimicrobials used to treat *H. pylori*-associated diseases.

2.2.1 Macrolide Resistance

Macrolides bind to the 50S subunit of bacterial ribosomes and interfere with protein synthesis by inhibiting the elongation of peptide chains [31, 32].

Cla is the macrolide of choice to treat *H. pylori* infection because of its bacteriological and pharmacological properties. Its metabolite 14OH Cla is also active [33]. When present, macrolide resistance concerns all of the drugs in the group. It is due to point mutations in the 23S rRNA gene [31, 34, 35], and not to adenine methylation like in the MLSb resistance type. The most common point mutations within domain V of the peptidyl transferase loop of 23S rRNA are adenine (A) to guanine (G) transition, rarely A to cytosine (C) transversion, at either of the two nucleotides position 2142 and 2143 in *H. pylori* coordinates (based on the determination of the transcription start site of *H. pylori* 23S rRNA) [35], corresponding to positions 2058 and 2059, respectively, using *Escherichia coli* coordinates. These mutations lead to a decrease in Cla binding to ribosomes. Other much less common mutations have been observed in the 23S rRNA, but their role in resistance has not been formerly established.

The A2142G mutation appears to be more frequent in *H. pylori* strains with an MIC >64 mg/L (65 %) than in those with an MIC <64 mg/L (35 %).

There are two rRNA operons on the *H. pylori* genome, but usually the mutations are found in both; heterozygotia is rare. These mutations appear spontaneously at a rate evaluated between 3.2×10^{-7} and 6×10^{-8}. This rate may be dependent on the inflammatory status at the mucosal level. The resistant mutants are then selected by administration of the macrolides [36]. The so-called primary resistance of *H. pylori* against macrolides is due to previous consumption of macrolides for diverse infections, notably respiratory tract infections. It varies widely according to the use of macrolides in the area or country. In Europe it varies from 5.6 to 36.6 % [37]. Unfortunately, there are no studies indicating the current rate for Cla resistance in the USA, but logically it should exceed the threshold of 15–20 %. The secondary resistance is that observed after treatment for *H. pylori* infection. It is normally in the range of 60–70 % [38].

Resistant mutants may remain in the stomach, depending on the cost of the mutation on the ability of the bacteria to grow and divide, i.e., the fitness of the strain [39]. Some studies showed that the mutations for Cla resistance had a low impact on the fitness of the strain, but other studies showed the contrary.

2.2.2 Fluoroquinolone Resistance

The fluoroquinolones (FQs) act via the inhibition of DNA gyrase and topoisomerase IV in DNA synthesis [29]. FQs are not generally used for primary eradication of *H. pylori*, but may be used in rescue treatment regimens when other antibiotics fail [40–43]. Resistance to FQs may be acquired rapidly; therefore, this group of agents should be used with caution for the treatment of *H. pylori*. In addition, FQs are not recommended for use in children. Primary resistance of *H. pylori* isolates to FQs varies from 4 to 28 % in Europe [37]. Secondary resistance is in the range of 50 % [44, 45].

In *H. pylori* strains, only the DNA gyrase is present and is comprised of two subunits encoded by the *gyr*A and *gyr*B genes. FQ resistance in *H. pylori* is essentially due to various mutations in the quinolone resistance-determining region (QRDR) of *gyr*A, the gene that encodes the A subunit of DNA gyrase [46, 47] as described for other bacteria [48]. Several types of base substitutions, usually resulting in a single amino acid change at Asp91 or Asn87 in the QRDR of

*gyr*A, are associated with an increase in MIC and with cross-resistance to other FQs [47]. However, there are FQ-resistant strains which do not harbor these mutations and for which the resistance mechanism remains to be elucidated.

The FQ essentially used is levofloxacin (Lvf) because it leads to good success rates when the strain is susceptible. In contrast, ciprofloxacin (Cip) is not recommended because of its low success rate [49]. Primary resistance to FQ is highly dependent on the FQ consumption in the area or country and varies widely. Secondary resistance is very common after failure of FQ-based eradication therapy. FQs with a higher activity at low pH, like sitafloxacin [50] and finafloxacin, may lead to better results. At this stage sitafloxacin is only available in the Far East, and finafloxacin is not yet available.

2.2.3 β-Lactam Resistance

β-Lactams interfere with cell wall peptidoglycan biosynthesis, resulting in lysis of replicating cells [51]. The only β-lactam used to treat *H. pylori* infection is amoxicillin (Amx) [52]. *H. pylori* strains for which Amx resistance has been well documented are extremely rare. One is the Hardenberg strain with a stable Amx resistance (MIC, 8 mg/L), reported in the Netherlands, isolated from a patient treated with multiple courses of Amx for a respiratory infection [53]. Mutations in the *pbp*1A gene have been found associated with this resistance, especially Ser414Arg [53]. The same results have been obtained by serial cultures of an Amx susceptible strain, with progressively increasing concentrations of Amx. In another study, the genes coding for PBP2 and PBP3 have been incriminated. Another type of resistance was described in Italy and the USA, but this resistance phenotype was unstable, i.e., it was lost after freezing of the strains [54]. This resistance could be due to a mosaicism of the C-terminal end of PBP1A.

When Amx resistance is found in the context of multiresistance, the mechanism is essentially a decrease in membrane permeability [55].

In the literature there are reports indicating relatively high prevalence of *H. pylori* resistance to Amx. When there is not a detailed analysis of the strains, we think that the results must be interpreted with caution because it could be a false resistance.

2.2.4 Tetracycline Resistance

Tetracycline inhibits protein synthesis by binding reversibly to the 16S rRNA in the 30S ribosomal subunits, blocking the binding of aminoacyl-tRNA, and thus stopping the synthesis of the growing peptide chains [56, 57].

In *H. pylori,* triple mutations in both copies of the 16S rRNA genes, ^{965}AGA^{967} to ^{965}TTC^{967} (*E. coli* numbering), were determined to be responsible for high-level Tet resistance [58, 59]. Single and double mutations at nucleotides 965 to 967 result in lower levels of Tet resistance [60, 61]. Decreased binding of Tet to *E. coli* ribosomes with nucleotide substitutions in positions 965 to 967 of the 16S rRNA has been demonstrated [62].

One study showed 16S rRNA mutations in only 54 % of Tet-resistant *H. pylori* isolates, while the remainder showed decreased Tet uptake [61]. A role for efflux was demonstrated by Li et al. who showed that inactivation of a Tet efflux homologue abrogated inducible Tet resistance [63].

While Tet-susceptible isolates of *H. pylori* show modal MICs of 0.5 μg/mL, Tet-resistant isolates show a wide range of MICs. The reason for this wide range of Tet MICs has not yet been clearly explained. Site-directed mutagenesis in *H. pylori* using limited (seven) substitutions within the triplet mutation suggested that single- and double-base-pair mutations mediate only low-level Tet resistance (MIC, 1–2 μg/mL) but also decrease growth rates in the presence of Tet [58]. This study thus offers a possible explanation for the prevalence of the ^{965}TTC^{967} mutation observed in clinical Tet-resistant isolates of *H. pylori*.

The prevalence of Tet resistance is usually low [37]. However, high levels have been described in Korea [64] and Brazil [65].

Further studies are necessary to understand exactly (1) how the mutations found in the Tet-resistant *H. pylori* are selected in vivo, (2) the reason for the presence of a wide variation in MICs in *H. pylori* isolates which contain similar 16S rRNA mutations, and (3) the possible importance of genes other than the 16S rRNA mutation which may contribute to Tet resistance.

2.2.5 Rifamycin Resistance

Resistance of *H. pylori* to rifamycins and its derivatives, especially rifampin (Rif) which is used in *H. pylori* rescue treatments, results from the inability of these compounds to bind to the β-subunit of RNA polymerase, which is encoded by *rpoB* [66–69].

A study performed on laboratory-induced mutants showed the presence of mutations at codons 524, 525, and 585 of the *rpo*B gene, i.e., at the same positions described for *Mycobacterium tuberculosis* and *E. coli.*

The prevalence of primary resistance to rifamycins is very low [37]. It concerns essentially strains isolated from subjects previously treated for tuberculosis [69].

2.2.6 Nitroimidazole Resistance

Nitroimidazoles include such compounds as metronidazole (Mtz) and tinidazole. Mtz is a prodrug that is reduced to a hydroxylamine derivative that damages DNA and appears to cause cell death by nicking DNA [70]. Nitroimidazoles, in general, and Mtz, in particular, were among the first groups of antibiotics to be used for the treatment of *H. pylori* [71].

Bacterial resistance to nitroimidazole compounds appears to be due to an inability to reduce the prodrug [52]. Mutations in *rdx*A, which encodes an oxygen-insensitive NADPH nitroreductase, resulted in Mtz resistance [72–74]. Later, Kwon et al. [75] and Jeong et al. [76] independently demonstrated that *frx*A, which codes for an NAD(P)H-flavin oxidoreductase, a paralog of RdxA, can also be involved in Mtz resistance. They showed that inactivation of *rdx*A alone resulted in moderate Mtz resistance (MIC, 16–32 μg/mL), whereas single mutations in both *rdx*A and *frx*A conferred higher levels of resistance (MIC >64 μg/mL). There is still controversy concerning the exact role of *rdx*A and *frx*A in Mtz resistance [77–79]. It has been suggested that other genes may play a role in Mtz resistance. Mutations in *rec*A [80] and *fdx*B (encoding a ferredoxin-like protein) [81], repression of pyruvate oxidoreductase (POR) and α-ketoglutarate oxidoreductase [82], and decreased transcription of *rdx*A and *for* (ferredoxin oxidoreductase) and possibly *por* and *fdx*B have all been implicated in Mtz resistance in *H. pylori* [83]. Therefore, diverse mutations in *H. pylori* may result in Mtz resistance. In addition, an efflux mechanism has been observed [84].

Primary resistance to Mtz is widespread. It is in the range of 30 % in developed countries and 70 % or more in developing countries because of the common use of this drug for parasitic infections. It increases after treatment failure.

2.2.7 Nitrofuran Resistance

The nitrofurans include furazolidone, nifuratel, and nitrofurantoin. Nitrofurans function through multiple mechanisms by binding to a variety of proteins. While none of these agents is commonly used in primary eradication of *H. pylori,* they may be used when primary treatment fails [15, 16]. The susceptibility of *H. pylori* to these antibiotics is not commonly tested; however, primary resistance to nitrofurans appears to be very seldomly found [85]. In other bacteria, resistance is associated with reduced nitrofuran reductase [86]. As yet, no studies have been published on the mechanisms of resistance to nitrofurans in *H. pylori*.

2.3 Molecular Methods of Detection

As was previously indicated, the genetic basis of antibiotic resistance in *H. pylori* involves essentially point mutations on the chromosome which can easily be detected by molecular tests. The most important clinical concerns relate to Cla resistance, and therefore a large number of molecular methods have been developed to detect this resistance, most being PCR based on the 23S rRNA gene.

Historically, PCR-restriction fragment length polymorphism was the first to be applied [31]. *H. pylori* specific primers were designed, and the amplicons obtained were submitted to restriction enzymes. Indeed, the point mutations associated with Cla resistance induced new restriction sites recognized by *Bsa*I or *Bsb*I, for example, leading to two bands instead of one [31]. This method has been surpassed by real-time PCR which gives a quicker result without the need to manipulate the amplicons produced, which is in itself a source of PCR contamination.

There are several formats of real-time PCR using either the SYBR Green I fluorophore or a biprobe in order to apply the fluorescence resonance energy transfer (FRET) principle. The amplification is performed directly on gastric biopsy samples and is followed by a melting curve analysis of the amplicons. The melting temperature is different between the wild-type strain and the mutants because of mismatches [87].

This method has even been applied to detect *H. pylori* and its resistance on stool specimens [88], but because of the difficulty to obtain purified DNA from stools, its sensitivity is not optimal. Kits using this technique are currently available.

There is also the possibility to detect *H. pylori* and its Cla resistance without DNA amplification by fluorescence in situ hybridization (FISH). Two probes with different labeling are used; one targeting the 16S rDNA to detect *H. pylori* and the other targeting the 23S rDNA to detect the mutations. This method can be applied on histological preparations [89].

When compared to phenotypic methods, molecular methods, especially those based on real-time PCR, lead to better results (1) for detection of *H. pylori*, compared to culture or histology, and (2) for detection of resistance, compared to the standard antibiogram. Indeed, real-time PCR allows a better detection when there is a mixture of susceptible and resistant organisms in a population. However, this heteroresistance may not be clinically significant. A study showed that resistance detected by Etest was a better predictor of the clinical outcome than PCR, since the extra hetero resistance detected could be eradicated [90]. Other studies are needed.

2.3.1 Fluoroquinolones

Real-time PCR based on melting curve analysis of the amplicons has also been applied to the detection of mutations associated with *H. pylori* resistance to Lvf. However, the results are more difficult to interpret because a number of silent mutations can be present in the QRDR [30]. For this reason a DNA strip test has been proposed. This method includes two steps: first, a multiplex PCR which allows an amplification of the relevant parts of the *gyr*A gene (for FQ resistance) as well as those concerning the 23S rRNA gene (for macrolide resistance) and, second, hybridization of the amplicons with biotin-labeled oligodeoxynucleotides immobilized on a strip and then visualized by a streptavidin-alkaline phosphatase reaction.

This test is commercially available (GenoType HelicoDR, Hain Lifescience GmbH, Germany). Its sensitivity and specificity were found to be satisfactory for both macrolide and FQ resistance [91].

2.3.2 Tetracycline

A PCR-RFLP was first developed using the Hinf1 restriction enzyme [65]. Later two real-time PCR were also proposed [92, 93], but, given the rarity of Tet resistance, they are rarely used.

2.3.3 Other Antibiotics

To detect the *rpo*B mutation associated with Rif resistance, no specific test has been developed, but it is possible to amplify and sequence the gene.

For Mtz, because a number of mutations present on different genes appear to be involved in resistance, there is no possibility to use a simple molecular test.

No molecular test has been developed to detect Amx resistance.

2.4 Clinical Significance of Resistance

H. pylori treatments are all complex. They are comprised of three or four drugs. The standard triple therapy consists of Cla, a PPI, and Amx or Mtz. Quadruple therapies containing bismuth salts or not are also used. Antimicrobial resistance is the first cause of failure of eradication therapies. However, this resistance does not concern all antibiotics at the same level. There is a clinical impact if the prevalence of resistance is high and if, in the case of resistance, there is a high rate of failure. In this respect, Cla is mainly concerned. We reviewed the clinical trials performed between 1999 and 2003 with the Cla-based triple therapy where Cla susceptibility was determined [94]. With PPI-Cla-Amx, the rate of success decreased by 70 % (from 87.8 % when the strain was Cla susceptible to 18.3 % when it was resistant). The same scenario was published later on by Fischbach et al. (66 % reduction) [95]. With PPI-Cla-Mtz, the decrease was only 47 %, i.e., from 97 % to 50 %. More recent studies confirmed these data. In contrast, in the same clinical trial review, the impact of Mtz resistance was less important: a decrease of 25 %, from 97 % to 72.6 % for PPI-Cla-Mtz [94] (35 % reduction in Fischbach et al. trial) [95] and from 89.4 % to 64.4 % for PPI-Amx-Mtz. When metronidazole is used in a quadruple therapy including bismuth such as the drug Pylera® as the 3-in-1 capsule containing bismuth subcitrate-Tet-Mtz administered with a PPI, only a 5 % decrease in success was observed for Mtz-resistant strains [96].

The other antibiotic for which the clinical significance is important is Lvf, as is pointed out in the few studies where susceptibility testing was performed. A 14-day treatment of PPI-Amx-Lvf led to 97.3 % eradication for FQ susceptibility strains but only 34.5 % for FQ-resistant strains in China [97]. In contrast, resistance to the other antibiotics is so rare that their impact cannot be determined.

3 *Campylobacter jejuni/coli*

Most cases of *Campylobacter* enteritis are sporadic in nature, occurring in individuals or small groups [98]. In infected humans, gastroenteritis is usually indistinguishable from that caused by other enteric bacterial pathogens such as *Salmonella* and *Shigella* [99]. In the USA, most studies to determine risk factors have identified consumption of unpasteurized milk, or contaminated food, especially poultry [100]. *Campylobacter* colonize a wide variety of mammalian and avian species. Among food animals, *C. jejuni* is most often isolated from chickens and cattle, while *C. coli* is more commonly isolated from pigs and turkeys [101]. Although the organisms can be transmitted directly to humans from farm animals [102] and pets [103–106], undercooked or mishandled fresh poultry meat is considered one of the main sources of infection [100, 107–112]. Therefore, interventions have focused on reducing the prevalence of *Campylobacter*-positive poultry flocks destined for human consumption or the freezing or further processing of meats derived from colonized birds [107].

Depending on host factors, inoculum size, and strain virulence, symptoms follow 1–7 days after ingesting the organism. In the only reported study with human volunteers [113], the infectious dose for some strains was as low as 500 organisms. Symptoms usually consist of diarrhea (with or without blood) with severe abdominal pain and fever. Headache, myalgia, and nausea are also common. Extraintestinal infections include cholecystitis, pancreatitis, hepatitis, bacteremia, and peritonitis [114]. Intestinal symptoms usually resolve within 3–7 days, and primary treatment consists of fluid and electrolyte replacement. As with other types of bacterial gastroenteritis, campylobacteriosis is usually self-limiting. Antimicrobial chemotherapy may be necessary only in cases of severe, relapsing, or invasive illness [99].

A number of different laboratory approaches have been examined for isolating *Campylobacter* on primary culture medium. Most clinical laboratories employ selective culture methods optimized for the recovery of *C. jejuni* and *C. coli*, which requires incubation in a microaerobic atmosphere (5 % O_2, 10 % CO_2, and 85 % N_2) at elevated temperatures (42 °C). Primary culture usually includes a medium containing one or more antimicrobial agents (e.g., cefoperazone) to inhibit competing enteric flora. Using this approach, Gram-stained smear showing small curved or spiral bacilli from typical *Campylobacter* colonies is a very reliable presumptive diagnosis. Additional chemical and genetic methods can be used to confirm the identification and determine species.

When antimicrobial therapy is indicated, erythromycin (Ery) or one of the newer macrolides such as Cla or azithromycin (Azi) is currently considered the drug of choice for treating culture-confirmed cases of campylobacteriosis [115]. Because symptoms are indistinguishable from salmonellosis and other diarrheal illness, a FQ is often given empirically in

adults [99]. In some countries, Tet and doxycycline (Dox) have been used therapeutically, but resistance to these agents can be common. Serious systemic infections are often treated with an aminoglycoside or a carbapenem [114, 116]. Although often used for other diarrheal disease, third-generation cephalosporins have not proven effective for treating *Campylobacter* infections, other than bacteremia due to *Campylobacter fetus* [117]. Clindamycin and tigecycline show potent in vitro activity and may prove valuable for treating infections.

3.1 In Vitro Antimicrobial Susceptibility Testing and Interpretive Criteria

The relatively recent recognition of *Campylobacter* as a common cause of diarrhea, the self-limiting nature of most infections, and the fastidious growth requirements of the organism all contributed to a delay in developing standardized in vitro susceptibility testing methods for this organism. In the absence of formal multi-laboratory trials, laboratories used an array of methods that differed in testing conditions and often lacked proper quality control parameters. The need for a standardized method became acute when surveillance studies began reporting rising resistances [118] that rendered empirical therapy less reliable.

A method based on agar dilution was the first testing process formally standardized, which consisted of quality control parameters for five antimicrobial classes [119]. A broth microdilution susceptibility testing method for *Campylobacter* was later developed, with quality control ranges for 14 antimicrobial agents [120]. This method requires testing in Mueller-Hinton broth supplemented with 2–5 % lysed horse blood and incubation in a humid atmosphere of 10 % CO_2 and 5 % O_2. Testing can be done at either 36–37 °C/48 h or 42 °C/24 h, the latter for testing thermotolerant species [119]. It is important that testing be done using a well-controlled gas mixture and constant temperature, since not all isolates will grow at incubation temperatures of 35 °C or 43 °C and not all commercially available gas-generating systems produce consistent results [120]. A similar method is published by the EUCAST using similar testing conditions and materials [121].

Other methods have been used to measure antimicrobial susceptibility. Disk diffusion testing is an attractive method because of its flexibility, convenience, and cost. The EUCAST recently published a disk-based testing method for *Campylobacter* that has quality control parameters for three antibiotics, Cip, Ery, and Tet [122]. A variation on the standard disk diffusion susceptibility testing is the use of commercially available antibiotic test disks to screen for resistance. This approach uses the lack of a zone of inhibition (growth up to the edge of the 6 mm disk) as an indicator of acquired resistance. The method works very well to predict resistant to Cip (5-μg disks) and Ery (15-μg disk) in *C. jejuni* [22] the drugs of choice for treating *Campylobacter* infections. The CLSI is currently reviewing a standard disk diffusion method with zone diameter interpretive criteria for Ery, Cip, and Tet.

As with *Helicobacter*, the Etest® method has been used to measure antibiotic susceptibility in *Campylobacter*. The Etest® is convenient and has the advantage of providing MIC values over a wide range (15 $\log_2$ dilutions). Using incubation at 36 °C, it has been observed that, for many agents, the Etest® endpoints fall one or more dilutions above or below those observed using agar dilution [123, 124]. The two methods compare favorably for some drugs, with a reported overall MIC agreement between Etest® and agar dilution ranging from 62 % [123] to 83 % [125]. The Etest® works well to predict strains above or below the clinical breakpoint, but is not consistent for monitoring drifts in MICs to detect emerging trends.

3.2 Interpretation of Susceptibility Testing Methods

There are two general approaches used to interpret antimicrobial susceptibility testing results, one for clinical purposes (clinical breakpoints) and one for monitoring purposes (epidemiological cutoff values, ECOFFs or ECVs). In order to establish clinical breakpoints, three data sets are normally required: (1) data on population MIC distributions generated using validated in vitro methods, (2) information on the pharmacokinetic/pharmacodynamic properties of the drug at the site of infection under specific dosing conditions, and (3) clinical outcome data on drug efficacy. Because controlled clinical studies are largely lacking, clinical breakpoints have not been formally established for *Campylobacter*. As noted above, formal clinical breakpoints are only established for a single anti-*Helicobacter* agent, clarithromycin.

In the absence of clinical outcome data, both the CLSI and EUCAST have resorted to ECOFFs for interpreting *Campylobacter* susceptibility data. ECOFFs are based only on MIC (or zone diameter) distributions. The standard ECOFF method distinguishes wild-type from non-wild-type populations, where the breakpoint is set at the highest MIC value of the susceptible population [126].

Both the CLSI and EUCAST publish ECOFFS (Table 62.2) along with in vitro susceptibility testing methods. Using population MIC data, the CLSI established tentative MIC breakpoints for resistance to Cip (MIC ≥ 4 μg/mL), Ery (MIC ≥ 32 μg/mL), doxycycline (MIC ≥ 8 μg/mL), and Tet (MIC ≥ 16 μg/mL) by defining resistance as the lowest MIC of the resistant population [22]. These values are highly correlated with the presence of known acquired resistance determinants and were established to help guide therapy.

Table 62.2 Interpretive criteria for *Campylobacter* susceptibility testing

Antimicrobial agent[a]	Organization	Disk content (μg)	Zone diameter (mm)[b]			MIC (μg/mL)		
			S	*I*	*R*	*S*	*I*	*R*
Erythromycin	CLSI	15	>6	>6	6	≤8	16	≥32
	EUCAST, *C. jejuni*	15	≥20	–	<20	≤4	–	>4
	EUCAST, *C. coli*	15	≥24	–	<24	≤8	–	>8
Ciprofloxacin	CLSI	5	>6	>6	6	≤1	2	≥4
	EUCAST	5	≥26	–	<26	≤0.5	–	>0.5
Tetracycline	CLSI	–	–	–	–	≤4	8	≥16
	EUCAST	30	≥30	–	<30	≤2	–	>2
Doxycycline	CLSI	–	–	–	–	≤2	4	≥8

[a]Erythromycin can be used to determine susceptibility to azithromycin (CLSI and EUCAST) and clarithromycin (CLSI, EUCAST), and tetracycline can be used to determine susceptibility to doxycycline (EUCAST)
[b]According to CLSI, no zone of inhibition (growth up to the edge of a 6-mm disk) indicates acquired resistance to macrolides and ciprofloxacin. Appearance of any zone of inhibition would require MIC determination for accurate categorization of susceptibility

ECOFFs are intended to identify non-wild-type bacteria for surveillance purposes, whereby MIC breakpoints are based on the highest MIC of the susceptible population. EUCAST publishes ECOFFS breakpoints for 14 antimicrobial agents including Cip (MIC>0.5 μg/mL), Ery (MIC>4 μg/mL), and Tet (MIC>2 μg/mL). These values are intended to identify strains with reduced susceptibility, which may include organisms still responsive to antibiotic therapy (i.e., not clinically resistant).

It should be noted that the EUCAST has decided to offer *Campylobacter* ECOFF values as clinical breakpoints in the absence of clinical outcome data [127]. While this lack of harmonization in determining and classifying breakpoints is being addressed by the CLSI and EUCAST, and although the breakpoints are many dilutions apart, it is important to note that when the two approaches are applied to the same *Campylobacter* data set, they match very well in categorizing strains with acquired resistance traits. This is because members of this genus generally exhibit broadly bimodal MIC distributions, with few intermediate phenotypes, for most antibiotics.

3.3 Clinical Significance of Resistance

Campylobacter enteritis is usually a self-limiting disease where treatment often consists of fluid and electrolyte replacement. Antimicrobial therapy is indicated for patients with high severe or relapsing enteritis, fever, or extraintestinal infections. In these cases, resistant strains limit therapeutic options.

There is conflicting evidence that antimicrobial resistance causes adverse health outcomes in patients with *Campylobacter* infections. The first report by Smith et al. [128] calculated that, among subjects treated with a quinolone, the median duration of diarrhea was 7 days if the causative strain was susceptible vs. 10 days if it was resistant. Engberg et al. [129] also observed a longer duration of illness in patients with a quinolone-resistant *C. jejuni* infection (median 13.2 days), compared to patients infected with a susceptible strain (median 10.3, $p=0.01$). Based on the analysis of 3471 patients with *Campylobacter* infections, quinolone resistance was associated with a sixfold increased risk of invasive illness or death within 30 days of infection [130]. Comparing infections caused by quinolone-resistant and quinolone-susceptible strains, one study estimated a 2-day increase in duration of diarrhea caused by resistant strains (9 vs. 7 days) [131]. This difference was greater among subjects who did not take antidiarrheal medications or antimicrobial agents (12 vs. 6 days). In contrast, Wassenaar et al. found no difference in duration of disease between cases caused by FQ-resistant and FQ-susceptible infections [132]. In a UK study of 653 patients, no association was detected in a cohort study of resistant and susceptible infections acquired abroad [133].

There are plausible biologically reasons to think that resistance and virulence might be linked, such as through the action of efflux pumps that have both antibiotics and bile components as substrates [134]. Hypothetically, increased bile resistance increases the survivability of the organism as it transits the upper gastrointestinal tract to colonize distal sites in the gut and cause illness, as it is a known colonization factor for *Campylobacter* [135]. In addition, cell culture assays showed that certain FQ-resistant mutants of *C. coli* and macrolide-resistant mutants of *C. jejuni* had higher rates of invasion, and in some cases cytotoxicity, of Caco-2 cells than their isogenic parental strain [134, 136]. The links between resistance and virulence are poorly understood, and further work is needed to understand the clinical importance of this phenomenon.

3.4 Resistance to Specific Antimicrobials

The genetic elements underlying *Campylobacter* resistance include the common chromosomal and plasmid-borne mechanisms present in other bacteria, namely, target-site modification, structural gene mutation, enzymatic inactivation, and energy-dependent drug efflux. Resistance to the major and relevant antimicrobial drug classes is presented below.

3.4.1 Macrolides

Macrolides are considered a primary treatment for *Campylobacter* infections. In many other countries, resistance is uncommon in *C. jejuni* with approximately 1–2 % of human isolates showing Ery MICs ≥8 μg/mL in the USA [2]; however, higher rates have been reported in other countries [137–140]. Resistance to macrolides (and other antimicrobials) is usually higher in *C. coli*, where resistance to Ery resistance ranges from 3 to 9 % in the USA [2].

In *C. jejuni* and *C. coli*, macrolide resistance is caused by target-site mutations and efflux. As in other bacteria, macrolide resistance results from target-site mutations in two positions of domain V (peptidyl transferase region) of the 23S rRNA genes. *Campylobacter* contains three copies of the rRNA gene; evidence suggests that at least two copies must be mutated to cause resistance [141]. Ribosomal gene mutations are present only in isolates with Ery MICs ≥32 μg/mL [142], supporting the use of 32 μg/mL as an MIC breakpoint denoting clinical resistance. Nucleotide changes at positions A2074 and A2075 are most common, corresponding in *E. coli* to positions 2058 and 2059 [143]. An A2075G transition is the most frequent mutation observed in clinical strains [141, 144–146]. It is usually present in all three copies of the 23S rRNA gene and can confer high MICs (>128 μg/mL) [141]. In vitro transformation experiments demonstrated that these mutations are readily transferred and stably incorporated into the chromosomes of susceptible *C. jejuni* and *C. coli* strains [141, 147]. Ribosomal mutations in *Campylobacter* can confer cross-resistance to tylosin, Azi, and Cla. Ribosomal mutations imparting Ery resistance also impact susceptibility to tylosin and Azi, but the MICs to those latter drugs are not always equivalent to those of Ery [148].

The only example of an extrachromosomal macrolide resistance determinant in *Campylobacter* is a plasmid-encoded rRNA methylase (*erm*). Until recently, this determinant had been found only in *C. rectus* [149]. A report by Wang et al. [150] examined 1554 *Campylobacter* from human and food-producing animal sources in China and found *erm*(B) in 58 strains, 57 of which were *C. coli* with 40 % on plasmids. This finding implies that the epidemiology of macrolide resistance might change in *Campylobacter*, with the possibility of horizontal spread.

It is known that efflux plays a role both in baseline Ery susceptibility levels and acts synergistically with other factors in elevated MICs conferring clinical resistance [142, 151]. The first report of a multidrug efflux system in *Campylobacter* was made by Charvalos et al. [152] using *C. jejuni* mutants selected on pefloxacin and on cefotaxime. The MDR phenotype included β-lactams, quinolones, chloramphenicol (Chl), and Tet, in addition to macrolides, but the genes were not identified.

In resistant clinical isolates, studies by Lin et al. [153] and by Pumbwe and Piddock [154] identified an efflux system encoded by the *cmeABC* locus. CmeB is related to multidrug transporters of the resistance nodulation and cell division (RND) superfamily, which includes AcrB in *E. coli* and MexB in *Pseudomonas*. This pump extrudes a variety of structurally unrelated antimicrobials, as well as detergents and dyes, and is widespread in *C. jejuni* and *C. coli* [155]. CmeABC also confers resistance to bile and is consequently required for intestinal colonization in chickens [156]. Inactivation of *cme* yielded a 4- to 16-fold reduction in Ery MICs in wild-type susceptible strains [153, 157]. Overexpression of *cmeB* also confers resistance to ampicillin, Chl, and Tet. A second macrolide efflux phenotype was revealed by exposure to the efflux pump inhibitor Phe-Arg-ß-naphthylamide (PAßN). This compound increased Ery susceptibility to wild-type levels in intermediately susceptible strains and to a lesser degree in resistant strains. Furthermore, it made a wild-type isolate hypersusceptible [151]. Further characterization of this phenotype confirmed that this pump was independent of *cmeB* [158]. Ge et al. examined ten putative *Campylobacter* efflux pumps, including CmeB and CmeF, which were identified based on sequence homology. Using site-directed mutagenesis, they found that only *cmeB* influenced susceptibility to Chl, Ery, nalidixic acid, and Tet [159]. Recent studies by Xia et al. [160] have taken a genomics approach to understanding macrolide resistance in *C. jejuni*. This work identified the upregulation of various other efflux pumps and other adaptive responses to macrolide exposure that will open new avenues to understanding macrolide resistance in *Campylobacter*.

3.4.2 Fluoroquinolones

In contrast to the relatively low and stable incidence of macrolide resistance to date, FQ-resistant *C. jejuni* has emerged in many countries over the past two decades [118, 143, 161, 162]. This rise has been attributed in part to the use of FQs (sarafloxacin and enrofloxacin) in poultry medicine. Endtz et al. reported that the emergence of FQ resistance in human *C. jejuni* infections in the Netherlands coincided with the approval of enrofloxacin in poultry in 1987 [161]. In Minnesota from 1992 to 1998, the number of quinolone-resistant infections increased from 1.3 to 10.2 %. In only 2 years after approval of the poultry FQ sarafloxacin in 1995, Cip^R among *Campylobacter* in Minnesota had doubled. Part

of this increase was attributed to the acquisition of resistant strains from poultry meats [128]. In a study examining *C. jejuni* infections among patients treated at Philadelphia-area hospitals, Nachamkin et al. reported Cip^R rising from 8.3 % in 1996 to 40.5 % in 2001 [163].

Among human *C. jejuni* isolates submitted to the CDC, Cip^R rose from 0 % in 1989–1990 [118] to 21.6 % in 2005 and was detected in about 25 % of isolates in 2012 [2]. In 2012, NARMS data also showed that 16.4 % of *C. jejuni* isolated from retail chicken breast samples were Cip^R [164]. The epidemiological and microbiological associations of Cip resistance *Campylobacter* in humans to selection in the poultry production environment prompted the Food and Drug Administration to withdraw approval of FQs in poultry [165], which became effective in September 2005.

Cip^R in *Campylobacter* results from a single topoisomerase mutation in *gyrA*, similar to that seen in *H. pylori*, but unlike *Salmonella* and *E. coli*, in which two mutations are required for clinical levels of Cip resistance [166]. The sufficiency of a single mutation in *Campylobacter gyrA* does not appear to be the case for all FQs. A study by Ruiz et al. [167] showed that moxifloxacin resistance required double topoisomerase mutations (Ile86, Asn90), suggesting that the efficacy of this newer FQ may be less subject to compromise by *gyrA* mutations. For Cip, however, the most common mutation associated with high-level MICs (≥32 μg/mL) is a substitution of Ile at Thr86 [168–171]. Mutations at Asp90 and Ala70 [168, 172] impart intermediate levels of Cip resistance (MICs 1–4 μg/mL). A small number of *Campylobacter* with resistance to nalidixic acid but not to Cip have been associated with a Thr86Ala substitution in *gyrA* [173]. Other *gyrA* mutations have been detected, but their respective contributions to quinolone resistance have not been measured [174]. No changes in GyrB have been associated with FQ resistance, and *C. jejuni* lacks the *parC* gene encoding topoisomerase IV [175]. The requirement of only a single-base change for high-level Cip MICs helps explain the rapid evolution of Cip^R in *Campylobacter* from animals [176, 177] and humans [178] exposed to FQs, as well as the widespread occurrence of Cip^R in retail raw meats [164] and human clinical isolates [2].

Multidrug efflux pumps, including CmeB, contribute to baseline levels of FQ susceptibility in *Campylobacter*. Wild-type susceptible isolates of *Campylobacter* display higher Cip MICs (0.125–0.5 μg/mL) than do wild-type strains of other Gram-negative enterics such as *E. coli* and *Salmonella* (MIC, 0.015–0.06 μg/mL). This intrinsic resistance appears to result from the constitutive expression of *cmeB* [153, 154]. Inactivation of *cmeB* by site-directed mutagenesis lowered Cip MICs in susceptible isolates to levels in the range for *E. coli* and *Salmonella* [153, 154]. Similarly, in resistant strains (also containing *gyrA* mutations), inactivation of the c*meABC* operon reduced Cip MICs near to that of wild-type isolates [179]. These findings show that, as with macrolide resistance [148], *cmeB* functions cooperatively in isolates with target-site mutations to maintain acquired high-level FQ MICs in *Campylobacter*. The expression of *cmeB*, and perhaps of *cmeF* as well as other uncharacterized loci [157], likely also contributes to acquired quinolone/multidrug resistance.

A putative efflux pump encoded by the *cmeG* gene has also been shown to play a role in both Cip and multidrug resistance in *C. jejuni* [180]. Insertional inactivation of *cmeG* caused a fourfold reduction in Cip MICs compared to the wild-type parental strain. Complementation in *trans* restored susceptibility to near wild-type levels and led to an eightfold increase in Cip MICs when *cmeG* was overexpressed.

3.4.3 Tetracycline

Tetracycline is considered as a second-line treatment for *Campylobacter*. It is used mainly in developing regions due to its low cost and low toxicity. Resistance to tetracycline has risen in many countries, making this class of antimicrobials less attractive for therapy. In Canada, Tet^R has increased from 7 to 9 % in 1980–1981 [181] to 43–68 % in 1998–2001 [182], with more recent resistant strains also showing even higher MIC values [183]. In the USA from 1997 to 2002, Tet^R ranged from 38 to 48 % [184]. In some countries, the proportion of resistant isolates is much higher [185, 186].

While efflux plays a role [159], Tet^R is mainly due to ribosomal protection mediated by the *tet*(*O*) gene product [187]. Tet(O) confers resistance by allosterically displacing tetracycline from its primary binding site on the ribosome [188, 189]. The *tet*(*O*) gene is prevalent in *Campylobacter,* worldwide, and is also present in various Gram-positive species. Alleles of *tet*(*O*) in *C. jejuni* usually impart MIC levels of tetracycline ranging from 32 to 128 μg/mL, but mutations in *tet*(*O*) can lead to MICs as high as 512 μg/mL [183].

The *tet*(*O*) gene is usually plasmid-borne [190] but may be located on the chromosome [191]. Two large self-transmissible Tet^R plasmids were sequenced by Batchelor et al. [192], one from *C. jejuni* and one from *C. coli*, which isolated on separate continents about 20 years apart. Both plasmids had mosaic sequence structures, with gene signatures suggesting origins in various commensal and pathogenic bacteria, including *H. pylori*. Remarkably, the two plasmids were 94.3 % identical at the DNA sequence level and are widespread in plasmid-containing Tet^R *Campylobacter* isolates [192]. Other plasmid vehicles, ranging in size up to 100 kb, also carry Tet^R determinants [190]. More recent whole genome sequencing data confirm *tet(O)* as the sole determinant for tetracycline resistance in *Campylobacter* to date [193].

3.4.4 Aminoglycosides

The genetic determinants that cause aminoglycoside resistance are well known and diverse in numerous bacteria. In *Campylobacter*, kanamycin resistance is due to the presence of the *aphA-3* gene [194], usually located on large plasmids (40 to >100 kb) that often carry *tet*(*O*) as well [195]. Integrons also have been identified in *Campylobacter* [196, 197], which in one report were found to be common (16.4 %) in isolates from different sources and to contain the aminoglycoside-modifying enzyme encoded by *aadA2* [198]. Spectinomycin/streptomycin resistance due to adenylyltransferases encoded by *aadA* and *aadE* has been associated with plasmids from human clinical isolates [199]. Resistance to the aminoglycoside streptothricin has been linked to the *sat4* gene product in animal and clinical isolates from Europe [200]. In isolates recovered from a poultry production house, integrons carrying the *aacA-4* gene were detected in isolates resistant to tobramycin and gentamicin [196].

In the USA, gentamicin resistance began a rapid upward trend mainly in *C. coli*, beginning in 2008 and peaking in human and retail chicken isolates in 2010 at 11.3 % and 12.8 %, respectively. Whole genome sequencing of two *C. coli* strains revealed an array of plasmid-borne resistances for gentamicin, kanamycin, streptomycin, streptothricin, and tetracycline on the pTet plasmid backbone [201]. GenR was conferred by a phosphotransferase encoded by *aph(2")-Ig*, along with *tet(O)*, *aad9*, *hph*, *aadE*, *sat4*, and *aphA*-3 [201].

3.4.5 Other Resistances

Most *Campylobacter* strains are resistant to β-lactam antimicrobials, with over 80 % of *C. jejuni* carrying β-lactamases [202]. *C. jejuni* are resistant to cefamandole, cefoxitin, and cefoperazone. Most isolates also are resistance to cephalothin and cefazolin, and resistance is variable for cefotaxime, moxalactam, piperacillin, and ticarcillin [203]. The most active β-lactam agents include ampicillin, amoxicillin, cefpirome, and imipenem [202]. Meropenem also shows good activity against *Campylobacter* [204] and has been recommended as a treatment option [205, 206].

Campylobacter are generally resistant to trimethoprim and sulfonamides, through mechanisms common to other bacteria. Trimethoprim resistance in *C. jejuni* is due to the chromosomal presence of acquired trimethoprim resistance-associated dihydrofolate reductase gene cassettes (*dfr1*, *dfr9*) [207]. Sulfonamide resistance in *Campylobacter*, as in other bacteria, results from mutations in dihydropteroate synthase [208], while streptomycin resistance is linked to the *rpsL* gene [209]. Chl resistance is rare in *Campylobacter* and results from acetylase activity encoded by *cat* genes [210]. In vitro selection identified a novel point mutation (G2073A) in all three copies of the 23S rRNA genes, which conferred resistance to Chl and florfenicol [211].

Antimicrobial Resistance of Anaerobic Bacteria

63

Itzhak Brook

1 Introduction: Infections Caused by Anaerobic Bacteria

Infections caused by anaerobic bacteria are common and may be serious and life-threatening. Anaerobes are the predominant components of the bacterial flora of normal human skin and mucous membranes [1] and they are a common cause of bacterial infections of endogenous origin. Because of their fastidious nature, they are difficult to isolate from infectious sites and are often overlooked. Their isolation requires appropriate methods of collection, transportation, and cultivation of specimens [2–5]. Treatment of anaerobic bacterial infections is complicated by the relatively slow growth of these organisms (which makes diagnosis in the laboratory only possible after several days), by the frequent polymicrobial nature of the infection, and by the growing resistance of anaerobic bacteria to antimicrobial agents.

Failure to direct therapy against anaerobic organisms often leads to clinical failures. The inadequate isolation, identification, and subsequent performance of susceptibility testing of anaerobes from an infected site can prevent detection of antimicrobial resistance. Therefore, correlation of the results of in vitro susceptibility and clinical and bacteriological response can be difficult or impossible [1, 3, 6]. This discrepancy occurs because of a variety of reasons. Individuals may improve without antimicrobial or surgical therapy and others can get better because of adequate drainage. In some instances of polymicrobial infection, eradication of the aerobic component may be adequate, although it is well established that it is important to eliminate the anaerobic pathogens [2, 7–14].

Reasons that may lead to failure in therapy include: variation in duration, severity, and extent of infection; lack of surgical drainage, or poor source control; patient age, nutritional status, and comorbidities; impaired host defenses; antimicrobial poor penetration and low levels at the site of infection; enzymatic inactivation of antimicrobials; low pH at the infection site; and inaccuracies in the susceptibility testing procedure.

Despite all of these factors, a correlation between the antimicrobial resistance of the anaerobic pathogens and poor clinical outcome has been reported in several retrospective studies [7–9]. There are a number of studies showing that inappropriate therapy will directly affect clinical outcome [10–15].

Microbiological semi-quantitation of all of the infecting flora is important; it is not necessary to eliminate all of the infecting organisms because reduction in counts or modification of the metabolism of certain isolates alone may be sufficient to achieve a good clinical response. Synergy between two or more infecting organisms, which is a common event in anaerobic infections, may confuse the clinical picture.

A prospective study of *Bacteroides* bacteremia reported the adverse clinical outcomes in 128 patients who were treated with an antibiotic to which the organism was resistant [14]. Clinical outcome was correlated with results of in vitro susceptibility testing of the isolates recovered from blood and/or other sites, and was determined by three endpoints: mortality at 30 days, clinical response (cure vs. failure), and microbiological response (eradication vs. persistence). The mortality rate among those who received inactive treatment (45 %) was higher than among patients who received active therapy (16 %; $P=0.04$). Clinical failure (82 %) and microbiological persistence (42 %) were higher for those who received inactive therapy than for patients who received active therapy (22 % and 12 %, respectively; $P=0.0002$ and 0.06, respectively). In vitro activity of agents directed at *Bacteroides* spp. reliably predicts outcome (specificity 97 %, and positive predictive value 82 %). The authors conclude that the antimicrobial susceptibility testing should be performed for patients whose blood specimens yield *Bacteroides* spp. [14].

Table 63.1 Anaerobic infections for which susceptibility testing is indicated

1. Serious or life-threatening infections (e.g., brain abscess, bacteremia, or endocarditis)
2. Infections that failed to respond to empiric therapy
3. Infections that relapsed after initially responding to empiric therapy
4. Infections where an antimicrobial will have a special role in the patients' outcome
5. When an empirical decision is difficult because of absence of precedent
6. When there are few susceptibility data available on a bacterial species
7. When the isolate(s) is often resistant to antimicrobial
8. When the patient requires prolonged therapy (e.g., septic arthritis, osteomyelitis, undrained abscess, or infection of a graft or a prosthesis)

These findings emphasize that it is important to perform susceptibility testing to isolates recovered from selected cases to guide therapeutic choices. Susceptibility testing should be performed to organisms recovered from sterile body sites, those that are recovered in pure culture, and isolates that are clinically important and have variable or unique susceptibility (Table 63.1). The standardization of testing methods by the Clinical Laboratory Standards Institute (CLSI) (Wayne, PA) allows for comparison of resistance trends among various laboratories [15–17]. Organisms that should be considered for individual isolate testing include highly virulent pathogens for which susceptibility cannot be predicted, such as *Bacteroides*, *Prevotella*, *Fusobacterium*, and *Clostridium* spp., *Bilophila wadsworthia*, and *Sutterella wadsworthensis*.

The routine susceptibility testing of all anaerobic isolates is very time-consuming and is not cost-effective. However, susceptibility testing should be performed for epidemiological and survey purposes for a limited and selected number of anaerobic isolates. Antibiotics tested should include penicillin, a beta-lactam plus a beta-lactamase (BL) inhibitor combination, clindamycin, metronidazole, and a carbapenem (i.e., imipenem, meropenem, or ertapenem). If needed, ancillary susceptibility can be performed for cefoxitin, tigecycline, and moxifloxacin that have approved anti-anaerobe indications.

Antimicrobial resistance among anaerobes has consistently increased in the past 30 years and the susceptibility of anaerobes to antimicrobials has become less predictable. The most commonly isolated antibiotic-resistant anaerobes are members of the *Bacteroides fragilis* group [18]. Resistance to several antimicrobial agents by *B. fragilis* group species and other anaerobic Gram-negative bacilli (AGNB) has increased over the past decade [15–17, 19–22]. Resistance has also increased among other anaerobes such as *Clostridium* spp. that were previously very susceptible. This increase makes the choice of appropriate empirical therapy even more difficult. Resistance patterns have been monitored through national and local surveys, but susceptibility testing of anaerobic bacteria at individual hospitals is rarely done [20].

2 Susceptibility Patterns of Anaerobic Bacteria

The increase in antibiotic resistance among anaerobes generated extensive studies of the mechanisms of resistance and resistance-gene transfer. These investigations brought about more insight into the causes of the rapid development of resistance. The observed resistance patterns to different antibiotics vary among the different groups of organisms as variations in the mechanisms of resistance exist.

2.1 Antimicrobial Resistance of Specific Anaerobic Species

Resistance among some anaerobes and especially *B. fragilis* group to all classes of antimicrobials has increased significantly over the last few decades [23–26]. Ongoing in vitro surveillance studies in the USA have reported significant increases in resistance among the *B. fragilis* group strains since the 1980s [27, 28]. These studies observed that there are unpredictable variations between medical center in susceptibility patterns. Variations in clindamycin activity were observed amongst different Chicago area hospitals [29]. Geographic area, sources of isolates, or quality control (QC) reading variations may also cause discrepancies even when the same methodology is employed. Caution must therefore be used in extrapolating survey report susceptibility data to an individual patient.

All anaerobes are resistant to aminoglycosides and sulfamethoxazole-trimethoprim. Chloramphenicol resistance is extremely rare although there is clustering of MICs around the breakpoint for some strains. When resistance is detected, it is due to inactivation of the drug by nitroreduction or acetyltransferase; this agent is also rarely used clinically in the USA due to potential hematopoietic toxicity.

2.1.1 *Bacteroides fragilis* Group

The *B. fragilis* group has 23 species; *B. fragilis* generally being the most susceptible to antimicrobials, although greater than 95 % are resistant to penicillin mostly due to BL production. A survey of 5223 *B. fragilis* group isolates from ten geographically US medical centers analyzed the trends from 1997 to 2004 using the reference agar dilution method [28]. The species isolated were *B. fragilis* (52.1 % of isolates), *B. thetaiotaomicron* (18.7 %), *B. ovatus* (10.4 %), *B. vulgatus*

(5.9 %), *Parabacteroides distasonis* (5.2 %), *B. uniformis* (3.2 %), and other species (4.5 %). Unexpectingly, the study found an increased susceptibility over the study period with decreases in geometric mean MICs for imipenem, meropenem, Piperacillin/tazobactam, and cefoxitin. *B. fragilis* was more susceptible to antimicrobials than the other species, while *P. distasonis* was the most resistant to beta-lactams. There was, however, an increase in geometric mean MICs to clindamycin and moxifloxacin for some isolates.

Of the ureidopenicillins, piperacillin is the most active against the *B. fragilis* group, even though susceptibility has declined from approximately 90–70 % over the study period [28]. Beta-lactam-resistant penicillins (e.g., oxacillin, nafcillin) and first-generation cephalosporins are not active against these organisms. Beta-lactam/BL inhibitor (BL/BLI) combinations, such as ampicillin/sulbactam, amoxicillin/clavulanate, ticarcillin/clavulanate, and piperacillin/tazobactam, are effective against nearly all *B. fragilis* group strains, with <2 % resistance [30, 31]. A study from Taiwan [25], however, reported 48 % resistance to ampicillin/sulbactam of *B. fragilis* group isolates. A European survey [26] observed a 10 % resistance of *Bacteroides* species to both amoxicillin/clavulanate and piperacillin/tazobactam.

Cefoxitin and cefotetan are generally active against *B. fragilis* but the latter is much less effective against the other members of the *B. fragilis* group [13, 26, 32]. Clindamycin resistance of about 40 % is reported against *Bacteroides* spp. worldwide [25, 28, 30, 31]. Chloramphenicol, metronidazole, tinidazole, and the carbapenems (imipenem, ertapenem, doripenem, and meropenem) are generally active against all members of the *B. fragilis* group [28, 33] although imipenem- and metronidazole-resistant strains have been recovered [25, 34]. A recent report from Taiwan [15] found the rates of nonsusceptibility to imipenem and meropenem was 7–12 % for *B. fragilis* and 3–7 % for *B. thetaiotaomicron*. Only five clinical cases of metronidazole resistance have been reported worldwide so far [34].

Resistance to fluoroquinolones in *B. fragilis* group species and other anaerobes is increasing. Trovafloxacin was approved for therapy of anaerobic infections in 1994 but is no longer used because of toxicity concerns. Moxifloxacin is also approved for intra-abdominal and skin and soft tissue anaerobic infections and can have good in vitro activity against *B. fragilis* and a broad range of other anaerobes but less so against *B thetaiotaomicron* [8, 28, 35]. Several studies reported an increase of *B. fragilis* resistance [29, 32, 36].

2.1.2 *Prevotella* and *Porphyromonas*

Prevotella and *Porphyromonas* species are more susceptible to antimicrobials than the *B. fragilis* group. Resistance due to BL production is 50 % in the USA and 94 in Europe [2, 37] and Taiwan [25], and to piperacillin, cefoxitin, and cefotetan ranges from 10 to 30 % [30, 38]. About 8–17 % of *Porphyromonas* spp. strains produce BL [37, 39]. Both genera are uniformly susceptible to carbapenems, metronidazole, and chloramphenicol, although clindamycin resistance has been observed in a few of strains [40].

2.1.3 Other Anaerobic Gram-Negative Bacilli

Penicillin resistance in *Fusobacterium nucleatum* has increased in children due to BL production and related to exposure to antimicrobial agents [41, 42]. A European survey reported 11 % of *Fusobacterium* species to produce BL [26]. More than 90 % of *Fusobacterium* spp. are susceptible to cephalosporins and cephamycins [30, 31]. Four percent of fusobacterium spp. were "nonsusceptible" to imipenem and 7 % to meropenem in a study from Taiwan [25]. *Bilophila wadsworthia* frequently produces BL, but is generally susceptible to clindamycin, cefoxitin, BL/BLI combinations, carbapenems, and metronidazole. *Sutterella wadsworthensis* may demonstrate resistance to clindamycin, piperacillin, and/or metronidazole.

2.1.4 Gram-Positive Organisms

Non-spore forming Gram-positive bacilli. The *Eubacterium* group, *Actinomyces*, *Propionibacterium*, and *Bifidobacterium* are generally susceptible to beta-lactam antimicrobials. *Lactobacillus* spp. exhibit wide species variably in susceptible patterns to cephalosporins and other agents; penicillin and ampicillin are frequently active [43]. There are no breakpoints for vancomycin and anaerobes. However, it has very good in vitro activity against all *Propionibacterium* spp., *Actinomyces* spp., *Eubacterium* group species, anaerobic Gram-positive cocci, and some *Lactobacillus* spp. vancomycin is much less effective against *L. casei* and several other species [43]. Linezolid, daptomycin, and telavancin also possess excellent in vitro activity against most anaerobic Gram-positive species. Most non-spore forming Gram-positive rods are resistant to metronidazole. Moxifloxacin has good activity against *Actinomyces* species, including *A. odontolyticus* and *A. viscosus*, *Pseudoramibacter alactolyticus*, and *Eubacterium limosum* and a variety of lactobacilli with MIC_{90}s <2 μg/mL (36.37). Most *Eggerthella lenta* and *Lactobacillus plantarum* were susceptible to moxifloxacin, there was strains variability and resistance in some isolates.

2.1.5 Clostridia

Clostridium perfringens is generally susceptible to most anti-anaerobic antimicrobials, as well as fluoroquinolones [44]. However, *Clostridium clostridioforme* and *C. innocuum* and *C. difficile* have variable susceptibility [31, 43, 45] and can resist clindamycin, fluoroquinolones, and beta-lactams, but not metronidazole. *C. difficile* is universally susceptible to metronidazole and vancomycin although there has been some MIC creep [19]; The MICs of *C. innocuum* to vancomycin is 8–32 μg/mL [43].

2.1.6 Gram-Positive Cocci

These Gram-positive cocci are very susceptible to all beta-lactams, BL/BLI, cephalosporins, carbapenems, chloramphenicol, and metronidazole [30, 31, 43]. Fluoroquinolone and clindamycin resistance is increasing among skin and soft tissue infections isolates [19]. Streptococci *milleri* group are always resistant to metronidazole.

3 Susceptibility Testing and Their Interpretation

The antibiograms of anaerobes have become increasingly unpredictable and multidrug-resistant clinical isolates are emerging confounding the assumption of foolproof empirical anti-anaerobic therapy [5, 46, 47]. Resistance to even the most effective antimicrobials such as BL/BLI, carbapenems, and metronidazole is documented [46, 48, 49]. Furthermore, there are clear differences in the geographic patterns of resistance, and resistance patterns in various hospitals within the same city [28]. Multidrug-resistant *B. fragilis* group strains have been increasingly reported [6, 11, 14, 22, 50]. Suboptimal therapy was found to select for emergence of antibiotic resistance and induce transfer of resistance determinants and more isolates are manifesting multiple resistance [21, 46].

These factors emphasize the need for antimicrobial susceptibility testing of anaerobes as well as periodic surveillance antimicrobial susceptibility studies to detect geographic or temporal trends. In the last few decades, testing methodologies used have been standardized. The most appropriate susceptibility testing method may differ depending on whether the test is performed for a specific isolate in a hospital laboratory (or by a commercial laboratory) or whether surveillance testing is performed at a hospital or reference laboratory [51].

3.1 Standardization of Testing

The US Clinical and Laboratory Standards Institute (CLSI) evolved from a voluntary consensus organization in 1967 to become a World Health Organization Collaborating Center for Clinical Laboratory Standards and Accreditation. CLSI has standardized the anaerobic susceptibility testing and has published documents for anaerobic susceptibility testing (also called M11) [16]. CLSI policy does not allow it to advocate any commercial technique; it presents two reference methods (agar dilution and broth microdilution) and underscores that other methods such as gradient techniques (generally referring to Etest®) or commercial broth microdilution plates can be used as long as equivalence to the reference methodology are established. CLSI presently recommends the broth microdilution method only for the testing of *B. fragilis* group because many other anaerobes will not consistently grow well in broth media.

Surveillance studies that are done in reference laboratories throughout the world commonly use the CLSI method (see below). The most recent document, M11-A8 was published in 2012 [16]. The CLSI reference standard is not for testing single isolates; it provides a standard against which other methods can be measured.

The European Committee on Antimicrobial Susceptibility Testing (EUCAST) has its own breakpoints which are not always identical to those of CLSI [52]. The EUCAST does not specify a testing method for anaerobes. Most susceptibility studies from Europe use CLSI methodology, although breakpoint interpretation is often based on EUCAST recommendations and which lead to differences in reported resistance rates.

Testing methods from Argentina [53] and Japan [54] have been published, which are based on CLSI methodology. European surveillance studies have also used CLSI methodology and frequently include both CLSI and EUCAST breakpoints [4, 51]. Some reports refer to other methods documents; a recent German multicenter study used a specific German testing methodology [47]. The differences between different methods may seem trivial; however in instances where minimal inhibitory concentrations (MICs) cluster around breakpoint values, minimal changes in MICs (due to differences in media, inoculum or endpoint reading method) may generate a perceived significant differences in resistance rates.

3.2 Surveillance Tests for Specific Hospitals or Geographic Regions

Surveillance tests have been performed for several decades by groups worldwide and illuminate overall general trends [18, 22, 25, 28, 47, 55]. However, the data do not necessarily reflect the patterns of specific patients or hospitals. Because of this, CLSI recommends that hospitals conduct at least annual surveillance antimicrobial susceptibility testing to find out their local patterns. The numbers and choice of species of strains tested should reflect the frequency with which they are recovered. At least 50–100 strains should be tested to get an accurate pattern of local isolates, which should include isolates from different body sites. It is recommended that at least 20 isolates of *Bacteroides* spp. and ten from other frequently isolated genera should be tested. The strains should be sent to a reference laboratory for testing if the expertise is not available in the hospital clinical laboratory.

Reference laboratories may use the CLSI-approved methods for the antimicrobials and adjust the tested antimicrobials to reflect the hospital's formulary. Ideally the test should

include at least one agent from each antimicrobial class, even if it is not part of the hospital's formulary.

The results of the surveillance study should be recorded so that trends in emerging resistance may be recognized. If routine surveillance testing cannot be performed, hospitals should summarize their antimicrobial susceptibility test results and generate a hospital-specific antibiogram that can be used if needed. A 2008 survey of clinical hospital laboratories in the USA [20] found that less than half of the laboratories did any anaerobic testing, either in-house or testing sent to an outside laboratory.

3.3 Testing in a Clinical Setting

Susceptibility testing may not be needed for many routine clinical isolates. The CLSI suggests testing isolates from brain abscess, blood, endocarditis, osteomyelitis, arthritis, and infection of prosthetic devices or vascular grafts (Table 63.1). Also, any organism recovered from normally sterile body sites should be tested (if they are not contaminants). Also isolates from patients undergoing long-term therapy, from a therapy failure or in a case in which the therapeutic decisions will be influenced by the results, should be tested.

Organisms to test should include those that are likely to be the most resistant (such as *B. fragilis* group species) or highly virulent (certain *Bacteroides*, *Prevotella*, *Fusobacterium*, *Clostridium*, *Bilophila*, and *Sutterella*), especially if their susceptibility patterns are not predictable. Antimicrobials to be tested should include those on the hospital formulary, and those considered or used for therapy.

Recent surveys of anaerobic susceptibility testing illustrate that only 21 % (21/98) of hospital laboratories performed anaerobic susceptibility testing in-house [20]. This is a sharp decline from earlier rates: in 1990, 70 % performed susceptibility testing [56] and 33 % in 1993 [40]. Blood isolates were always tested when testing was performed. Isolates from sterile body sites were tested by 85 % (17/20) of laboratories and selected surgical wound isolates by 14/20 (70 %). Most hospital laboratories used the Etest® (62 %; 13/21) for susceptibility testing, while only 17 % of reference laboratories used it. Since almost two-thirds of laboratories do not perform testing, the clinicians often chose therapy based on manufacturers' information, FDA's indications, published studies, or their clinical judgment [20].

The majority of commercial labs use Etest® methodology for performing anaerobic susceptibility on isolates sent to them for testing. This testing method is especially suitable for testing one or a few isolates against multiple agents (as long as that agent is available on an Etest® strip). At present, there is no commercially available readymade broth microdilution panels that are "FDA approved" for clinical diagnostic use. Thus, a clinical laboratory would have the option of either using the FDA-approved Etest®, using a noncommercial panel with CLSI-approved methodology, or sending the isolates to a commercial or reference laboratory for testing.

3.4 Testing in a Research or Reference Laboratory

3.4.1 Agar Dilution

Agar dilution requires the incorporation of diluted concentrations of the antimicrobials into a nutrient agar medium followed by the plating standardized number of bacterial cells to the surface of the plate. Plates are read following 48 h of growth by comparing the growth of different strains in the series and the MIC is designated as the lowest antimicrobial concentration that inhibits growth. The CLSI method specifies using control strains including *B. fragilis* ATCC 25285, *Bacteroides thetaiotaomicron* ATCC 29741, and *Clostridium difficile* ATCC 700057.

3.4.2 Broth Microdilution

In this assay, a polystyrene tray wells is filled with small volumes of serial twofold dilutions of different antibiotics. The drugs and concentration ranges needed can be tailored in trays that are made in-house. The panels can be prepared and frozen until use [16].

3.4.3 Etest®

The Etest® (©AB BIODISK, bioMerieux) has become the most popular test for testing individual isolates. An individual isolate is suspended in broth or saline and swabbed onto a Brucella blood agar plate. The Etest is a plastic strip with a predetermined antimicrobial concentration gradient on one side and an interpretative MIC scale on the other. The MIC is read as that concentration where the elliptical zone of inhibition intersects the strip. The Etest® correlates well with the reference procedure; there are some discrepancies for certain drugs [57–63].

3.4.4 Spiral Gradient Endpoint (SGE) System

The Autoplate 4000 (Advanced Instruments, Inc., Boston, MA) deposits a specific amount of antimicrobial stock solution in a spiral pattern on a 150 mm agar plate, generating a concentration gradient that decreases radially from the center to the edge of the plate. After the antimicrobials are allowed to diffuse, the isolates are plated with an automated inoculator or manually streaked from the center to the edge of the plate. After incubation, endpoints of growth are marked and the distance is measured in millimeters from the center of the plate to the point where growth ceases. A computer software program determines the concentration of drug from the radius of growth and the molecular weight

(i.e., diffusion characteristics) of the antimicrobial agent. This procedure is compared favorably with standard agar dilution [64–66]. Also, it can detect any tendency for spontaneously resistant mutants that may develop (i.e., colonies that grow beyond the "endpoint").

3.5 Commercially Available Testing

There are several commercially available test panels available in the USA through Thermo Fisher Scientific, Oxoid and Sensititre Trek. However, if the panels contain antimicrobials that are not approved by the FDA for use in anaerobic infections, the panel is not approved by the FDA for clinical diagnostic use. In practice, most hospitals that use microbroth panels order panels that reflect their needs based on hospital formulary and drug used and not on FDA approval.

Specialty Laboratories in the USA (operated by Quest Diagnostics Inc.) provides testing services for 6 antimicrobials (Cefoxitin, Penicillin, Clindamycin, Piperacillin/Tazobactam, Metronidazole, and Imipenem) using Etest® methodology. Focus Diagnostics (also a subsidiary of Quest Diagnostics Inc.) and Mayo Medical Laboratories (Rochester, Minn.) offers routine testing using Etest. Six to nine drugs are tested routinely, depending on the organism tested. For *B. fragilis* group organisms, ampicillin/sulbactam, clindamycin, imipenem, meropenem, metronidazole, and piperacillin/tazobactam are included in the panel. The addition of penicillin, cefoxitin, and cefotetan may be ordered for testing *Clostridium*. Other drug testing can be custom ordered (depending on the availability of the Etest® strip).

3.5.1 Beta-Lactamase Test

Anaerobes can be tested for the presence of the enzyme BL using a chromogenic cephalosporin test such as nitrocefin disks. These are colorimetric tests that are easy to perform and results can be read within 5–30 min. Because most *B. fragilis* group isolates generate BL, testing for BL production is generally not recommended for this group. Other isolates that have less predictable patterns and certain anaerobes include some *Clostridium*, *Fusobacterium,* and *Prevotella*. Isolates with positive BL test should be considered resistant to penicillin and ampicillin. A negative test does not necessarily predict susceptibility to these agents, as some anaerobes are resistant to beta-lactam antimicrobial agents through other mechanisms.

Increased activity of efflux pumps and changes in penicillin-binding proteins have been shown to affect MICs of BL for many *Bacteroides* isolates. However, systematic surveys of these mechanisms have not been conducted, so the percentage of strains that have or utilize these mechanisms is not known [67, 68].

3.6 Factors Contributing to Variability in MIC Results

Technical variability among laboratories was a major factor in variability in MIC in the past [68] as laboratories used different media, different inocula sizes, and may have read results after different incubation times [68]. However, since the CLSI (formerly NCCLS) extensively revised these procedures, they were adopted by virtually all testing laboratories across the world. Consequently, most technical variability among laboratories has been reduced. Variable breakpoints do not effect the individual MIC for a certain strain, but will alter the percent of strains reported as susceptible or resistant in surveillance reports. Most studies adhere to CLSI breakpoints, but some EUCAST breakpoints are different. Many studies recognize these differences and report results with both breakpoints.

Another factor that can affect survey antibiograms' results include the particular composition of the groups of strains included. The bacterial species of a particular genus may possess different susceptibility patterns. Studies of different proportions of the various *B. fragilis* group species may reflect different antibiograms for the *B. fragilis* group as a whole, because members of the group have variable susceptibilities. The source of isolates included in the report (i.e., normal flora, clinical infection) can also influence the resistance profile of the entire species and should be taken into consideration when the survey is evaluated.

The most common cause of variability in MIC reports is the variation in interpretation of what the MIC is in instances where endpoints are not very clear. A margin of error (usually + one twofold dilution) exists for any of the susceptibility techniques. The MICs for a large percentage of *B. fragilis* group strains cluster within one twofold dilution range of the breakpoint for some antimicrobial agents. All testing methods exhibit clustering of the breakpoint and this is a characteristic feature of the organism–drug interaction. When a MIC is near the breakpoint, an organism may be called susceptible on one occasion and called resistant when retested. Because of this, in the case of single isolates, it is helpful to know the MIC of a drug for the strain as well as the established breakpoint, rather than just the laboratory determination. Even though variabilities in results may exist between survey studies, they provide useful information on trends and patterns in antimicrobial susceptibility.

Large survey studies can detect changes in susceptibility due to specific resistance mechanisms. These initially induce relatively modest changes in resistance rates that may quickly increase as the resistance determinant disseminate. This can pinpoint the relevant mechanisms of resistance and help monitor, understand and perhaps even control these shifts by making recommendations based on the molecular traits of the pathogen.

3.7 Detection of Resistance Using Molecular Methods

These detection methods are limited at present to research laboratories. The commonest molecular techniques are PCR amplifications to identify *nim* genes responsible for metronidazole resistance or *cfiA*-type genes that confer resistance to carbapenems.

3.8 Investigational Rapid Tests

It is hoped that simple molecular or multiplex PCR tests, that would determine the actual or potential resistance of an organism to multiple antibiotics would be developed. Future tests could measure many genetic determinants that confer drug resistance including enzymes that confer resistance to carbapenems (e.g., *cfiA*), metronidazole (*nim*), chloramphenicol (*cat*), erythromycin (*erm*), tetracycline (*tet*), or quinolones (changes in *gyr* or *parC* genes). Pumbwe et al. [69] described a multiplex PCR test that detected multiple resistance determinants in *B. fragilis* isolates and predicted likely resistance patterns. Unfortunately, the presence of systems of multidrug efflux pumps may not permit a definitive determination of a resistance profile by molecular techniques. Such multidrug resistance of multidrug efflux pumps was observed in aerobes, and may be operative in anaerobes as well. A 16 homologs of tripartite efflux pumps of the resistance nodulation division (RND) family have been described (Bme 1–16) in *B. fragilis* and are important in conferring multidrug resistance [46, 70–73]. Pump activity related to resistance has also been found in *Clostridium* [74–76]. Several multidrug-resistant isolates seem to exhibit significantly increased efflux pump activity. Because genes for efflux pumps are present in all bacterial strains, a PCR test to detect the gene would always be positive. It is possible that the levels of efflux pump genes transcribed and expressed are important. Currently, the only way to measure these in clinical isolates is to quantitatively identify and sequence RNA transcripts, which is time consuming and impractical.

3.9 Resistance to Antimicrobial Agents Effective Against Anaerobic Bacteria

Table 63.2 illustrates the antimicrobial effective against anaerobic bacteria and their efficacy against both aerobic and anaerobic bacteria. Many of the older antimicrobial agents do not have an FDA-approved indication for treatment of anaerobic infection(s), and many of the newer agents have only limited number of indications for anaerobic infections. However, many of these agents are administered for the treatment of anaerobic infections without an FDA indication. Tables 63.3 and 63.4 illustrate the resistance of *B. fragilis* group and other anaerobes to antimicrobial agents [77].

3.10 Beta-Lactam Antibiotics

Penicillin G is the drug of choice whenever the infecting organism is susceptible to this agent in vitro. Most *Clostridium* strains (with the exception of some strains of *Clostridium ramosum*, *Clostridium clostridioforme,* and *Clostridium innocuum*) and *Peptostreptococcus* spp. are susceptible to penicillin. Most *B. fragilis* group are resistant to penicillin G, and it should not be used for the treatment of

[a]The order of listing of drugs within percent susceptible categories is not significant. According to the NCCLS approved breakpoints (M11-A3), using the intermediate category as susceptible. AMP, ampicillin; AMX, amoxicillin; TIC, ticarcillin, see Table 63.2 footnote for other antimicrobial agents

[b]Breakpoint is used only as a reference point. *C. difficile* is primarily of interest in relation to antimicrobial induced pseudomembranous colitis. These data must be interpreted in the context of level of drug achieved in the colon and impact of agent on indigenous colonic flora

infections caused by these organisms. Other strains that may be resistant to penicillins are growing numbers of AGNB, such as the pigmented *Prevotella* and *Porphyromonas* spp., *Prevotella oralis*, *Prevotella bivia*, *Bacteroides disiens*, strains of clostridia, *Fusobacterium* spp. (*Fusobacterium varium* and *Fusobacterium mortiferum*), and microaerophilic streptococci. Some of these strains show MIC of 8–32 units/mL of penicillin G. In such instances, administration of very high dosages of penicillin G (for non-BL producers) may eradicate the infection.

Clinical experience with penicillin G in the management of bacterial infections caused by susceptible anaerobes has been good. Penicillin, ampicillin, and amoxicillin (AMX) generally are equally active, but the semisynthetic penicillins are less active. Methicillin, nafcillin, and the isoxazolyl penicillins (oxacillin, cloxacillin, and dicloxacillin) are ineffective against *B. fragilis* group, have unpredictable activity, and frequently are inferior to penicillin G against anaerobes [78].

Penicillin, ampicillin, and amoxicillin are of limited utility due to the production of BLs by many oral and most intra-abdominal anaerobes. Clavulanate, sulbactam, and tazobactam are BL inhibitors that resemble the nucleus of penicillin but differ in several ways. They irreversibly inhibit BL enzymes produced by some *Enterobacteriaceae*, staphylococci, and BL-producing *Fusobacterium* spp. and AGNB [78–80]. When used in combination with a beta-lactam antibiotic (such as ampicillin/sulbactam, amoxicillin/clavulanate, and piperacillin/tazobactam) they are effective in treating anaerobic infections caused by BL-producing bacteria (BLPB).

Beta-lactam/BL inhibitor combinations (BL-BLIs) are appropriate choices for mixed aerobic–anaerobic infections as they have good activity against the majority of anaerobes. While 89 % of *B. fragilis* are susceptible to ampicillin/sulbactam, 98 % are susceptible to piperacillin/tazobactam [80] compared to 86 % and 92 % respectively, for *B. thetaiotaomicron* isolates. The Infectious Diseases Society of America (IDSA) has removed ampicillin/sulbactam from the recommended agents list for treatment of intra-abdominal infections because of the increased *E. coli* resistance worldwide even though it has maintained good activity against *B. fragilis* group and other anaerobes [81]. AMX-C is the drug of choice for human and animal bite wound infections [82], especially when anaerobes may be involved. Piperacillin/tazobactam is an appropriately agent for serious intra-abdominal infections as it has maintained good activity against the majority of anaerobic bacteria [80].

The *semisynthetic penicillins*, the carboxy-penicillins (carbenicillin and ticarcillin), and ureidopenicillins (piperacillin, azlocillin, and mezlocillin), generally are given in large quantities to achieve high serum concentration. These

agents are effective against *Enterobacteriaceae* and posses good activity against most anaerobes in these concentrations. However, up to 30 % of the *B. fragilis* group are resistant to these agents [83].

Many anaerobes produce cephalosporinases and therefore as a class, cephalosporins have very limited efficacy [81, 83]. The activity of *cephalosporins* against the BL-producing AGNB is variable. The spectrum of activity of the first-generation cephalosporins against anaerobes is similar to penicillin G, although on a weight basis, they are less active. Most strains of the *B. fragilis* group and many *Prevotella*, *Porphyromonas,* and *Fusobacterium* spp. are resistant to cephalosporins by virtue of cephalosporinase production [84]. The enzyme has little or no activity against the second-generation cefoxitin (a cephamycin) which is the most effective cephalosporin against the *B. fragilis* group. However, efficacy may vary by geographic location and is generally directly related to cefoxitin clinical use. It is relatively inactive against most of *Clostridium* species including *C. difficile*, with the exception of *C. perfringens* [6, 7, 84].

Studies performed in the 1980s found cefoxitin to be effective in eradication of anaerobic infections [85–87]. It has frequently been used for surgical prophylaxis at body sites that evolve exposure to mucus membrane. Third-generation cephalosporins have improved activity against *Enterobacteriaceae*, but with the exception of moxalactam, they are not as active against *B. fragilis* as cefoxitin.

Currently about 85 % of *B. fragilis* group isolates are susceptible to cefoxitin but the other group's species are more resistant [17]. Cefotetan is less effective than cefoxitin against *B. fragilis* group.

The *B. fragilis* group includes more than 20 *Bacteroides* spp. that were promoted to a genus level [88]. Among the group, *B. fragilis* accounts for 40–54 % of the *Bacteroides* isolates recovered from all infections [4, 89–91]. *B. thetaiotaomicron*, a member of the *B. fragilis* group, accounts for 13–23 % of the isolates, and other members of the *B. fragilis* group account for 33–39 %. The antimicrobial susceptibility of some members of the *B. fragilis* group varies, especially to the second- and third-generation cephalosporins. *B. fragilis* is the most susceptible, and *B. thetaiotaomicron* and *Parabacteroides distasonis* generally are more resistant [27, 92].

The *cephamycins*, cefoxitin and cefotetan are often used for surgical prophylaxis for abdominal surgery and for the treatment of aspiration pneumonia. Recently, the IDSA has removed cefotetan from the recommended list of agents used for intra-abdominal infections because of its poor activity against *B. fragilis* group and documented clinical failures [93–95].

The *carbapenems* (Imipenem, meropenem, doripenem, and ertapenem) have excellent activity against anaerobes [96]. *Imipenem*, a thienamycin, is a beta-lactam antimicrobial active against a broad variety of aerobic and anaerobic Gram-positive and Gram-negative organisms including multiresistant species such as *Pseudomonas aeruginosa*, *Serratia* spp., *Enterobacter* spp., *Acinetobacter* spp., and enterococcus [32, 97]. It has also excellent activity and low MIC against BL-producing AGNB including *B. fragilis* group. It is also effective against most Enterobacteriaceae with about 5–15 % of *Pseudomonas* spp. resistance [98].

Imipenem is poorly absorption from the gastrointestinal tract, reaches high plasma concentration after intravenous administration, is minimally metabolized, and is renally excreted. In the kidney, imipenem is metabolized by breakage of the BL bond in the proximal tubular cells. This results in low urinary excretion of the active drug, which can impair its ability to inhibit some urinary pathogens. To overcome the renal metabolism of imipenem, it is combined at a 1:1 ratio with an inhibitor of the renal dipeptidase, cilastatin. This increases the urinary excretion of the active agent and its half life in the serum. Imipenem is an effective single agent for the treatment of mixed aerobic–anaerobic infections.

Meropenem is a carbapenem with a broad spectrum of activity against aerobic and anaerobic organisms, similar to that of imipenem. Imipenem is more activity against staphylococci and enterococci, but meropenem possesses greater coverage of aerobic and facultative Gram-negative bacteria such as *Pseudomonas*, *Enterobacter*, *Klebsiella*, *Providencia*, *Morganella*, *Aeromonas*, *Alcaligenes*, *Moraxella*, *Kingella*, *Actinobacillus*, *Pasteurella*, and *Haemophilus* spp. [99, 100]. Meropenem is effective in treating abdominal infections, meningitis, community-acquired and nosocomial pneumonia, and neutropenic fever [101].

Ertapenem is a newer 1-beta-methyl carbapenem, stable to dehydropeptidase. It manifests a broad antibacterial spectrum for penicillin-susceptible *Streptococcus pneumoniae*, *Streptococcus pyogenes*, methicillin-sensitive *Staphylococcus aureus*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Escherichia coli*, *Citrobacter* spp., *Klebsiella* spp., *Serratia* spp., *Proteus* spp., *C. perfringens*, *Fusobacterium* spp., *Peptostreptococcus* spp., and AGNB [102]. It is indicated for treatment of complicated intra-abdominal and skin structure infections, including diabetic foot infections without osteomyelitis, and acute pelvic infections including postpartum endomyometritis, septic abortion, and postsurgical gynecologic infections. In comparison to other carbapenems, it has a long half-life of 4.5 h and is given in a single daily dose. It is not active against *P. aeruginosa*, *Enterococcus* spp., and *Acinetobacter* spp.

Doripenem, a synthetic 1-beta-methyl carbapenem, is the newest available carbapenem. Its antimicrobial spectrum resembles those of meropenem and imipenem [97]. It possesses excellent in vitro activity against streptococci, methicillin-susceptible staphylococci, *Enterobacteriaceae* (including extended-spectrum BL-producing strains), *P.*

aeruginosa, *Acinetobacter* spp., and *B. fragilis* group. It is not active against methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci, and most Gram-negative bacilli that are resistant to meropenem or imipenem [97]. Doripenem has been approved in the USA for use in treatment of complicated intra-abdominal infection and complicated urinary tract infection.

Two recent reports have observed the development of some carbapenem resistance among anaerobic bacteria [22] ranging from 1.1 to 2.5 % in a multicenter US survey but higher in a small number of isolates from Taiwan [25].

Anaerobes manifest three major resistance mechanisms to beta-lactam antibiotics: inactivating enzymes, mainly BLs, which include penicillinases and cephalosporinases; low affinity penicillin-binding proteins (PBPs); and decreased permeability through alterations in the porin channel [67]. All *B. fragilis* group species are generally resistant to penicillins (average 90 %), piperacillin (25 %) cefoxitin (25 %), cefotetan (30–85 %), and third-generation cephalosporins [27, 28, 86].

3.10.1 Beta-Lactamase Production

The production of BLs is the most common mechanism of resistance to beta-lactam antibiotics in anaerobes, especially among the *B. fragilis* group and *Prevotella* spp. [103]. The cephalosporinases are most often of the 2e class type and can be inhibited by BL inhibitors (e.g., clavulanic acid, sulbactam, tazobactam). Each individual cephalosporin may have either a class or specific BL enzyme that is able to inactivate it.

BL hydrolyzes the cyclic amide bond of the beta-lactam nucleus, causing its inactivation. There are a variety of BLs produced by different organisms which can be exoenzymes, inducible or constitutive, and genetically they can be of either chromosomal or plasmid origin [104]. There are different classifications of the enzymes. A classification based on amino acid sequence has been proposed by Ambler [105], and one based upon substrate of inhibition profiles, molecular weight, and isoelectric points was created by Richmond and Sykes [106].

Most *B. fragilis* group produce constitutive BLs that are primarily cephalosporinases [107]. More than 97 % of *Bacteroides* isolates in the USA and 76 % in Great Britain produce BLs [108]. Of the non-*fragilis* AGNB 2/3 produce BLs [51, 109]. Pigmented *Prevotella* and *Porphyromonas*, *Prevotella bivia*, *Prevotella disiens*, and *Fusobacterium nucleatum* produce primarily penicillinases [109].

Carbapenem resistance in *B. fragilis* is related to *cfiA*- or *ccrA*-encoded class B metallo-BL. Although not all *cfiA*-positive *B. fragilis* strains are carbapenems resistant, they are all capable of becoming resistant to these antibiotics through acquisition of an appropriate insertion sequence (IS) element for full expression of the *cfiA* gene, which can lead to treatment failure. The presence of the *cfiA* gene, as well as associated IS elements, can be determined by a PCR method [110–112]. Two new studies used matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) to identify division II type strains of *B. fragilis* that possess the *cfiA* gene [113, 114].

Carbapenemases act against the carbapenems as well as all beta-lactam antimicrobials. Although they are usually chromosomally mediated, a plasmid-mediated metallo-BL has been reported in Japan [115]. Carbapenem resistance is present in <1 % of US isolates, and in up to 3 % of *Bacteroides* strains harbor one of the genes which is expressed at a very low level. BL inhibitors are unable to inactivate carbapenemases which are a zinc metalloenzymes, encoded by either *ccrA* or *cfiA* genes of *B. fragilis* group [116].

A study of the molecular characterization of imipenem-resistant *cif*A-positive *B. fragilis* strains noted that the *cfiA* genes of 10 of the 15 evaluated strains were upregulated by insertion sequence (IS) elements while 5 others did not contain an IS insertion but produced carbapenemase [116]. These observations illustrate that some isolates possessed novel inactivation mechanisms suggesting that more than one mechanism of inactivation exists. A study from Taiwan observed increased carbapenem resistance in *B. fragilis* group and some *Prevotella* spp. [25].

Clostridium, *Porphyromonas*, and *Fusobacterium* strains have also been found to BLs. The BLs producing *Fusobacterium* and *Clostridium* spp. are generally inhibited by clavulanic acid [117]. Resistance to beta-lactams through changes in the OMP/porin channels, efflux pumps, and decreased PBP affinity [118] are less well studied.

The carbapenems and the combinations of BL/BLIs inhibitors have maintained their excellent antibacterial activity against anaerobes. The combination agents of amoxicillin/clavulanate (AMX-C), ampicillin/sulbactam, ticarcillin/clavulanate, and piperacillin/tazobactam are generally very active against members of the *B. fragilis* group [28]. However, variation in susceptibility occurs among species, and many non-BL producing *P. distasonis* have elevated MICs at or close to the susceptible breakpoint [119]. *B. fragilis* group resistance rates for piperacillin/tazobactam is generally <1 % [28]. However, resistance of *P. distasonis* to ampicillin/sulbactam has increased to 20 % in 2002–2004 but continued to be low for the species of other *B. fragilis* group.

The carbapenems continue to be very effective against all members of the *B. fragilis* group, and resistance is rare at <0.1 % [28, 29, 119]. Geometric mean MICs for imipenem and meropenem for *P. distasonis*, *B. thetaiotaomicron*, and *Bacteroides ovatus* are onefold dilution lower than those for ertapenem [28]. In a study of pediatric intra-abdominal infections [85] all *Bacteroides* isolates produced BL and were susceptible to carbapenems and BL/BLIs. Cefoxitin had poor activity against *B. thetaiotaomicron* isolates.

Beta-lactams are usually active against non-*B. fragilis* group isolates and resistance to them is generally low. However, more

than half of *Prevotella* spp. may also produce BLs. A multicenter survey [32] found penicillin resistance to be 9% for *Fusobacterium* spp., 21% for *Porphyromonas* spp., and 6% for *Peptostreptococcus* spp. That survey found no resistance to cefoxitin, cefotetan, BL/BLI combinations, and carbapenems. An exception was 4% *Peptostreptococcus* spp. and 5% *Porphyromonas* spp. resistance to ampicillin-sulbactam. BLs were noted in several *Prevotella and Porphyromonas* spp. recovered from pediatric intra-abdominal infections.

3.10.2 Penicillin-Binding Proteins

Penicillin binding to the PBPs determines whether a beta-lactam antimicrobial will be effective. Maintaining PBPs function in the final stage of cell wall synthesis is essential for bacterial growth. Beta-lactams work by successfully competing for binding to the active site of the essential PBP, thus causing cell death. Three to five PBPs can be found in *Bacteroides* strains: a PBP 1 complex with one to three different enzymes, PBP 2, and PBP 3. These PBPs are most likely similar to the high-molecular-weight PBPs present in aerobic Gram-negative bacteria. It may be possible that other low-molecular-weight PBPs also exist, but the number of these proteins vary among strains, and are probably not essential for bacterial growth [120].

Alteration in PBP are not a major mechanisms of resistance in anaerobes as the binding of most beta-lactam agents to PBP 1 complex and PBP 2 is adequate. An exception are the monobactams (i.e., aztreonam) who are not active against *B. fragilis* because they do not have good affinity for their PBPs [121]. Decreased affinity of cephalosporins for PBP 3 was demonstrated in *B. fragilis* G-232 recovered in Japan [122]. Cefoxitin resistance in some *Bacteroides* strains has also been attributed to decreased binding to the PBP 1 complex or the PBP 2 [123, 124]. This resistance was also inducible in vitro [125].

3.10.3 Permeability

Increased BL production was associated with decreased permeability in Gram-negative bacteria. Permeability factors can vary among strains of *B. fragilis* [126–128], and in certain *B. fragilis* strains, resistance was associated with both reduced permeability and BL production [128]. Cefoxitin resistance correlated with a decrease in outer-membrane permeability and the loss of an outer-membrane protein with a molecular size of 49–50 kid [124].

Studies of pore-forming proteins of *Bacteroides*, *Porphyromonas*, and *Fusobacterium* spp. identified and cloned outer-membrane proteins from these AGNB. The absence of at least one outer-membrane protein was associated in some strains with resistance to ampicillin/sulbactam [129].

Selective pressure similar to that observed for many aerobic species most likely also plays a role in the development and selection of resistance to beta-lactams. Although the prevalence of resistance of anaerobes to beta-lactams has increased, several of these antibiotics are still clinically useful. However, their utilization should be determined according to the local resistance patterns or the susceptibility of individual isolates.

3.11 Chloramphenicol

Chloramphenicol, a bacteriostatic agent, is active against most anaerobic bacteria but is rarely used in the USA [3, 84]. Resistance to this agent is rare, although it has been reported in some *Bacteroides* spp. [29] strains. One must be aware that MICs of chloramphenicol often cluster around the susceptibility break point. Although several failures to treat anaerobic infections, including bacteremia, with chloramphenicol have been documented [130], this drug has been used for over 65 years for treatment of anaerobic infections. Chloramphenicol was regarded for many years as the drug of choice for treatment of serious anaerobic infections when the nature and susceptibility of the causative organism(s) are unknown and in central nervous system infections (CNS). However, the agent has potential significant toxicity. Fatal aplastic anemia with chloramphenicol is estimated to occur in approximately one per 25,000–40,000 patients treated. This complication is not related to the reversible, dosage-dependent leukopenia. Other side effects include the potentially fatal "gray baby syndrome" when administered to neonates, hemolytic anemia in individuals with G6PD deficiency, and optic neuritis in patients who take chloramphenicol for a prolonged time.

Serum level measurements are often indicated for infants, young children, and sometimes for adults, because of their wide variations [131]. The usual goal is the therapeutic levels of 10–25 μg/mL. Levels above 25 μg/mL can cause reversible bone marrow suppression, and levels of 40–200 μg/mL have been associated with the gray syndrome in neonates or encephalitis in adults [131].

Chloramphenicol distributes throughout the body fluids and tissues, with a mean volume distribution of 1.4 L/kg [131]. The drug possesses a unique property of lipid solubility to enabling its penetration across lipid barriers. It consistently achieves high concentrations in the CNS, even in the absence of inflammation. Cerebrospinal fluid levels with or without meningitis, usually are one-third to three-fourths the serum concentrations. Brain tissue levels may be substantially higher than serum levels [132].

3.11.1 Chloramphenicol Resistance

Even though no resistance of anaerobic bacteria against chloramphenicol has been noted [133–136], clinical failures using this drug have been reported [137]. The absence of resistance can be explained by the infrequent clinical use of this agent.

Bacteroides spp. possess two unique classes of chloramphenicol resistance genes that produce resistance through drug inactivation, either by nitroreduction at the p-nitro group on the benzene ring [138] or by acetylation [139, 140]. Resistance through acetylation is transferable and associated with a 39.5-kb plasmid, pRYC3373 [139].

3.12 Macrolides: Erythromycin, Azithromycin, Clarithromycin

The macrolides, which cause little toxicity, have moderate to good in vitro activity against anaerobes other than *B. fragilis* group and fusobacteria [84]. Macrolides are active against pigmented *Prevotella* and *Porphyromonas*, microaerophilic streptococci, Gram-positive non-spore-forming anaerobic bacilli, and certain clostridia. They are less effective against *Fusobacterium* and *Peptostreptococcus* spp. [141]. They show relatively good activity against *C. perfringens* and poor or inconsistent activity against AGNB.

Clarithromycin is the most active macrolide against Gram-positive oral flora anaerobes, including *Actinomyces* spp., *Propionibacterium* spp., *Lactobacillus* spp., and *Bifidobacterium dentium*. Azithromycin is slightly less active than erythromycin against these species [141]. Azithromycin is, in general, the most active macrolide against AGNB: *Fusobacterium* spp., *Bacteroides* spp., *Wolinella* spp., and *Actinobacillus actinomycetemcomitans*, including those resistant to erythromycin. Clarithromycin has similar activity to erythromycin against most AGNB [142].

Erythromycin-resistant organisms can emerge during therapy [143, 144]. Erythromycin is effective in the treatment of mild to moderately severe anaerobic soft tissue infections when combined with adequate debridement or drainage of infected tissue. Phlebitis can develop in about one-third of those receiving intravenous erythromycin.

Five genes conferring macrolide-lincosamide-streptogramin (MLS) resistance have been identified in anaerobes, including erm(B), erm(C), erm(F), erm(G), and erm(Q). In contrast, no genes coding for MLS-resistant efflux proteins or inactivating enzymes have been described in anaerobic species [144].

3.13 Clindamycin

Clindamycin has a broad spectrum of activity against anaerobic bacteria and has proven its efficacy in past clinical trials. It is used for dental infections, especially for penicillin allergic patients and for aspiration pneumonia. Clindamycin hydrochloride is rapidly and almost completely absorbed from the gastrointestinal tract [145–147]. It penetrates well into body tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, prostate, semen, bones, and joints [148].

3.13.1 Clindamycin Resistance

Clindamycin resistance is conveyed by a macrolide-lincosamide-streptogramin (MLS) type 23S methylase, generally encoded by one of several *erm* genes which are regulated and expressed at high levels [149].

B. fragilis resistance to clindamycin is increasing worldwide and varies by region. Clindamycin is no longer recommended as empiric therapy for intra-abdominal infections [22, 28, 29, 81]. A recent study (1997–2004) found 19.3 % of 2721 *B. fragilis* group isolates, 29.6 % of *P. distasonis*, 33.4 % of *B. ovatus*, 33.3 % of *B. thetaiotaomicron*, and 35.6 % of *B. vulgatus* strains to be clindamycin resistant. This is a significant increase compared to only 3 % clindamycin resistance in 1987 [27]. A study of pediatric intra-abdominal isolates found clindamycin resistance in only 6 % of *B. fragilis* isolates compared to 80 % for *B. thetaiotaomicron* and 45 % for other *B. fragilis* group strains [85].

Resistance has also increased, for many non-*Bacteroides* anaerobes. Up to 10 % resistance was noted for *Prevotella* spp., *Fusobacterium* spp., *Porphyromonas* spp., and *Peptostreptococcus* spp., with higher rates for some *Clostridium* spp. (especially *C. difficile*) [98]. *Propionibacterium acnes* isolates have also become more resistant to clindamycin and this has been associated with prior therapy for acne [150].

Clindamycin has lost some of its activity against anaerobic Gram-positive cocci, and *Prevotella* spp., although its activity against *Fusobacterium* and *Porphyromonas* spp. remains good [83].

Other resistant anaerobes are several species of clostridia, especially *C. difficile.* Approximately 20 % of *C. ramosum* are resistant to clindamycin, as are a smaller number of *C. perfringens* [83].

3.14 Metronidazole and Tinidazole

These nitroimidazoles have similar in vitro efficacy against anaerobes. Metronidazole has excellent in vitro activity against most obligate anaerobes, including *B. fragilis* group, other species of Bacteroides, fusobacteria, and clostridia [28]. Only six strains of *B. fragilis* group were ever reported to be clinically resistant and associated with therapeutic failure [21].

Anaerobic Gram-positive nonsporulating bacilli are commonly resistant while anaerobic Gram-positive cocci are rarely resistant. Microaerophilic streptococci, *P. acnes*, and *Actinomyces* spp. are almost uniformly resistant [151]. Aerobic and facultative anaerobes are usually very resistant.

Over 90 % of anaerobes are susceptible to less than 2 μg/mL of metronidazole [84].

Because of metronidazole lack of activity against aerobic bacteria, an antimicrobial effective against these organisms (e.g., beta-lactam, cephalosporin, fluoroquinolone) need to be added when treating a polymicrobial aerobic–anaerobic infection.

Gastrointestinal side effects are frequent and include nausea, vomiting, metallic taste, anorexia, and diarrhea. Other adverse reactions to metronidazole are infrequent and include CNS toxicity, such as ataxia, vertigo, headaches, and convulsions. Peripheral neuropathy is associated with prolonged use of the agent. Tinidazole may be better tolerated in individuals with gastrointestinal side effects caused by metronidazole. Other adverse reactions include reversible neutropenia, phlebitis at intravenous infusion sites, and drug fever. Metronidazole is generally well tolerated.

Some studies in mice [152] have shown possible mutagenic activity associated with administration of large doses of metronidazole. However, the drug has generally been administered for the lifetime of the animal, a situation that may not be relevant for humans. Other experiments [153] have illustrated that administration of metronidazole to rats and hamsters does not induce any pathology. Furthermore, evidence of mutagenicity was never found in humans despite metronidazole use for over two decades [154]. Because of safety concerns, the FDA approved the use of metronidazole for the treatment of serious anaerobic infections only in adults.

Clinical experiences in adults [155] illustrated metronidazole's efficacy in the treatment of anaerobic infections, including CNS infections [156]. Safety data during pregnancy are contradictory and more data on the safety of metronidazole in pregnancy are needed. The non-teratogenicity of metronidazole is difficult to prove, but the existing information indicates no major risks and or need to terminate pregnancies in those receiving the drug [157].

3.14.1 Metronidazole Resistance

Metronidazole resistance is usually attributed to nitroimidazole reductase (*nim*) resistance gene. This gene codes for an enzyme that converts 4- or 5-nitroimidazole to 4- or 5-aminoimidazole (thus avoiding the formation of toxic nitroso radicals that are essential for antimicrobial activity.) *Nim* homologs are present in both Gram-positive and -negative genera of aerobic and anaerobic bacteria and Archaea, suggesting that the *nim* gene family is ancient and widespread. The *nim* genes are often found on mobilizable plasmids and pose a significant threat to the continuing utility of 5-Ni drugs, including metronidazole [158].

Polymerase chain reaction (PCR) can detect the presence of the *nim* gene. This was first described using the universal primers NIM-3 and NIM-5 [159] followed by restriction analysis to identify the specific *nim* type [160]. Nine *nim* genes were described in *B. fragilis* (*nim A-I*) and an additional *nimI* gene was described in *Prevotella* [161, 162]. However, increasing numbers of metronidazole-resistant isolates are recovered that do not possess any of the *nim* A-H genes. Also, metronidazole resistance could be induced in *nim*-negative strains by exposure to sub-MIC concentrations of metronidazole [162, 163].

Resistance to metronidazole among *B. fragilis* group has rarely been observed [24, 25]. Resistant *B. fragilis* group isolates carry one of nine known *nim* genes [*nim* A-I] on either the chromosome or on a mobilizable plasmid that seems to encode a nitroimidazole reductase that converts 4- or 5-nitroimidazole to 4- or 5-aminoimidazole, thus preventing the formation of toxic nitroso residues necessary for the agents' activity. These *nim* genes were observed in 50/206 (24 %) of *Bacteroides* spp. isolates and resulted in MICs of 1.5 to >256 μg/mL for metronidazole, including 16 isolates with MICs >32 μg/mL [162]. These findings suggested incomplete mobilization of *nim* gene associated resistance. It was speculated [162] that other mechanisms of resistance can occur and that prolonged exposure to metronidazole may select them. The mechanism of metronidazole resistance for non-*Bacteroides* anaerobes is unknown. Resistance of Gram-positive organisms that are not strict anaerobes is frequent, mostly for *P. acnes* and *Actinomyces* spp.

3.15 Tetracyclines

Tetracycline is currently of limited use for treating anaerobic infection because of the development of resistance to it by all types of anaerobes including *Bacteroides* and *Prevotella* spp. Resistance to *P. acnes* has been related to previous use [150]. Only about 45 % of all *B. fragilis* strains presently are susceptible to tetracycline [84]. The newer tetracycline analogues, doxycycline and minocycline, are more effective than the parent compound. Because of the significant resistance to these agents, they are useful only when susceptibility tests can be performed or in less severe infections in which a therapeutic trial is possible. The use of tetracycline is not recommended before 8 years of age because of the adverse effect on teeth.

Tigecycline is the first glycylcyclines antibiotic approved. Glycylcyclines are tetracycline class antibiotics containing a glycylamido moiety attached to the 9-position of a tetracycline ring; tigecycline is a direct analog of minocycline with a 9-glycylamide moiety. It is active against both aerobic Gram-negative and Gram-positive bacteria, anaerobes, and some drug-resistant pathogens [164]. These include MRSA, penicillin-resistant *Streptococcus pneumoniae*, vancomycin-resistant enterococci, *Acinetobacter baumannii*, BL-producing strains of *H. influenzae* and *M. catarrhalis*,

and extended-spectrum BL-producing strains of *E. coli* and *Klebsiella pneumoniae*. In contrast, MICs for *Pseudomonas* and *Proteus* spp. are significantly elevated. It is effective against *Streptococcus anginosus* group (includes *S. anginosus*, *S. intermedius*, *and S. constellatus*), *B. fragilis*, *B. thetaiotaomicron*, *Bacteroides uniformis*, *Bacteroides vulgatus*, *C. perfringens*, *C. difficile*, and *Parvimonas micra* (*Peptostreptococcus micros*) [38]. Resistance of members of the *B. fragilis* group is 3.3–7.2 % [28].

3.15.1 Tetracycline Resistance

Four tetracycline efflux genes were identified in anaerobes: *tet*(*B*), *tet*(*K*), *tet*(*L*), and *tetA*(*P*). There are five genes confirming ribosomal protection proteins, *tet*(*M*), *tet*(*O*), *tetB*(*P*), *tet*(*Q*), *tet*(*W*), and *tet*[32], have been found in anaerobes. Three enzymes which inactivate tetracycline; *tet*(*X*), *tet*(*X*1), and *tet*(*Q*); have been found in *Bacteroides* [144, 165].

The mechanism of tetracycline resistance in *Bacteroides* spp. is through changes or shielding of the target site. The *tetQ* gene encodes a protein that makes the ribosomal protein synthesis resistant to tetracyclines' inhibitory effects [166–168]. The DNA sequences of several *Bacteroides tetQ* genes have been discovered [167, 168]. The TetQ is 40 % homologous with TetM and TetO proteins and may represent a new class of ribosomal protection proteins [167, 168].

DNA cross-hybridization demonstrated that a *tetQ*- or *tetQ*-related gene is found in most tetracycline-resistant *Bacteroides* isolates [166]. However, other mechanisms (such as tetracycline efflux) or other classes of ribosomal protection proteins may also assist in tetracycline resistance because some tetracycline-resistant isolates do not contain *tetQ* DNA sequences. This possibility is supported by the identification of a tetM-related determinant in some tetracycline-resistant isolates of *Bacteroides ureolyticus* [169].

C. perfringens harbors two tetracycline resistance genes—the *tetA*(*P*) and *tetB*(*P*) genes that create an operon that encodes two unrelated proteins which conveys resistance by two unique mechanisms [170]. The *tetA*(*P*) gene generates a tetracycline efflux pump, and the *tetB*(*P*) creates a protein generating ribosomal resistance [170].

Bacteroides spp. can harbor two additional genes related to tetracycline resistance that may not contribute to clinical resistance. The oxidation of tetracycline is through product of the *tetX* gene that is active only in aerobic conditions [171–173]. Another gene encodes a protein that produces tetracycline efflux in *Bacteroides* but is not able to produce tetracycline resistance in *E. coli* [174, 175].

The *tetQ* resistance gene is inducible [167, 176] and transferable [177, 178]. The tetracycline resistance is transferred by conjugation mediated through the tetracycline resistance transfer element [176, 179, 180]. The frequency of transfer is generally very low except when the organisms are preexposed to tetracycline [181, 182]. Controlled of the transfer is by a prokaryotic two-component regulatory system [178, 180]. The two regulatory genes, *rteA* and *rteB*, are located in the *tetQ* operon downstream from the *tetQ* gene [180], and their expression is enhanced by the presence of tetracycline.

RteA, the cytoplasmic membrane protein component is encoded by the *rteA* gene, and the RteB is encoded by the *rteB* gene [180]. RteB takes part in the transfer and mobilization of the tetracycline resistance transfer element. An additional gene, *rteC*, that produces RteC, may participate in the self-transfer of tetracycline resistance [176].

RteA and RteB also control the transfer of unlinked chromosomal elements called nonreplicating *Bacteroides* units (NBUs) [166, 181, 182]. Even though most NBUs do not contain an identifiable phenotype, a cefoxitin-hydrolyzing, BL gene (*cfxA* [54]) can be present on an NBU [183]. The transfer of the cefoxitin-hydrolyzing BL is enhanced by pretreatment with tetracycline [183, 184].

The transfer elements of tetracycline resistance are chromosomally located, are similar to the conjugal transposon *Tn916* in *Enterococcus faecalis* [166, 185–187], the rarer large (70–80 kbp) [179], and they often contain other resistance genes (e.g., *ermF*) [188].

Tetracycline resistance is common among *Bacteroides* and *Prevotella* species and many other anaerobic bacteria, limiting its clinical utility [167]. Several encoding tetracycline resistance genes have been found in several anaerobes, which encode protective proteins leading to protection of the ribosomes. Tetracycline resistance and the inducible transfer of resistance determinant can take place after exposure to low levels of this agent. The emergence of tetracycline resistance in *P. acnes* has been correlated with previous tetracycline therapy [150].

Tigecycline has been approved by the FDA for treatment of complicated skin and soft tissue infections including those caused by *B. fragilis* and intra-abdominal infections including those due to *B. fragilis*, *B. thetaiotaomicron*, *B. uniformis*, *B. vulgatus*, *C. perfringens,* and *Ps. micros* [189, 190]. In the study that compared tigecycline's efficacy in the treatment of abdominal infections tigecycline to imipenem-cilastatin, sepsis/shock developed in six tigecycline treated patients compared to two imipenem treated patients [190].

Tigecycline is considered to be effective against anaerobic bacteria [38, 191], and has a low rate (5.5 %) of resistance against *B. fragilis* group [22]. Jacobus et al. [191] found that 90 % of 831 *B. fragilis* group isolates were susceptible to <8 μg/mL of tigecycline and that *P. distasonis* isolates were the most resistant. Snydman et al. [28] observed that 4.7 % of *B. fragilis*, 3.6 % of *B. thetaiotaomicron*, 5.8 % of *B. ovatus,* and 3.2 % of *B. distasonis* showed resistance to tigecycline. Goldstein et al. [38] found all 164 Gram-positive anaerobes and 228/232 Gram-negative anaerobes to be susceptible to <1 μg/mL of tigecycline.

3.16 Fluoroquinolones

The first-generation fluoroquinolones are inactive against most anaerobes. However, several newer quinolones possess significant anti-anaerobic activity. Quinolones with low activity against anaerobes include ciprofloxacin, ofloxacin, levofloxacin, fleroxacin, pefloxacin, enoxacin, and lomefloxacin. Agents with intermediate antianaerobic activity include sparfloxacin and grepafloxacin [192]. Trovafloxacin, gatifloxacin, and moxifloxacin are effective against most anaerobes [59]. The use of trovafloxacin has been restricted because of hepatotoxicity. Quinolones with the greatest in vitro activity against anaerobes include clinafloxacin and sitafloxacin [193].

Moxifloxacin has been evaluated and approved by the FDA as single agent therapy in intra-abdominal infections in adults [81, 94] and is active against intra-abdominal anaerobic isolates [36, 194]. However, because of increasing fluoroquinolone resistance in both *B. fragilis* group [19, 22, 36] and *E. coli*, it has limited use in intra-abdominal infections [81].

A pooled analysis of 4 randomized clinical trials (2000–2010) assessed the comparative efficacy of moxifloxacin in complicated intra-abdominal infections in 745 microbiologically evaluable cases and evaluated its efficacy against *B. fragilis* [194]. Of pre-therapy anaerobes from moxifloxacin-treated patients, 561 (87.4 %) were susceptible at ≤2 mg/L, 34 (5.3 %) were intermediate at 4 mg/L, and 47 (7.3 %) were resistant at ≥8 mg/L. Moxifloxacin had similar clinical success rates against all anaerobes including those isolated from patients infected with *B. fragilis* (158 [82.7 %] of 191 patients), *B. thetaiotaomicron* (74 [82.2 %] of 90 patients), and *Clostridium* spp. (37 [80.4 %] of 46 patients). The overall clinical success rate for all anaerobes was 82.3 %. For all anaerobes combined, the clinical success rate was 83.1 % (466 of 561 patients) for an MIC of ≤2 mg/L, 91.2 % (31 of 34 patients) for an MIC of 4 mg/L, 82.4 % (14 of 17 patients) for an MIC of 8 mg/L, 83.3 % (5 of 6 patients) for an MIC of 16 mg/L, and 66.7 % (16 of 24 patients) for an MIC of ≥32 mg/L. This data suggests that moxifloxacin can be used for anaerobic intra-abdominal infections provided that the patient has mild or moderate disease and has not been recently exposed to a fluoroquinolone therapy. Moxifloxacin can be an alternative agent in the highly penicillin allergic patient.

The use of the quinolones is restricted in growing children because of their potential adverse effects on the cartilage. The main concerns with expanding the use of fluoroquinolones to treat anaerobic infections have been the increasing resistance in *B. fragilis* group as well as anaerobic Gram-positive cocci and the impact of these antibiotics on the growing incidence of *C. difficile*-associated disease [193].

3.16.1 Fluoroquinolone Resistance

Bacteroides spp. resistance to fluoroquinolone can be caused by either an alteration in efflux of the antibiotic or a mutation in the quinolone resistance determining region (QRDR) of the gyrase A gene (*gyrA*) from single or multiple mutations [8]. Both mechanisms can cause high-level resistance.

A study [195] of 4434 *B. fragilis* group isolates obtained from 12 US medical centers between 1994 and 2001 found that fluoroquinolones resistance was species and source of isolation dependent. *B. vulgatus* isolates from decubitus ulcers were the most resistant (71 %). Moxifloxacin resistance rates ranged from 17 % for *B. fragilis* recovered from the female genitourinary tract to 52 % isolated from blood culture (moxifloxacin MIC breakpoint, 4 μg/mL).

A recent US survey [28] illustrated that 27 % of *B. fragilis*, 26 % of *B. thetaiotaomicron*, 38 % of *B. ovatus*, and 55 % of *B. vulgatus* were moxifloxacin resistant. A study of strains recovered from intra-abdominal infections (2001–2004) found moxifloxacin resistance in 13 % of both of *B. fragilis* and *B. thetaiotaomicron* [194]. Overall 86 % (303/363) of all *B. fragilis* group and 417/450 of all other anaerobic genera and species, including *Fusobacterium*, *Prevotella*, *Porphyromonas*, *C. perfringens*, *Eubacterium*, and *Peptostreptococcus* spp., were susceptible to <2 μg/mL of moxifloxacin. AS study of 179 respiratory tract anaerobes identified a single resistant strain of *C. clostridioforme* [196]. A study of 550 anaerobes recovered from intra-abdominal and diabetic foot infections reported that 97 % were susceptible to moxifloxacin [59]. A study from Taiwan of nosocomial infections and bacteremias observed that 90 % of *B. fragilis* isolates were susceptible to moxifloxacin [25]. In contrast, a report from Europe [26] found 15 % fluoroquinolone resistance with geographic variations from 7 % in southern Europe to 30 % in northern Europe. Factors that may account for these variations include differences in susceptibility that depend on the sources of isolation and local antimicrobial utilization patterns. Supportive of this theory was that 41/42 *B. fragilis* group strains isolated from pediatric intra-abdominal infections were susceptible to moxifloxacin, which is infrequently utilized in children [85].

Fusobacterium canifelinum, isolated from cat and dog bite wound infections, is intrinsically resistant to fluoroquinolones because of Ser79 replacement with leucine and Gly83 replacement with arginine on *gyr*A [197].

Moxifloxacin has been approved by the FDA for the treatment of complicated skin and skin structure infections including those caused by *B. fragilis* and for mixed intra-abdominal infections due to *B. fragilis*, *B. thetaiotaomicron*, *Peptostreptococcus* spp., and *C. perfringens*.

3.17 Aminoglycosides

Anaerobes are resistant to all aminoglycosides because these agents do not reach their target site in these bacteria. Of interest is that anaerobic bacteria do not inactivate aminoglycosides and that in a cell-free system both streptomycin and gentamicin are able to bind and inhibit protein synthesis in both *B. fragilis* and *C. perfringens* ribosomes [198].

The uptake of aminoglycosides involves a two-step process: an energy-independent and an energy-dependent one. The energy necessary for the energy-driven phase of drug uptake is obtained from an oxygen- or nitrogen-dependent electron transport system. Strictly anaerobes do not possess this electron transport system and are therefore incapable of importing aminoglycosides [199, 200]. This is supported by the fact that aminoglycosides do not accumulate inside either *B. fragilis* or *C. perfringens* [36].

3.18 Other Agents

In vitro data is available for several antimicrobials. Bacitracin is active against pigmented *Prevotella* and *Porphyromonas* spp. but is not effective against *B. fragilis* and *Fusobacterium nucleatum* [84]. Vancomycin and daptomycin are active against all Gram-positive anaerobes, but is inactive against AGNB [201]. Quinupristin/dalfopristin possesses antibacterial activity against *C. perfringens*, *Lactobacillus* spp., and *Peptostreptococcus* spp. [202]. Linezolid is effective against *Fusobacterium nucleatum*, other *Fusobacterium* spp., *Porphyromonas* spp., *Prevotella* spp., and *Peptostreptococcus* spp. [141]. Minimal clinical experience has, however, been gained in the treatment of anaerobic bacteria using these agents.

4 Transfer of Antibiotic Resistance

Anaerobic bacteria are capable of acquiring and disseminating by conjugation a variety of mobile DNA transfer factors, many of which harbor antibiotic resistance genes. These organisms are the main component of the normal human gastrointestinal flora, contribute to polymicrobial infections including abscesses, and can survive in hypoxic/anoxic environments. All these environments can provide conditions for the rapid disseminate of antibiotic resistance determinants.

The transfer of resistance genes has been observed in the *B. fragilis* group and in *Prevotella*, *Clostridium*, and *Fusobacterium* spp. [203]. Bacterial conjugation, which is the dominant mechanism in the *Bacteroides*, is the most common transmission method of antibiotic resistance genes in anaerobes. The resistance genes are situated in DNA transfer factors that contain sometimes mobile transposons, plasmids, and chromosomal elements [149, 204]. These elements can be small harboring only the genes needed for initiation of DNA transfer. The actual transfer of the DNA from one cell to another cell requires a mating connector bridge that is encoded by much larger transferable conjugative transposons [149]. Two sets of biochemical processes are needed for successful horizontal transmission of the transmissible DNA. One process forms a DNA protein complex (called the relaxosome), comprising transfer factor-encoded mobilization proteins that is assembled on the origin of transfer (*oriT*), and results in the formation of a single-stranded nick that creates the transferred molecule. The nicked DNA is then unwound and is transmitted from the donor to the recipient cell. This process occurs during conjugation alongside with the restoration to the double-stranded form in both cells. One to three mobilization proteins are required for adequate relaxosome formation in *Bacteroides* spp. with mobilization proteins specific for their cognate *oriT*s.

The second process needed for transfer is the formation of the mating or conjugal apparatus. This apparatus is a proteinaceous structure that spans the donor and recipient cell membranes and facilitates the transfer of DNA and has not been well characterized among the anaerobes. It is believed to be encoded by the transfer region of conjugative transposons. Genes that possibly encode this apparatus have been found on a conjugative transposon called cTnDOT [205], and the formation of a pilus-like cell-surface appendage is required for the conjugation [206].

Members of the *B. fragilis* group that resist tetracycline are likely to harbor conjugative transposons. CTnDOT, which is the most thoroughly investigated conjugative transposon, contains a tetracycline resistance determinant and genes whose by-products are involved in the formation of the mating bridge [207].

Anaerobic conjugative transposons are mobile genetic elements that are also called Tet elements. The name entails their ability to harbor a tetracycline resistance gene that confers ribosomal protection [208]. These elements encode the conjugative transfer apparatus that assembles at the interface of donor and recipient cells and forms the physical conduit through which DNA containing antibiotic resistance genes is transferred from cell to cell [205, 206]. Exposure of the bacteria to a low, subinhibitory concentration of tetracycline seems to upregulate the expression of transfer apparatus proteins in *Bacteroides* spp. [175]. This exposure increases the conjugative transfer frequency of the intracellular Tet element and the other coresident mobile [209]. Multiple unrelated transfer factors that may carry different antibiotic resistance genes can therefore be transferred during conjugation. This may result in the rapid rise in stable antibiotic resistance among the different bacterial genera of anaerobic bacteria [210]. A conjugative transposon named CTnGERM1

that carries an erythromycin resistance gene and was previously identified only in Gram-positive bacteria was also found in *Bacteroides* spp. [211]. Based on hybridization and DNA sequence analyses, it is assumed that Gram-positive bacteria are likely to be the origin of this transposon. This phenomenon of transposon transfer can be demonstrated in the laboratory, where resistance determinants can be efficiently transferred by conjugation within *Bacteroides* spp. and from *Bacteroides* spp. to *E. coli* and other unrelated bacteria.

Animal bacterial flora may also be a source of resistant anaerobic bacteria as transfer factors can also be transmitted from ruminal animals to humans [212]. Human colonic bacterial flora may acquire resistance determinants from animal sources. The extensive use of antibiotic in livestock has generated an increase in the spread of resistant determinants among ruminal gut flora, many of which may also be acquired by humans.

5 The Role of Beta-Lactamase Producing Bacteria in Mixed Infections

Penicillins have been the agents of choice for the therapy of a variety of anaerobic infections at different anatomical locations (Table 63.8). However, within the last 50 years, an increased resistance to these drugs has been observed, especially in AGNB (*Bacteroides fragilis* group, Pigmented *Prevotella* and *Porphyromonas*, *Prevotella bivia*, and *Prevotella disiens*) and *Fusobacterium* spp. [2, 3, 42].

BLPB may have an important clinical role in infections. Not only can these organisms cause the infection, but they may also have an indirect effect through their ability to produce the BLs. BLPB may not only survive penicillin therapy but also may protect other penicillin-susceptible bacteria from penicillins by releasing the free enzyme into their environment [213].

Anaerobic BLPB were isolated in a variety of mixed infections. These include respiratory tract, skin, soft tissue, and surgical infections and other infections. The clinical in vitro and in vivo evidence supporting the role of these organisms in the increased failure rate of penicillin in eradication of these infections and the implication of that increased rate on the management of infections is discussed below.

5.1 Mixed Infections Involving Anaerobic BLPB

Anaerobic BLPB can be isolated from a variety of infections in adults and children, sometimes as the only isolates and sometimes mixed with other flora (Table 63.5). Table 63.6 summarizes our experience in the recovery of these organisms from skin and soft tissue infections [214–223], upper respiratory tract [224–236], lower respiratory tract [237–240], intra-abdominal [241–243], obstetric and gynecologic [244], and miscellaneous infections [245–248].

The rate of isolation of these organisms varies in each infection entity (Table 63.6) [248]. BLPB were present in 288 (44 %) of 648 patients with *skin and soft tissue infections*,

Table 63.5 Infections involving beta-lactamase-producing bacteria (BLPB)

Infections	Predominant BLPB
Respiratory tract	
Acute sinusitis and otitis	*H. influenzae*, *M. catarrhalis*
Chronic sinusitis and otitis	*S. aureus*, anaerobic Gram-negative bacilli
Tonsillitis	*S. aureus*, anaerobic Gram-negative bacilli
Bronchitis, pneumonia	*H. influenzae*, *M. catarrhalis*, *L. pneumophila*
Aspiration pneumonia, lung abscesses	*S. aureus*, anaerobic Gram-negative bacilli, *Enterobacteriaceae*
Skin and soft tissue	
Abscesses, wounds, and burns in the oral areas, paronychia, bites	*S. aureus*, pigmented Prevotella and Porphyromonas
Abscesses, wounds, and burns in the rectal area	*E. coli*, *B. fragilis* group, *P. aeruginosa*
Abscesses, wounds, and burns in the trunk and Extremities	*S. aureus*, *P. aeruginosa*
Obstetric and gynecologic	
Vaginitis, endometritis, salpingitis, pelvic inflammatory disease	*N. gonorrhoeae*, *E. coli*, *Prevotella* spp.
Intra-abdominal	
Peritonitis, chronic cholangitis, abscesses	*E. coli*, *B. fragilis* group
Miscellaneous	
Periapical and dental abscesses	pigmented Prevotella and Porphyromonas
Intracranial abscesses	*S. aureus*, anaerobic Gram-negative bacilli
Osteomyelitis	*S. aureus*, anaerobic Gram-negative bacilli

Anaerobic Gram-negative bacilli = Bacteroides, prevotella and porphyromonas

Table 63.6 Recovery rate of anaerobic BLPB from various sites [248]

Infection	No. patients with BLPB/total no. patients (%)	Total no. of BLPB	Pigmented *Prevotella* and *Porphyromonas* spp.	*P. oralis*	*P. oris* and *buccae*	*B. fragilis* group	*Bacteroides* and other anaerobic Gram-negative bacilli
Skin/subcutaneous	288/648 (44 %)	332	19/87	2/9	2/3	75/75	8/63
	% of patients[b]		7 %	1 %	0.6 %	26 %	3 %

3 %	% of patients		15 %	3 %	1 %	35 %	2 %

[a]Number of strains producing beta-lactamase/total number of strains
[b]Number of patients with the specific BLPB/total number of patients with BLPB

75 % harbored aerobic and 36 % had anaerobic BLPB. The infections in which BLPB were most frequently recovered were vulvovaginal abscesses (80 % of patients), perirectal and buttock abscesses (79 %), decubitus ulcers (64 %), human bites (61 %), and abscesses of the neck (58 %). The predominant BLPB were *S. aureus* (68 % of patients with BLPB) and the *B. fragilis* group (26 % of patients with BLPB).

BLPB were found in 262 (51 %) of 514 patients with *upper respiratory tract infection* (URTI); 72 % had aerobic BLPB and 57 % had anaerobic. The infections in which these organisms were most frequently recovered were adenoiditis (83 % of patients), tonsillitis in adults (82 %) and children (74 %), and retropharyngeal abscess (71 %). The predominant BLPB were *S. aureus* (49 % of patients with BLPB), pigmented *Prevotella* and *Porphyromonas* (28 % of patients with BLPB) and the *B. fragilis* group (20 % of patients with BLPB).

BLPB were isolated in 81 (59 %) of 137 children with *pulmonary infections*; 75 % had aerobic BLPB, and 53 % had anaerobic BLPB. The largest number of patients with BLPB was found in patients with cystic fibrosis (83 % of patients), followed by pneumonia in intubated patients (78 %) and lung abscesses (70 %). The predominant BLPB was *B. fragilis* group (36 % of patients with BLPB), *S. aureus* (35 % of patients with BLPB), pigmented *Prevotella* and *Porphyromonas* spp. (16 % of patients with BLPB), *P. aeruginosa* (14 % of patients with BLPB), *K. pneumoniae* (11 % of patients with BLPB), and *E. coli* (10 % of patients with BLPB).

BLPB were recovered in 104 (92 %) of 113 patients with *surgical infections*; 5 % of the patients had aerobic BLPB and 98 % had anaerobic BLPB (Table 63.3). The most predominant BLPB was the *B. fragilis* group (98 % of patients with BLPB).

BLPB were recovered in 16 (28 %) of 57 patients with *miscellaneous infections*, which included periapical and intracranial abscesses and anaerobic osteomyelitis; 25 % had aerobic BLPB and 80 % had anaerobic BLPB. The rate of recovery of BLPB was not significantly different in these infections. The most frequently recovered BLPB were pigmented *Prevotella* and *Porphyromonas* spp. (37 % of patients with BLPB), *S. aureus* and *B. fragilis* groups (25 % each of patients with BLPB).

Pelvic inflammatory disease (PID) is a polymicrobial infection [249] involving in most cases numerous isolates, including *N. gonorrhoeae*, *Chlamydia trachomatis*, *Enterobacteriaceae*, and AGNB (*B. fragilis*, *P. bivius*, and *P. disiens*). All of the above organisms (except for *C. trachomatis*) are capable of producing BL. In a summary of 36 studies published from 1973 to 1985, Eschenbach found BLPB in 1483 (22 %) of 6637 specimens obtained from obstetric and gynecologic infections [249]. The predominant BLPB were *Enterobacteriaceae*, *S. aureus*, *B. fragilis* group and pigmented *Prevotella* and *Porphyromonas* spp. The increase in the failure rate of penicillin in eradicating these infections is an indirect proof of their importance [244, 250, 251].

We have recovered 2052 isolates from 736 patients with obstetrical and gynecological infections [244]. Of these isolates, 355 (17 %) were BLPB, 211 (59 %) were anaerobes, and 144 (41 %) were aerobes and facultative. These BLPB were recovered from 276 (37 %) of all 736 patients. The most frequently recovered BLPB were *Bacteroides* spp. Among them *B. fragilis* group accounted for 129 (36 %) of all 355 BLPB. Ninety-nine percent of *B. fragilis* group were BLPB. Others were *P. bivia* (49 of 151 isolates, or 32 %, were BLPB), *P. disiens* (6 of 17, or 35 %), and *P. melaninogenica*

(23 of 110, or 21 %). *S. aureus* was the second most common BLPB isolated in 21 % of patients.

5.2 Production of Beta-Lactamase by Anaerobic Gram-Negative Bacilli in Clinical Infections

B. fragilis group has been known to be capable of producing BL. These organisms are the predominant anaerobic Gram-negative bacilli present in intra-abdominal infections [242] and anaerobic bacteremias [252]. Within the last decade, however, other AGNB previously not recognized as capable of producing BL have acquired this ability. These include the pigmented *Prevotella* and *Porphyromonas* (*P. intermedia*, *P. melaninogenica*, *Porphyromonas asaccharolytica*, and *Porphyromonas gingivalis*), *Prevotella oralis* and *Prevotella oris-buccae* (all are the most common AGNB in respiratory tract infections), and *Prevotella disiens* and *Prevotella bivia* (the most prominent AGNB in pelvic and other obstetrical and gynecological infections) [250].

All 262 isolates of *B. fragilis* group that we recovered from our patients produced BL (Table 63.6). These isolates accounted for 29 % of the BLPB and were isolated in 35 % of the patients with BLPB. *B. fragilis* was recovered in 98 % of patients with BLPB with surgical infections, in 36 % of those with pulmonary infections, in 26 % of those with skin and soft tissue infections, and in 20 % of those with URTI.

One-hundred eleven of 387 (29 %) pigmented *Prevotella* and *Porphyromonas* spp., which accounted for 12 % of BLPB, were isolated in 15 % of the patients with BLPB. The highest frequency of recovery of BL-producing pigmented *Prevotella* and *Porphyromonas* spp. isolates was found in URTI (38 % of all pigmented *Prevotella* and *Porphyromonas* spp. isolates); the isolates were recovered in 28 % of patients with URTI, mostly in those with recurrent tonsillitis and chronic OM. In pulmonary infections 22 % of the pigmented *Prevotella* and *Porphyromonas* spp. isolates produced BL, and they were isolated in 16 % of the patients. Although 22 % of the isolates of the pigmented *Prevotella* and *Porphyromonas* spp. produced BL in skin and soft tissue infections, these organisms were isolated only in 7 % of patients with these infections, mostly in those that were in close proximity or originated from the oral cavity.

Although 37 % of isolates of *P. oralis* produced BL, they were isolated in 3 % of the patients. Smaller percentages of *P. oris-buccae* and other AGNB were also detected. Their distribution among the infectious processes was similar to the distribution of pigmented *Prevotella* and *Porphyromonas* spp.

Penicillin resistance through production of BL is increasingly seen in the genus *Fusobacterium*. This is most commonly seen in *F. nucleatum*, but also in other member of the genus such as in *Fusobacterium varium* and *Fusobacterium mortiferum* [253, 254]. Since *Fusobacterium* spp. is predominant in oral infection, it is not surprising that their presence was associated with failure of therapy of respiratory infections [255].

5.3 Evidence for Indirect Pathogenicity of Anaerobic BLPB

The production of the enzyme BL is an important mechanism of indirect pathogenicity of aerobic and anaerobic bacteria that is especially apparent in polymicrobial infection. Not only are the organisms that produce the enzyme protected from the activity of penicillins, but other penicillin-susceptible organisms can also be shielded. This protection can occur when the enzyme BL is secreted into the infected tissues or abscess fluid in sufficient quantities to break the penicillin's beta-lactam ring before it can kill the susceptible bacteria [256–260] (Fig. 63.1). Clinical and laboratory studies will be described that provide support for this hypothesis.

5.3.1 In Vivo and In Vitro Studies

Animal studies demonstrated the ability of the enzyme BL to influence polymicrobial infections. Hackman and Wilkins showed that penicillin-resistant strains of *B. fragilis*, pigmented *Prevotella* and *Porphyromonas* spp., and *P. oralis* protected a penicillin-sensitive *Fusobacterium necrophorum* from penicillin therapy in mice [261]. Brook et al. [256–260], using a subcutaneous abscess model in mice, demonstrated protection of group A beta-hemolytic streptococci (GABHS) from penicillin by *B. fragilis* and *P. melaninogenica*. Clindamycin or the combination of penicillin and clavulanic acid (a BL inhibitor), which are active against both GABHS and AGNB, were effective in eradicating the infection. Similarly, BL-producing facultative bacteria protected a penicillin-susceptible *P. melaninogenica* from penicillin

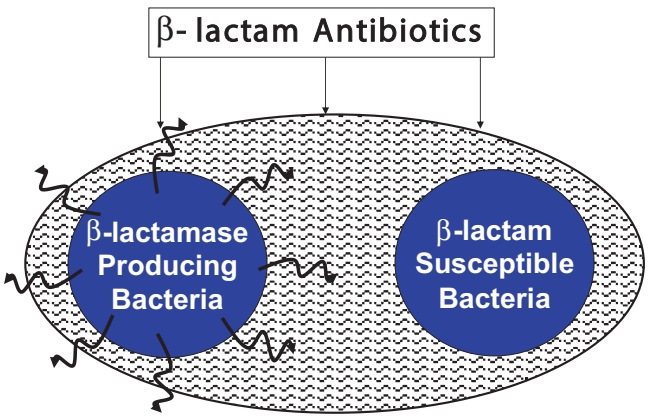

Fig. 63.1 Protection of penicillin-susceptible bacteria from penicillin by beta-lactamase-producing bacteria

[257]. O'Keefe et al. [262] demonstrated inactivation of penicillin-G in an experimental *B. fragilis* infection model in the rabbit peritoneum.

In vitro studies have also demonstrated this phenomenon. A 200-fold increase in resistance of GABHS to penicillin was observed when it was inoculated with *S. aureus* [258]. An increase in resistance was also noted when GABHS was grown with *Haemophilus parainfluenzae* [259]. When mixed with cultures of *B. fragilis* the resistance of GABHS to penicillin increased 8500-fold [263].

BL in clinical infections: Several studies demonstrate the activity of the enzyme BL produced by anaerobic bacteria in polymicrobial infections. De Louvois and Hurley [264] demonstrated degradation of penicillin, ampicillin, and cephaloridine by purulent exudates obtained from 4 of 22 patients with abscesses. Studies by Masuda and Tomioka [265] demonstrated BL activity in empyema fluid. Most infections were polymicrobial and involved both *K. pneumoniae* and *P. aeruginosa.*

The presence of the enzyme BL in clinical specimens was also reported. Bryant et al. [266] detected strong enzyme activity in 4 of 11 pus specimen obtained from 12 patients with polymicrobial intra-abdominal abscess or polymicrobial empyema.

We measured BL activity in 40 (55 %) of 109 abscesses [241]. One hundred BLPB were recovered in 88 (77 %) specimens. These included all 28 isolates of *B. fragilis*, 18 of 30 pigmented *Prevotella* and *Porphyromonas* spp., 42 of 43 *S. aureus*, and 11 of 14 *E. coli.*

We detected the presence of BL activity in 46 of 88 (55 %) ear aspirates that contained BLPB [251]. We were also able to find BL activity in ear aspirates of 30 of 38 (79 %) children with chronic otitis media [267], in 17 of 19 (89 %) ear aspirates of children with acute otitis media who failed AMX therapy [268], and in 12 sinus aspirates (three acute and nine chronic infection) of the 14 aspirates that contained BLPB. The predominant BLPBs in acute sinusitis were *H. influenzae* and *M catarrhalis*; those in chronic sinusitis were *S. aureus*, *Prevotella* spp., *Fusobacterium* spp., and *B. fragilis* (Table 63.7) [269].

A study investigated the monthly changes in the rate of recovery of aerobic and anaerobic penicillin-resistant bacteria in the oropharynx of children [270]. Each month over a period of year, 1993, 30 children who presented with URTI were studied. The maximal total number of aerobic and anaerobic BLPB and number of patients with BLPB was in April (60 % of patients) and the lowest was in September (13 %). A gradual increase of BLPB and penicillin-resistant *S. pneumoniae* occurred from September to April, and a slow decline took place from April to August. These changes correlated directly with the intake of beta-lactam antibiotics. The study was reported over the following year with similar results. The crowding and the increased use of antibiotics that are more common in the winter might have also contributed to the spread of BLPB. Monitoring the local seasonal variation in the rate of BLPB may be helpful in the empiric choice of antimicrobials. Judicious use of antimicrobials may control the increase of BLPB.

Table 63.7 Beta-lactamase detected in four patients with chronic sinusitis aspirates [269]

	BL+ = beta-lactamase-producing bacteria				

Clinical studies illustrating failure of penicillins due to anaerobic BLPB: The recovery of penicillin-susceptible bacteria mixed with BLPB in patients who have failed to respond to penicillin or cephalosporin therapy suggests the ability of BLPB to protect a penicillin-susceptible or cephalosporin-susceptible organism from the activity of those drugs.

Selection of BLPB following antimicrobial therapy may account for many of the clinical failures after penicillin therapy. Heimdahl et al. [263] described five adults with clinical failures after penicillin therapy associated with the isolation of anaerobic BLPB. In a study of 185 children with orofacial and respiratory infections who failed to respond to penicillin, BLPB were recovered in 75 (40 %) [271]. The predominant BLPB were *S. aureus*, pigmented *Prevotella* and *Porphyromonas* spp., *B. fragilis* group, and *P. oralis.*

Increased failure rate of penicillins in the therapy of pelvic inflammatory disease (PID) has also been noticed and these agents are no longer recommended for this infection. Treatment failure has been noticed in as many as 33 % of patients and increased frequency of abscess formation has been observed [272]. Therapy with penicillin, either alone or with an aminoglycoside or tetracycline, failed in 15–25 % of cases [251]. This increased failure rate may be due to the increased resistance to penicillin of anaerobic Gram-negative bacilli and *Neisseria gonorrhoeae* as well as that of the *Enterobacteriaceae* involved in PID.

The URTI in which the phenomenon of indirect pathogenicity was most thoroughly studied is recurrent tonsillitis due to GABHS. Penicillin was considered the drug of choice for the therapy of this infection. However, the frequently reported inability of penicillin to eradicate GABHS is of

concern. GABHS persists in the pharynx despite treatment with intramuscular penicillin in 21 % of the patients after the first course of therapy and in 83 % of the remainder of the patients after retreatment [273]. Two randomized, single-blind, trials illustrated that either oral penicillin V or intramuscular penicillin failed to eradicate GABHS in pharyngitis in 35 % children treated with oral penicillin V and 37 % of intramuscular penicillin [274].

Various theories have been offered to explain this penicillin failure. One theory is that repeated penicillin administration results in a shift in the oral microflora with selection of BL-producing strains of *Haemophilus* spp., *S. aureus*, *M. catarrhalis*, and AGNB [258, 259, 263, 271, 275, 276]. It is possible that these BLPB can protect the GABHS from penicillin by inactivation of the antibiotic.

Clinical evidence supporting the ability of a BLPB to protect a penicillin-susceptible pathogen was reported in numerous studies [258, 259, 277].

The role of anaerobic BLPB in persistence of GABHS was suggested by Brook et al. [233, 234] who studied core tonsillar cultures recovered from children and young adults suffering from recurrent tonsillitis. One or two strains of aerobic and/or anaerobic BLPB were recovered in over 3/4 of the tonsils. The anaerobic BLPB included strains of *B. fragilis* group, pigmented *Prevotella* and *Porphyromonas* spp., and *P. oralis*, while the aerobic bacteria were *S. aureus*, *Haemophilus* spp., and *M. catarrhalis*. This observation was confirmed by Reilly et al. [278], Chagollan et al. [279], and Tuner and Nord [280]. Assays of the free enzyme in the tissues demonstrated its presence in 33 of 39 (85 %) tonsils that harbored BLPB, while the enzyme was not detected in any of the 11 tonsils without BLPB [281].

Tuner and Nord [282] and Brook and Gober [283] have demonstrated the rapid emergence of aerobic and anaerobic BLPB following penicillin therapy. Tuner and Nord [282] studied the emergence of BLPB in the oropharynx of ten healthy volunteers treated with penicillin for 10 days. A significant increase in the number of BL-producing strains of *Bacteroides* spp., *F. nucleatum*, and *S. aureus* was observed. BL activity in saliva increased significantly in parallel to the increase of BLPB.

Brook and Gober [283] isolated BLPB in 3 of 21 (14 %) children prior to penicillin therapy, and in 10 of 21 (48 %) following one course of penicillin. These organisms were also isolated from household contacts of children repeatedly treated with penicillin, suggesting their possible transfer within a family. The organisms were members of the pigmented *Prevotella* and *Porphyromonas* spp., *S. aureus*, *M. catarrhalis*, and *H. influenzae.* In a study of 26 children who received 7 days' therapy with penicillin, prior to therapy 11 % harbored BLPB in their oropharyngeal flora [284]. This increased to 45 % at the conclusion of therapy, and the incidence was still 27 % 3 months later. These data suggest that it is easy to induce BL production in the upper respiratory tract. Following penicillin therapy, these patients became colonized with BLPB.

Certain groups of children are at greater risk for developing penicillin-resistant flora. The daily administration of amoxicillin chemoprophylaxis selected for colonization with aerobic and anaerobic BLPB in all 20 children studied by Brook and Gober [285].

An association has been noted between the presence of BLPB even prior to therapy of acute GABHS tonsillitis and the outcome of 10-day oral penicillin therapy [286]. Of 98 children with acute GABHS tonsillitis, 36 failed to respond to therapy. Prior to therapy, 18 isolates of BLPB were detected in 16 (26 %) of those cured and following therapy 30 such organisms were recovered in 19 (31 %) of these children. In contrast, prior to therapy, 40 BLPB were recovered from 25 (69 %) of the children who failed, and following therapy, 62 such organisms were found in 31 (86 %) of the children in that group.

A correlation was noted between the rate of recovery of BLPB in healthy children and the rate of AMX failure to eradicate GABHS pharyngo-tonsillitis. Brook and Gober obtained pharyngo-tonsillar cultures from 228 children with GABHS PT, treated with AMX for 10 days, and 663 healthy children [287]. AMX failed to eradicate GABHS from 48 of the 228 treated children (21 %). AMX failure rate varied from month to month; it was high between October and May (22–32 %), with the exception of April (11 %), and low between June and September (8–12 %). BLPB were recovered from 226 of 663 (34 %) well children. The rate of recovery of BLPB varied; it was also high between October and May (40–52 %), with exception of April (23 %), and the lowest between June and September (10–12 %). Prior to their treatment, BLPB were recovered from 26 of the 48 (54 %) children who eventually failed AMX therapy, and from 28 of the 180 (16 %) who did not fail ($p < 0.001$). A high failure rate of penicillins in eradication of GABHS in pharyngo-tonsillitis can serve as sensitive indicator for a high prevalence rate of BLPB in the community.

Roos et al. [288] observed high levels of BL in saliva reflecting colonization with numerous BLPB. These investigators also demonstrated that patients with recurrent GABHS tonsillitis had detectable amounts of BL in their saliva compared to patients with tonsillitis that did not recur.

5.4 Therapeutic Implications of the Presence of BLPB

The presence of BLPB in mixed infection warrants administration of drugs that will be effective in eradication of BLPB as well as the other pathogens. The high failure rate of penicillin therapy associated with the recovery of BLPB in a

growing number of cases of mixed aerobic–anaerobic infections highlights the importance of this therapeutic approach [263, 270].

One infection in which this therapeutic approach has been successful is recurrent tonsillitis [273, 288–301]. Antimicrobial agents active against BLPB as well as GABHS were effective in the eradication of this infection. Studies demonstrated the superiority of lincomycin [289–292], clindamycin [293–298], AMX-C [302], and penicillin plus rifampin [299, 300], over penicillin alone. The superiority of these drugs compared to penicillin is due to their efficacy against GABHS, *S. aureus* as well as AGNB.

Over 83 % of the adenoids in children with chronic adeno-tonsillitis are colonized with aerobic and anaerobic BLPB [303]. The existence of BLPB within the adenoids core may explain the persistence of many pathogens, including *S. pneumoniae*, where they may be shielded from the activity of penicillins. The effect on the adenoid bacterial flora of 10 day therapy with either AMX, AMX-C [304], or clindamycin [305] prior to adenoidectomy for recurrent OM was recently studied. The total number of isolates and bacteria per gram of tissue were lower in those treated with any of the antibiotics. However, the number of potential pathogens and BLPB was lower in those treated with AMX-C [304] and clindamycin [305] as compared to AMX and controls ($P<0.001$).

A similar study evaluated the effects of AMX-C and AMX therapy on the nasopharyngeal flora of 50 children with acute otitis media [306]. After therapy, 16 (64 %) of the 25 patients treated with AMX and 23 (92 %) of the 25 patients treated with AMX-C were considered clinically cured. A significant reduction in the number of both aerobic and anaerobic isolates occurred after therapy in those treated with either agent. The number of all isolates recovered after therapy in those treated with AMX-C was significantly lower (60 isolates) than in those treated with AMX (133 isolates, $P<0.001$). The recovery of known aerobic pathogens (e.g., *S. pneumoniae*, *S. aureus*, GABHS, *Haemophilus* spp., and *M. catarrhalis*) and penicillin-resistant bacteria after therapy was lower in the AMX-C group than in the AMX group ($P<0.005$).

The superiority of AMX-C and clindamycin over AMX in eradicating penicillin-susceptible pathogens such as *S. pneumoniae* and GABHS may be due to their activity against aerobic and anaerobic BLPB. The elimination of both potential pathogenic and nonpathogenic BLPB may be beneficial, as these organisms might "shield" penicillin-susceptible pathogens from penicillins. This phenomenon might explain the survival of penicillin-susceptible bacteria such as *S. pneumoniae* in children treated with AMX.

Two studies compared the efficacy of clindamycin to penicillin in the therapy of lung abscesses [307, 308]. Clindamycin was superior to penicillin in treating the infection. The superiority of clindamycin over penicillin was postulated to be due to its ability to eradicate the BL-producing anaerobic Gram-negative bacilli present in lung abscess.

Antimicrobials effective against anaerobic BLPB (ticarcillin-clavulanate or clindamycin) were superior to an antibiotic without such coverage (ceftriaxone) in the therapy of aspiration or tracheostomy-associated pneumonia in children (93 % vs. 46 %, $p<0.05$) [309].

5.5 Antimicrobial Therapy of Anaerobic Infections

The recovery from an anaerobic infection depends on prompt and proper management. The principles of managing anaerobic infections include neutralizing bacterial toxins, preventing bacterial proliferation by changing the environment, and hampering bacterial spread into healthy tissues.

Toxin neutralization by specific antitoxins may be employed, especially in infections caused by *Clostridium* spp. (tetanus and botulism). Controlling the environment is achieved by debriding of necrotic tissue, draining the pus, improving circulation, alleviating the obstruction, and increasing the tissue oxygenation. In many cases surgical therapy is the most important and sometimes the only form of treatment required, whereas in others it is an adjunct to a pharmacologic approach. Without drainage the infection may persist despite antimicrobial therapy and serious complications can develop. The primary role of antimicrobials is in limiting the local and systemic spread of the organism.

Because anaerobic infection is often polymicrobial and is caused by aerobic and anaerobic organisms, antimicrobials that are effective against both components of the infection should be administrated. When such therapy is not given, the infection may persist, and serious complications may occur [2, 3, 310]. A number of factors should be considered when choosing appropriate antimicrobial agents: They should be effective against all target organism(s), induce little or no resistance, achieve sufficient levels in the infected site, have minimal toxicity, and have maximum stability and longevity.

When selecting antimicrobials for the therapy of mixed infections, their aerobic and anaerobic antibacterial spectrum and their availability in oral or parenteral form should be considered (Tables 63.2 and 63.8). Some antimicrobials have a limited range of activity. For example, metronidazole is active against only anaerobic bacteria and therefore cannot be administered as a single agent for the therapy of mixed infections. Other antimicrobials, such as carbapenems, tigecycline, and the combinations of BL/BLIs, possess a broader spectrum of activity against aerobic and anaerobic bacteria.

Selecting antimicrobial agents is simplified when a reliable culture result is available. However, this may be particularly difficult in anaerobic infections because of the difficulties in obtaining appropriate specimens. For this reason, many

Table 63.8 Antimicrobial recommended for the therapy of site-specific anaerobic infections

	Surgical		
	Prophylaxis	Parenteral	Oral

patients are treated empirically on the basis of suspected, rather than established pathogens. Fortunately, the types of anaerobes involved in many anaerobic infections and their antimicrobial susceptibility patterns tend to be predictable [2, 3]. However, some anaerobic bacteria have become resistant to antimicrobial agents, and many can develop resistance while a patient is receiving therapy [118, 283].

Anaerobic bacteria have always been resistant to aminoglycosides and trimethoprim-sulfamethoxazole. Resistance among some anaerobes has increased significantly over the past three decades. The potential for growing resistance of anaerobes to antimicrobials is especially noted with penicillins, fluoroquinolones, clindamycin, and cephalosporins. Chloramphenicol is rarely used in the United States and resistance is very rare and when present it is due to its inactivation by acetyltransferase.

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on the normal flora, and bactericidal activity [2, 3]. Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may indicate the types of anaerobes present in the infection as well as the nature of the infectious process.

Antimicrobial therapy for anaerobic infections usually should be given for prolonged periods because of their tendency to relapse. This may range from 3 weeks to 3 months depending on the site and severity of the infection.

Because anaerobic bacteria generally are recovered mixed with aerobic organisms, selection of proper therapy becomes more complicated. In the treatment of mixed infection, the

choice of the appropriate antimicrobial agents should provide for adequate coverage of most of the pathogens, aerobic and anaerobic. Some broad spectrum antibacterial agents possess such qualities, while for some organisms additional agents should be added to the therapeutic regimen.

6 Choice of Antimicrobial Agents

The available parenteral antimicrobials in most infections (Tables 63.2 and 63.8) are clindamycin, metronidazole, chloramphenicol, cefoxitin, a penicillin (i.e., ticarcillin, ampicillin, piperacillin) and a BL inhibitor (i.e., clavulanic acid, sulbactam, tazobactam), and a carbapenem (i.e., imipenem, meropenem, ertapenem). An agent effective against Gram-negative enteric bacilli (i.e., aminoglycoside) or an antipseudomonal cephalosporin (i.e., cefepime) are generally added to clindamycin, metronidazole, and, occasionally, cefoxitin when treating intra-abdominal infections to provide coverage for these bacteria. Penicillin can be added to metronidazole in the therapy of intracranial, pulmonary, and dental infections to cover for microaerophilic streptococci, and *Actinomyces*. A macrolide (i.e., erythromycin) is added to metronidazole in upper respiratory infections to treat *S. aureus* and aerobic streptococci. Penicillin is added to clindamycin to supplement its coverage against *Peptostreptococcus* spp. and other Gram-positive anaerobic organisms.

Doxycycline is added to most regimens in the treatment of pelvic infections for chlamydia and mycoplasma. Penicillin is still the drug of choice for bacteremia caused by non-BLPB. However, other agents should be used for the therapy of bacteremia caused by BLPB.

Because the duration of therapy for anaerobic infections, which are often chronic, is generally longer than for infections caused by aerobic and facultative anaerobes, oral therapy is often substituted for parenteral therapy. The agents available for oral therapy are limited and include clindamycin, amoxicillin/clavulanate, chloramphenicol, and metronidazole.

Clinical judgment, personal experience, safety, and patient compliance should direct the physician in the choice of the appropriate antimicrobial agents. The length of therapy generally ranges between 2 and 4 weeks, but should be individualized depending on the response. In some cases, such as lung abscesses, treatment may be required for as long as 6–8 weeks, but can often be shortened with proper surgical drainage.

Mycobacteria: Tuberculosis

64

Akos Somoskovi and Max Salfinger

1 Introduction

In 2014, there were 9.6 million incident tuberculosis (TB) cases, equivalent to 133 cases per 100,000 population, with 1.5 million TB deaths. Patients with infectious pulmonary TB, which is mainly caused by *M. tuberculosis* and to a lesser degree *M. bovis* and *M. africanum*, are the main sources of transmission of the disease. Their timely diagnosis (including detection of drug resistance) and prompt treatment have four goals:

1. To cure the patient by killing the rapidly multiplying pathogens
2. To prevent transmission
3. To prevent development of drug resistance
4. To sterilize the infected tissue from dormant bacteria to prevent relapse

Non-pulmonary TB cases are usually not infectious to others. In 2014, there were an estimated 1.2 million new HIV-positive TB cases (12 % of all TB cases) [1].

Drug resistance is often divided into two different types. *Acquired drug resistance* (or drug resistance among previously treated cases) develops in a patient who has received or is currently receiving treatment due to interruptions in therapy or an inadequate therapeutic regimen. *Primary* (*or initial*) *drug resistance* is a resistance in newly diagnosed TB cases, which have previously not received anti-TB treatment, i.e., they have been infected with a resistant strain of bacteria. Multidrug resistance (MDR), i.e., resistance to at least rifampin (RIF) and isoniazid (INH), is a problematic form of resistance. High MDR-TB rates are often used as a marker of contemporary weaknesses in the TB control program as they reflect problems with TB treatment and active transmission of resistant cases. Early detection of drug resistance allows the use of appropriate treatment regimens for patients, which has an important impact on improved TB control. Extensively drug-resistant TB (XDR-TB) is defined as resistance to INH and RIF, plus resistance to any fluoroquinolone (FQ) and at least one of three injectable second-line anti-TB drugs.

Acquired drug resistance is the result of inadequate, incomplete, or poor treatment quality that allows the selection of mutant resistant strains. If drug-susceptible TB is treated with a regimen exclusively based on a single effective TB medicine, there is a risk that bacteria with drug-resistant mutations will be selected and multiply further during the course of treatment, eventually becoming the dominant strain. If a person infected with a strain, initially resistant to a specific drug, is treated with that drug plus a new additional drug, then there is a risk of developing resistance to the additional drug. Stepwise additions of drugs may eventually lead to more severe patterns of drug resistance and eventually to untreatable forms of TB [2].

A person has been infected with a drug-resistant TB strain that has primary drug resistance. Transmission of drug-resistant TB occurs in the same way as transmission of drug-susceptible TB. High prevalence of drug-resistant TB in the community increases the risk of drug-resistant TB exposure in the community. Undiagnosed, untreated, or poorly treated drug-resistant TB contributes to sustained high drug-resistant TB prevalence, as well as high proportions of infectious drug-resistant TB cases among the community [2].

The World Health Assembly, convened annually by the World Health Organization (WHO), passed a resolution in May 2014 approving the new post-2015 Global TB Strategy with its ambitious targets (Table 64.1). The "End TB Strategy" (2016–2035) aims to end the global TB epidemic, with targets to reduce TB deaths by 95 % and to cut new cases by 90 % between 2015 and 2035 and to ensure that no family is burdened with catastrophic expenses due to TB. It sets interim milestones for the years 2020, 2025, and 2030 [3].

Table 64.1 2015 global tuberculosis strategy framework

Vision	A world free of tuberculosis
	– Zero deaths, disease, and suffering due to tuberculosis
Goal	End the global tuberculosis epidemic
Milestones for 2025	– 75 % reduction in tuberculosis deaths (compared with 2015)
	– 50 % reduction in tuberculosis incidence rate (less than 55 tuberculosis cases per 100,000 population)
	– No affected families facing catastrophic costs due to tuberculosis
Targets for 2035	– 95 % reduction in tuberculosis deaths (compared with 2015)
	– 90 % reduction in tuberculosis incidence rate (less than 10 tuberculosis cases per 100,000 population)
	– No affected families facing catastrophic costs due to tuberculosis
Principles	
1	Government stewardship and accountability, with monitoring and evaluation
2	Strong coalition with civil society organizations and communities
3	Protection and promotion of human rights, ethics, and equity
4	Adaptation of the strategy and targets at country level, with global collaboration
Pillars and components	
1	Integrated, patient-centered care and prevention
A.	Early diagnosis of tuberculosis including universal drug-susceptibility testing and systematic screening of contacts and high-risk groups
B.	Treatment of all people with tuberculosis including drug-resistant tuberculosis and patient support
C.	Collaborative tuberculosis/HIV activities and management of comorbidities
D.	Preventive treatment of persons at high risk and vaccination against tuberculosis
2	Bold policies and supportive systems
A.	Political commitment with adequate resources for tuberculosis care and prevention
B.	Engagement of communities, civil society organizations, and public and private care providers
C.	Universal health coverage policy and regulatory frameworks for case notification, vital registration, quality and rational use of medicines, and infection control
D.	Social protection, poverty alleviation, and actions on other determinants of tuberculosis
3	Intensified research and innovation
A.	Discovery, development, and rapid uptake of new tools, interventions, and strategies
B.	Research to optimize implementation and impact and promote innovations

2 Epidemiology

Since 1994, the WHO and the International Union Against Tuberculosis and Lung Disease Supranational Reference Laboratories Network have been a driving force in strengthening national and central level laboratories globally. The network, comprising more than 30 laboratories covering all six WHO regions, is also instrumental in supporting antimicrobial resistance surveys, providing quality assurance through proficiency testing and validating antimicrobial susceptibility test (AST) data [2].

In 2014, globally, an estimated 3.3 % of new cases (Fig. 64.1) and 20 % of previously treated cases have MDR-TB (Fig. 64.2); these levels have remained virtually unchanged in recent years. In 2014, there were an estimated 480,000 new cases of MDR-TB worldwide and approximately 190,000 deaths from MDR-TB. More than half of these patients were in India, China, and the Russian Federation. XDR-TB had been reported by 105 countries by 2015. An estimated 9.7 % of people with MDR-TB have XDR-TB [1].

The 22 high-burden countries that have been given highest priority at the global level since 2000 (listed in Table 64.2) accounted for 83 % of all estimated incident cases worldwide. The six countries that stand out as having the largest number of incident cases in 2014 were India, Indonesia, China, Nigeria, Pakistan, and South Africa [1].

The proportions of new and previously treated TB cases with MDR-TB are shown for the 27 high MDR-TB burden countries in Table 64.3. Eastern European and Central Asian countries continue to have the highest levels of MDR-TB. Among new cases, the proportions with MDR-TB were highest in Belarus, Estonia, Kazakhstan, Kyrgyzstan, the Republic of Moldova, the Russian Federation, Ukraine, and Uzbekistan. Among previously treated TB cases, the proportions with MDR-TB were highest in Belarus, Estonia, Kazakhstan, Kyrgyzstan, the Republic of Moldova, Tajikistan, Ukraine, and Uzbekistan. In the Russian Federation, even though the average proportion of previously treated cases with MDR-TB does not exceed 50 %, the proportion is well above 50 % in several federal subjects [1].

[a]Best estimates are for the latest available year

[b]The estimates for DR Congo are indirect estimates based on data from countries in the same epidemiological region

Levels of drug resistance among new cases remain low (<3 %) in many parts of the world, including in almost all countries in the Region of the Americas, most African countries where antimicrobial resistance surveys have been conducted, most of the Southeast Asia Region, most of Western Europe, and several countries in the Western Pacific Region [1].

2.1 Data from the United States

For the first time since 1992, the number of US TB cases (9,557) reported increased over the previous year by 1.6 %. Despite this slight increase in case count, the TB incidnce rate per 100,000 persons has remained relatively stable at approximately 3.0 since 2013. Since the 1992 TB resurgence peak in the United States, the number of TB cases reported annually has decreased by 64 % [4].

In foreign-born persons, the percentage of primary INH resistance declined from 12.1 % in 1993 to 10 % in 2015. In US-born persons, the percentage decreased from 6.7 % in 1993 to 4.2 % in 2007 but has increased since then to 6.4 % in 2015 (Fig. 64.3a). From 1996 to 2015, the percentage of primary MDR-TB cases has fluctuated between 1.3 and 0.9 % (Fig. 64.3b). Since 1996, the percentage of US-born patients with primary MDR-TB has remained below 1 %. However, of the total number of reported primary MDR-TB cases, the proportion occurring in foreign-born persons increased from 25 % (103 of 407) in 1993 to 86 % (63 of 73) in 2015 (Fig. 64.3c). One case of XDR-TB was reported in 2015, and the most reported in a single year was 10 in 1993. No cases were reported in 2003 and 2009, and no apparent trend exists in the number of cases over time (Fig. 64.3d) [4].

2.2 Europe

Fifteen of the world's 27 countries with a high MDR- and XDR-TB burden are in the WHO European Region (Fig. 64.4). With the dissolution of the Soviet Union in the early 1990s, TB and MDR-TB case rates began to increase in the newly independent states, largely due to the ensuing

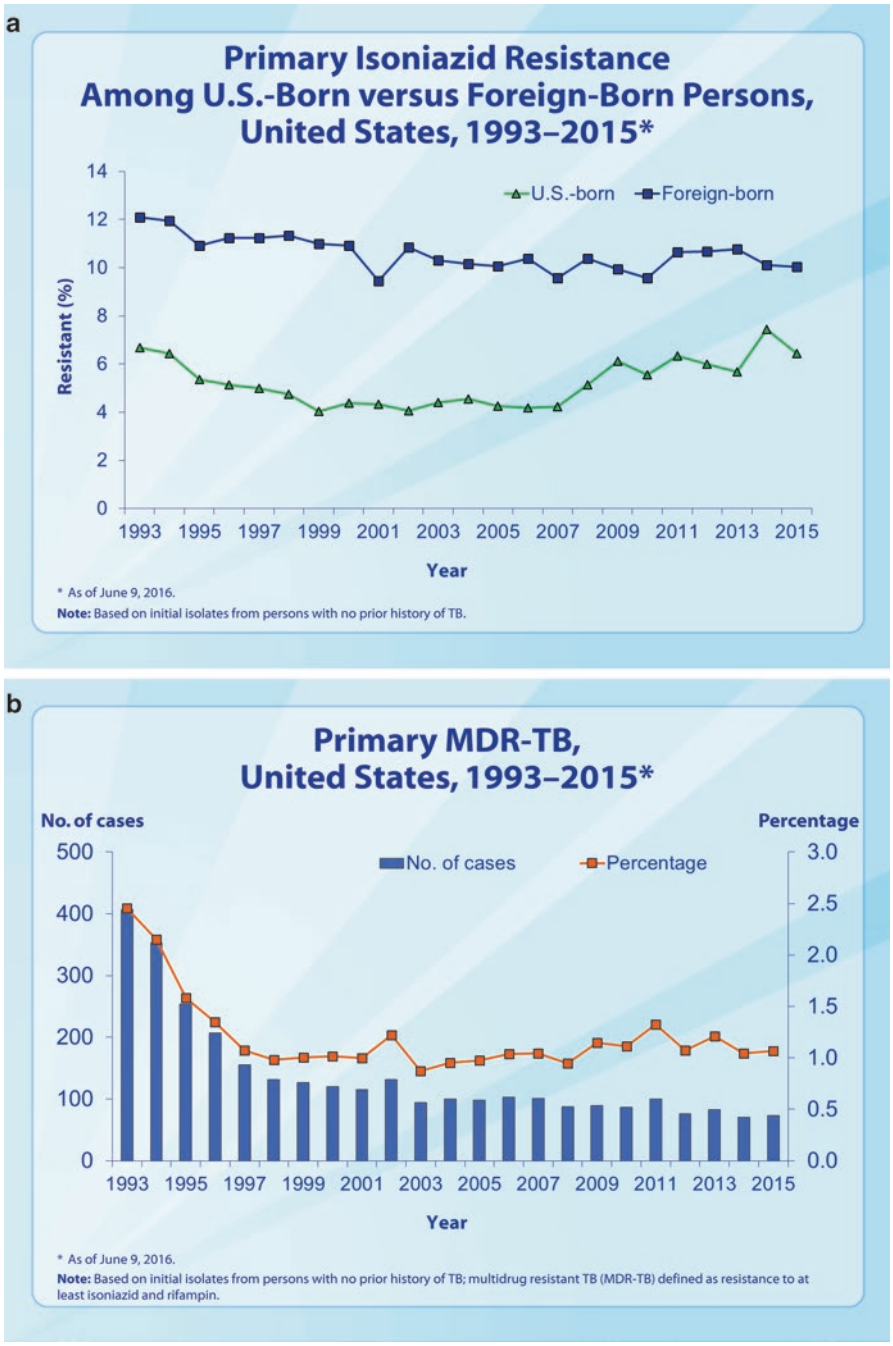

Fig. 64.3 (**a**) This graph shows primary INH resistance in US-born vs. foreign-born persons. The percentage of primary INH resistance has remained higher among foreign-born persons than among US-born persons for all years measured. In foreign-born persons, the percentage declined from 12.1 % in 1993 to 10 % in 2015. In US-born persons, the percentage decreased from 6.7 % in 1993 to 4.2 % in 2007 but has increased since then to 6.4 % in 2015. (**b**) This graph focuses on trends in primary MDR-TB in the United States from 1993 through 2015. The number of primary MDR-TB cases steadily declined from 407 in 1993 to 132 in 2002. Since then, the total number of primary MDR-TB cases has fluctuated between 87 and 103 cases, with 89 cases reported for 2015. Primary MDR-TB decreased from 2.5 % in 1993 to approximately 1.0 % in 1998 and has fluctuated around 1.0 % since then. In 2015, the percentage of primary MDR-TB was 1.1 %. (**c**) This graph highlights primary MDR-TB in US-born versus foreign-born persons. The proportion of primary MDR-TB cases in the United States that are attributed to foreign-born persons increased from approximately 25 % in 1993 to 86 % in 2015 (not shown on slide). Among the US born, the percentage with primary MDR-TB has been less than 1 % since 1997 and was 0.5 % in 2015. The percentage among foreign-born persons has fluctuated year by year, although it has remained between 1.2 and 1.8 % since 1995. In 2015, the percentage of primary MDR-TB among foreign-born persons in the United States was 1.4 %. (**d**) This graph shows the annual number of counted XDR-TB cases from 1993 to 2015. One case of XDR-TB was reported in 2015. The most XDR-TB reported in a single year was 10 in 1993, while there were no cases reported in 2003 and 2009, and no apparent trend exists in the number of cases over time

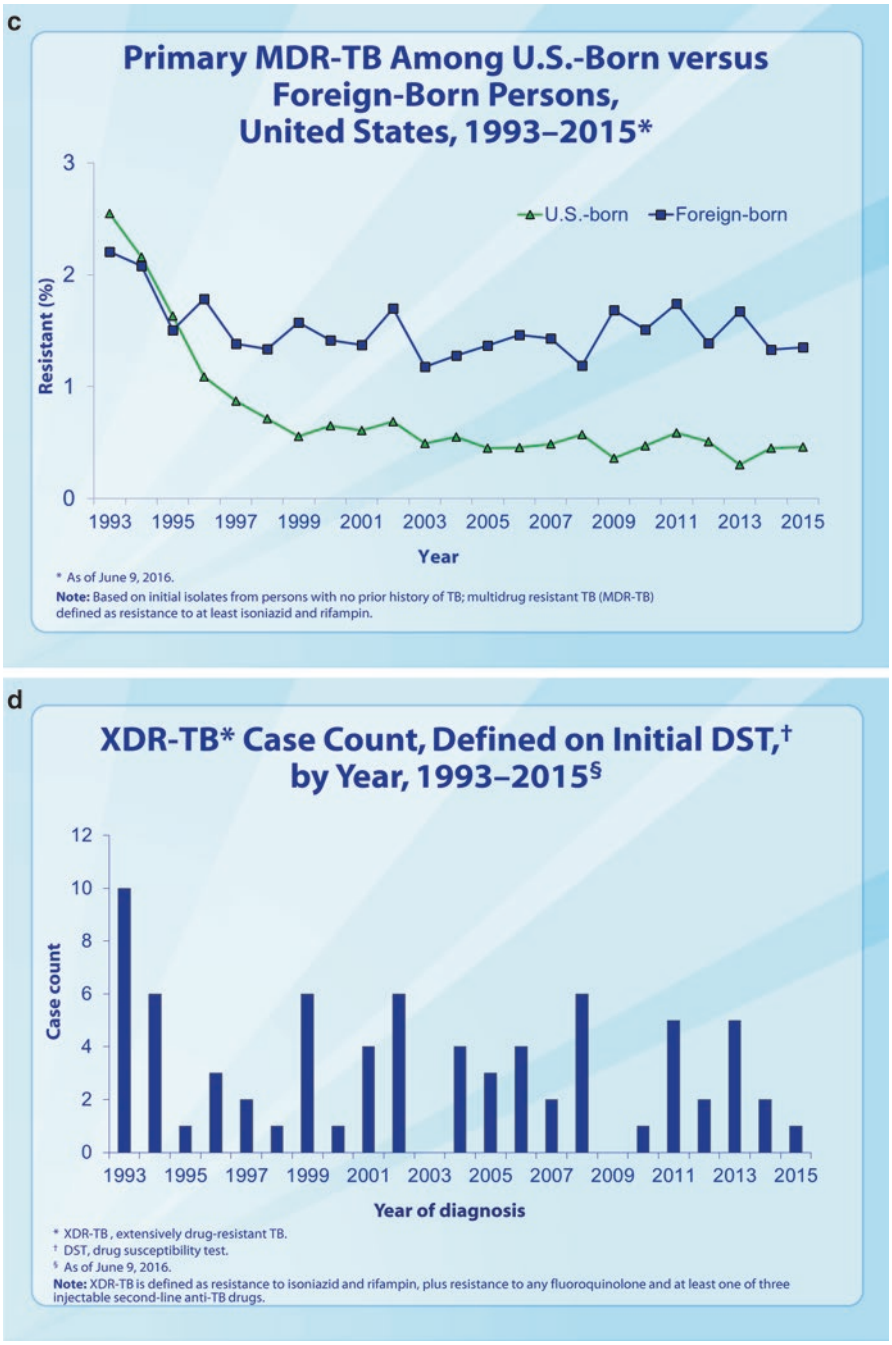

Fig. 64.3 (continued)

socioeconomic crisis and deterioration of the healthcare system. Currently, all high-burden MDR-TB countries in the WHO European Region are in the east, and 99 % of the region's MDR-TB cases occur in these countries [5].

The emergence of drug-resistant TB is a challenge to TB control in Europe. Guenther et al. evaluated second-line AST in *M. tuberculosis* isolates from patients with MDR-TB, pre-XDR-TB, and XDR-TB at 23 Tuberculosis Network European Trials (TBNET) sites. Table 64.4 shows low AST figures for test performed for later-generation FQs (levofloxacin and moxifloxacin) and linezolid at these sites in 16 European countries. Isolates from patients with pre-XDR-TB showed >30 % resistance to any FQ and almost 70 % to any second-line injectable drugs such as amikacin,

capreomycin, and kanamycin. Of the tested XDR-TB, *M. tuberculosis* strains showed phenotypic resistance to pyrazinamide (PZA) and ethambutol (EMB), >90 % and >80 %, respectively. Additional resistance to prothionamide/ethionamide was high in isolates from both pre-XDR (43 %) and XDR-TB patients (49 %). AST against Group 5 drugs was rarely performed [6].

3 Clinical Significance and Treatment

3.1 Drug-Susceptible Tuberculosis

Treatment of drug-susceptible TB is highly effective and is based on a standardized strategy proved over several decades in international clinical trials; a treatment regimen includes a combination of drugs administered for a defined period, usually 6–9 months depending on the form of TB and history of anti-TB treatment in the past. Modern treatment regimens include four so-called first-line drugs [INH, RIF, PZA, and EMB or streptomycin (SM)], and treatment is divided into a 2-month intensive phase using three or four of the first-line drugs followed by a continuation phase usually with isoniazid and rifampin for a total of 6 months (sometimes 9 months or 12 months for TB meningitis). The goal of the intensive phase is to kill the actively metabolizing and multiplying bacteria, while the continuation phase is aiming to sterilize the infected tissue from the metabolically sporadically active semi-dormant pathogens [7–10]. Tables 64.5 and 64.6 describe the main doses, different forms of treatment of first-line drugs [7–10].

In case of a higher than 4 % rate of INH resistance in setting of the patient, treatment should be initiated with the combination of INH, RIF, PZA, and EMB or SM for 2 months (intensive phase) followed by INH and RIF for 4 months (continuation phase) [7, 9, 10]. The role of SM in first-line therapy has diminished based on the more common occurrence of resistance and the inconvenience of parenteral administration. Inclusion of EMB or SM in the regimen is not necessary if the rate of INH resistance is below 4 %, or the administration of these drugs can be discontinued if AST results are available before the end of the intensive phase and indicate the presence of a fully susceptible strain. However, if AST results are not available at the end of the intensive phase, treatment should be continued with EMB (in combination with INH and RIF); however, a dose adjustment is necessary to avoid ototoxicity [7–10]. Bacteriologic follow-up is recommended with acid-fast bacilli (AFB) smears and culture bi-weekly or at least monthly until two subsequent cultures are negative and at the end of the treatment. Time to culture negativity (culture conversion) is one of the most valuable measures of response to therapy.

The likelihood of relapse after completion of therapy shows a high correlation with the initial extent of the disease and the results of cultures at the end of the intensive phase. Therefore, in patients with advanced and cavitary disease (and AFB smear positive) whose month 2 cultures are still positive, it is recommended to extend the duration of the continuation phase with INH and RIF for an additional 3 months and prolong the total time of therapy to 9 months [7]. This approach has proven to be an effective measure to significantly decrease the chance of later relapse of the disease in these patients.

If cultures during the continuation phase are repeatedly positive or become positive again in spite of a properly administered therapy, additional molecular screening and conventional AST are highly recommended to rule out emerging drug resistance.

The completion of therapy is based both on the duration of treatment and the number of recommended doses taken (Table 64.6) [7]. However, it is not uncommon that the required number of doses is not or could not be completed during the recommended duration of the therapy. If treatment of the intensive phase is interrupted for more than 2 weeks, the treatment should be restarted from the beginning. If the interruption is less than 2 weeks, treatment should be

Table 64.5 Doses of first-line antituberculosis drugs for adults and children

	Adults/children	Daily	Twice weekly	Thrice weekly
INH	Adults (max.)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)
	Children (max.)	10–15 mg/kg (300 mg)	20–30 mg/kg (900 mg)	–
RIF	Adults (max.)	10 mg/kg (600 mg)	10 mg/kg (600 mg)	10 mg/kg (600 mg)
	Children (max.)	10–20 mg/kg (600 mg)	10–20 mg/kg (600 mg)	–
PZA	Adults	1.0 g (<55 kg)	1.5 g (<55 kg)	2.0 g (<55 kg)
		1.5 g (56–75 kg)	2.5 g (56–75 kg)	3.0 g (56–75 kg)
		2.0 g (75+ kg)	3.0 g (75+ kg)	4.0 g (75+ kg)

continued with the goal to give the total number of the doses recommended for the intensive phase within 3 months. If the total number of doses of the intensive phase could not be completed within 3 months, the treatment should be restarted. In the case treatment of an initially AFB smear-negative patient is interrupted during the continuation phase and the patient has completed at least 80 % of the recommended doses for this period, prolongation of the treatment may not be necessary. However, for an initially AFB smear-positive patient, completion of the therapy is recommended with the total number of doses [7].

Those patients that received less than 80 % of the recommended doses for the continuation phase may have two options. If the duration of interruption was less than 3 months, the continuation phase therapy should be continued. The patient should take all the initially planned doses for this period within 6 months (after the restart or within 9 months of original start date) if cultures performed after the return of the patient are negative. If these cultures are positive, restart the four-drug first-line regimen. If the lapse was 3 months or more, the entire treatment (both initial and continuation phase) should be restarted from the very beginning. However, in case of a negative follow-up culture, treatment may be stopped if the patient has received a total of 9 months therapy [7].

Conducting and enforcing directly observed therapy (DOT) in patients with any therapy interruption is indispensable. Bacteriologic follow-up of patients with treatment interruption is extremely important, and if cultures after the return of the patients are positive, additional molecular and conventional AST is recommended without delay to reveal any drug resistance.

Recently, three major phase 3 non-inferiority trials assessed the efficacy of FQs in shortening the duration of the 6-month treatment of susceptible tuberculosis to 4 months [11–13]. The concept of these trials was based on the findings of in vitro and murine model studies that indicated that moxifloxacin and gatifloxacin in combination with INH, RIF, and PZA or high-dose rifapentine resulted in a reduced time to sterilize the lung tissue from *Mycobacterium tuberculosis* and cure using a 4-month regimen. The Rapid Evaluation of Moxifloxacin in Tuberculosis (REMoxTB) trial was a randomized, double-blinded, placebo-controlled trial that evaluated two regimens in which INH or EMB was substituted to moxifloxacin in a 4-month regimen. The Ofloxacin-Containing Short-Course Regimen for the Treatment of Pulmonary Tuberculosis (OFLOTub) evaluated the standard 6-month regimen against a 4-month regimen in which gatifloxacin was substituted for EMB. The High-Dose Rifapentine with Moxifloxacin for Pulmonary Tuberculosis (RIFAQUIN) trial examined the efficacy of a 4-month and 6-month combination in which moxifloxacin replaced INH in the intensive phase. Unfortunately none of these trials were able to demonstrate that FQs could achieve the goal and shorten the duration of treatment as anticipated. However, it is important to note that in the RIFAQUIN trial, the 6-month regimen with moxifloxacin and rifapentine once weekly in the continuation phase was very effective. Using DOT, this once-weekly approach for the last 4 months of the treatment could be extremely beneficial in certain settings to assure compliance, simplify successful completion of treatment, and spare resources for follow-up. Additional studies are ongoing to examine the role of rifapentine, high-dose RIF, or clofazimine to shorten treatment of susceptible TB [14].

The early institution of appropriate therapy is essential to both prevent the emergence of MDR-TB and to treat it when it occurs [9, 10]. The WHO has adopted the directly observed therapy short course (DOTS) strategy, pioneered in studies performed in many parts of the world to treat drug-susceptible TB and to prevent MDR-TB from developing. A DOTS-Plus strategy is used to treat cases that do occur [9, 10]. Ensuring adherence and completion of therapy is the key aim, and DOTS is one effective strategy for achieving it.

3.2 Drug-Resistant Tuberculosis

3.2.1 Treatment of Different Forms of Single Drug Resistance

The standardized treatment approach is greatly jeopardized by the presence of drug resistance. Testing for molecular drug resistance mutations and complete phenotypic AST including quantitative phenotypic AST can provide valuable support to determine the best approach to successfully handle single drug resistance. This treatment may be the extension of therapy with the remaining first-line drugs, the addition of second-line drugs, or an increase of the dose of the drug involved.

INH mono-resistance can be quite high in certain high-burden settings such as India, where the rate of INH mono-resistance may reach 10 % [15]. In case of isolated phenotypic INH resistance, rapid molecular resistance screening is especially important to adequately orientate the clinician if INH could be continued or should be excluded from the regimen. In the presence of *inhA* mutations, a low level of phenotypic INH mutation can be expected which usually can be successfully controlled with high-dose INH therapy [16, 17]. In these patients, treatment could be started with an increased dose of INH in combination with RIF, EMB, and PZA for 2 months followed by high-dose INH, RIF, and EMB for 4 months. With quantitative AST, the isolates of these patients usually show resistance to 0.1 μg/mL and susceptibility at 0.4 μg/mL to INH in the liquid culture-based MGIT system [18]. However, when rapid molecular screening confirms the presence of a mutation of the *katG* gene in locus 315, the presence of a clinically meaningful and high-level phenotypic resistance (resistance at both 0.1 and 0.4 μg/mL INH in the MGIT system) is confirmed, which may clearly indicate that INH treatment is not an option for these patients and should not be continued in the treatment regimen, not even with an increased dose [19, 20]. Although molecular testing can be quite informative for the clinician, one would not need to exercise caution in the case of detection of a less common *katG* mutation (other than locus 315 mutations) which may be associated with moderate-level phenotypic resistance before making any therapeutic decisions. The level of phenotypic resistance of a less common *katG* mutation needs to be assessed with quantitative AST, i.e., minimal inhibitory concentrations (MICs). Patients with moderate, or especially with high level of INH resistance that cannot benefit from high-dose INH treatment, may be treated with RIF, EMB, and PZA for 6 months [7]. The length of therapy in patients with isolated INH resistance may be prolonged to 9 months if the patient was initially AFB smear-positive and had cavitary disease and follow-up cultures at second month were still positive. The addition of an FQ to the regimen may not be beneficial due to the unfavorable serum concentration changes due the interactions between RIF and the FQs [21, 22] but may be considered in case of an extensive disease. However, it is important to keep in mind that the RIFAQUIN trial that examined the efficacy of moxifloxacin replacing INH in the intensive phase followed by moxifloxacin and rifapentine once weekly in the continuation phase was very effective [13]. Patients who do not tolerate PZA, or in case of pregnancy, a regimen with RIF and EMB for 12 months could be an option [7]. *Ex juvantibus* high-dose INH treatment may not be recommended to all patients with isolated INH resistance since treatment in case of high-level phenotypic resistance may lead to serious polyneuropathy in these patients unnecessarily. Therefore, every effort should be taken to clarify the level of INH resistance.

Isolated rifamycin resistance is usually rare. However, a recent review of the data from various diagnostic settings worldwide supported by 14 WHO supranational laboratories revealed that RIF mono-resistance was as high as 11.6 % in certain geographic regions [23]. Mukinda et al. reported that in the Western Cape of South Africa, RIF mono-resistance tripled in 5 years, and 12 % of these patients were falsely diagnosed and treated for MDR-TB instead of a 12-month regimen with the more effective remaining first-line drugs enhanced with FQ [24]. Rufai et al. also reported a high rate of RIF mono-resistance (22.2 %) in a selection of 285 smear-positive MDR-TB suspects in India after line probe assay AST [15]. Patients with isolated RIF resistance can be treated with INH, PZA, EMB, and FQ for a minimum of 12 rather than 18 months. The preferable choice of FQ is moxifloxacin over ofloxacin due to its more favorable pharmacokinetics and MIC [7–10, 25]. This regimen can be enhanced by the addition of an injectable drug for the first 2–3 months in case of an advanced (cavitary) disease to rapidly decrease the bacterial load and/or to shorten duration to 12 months. Alternatively, an INH, PZA, and SM (or another injectable drug) combination may also be considered that could be given for 9 months [7–10, 25]. Mutations in the *rpoB* gene generally result in cross-resistance to all rifamycins. However, mutations at codon 516, Phe514PhePhe, and Ser522Leu are associated with resistance to RIF but susceptibility to rifabutin [26]. In these patients, detection of these mutations by molecular *rpoB* screening may be extremely beneficial because a standard rifabutin-based 6-month regimen can be implemented which may offer a significantly better outcome, shorter treatment period, and potentially fewer side effects.

Isolated resistance to PZA is extremely uncommon in case of *M. tuberculosis* and is usually associated with *M. bovis*, *M. bovis* BCG, or *M. canettii* infections due to their natural resistance to PZA [27]. Therefore, differentiation between the members of the *M. tuberculosis* complex is recommended by rapid identification molecular methods especially in case of phenotypic PZA mono-resistance. Treatment for a patient with mono-resistant PZA can be administered by a 9-month regimen with INH, RIF, and EMB for 2 months and with INH and RIF for 7 months thereafter [7–10, 25].

In case of isolated SM resistance, the standard first-line treatment regimen for drug-susceptible *M. tuberculosis* still applies (INH, RIF, PZA, and EMB for 2 months followed by INH and RIF for 4 months if the strain is susceptible to INH and RIF). For isolated EMB resistance (which is also uncommon), the intensive phase remains 2 months of INH, RIF, and PZA followed by 4 months of INH and RIF [7–10, 25].

To follow up the efficacy of treatment in patients with isolated antituberculosis drug resistance, a follow-up monthly AFB smear and culture with minimum bimonthly phenotypic AST and monthly molecular resistance testing could be appropriate.

3.3 Treatment of Multidrug- and Extensively Drug-Resistant Tuberculosis (MDR-TB and XDR-TB)

Treatment of MDR-TB is complex and often challenging. In order to ensure the best possible treatment outcome, the following principles should be followed regarding (1) the number of drugs necessary to treat, (2) the rational use of most effective and less effective drugs available, (3) and the duration of therapy also on emphasis on the length of administration of the injectable drug, when designing and initiating an MDR-TB regimen. Main doses and potential side effects of first- and second-line drugs are summarized in Table 64.7 [7–10, 25, 29].

According to the most recent WHO and International Union Against Tuberculosis and Lung Disease guidelines, a second-line treatment regimen should include at least four drugs certain to be effective [7–10, 25]. An injectable agent should be used for at least after 4–6 months after culture conversion [9, 10, 25]. A minimum of 18- to 24-month treatment should be given after culture conversion using DOT during the entire course of treatment with daily administration of the drugs [7–10, 25, 29]. Intermittent therapy is not recommended. Whenever it is possible based on the toxicity and tolerability of the medication, high-end doses of the available drugs should be administered [7–10, 25, 29].

Treatment can be initiated with an expanded empiric therapy based on the treatment history of the patient, potential cross-resistance mechanisms based on first-line phenotypic and molecular AST results, local antimicrobial resistance survey findings, and information on drugs commonly used in the area. Initial empiric treatment can thereafter be optimized later in line with second-line molecular and phenotypic AST results [7–9, 25, 29]. Quantitative AST results could especially be helpful to clarify the presence of cross-resistance within or among drug classes and to determine if the level of resistance, especially in case of the more potent drugs such as rifamycins, FQs, or aminoglycosides, is high or low so that their expected clinical impact can be better evaluated [30].

Antituberculosis drugs are organized into five groups presented in Table 64.8, based on the potency and efficacy (bactericidal or bacteriostatic) and route of administration [2, 7–9, 25, 29]. The selection of at least four efficient drugs should be started from Group 1 with the inclusion of all possible drugs. There is a prevailing assumption that since silent mutations in the *rpoB* gene are rare, molecular assays that screen for the presence or absence of mutations in this gene can be adequate tools for the identification of MDR-TB patients [20, 30]. Information on the type of the *rpoB* mutation can be indispensable to rule out cross-resistance to rifabutin (RFB) since mutations at codon 516, Phe514PhePhe, and Ser522Leu are usually associated with RFB susceptibility in spite of RIF resistance [26, 30]. Therefore, if this information is available and properly interpreted, these MDR-TB patients may receive a rifamycin-based therapy that may offer a much better clinical outcome [20, 30, 31]. A recent study from Bangladesh that was based on MIC testing of MDR-TB patient isolates showed that 19 % of the 62 RIF-resistant isolates in this setting showed susceptibility to RFB [32]. Molecular testing that could have provided a more rapid elucidation in this regard was not available for these patients. In addition, it is clear that some of these less common mutations (*rpoB* Leu511Pro, Asp 516Tyr, Leu533Pro, His526Leu/Ser, Ile572Phe), which may reach 22 % of all RIF-resistant cases in certain settings [33, 34], are associated with a <1.0 μg/mL phenotypic RIF resistance, which is also the definition criteria for MDR-TB. Since phenotypic tests usually only test for this single RIF concentration in the absence of routine quantitative AST (for additional lower concentrations) and molecular resistance screening, these patients are often detected as infected with fully RIF-susceptible strains. Preliminary results indicate that patients with such mutant strains may fail more often under first-line therapy with standard RIF doses [33]. Therefore, future molecular and conventional AST using a quantitative approach must be able to rapidly and adequately identify these mutations as well. However, the question has to be raised if these patients should also be considered MDR-TB in cases of associated low- or high-level INH resistance. Should one, therefore, reexamine the current critical concentration used

Table 64.7 First- and second-line antituberculosis drugs, recommended dosages, and common side effects

Drug	Route	Dose in adults	Major side effects and comments
Isoniazid	Oral, IV	5 mg/kg daily	Hepatotoxicity, peripheral neuropathy, administer with pyridoxine
Rifampin	Oral, IV	10 mg/kg daily	Hepatotoxicity, gastrointestinal upset, rash, flu-like symptom, many drug interactions (e.g., antiretroviral therapy)
Rifabutin	Oral	5 mg/kg daily (up to 450 mg daily)	Hepatotoxicity, leukopenia, thrombocytopenia, uveitis, rash arthralgia, drug interactions
Rifapentine	Oral	Not recommended in the United States for intensive phase, 600–1200 mg once weekly in continuation phase	Hepatotoxicity, drug interactions
Ethambutol	Oral, IV	15–25 mg/kg daily	Retrobulbar neuritis, visual changes, color discrimination, monitor visual acuity
Pyrazinamide	Oral	25–35 mg/kg daily	Hepatotoxicity
Levofloxacin	Oral, IV	10–15 mg/kg daily	QTc interval prolongation, Achilles tendon rupture, peripheral neuropathy
Moxifloxacin	Oral, IV	400 mg/daily	QTc interval prolongation, diarrhea, concomitant administration with bedaquiline or delamanid not recommended, peripheral neuropathy
Amikacin	IM, IV	15 mg/kg daily (max 1 g daily) 15 mg/kg daily thrice weekly after culture conversion	Nephro- and ototoxicity, monitor renal function, hearing and electrolytes
Kanamycin	IM, IV	15 mg/kg daily (max 1 g daily) 15 mg/kg daily thrice weekly after culture conversion	Nephro- and ototoxicity, monitor renal function, hearing and electrolytes
Capreomycin	IM, IV	15 mg/kg daily (max 1 g daily) 15 mg/kg daily thrice weekly after culture conversion	Nephro- and ototoxicity, monitor renal function, hearing and electrolytes
Streptomycin	IM, IV	15 mg/kg daily (max 1 g daily) 15 mg/kg daily thrice weekly after culture conversion	Nephro- and ototoxicity, monitor renal function, hearing and electrolytes
Ethionamide/ prothionamide	Oral	15–20 mg/kg daily (usually 750 mg single dose)	Hepatotoxicity, hypothyroidism, peripheral neuropathy, administer with pyridoxine,
Terizidone or cycloserine	Oral	15–20 mg/kg daily (usually 750 mg single dose)	CNS toxicity, depression, psychosis, peripheral neuropathy, administer with pyridoxine,
Para-aminosalicylic acid	Oral, IV	Oral: 4 g thrice daily: iv 12 g daily	Hypothyroidism, gastrointestinal distress
Linezolid	Oral, IV	600 mg daily	Optic and peripheral neuropathy, myelosuppression, diarrhea, and nausea
Clofazimine	Oral	100–200 mg daily	Severe skin discoloration, QTc interval prolongation, photosensitivity, gastrointestinal distress, retinopathy
Amoxicillin-clavulanate	Oral, IV	40 mg/kg daily two or three times (max. 3000 mg daily)	Diarrhea and nausea
Clarithromycin	Oral	500 mg twice daily	Diarrhea and nausea, QTc interval prolongation, *M. tuberculosis* contains *erm* [28] gene which may be associated with inducible resistance to macrolides
Imipenem-cilastatin	Oral	1000 mg two or three times daily	Diarrhea and nausea
Meropenem	IV	1000 mg two or three times daily	Diarrhea and nausea

CNS central nervous system, *GI* gastrointestinal, *IM* intramuscular, *IV* intravenous

in conventional AST assays for defining RIF resistance and, consequently, the diagnosis of MDR-TB in these patients [17]? Further clinical studies should also clarify if these patients could be better treated with increased dose of RIF.

The selection of appropriate drugs should be continued by the addition of an FQ from Group 2 and an injectable agent from Group 3 [7–10, 25, 29]. Because of the known cross-resistance mechanisms within the respective classes, only one drug is recommended to be selected from either Group 2 or Group 3. However, it is important to underline that due to their more favorable pharmacokinetics, pharmacodynamics, and low MICs, newer-generation FQs such as levofloxacin, gatifloxacin, or moxifloxacin should be given preference over ofloxacin [8–10, 25]. Based on their efficacy, tolerability, and cost, the first choice of injectable aminoglycosides should be SM, followed by kanamycin, capreomycin, and amikacin [7–10, 25, 29]. However, the rate of SM resistance may often be high in drug-resistant TB, and therefore often kanamycin or amikacin is the first choice within the class. Rapid molecular prescreening for mutations in the *rpsl* or

Table 64.8 Groups of drugs to treat MDR-TB

Group 1 (first-line oral agents)	Pyrazinamide
	Ethambutol
	Rifabutin
Group 2 (injectable agents)	Kanamycin
	Amikacin
	Capreomycin
	Streptomycin
Group 3 (fluoroquinolones)	Levofloxacin
	Moxifloxacin
	Ofloxacin
Group 4 (oral bacteriostatic second-line agents)	Para-aminosalicylic acid
	Cycloserine
	Terizidone
	Ethionamide
	Prothionamide
Group 5 (agents with unclear role)	Linezolid
	Clofazimine
	Amoxicillin/clavulanate
	Imipenem/cilastatin
	Meropenem
	Clarithromycin
	High-dose isoniazid

rrs genes from AFB smear-positive specimens directly or on culture isolates by commercially available molecular line probe assays can be a valuable tool to confirm or rule out potential SM resistance rapidly [20, 30]. Although the side effect profile of capreomycin is similar to that of the other aminoglycosides, the occurrences of these adverse effects are lower. Therefore, this drug should be considered as a first choice in patients with renal insufficiency, hearing loss, or documented peripheral neuropathy [7–10, 25, 29].

In the routine practice, inclusion of more than four (e.g., 5–7 drugs) potentially efficient drugs is often necessary if there is a suspicion that some of the drugs may be compromised (there has been a prior use in a failing regimen), or are less potent (weaker in action), or in case of an advanced cavitary and bilateral disease presentation [7–10, 25, 29]. Therefore, many MDR-TB patients' initial regimen may require the inclusions of at least one or two drugs from Group 4.

Ethionamide and prothionamide are drugs that are often used as a first choice from Group 4 based on their efficacy and low cost. However, one has to carefully consider the inclusion of these drugs since cross-resistance with INH may be relatively common in the presence of mutations in the *inhA* [20, 30]. Therefore, these drugs should not be included in the treatment regimen if rapid molecular prescreening shows mutations in this gene. However, the inclusion of high-dose INH (although not counted as one of the minimum four effective drugs) may be beneficial to enhance the standard second-line regimen of these patients (10 mg/kg/die daily or 16–20 mg/kg/die thrice weekly) [8–10, 25, 35]. Other potential drugs that can be considered from this group are cycloserine or terizidone and finally *p*-aminosalicylic acid (PAS).

Present WHO and International Union Against Tuberculosis and Lung Disease treatment guidelines suggest that since PZA was used in the failing regimen that led to the development of MDR-TB and AST to this drug may be complicated in many settings, PZA should not be counted in the total of minimum four drugs to be selected [9, 10, 25]. However, recent clinical investigations clarified that PZA resistance has become an underestimated problem since it may occur in up to 43 % of MDR-TB strains [36, 37]. Additional treatment outcome studies that aimed to address the clinical significance of in vitro PZA resistance have shown that an FQ-based MDR regimen increased early culture conversion and treatment completion by 38 % versus a similar treatment without PZA [28, 38]. Another more recent study from Bangladesh that examined the efficacy of a 9-month MDR-TB treatment regimen also confirmed that bacteriologic treatment failures and relapses were rare, in general, except among patients with high-level FQ in the presence of PZA resistance [16]. Clearly, the consequence of losing PZA for the treatment of MDR-TB and XDR-TB is highly significant. In comparison, the addition of PZA to INH and RIF for the treatment of drug-susceptible TB increased the 2-month culture conversion by 15–20 % [28]. Therefore, rapid screening of the *pncA* and *rpsA* genes for mutations known or likely to be associated with phenotypic PZA resistance is indispensable. In addition, oftentimes, empiric MDR-TB regimens that include PZA in the initial phase of the treatment suggest discontinuing that administration of the drug in the continuation phase if 3-month follow-up cultures are negative. This approach may also need reconsideration in light of the clinical data presented above.

Group 5 consists of a diverse group of drugs of which either have a low efficacy against *M. tuberculosis*, an unfavorable toxicity profile, or experience is lacking regarding their adequate long-term dosing. Therefore, their role in a combined antituberculosis drug regimen against MDR-TB remains unclear [39, 40]. These drugs should be considered when a minimum of efficient and susceptible (confirmed by phenotypic AST) four drugs cannot be selected from the first four groups for MDR-TB treatment due to confirmed resistance, suspected inefficacy, and presence of adverse effects. They become especially important in developing an adequate therapy in case of XDR-TB. The two most potent drugs in Group 5 are linezolid and clofazimine, which should always be considered in case of treatment of XDR-TB. A recent study indicated that the use of a daily 150 mg dose of clofazimine was effective in the treatment of MDR- and XDR-TB patients. However, an even more significant indicator and contributor of treatment success was the concurrent or subsequent use of linezolid [41]. Another important clinical trial that examined the role of linezolid for treatment of chronic XDR-TB revealed that 87 % of the patients had a

negative culture conversion within 6 months after the addition of linezolid to their drug regimen. Unfortunately 82 % of the patients developed clinically significant adverse effects in spite of the dose reduction of the drug to either 600 mg or 300 mg per day. The frequency of adverse effects was higher (88 %) among patients that received daily 600 mg linezolid compared to that of those (69 %) that received daily 300 mg [42]. It is important to note that three of the four patients that developed drug resistance against linezolid were from the group with the lower dose of the drug, although the frequency of drug resistance (11 %) was relatively low. In order to optimize prolonged linezolid treatment of XDR-TB patients, a more recent study reported favorable treatment outcome and adverse event frequencies with more optimized serum concentration when using a 1–4 month once-daily 800 mg linezolid treatment guided by culture status and tolerance, followed by a 1200 mg daily thrice-weekly therapy until over 1 year after culture conversion [43]. In addition, it is important to keep in mind that both aminoglycosides and linezolid inhibit the protein synthesis by targeting the mycobacterial ribosome. Therefore, theoretically linezolid may have a more significant effect in XDR-TB patients that do not receive aminoglycoside treatment, and consequently there is no target competition between the two drugs in these patients.

The recommended treatment duration for MDR-TB is 18–24 months, with a continuation phase of minimum 12–18 months after culture conversion [8–10, 25, 35]. A recent meta-analysis based on data of 9153 MDR-TB patients recommends an intensive phase of at least 8 (7–8.4) months (regardless of follow-up AFB smear and/or culture result) and a total duration of at least 20 [19–21] months in patients without previous MDR-TB history or treatment [10]. It is important to note that only 14 % of these patients had access to later-generation FQ. The transition from the initial treatment phase to the continuation phase in MDR-TB treatment is marked by the discontinuation of the injectable drug. Usually the injectable drug is not given during the entire course of the treatment based on their toxicity and adverse effects and due to their low sterilizing capacity. Therefore, with the decrease of the bacterial load which can be monitored by culture conversion, it can be discontinued. However, the ideal length of aminoglycoside therapy after culture conversion is still controversial. Previous WHO guidelines recommended discontinuing aminoglycoside therapy 4 months after culture conversion or 6 months after AFB smear negativity, while others recommend a minimum of 6-month treatment after culture conversion [9, 10]. The 2013 International Union Against Tuberculosis and Lung Disease guideline indicates that if a regimen is based on at least three effective drugs from Groups 1, 2, and 4 after discontinuation of the aminoglycoside, the injectable therapy can be stopped when AFB smear and/or cultures become negative. When there are less than three effective drugs available, or any of the three belongs to Group 5, a longer treatment is needed with the aminoglycoside [25]. However, this approach may oversimplify the problem, since one would also need to consider the grade of drug resistance (e.g., the presence of additional FQ or PZA resistance), the radiologic extent of the disease, and the resulting lung damage. The clinical status of the patient may well justify an aminoglycoside therapy even during the entire length of the treatment. Van Deun and coworkers reported notable treatment outcomes in MDR-TB patients with no prior evidence of treatment with second-line drugs using a shorter, 9-month regimen with an intensive phase of a minimum of 4 months of gatifloxacin, clofazimine, EMB, PZA, kanamycin, and high-dose INH followed by a 5-month continuation phase treatment with gatifloxacin, clofazimine, EMB, and PZA. The relapse-free cure rate was 87.9 % in these patients [44]. Based on these findings, a randomized controlled clinical trial STREAM (Standardized Treatment Regimen of Anti-TB drugs for patient with MDR-TB) was initiated to evaluate a shorter, 9-month treatment regimen.Based on the findings of this study, in May 2016 the WHO made a conditional recommendation regarding this new treatment regimen (gatifloxacin was replaced by moxifloxacin) to eligible patients (patients with non-complicated MDR-TB) [45].

A meta-analysis for response to treatment of 6724 MDR-TB patients from 26 centers revealed that treatment success of patients with only MDR-TB was 64 %, with MDR-TB plus aminoglycoside resistance 56 %, with MDR-TB plus FQ resistance 48 %, and with XDR-TB 40 % [46]. This clearly indicates the need for routine molecular screening for FQ and aminoglycoside resistance-associated molecular markers so that the different types of MDR- and XDR-TB associated with significantly different clinical outcomes can be rapidly identified and the treatment of these patients can be better optimized without delay [30]. However, since discontinuation of FQ has such a significant impact on the outcome of therapy and due to different levels of cross-resistance between aminoglycosides, detection of FQ and aminoglycoside resistance-associated mutations and phenotypic drug resistance to these drugs should not be automatically interpreted regarding resistance to the entire class of the drug. A more meaningful interpretation of these laboratory results depending on the type of the mutation and the associated different level of phenotypic resistance by conventional AST may enable the continuation of treatment with these key drugs under certain conditions. Indeed, laboratory studies indicate that mutations associated with *gyrA* and *gyrB* mutations are associated with low or moderate levels of phenotypic drug resistance to FQs [47]. It is important to note that while this level of resistance already results in MICs for ofloxacin which are already at or above the achievable drug serum concentration, later-generation FQs within the class may still be considered as a therapeutic option in the case of certain mutations [48]. The reason is that the associated elevated MIC of these newer FQs may still be below the achievable drug

serum concentration [20]. Therefore, it is important to clarify what FQ therapy the patient received. In case of a previous ofloxacin treatment (and the absence of newer-generation FQ therapy), if the mutation profile and the confirmatory quantitative AST for the level of resistance supports, and if the toxicity profile allows, increased doses of some of these newer FQs (such as levofloxacin or sparfloxacin) may further assure therapeutic efficacy in MDR-TB patients or offer more hope in case of XDR-TB. This concept was confirmed by the recent clinical trial from Bangladesh that revealed that treatment of MDR-TB patients with low levels of resistance to sparfloxacin resulted in a 90.5 % favorable outcome probability compared to that of high-level FQ-resistant MDR-TB patients with 51 % [16].

Rapid screening for mutations in the *eis*, *rrs*, and *tlyA* genes can provide similarly valuable information: first, regarding the presence of resistance to the aminoglycoside and polypeptide class of agents such as kanamycin, amikacin, and viomycin or capreomycin and, second, on the level of predictable phenotypic resistance that can be confirmed by quantitative AST [20, 30]. Mutations in the *eis* are associated with low levels of aminoglycoside resistance which is much lower than that of the drug serum concentration so that exclusion of the drug from the regimen may not be necessary, especially if a high-end dose is administered [20, 30]. In addition, the type of *rrs* mutations cannot only predict aminoglycoside and polypeptide resistance but may also provide information on the absence or presence of cross-resistance within these classes. TB strains with mutation *rrs* A1401G are usually highly resistant to kanamycin and amikacin, while they are susceptible to viomycin, or show low levels of resistance to capreomycin, which is still significantly below the achievable drug serum concentration [49, 50]. Strains with *rrs* C1402T mutations are usually associated with high levels of resistance to capreomycin, viomycin, and kanamycin but susceptibility to amikacin, while strains with *rrs* G1484T are usually highly resistant to all aminoglycosides and polypeptides. Mutations in the *tlyA* are good predictors of clinically meaningful polypeptide resistance with intact aminoglycoside susceptibility.

It is also well known that there is no cross-resistance between the SM and the other aminoglycoside or polypeptide drugs [20, 30]. The reason is that phenotypic SM resistance is usually associated with different genetic alterations, in the *Rpsl* and most commonly in the codons 513–517 of the *rrs* gene, than that of with second-line injectable drugs [20, 30]. In case of clinically significant resistance to kanamycin, amikacin, or capreomycin, the absence of mutations in these loci may suggest phenotypic susceptibility to SM of which, when confirmed by conventional AST, can be extremely valuable in the treatment of XDR-TB. This was also underlined by the observation that SM susceptibility was found to be an important predictor of long-term survival of patients with pre-XDR [51, 52]. This information, when well interpreted and completed with quantitative AST for adequate confirmation of the level of resistance in a particular patient and communicated to the healthcare provider, may allow continuation of the treatment of the patients with another aminoglycoside. This could save the patient from being labeled as XDR-TB and treated accordingly with a less potent regimen or offered potentially more effective treatment for XDR-TB. However, in these patients the clinician should clearly consider a longer than 4–6-month treatment with the aminoglycoside or continue it during the entire treatment [7–10, 25, 29].

The need to provide more comprehensive molecular and quantitative phenotypic AST information on the level of resistance of a particular class of drug is also underlined by a recent clinical finding. This finding shows that aggressive therapy (minimum of six drugs in the initial phase and four drugs in the continuation phase) [46] or treatment with at least five so-called efficacious drugs [53] provides a significantly better outcome for patients. In order to adequately determine such a powerful regimen, the laboratory must rapidly guide the healthcare provider with a comprehensive analysis and interpretation of more detailed molecular and phenotypic AST results.

The approach to design a treatment regimen for XDR-TB using drugs from the five groups recommended is the same as with MDR-TB. Regimens based on this approach have resulted in a cure rate of 56–83 % with MDR-TB [7–10, 25, 29, 35]. In case of a focal and cavitary disease, surgery can or should be considered depending on pattern and level of resistance and the efficacy of available treatment of the patient (also based on toxicity and occurrence of adverse effects) [7–10, 25, 29, 35]. The treatment of patient with XDR-TB is far more complicated in the absence of adequate number of potent drugs, and, therefore, surgery should always get an even stronger consideration in these patients [7–10, 25, 29, 35].

3.4 New Drugs

Recent advances in searching for new therapeutic options for the treatment of drug-susceptible and drug-resistant TB resulted in the development of two promising new drugs: bedaquiline and delamanid.

Bedaquiline inhibits the proton pump ATP synthase of *M. tuberculosis*, and in vitro studies indicate an increased bactericidal activity over INH or RIF [14]. The results of a recent phase 2 trial showed a significant and rapid improvement of the culture conversion rate with a 2-month bedaquiline therapy as an add-on to an MDR-TB regimen [14]. As a consequence, WHO and US Centers for Disease Control and Prevention recommended the use of bedaquiline at a dose of 400 mg per die for 2 weeks followed by 200 mg per die three times a week for 22 weeks as a therapy added to an optimized MDR-TB treatment regimen in adults when phar-

macovigilance is available and informed consent is ensured with adequate QT monitoring [54, 55].

Delamanid and pretonamid (PA-824) are first-generation nitroimidazoles that exhibit an inhibitory effect on mycolic acid synthesis and showed good effect on improving the treatment outcome of MDR-TB patients [14]. They are currently in phase 2 and 3 clinical trials. Tuberculosis-354 is a second-generation nitroimidazole that recently entered to a phase 1 trial [14]. WHO recommends the use of delamanid at the dose of 100 mg twice daily for a 6-month period in combination with an optimized MDR-TB regimen in adults when pharmacovigilance is available and informed consent is ensured [56]. Safety studies are ongoing to assess the side effects and toxicity of the combined use of bedaquiline and delamanid [14].

Recently several new or repurposed drugs (metronidazole, avermectin, disulfiram, tigecycline, inhaled colistin, benzothiazinones, and sutezolid) were reported with promising in vitro activity against TB or MDR-TB that could be potential candidates for evaluation in controlled clinical trials [14].

The availability of these new drugs for the treatment of MDR- and XDR-TB requires a careful update and reorganization of the hierarchical selection order of drugs from the five groups so that development of acquired drug resistance, unfavorable interactions, and cross-resistance for these new drugs can be minimized. In addition, the development of accurate molecular and conventional AST and their routine implementation to guard these drugs is also indispensable. The present lack of these approaches is indicated by recent reports that identified a surprising cross-resistance mechanism between bedaquiline and clofazimine and the first cases of non-trial clinical drug-resistant case with both bedaquiline and delamanid [57–60].

3.5 Special Considerations for MDR- and XDR-TB

3.5.1 Children

Sufficient evidence is missing on adequate therapeutic recommendations for management of MDR-TB and XDR-TB in children or in children exposed to infectious MDR-TB and XDR-TB cases. Diagnosis and, in turn, establishment of an appropriate and effective treatment regimen is often hampered by the fact that these patients are usually paucibacillary and a culture isolate therefore cannot be obtained. Treatment under such circumstances can be designed in line with the ADST of the isolate of the index case [7–10, 25, 29, 35].

3.5.2 Pregnancy

Pregnancies should not be terminated due to MDR-TB or XDR-TB. Although the use of aminoglycosides is not recommended, safe treatment regimens without adverse effect on the newborn can be developed using an individualized treatment approach [7–10, 25, 29, 35]. The use of PZA in pregnancy is not recommended in the United States but based on more recent evidence [61] is recommended by WHO and International Union Against Tuberculosis and Lung Disease [7–10, 25, 29, 35]. The same report also indicated that the treatment of pregnant females was also harmless to both them and their children with amikacin, ofloxacin, prothionamide, and cycloserine. Patients that are under therapy and are not AFB smear positive may continue breast-feeding.

3.5.3 HIV

The association of HIV and risk of MDR-TB and XDR-TB is low. However, HIV-coinfected individuals have a significantly higher mortality rate as that of HIV-negative MDR-TB or XDR-TB patients. Therefore, rapid diagnosis and confirmation of TB or drug-resistant TB are pivotal in these individuals. Intermittent therapy is not recommended for HIV-infected individuals even in case of treatment of drug-susceptible tuberculosis to avoid development of drug resistance especially for RIF. Antiretroviral therapy (ART) should be started without delay and regardless of CD4 cell count following the initiation of antituberculosis therapy because it reduces the risk of death and increases cure rate in patients with MDR-TB or XDR-TB [7–10, 25, 29, 35].

3.5.4 Surgery

Surgery to cure patients with MDR-TB or XDR-TB should be considered when culture conversion is not obtained in spite of 4–6-month treatment and/or the AST shows high level of drug resistance. In turn, treatment options are only with less efficient and potent drugs, and a curative therapy with chemotherapy alone seems to be questionable. In such circumstances, surgery is primarily recommended to those patients with a presentation of a focal cavitary disease. However, in dire clinical situations with limited therapeutic options, surgical resection of a primary site of a focal non-cavitary disease may also be considered. Surgery does not allow the shortening of the therapy, and patients must receive a full course of MDR-TB or XDR-TB treatment [7–10, 25, 29, 35].

Drug Resistance of Non-tuberculous Mycobacteria

65

Kathleen L. Horan and Gerard A. Cangelosi

1 Introduction

Non-tuberculous *Mycobacterium* species (NTMs) are considered opportunistic pathogens as they cause disease in animals as well as in susceptible humans. Infections can vary from asymptomatic nodules to chronic, debilitating lung and skin infections. Depending on species- and strain-specific characteristics, some NTM infections respond readily to antibiotic treatment, while others exhibit intrinsic and non-intrinsic resistance to multiple antibiotics. Intrinsic drug resistance by NTMs may have evolutionary roots in the soil.

Antiretroviral therapy has decreased AIDS-associated NTM disease, but the reported incidence of *M. avium* complex (MAC) infection of non-AIDS patients has increased in recent years, especially among women [1–6]. Exposure to NTM infection remains poorly understood, but is thought to occur mainly from diverse environmental sources. Most NTMs are slowly growing mycobacteria like their close cousin, *M. tuberculosis*, with which they share many similarities in genomic composition, cellular physiology, and mechanisms of pathogenesis. Chemotherapeutic treatments, and mechanisms of resistance to these treatments, also bear many similarities to tuberculosis. However, there are critical distinctions, especially in the case of the most common NTM pathogen of humans, MAC. This chapter addresses the spectrum of common NTM infections, the species associated with human disease, treatment issues, prophylaxis and prevention, and biological mechanisms of intrinsic and acquired drug resistance.

2 Clinical Presentations

NTMs cause five major categories of human disease: skin, lymphadenitis, medical device and nosocomial infections, pulmonary disease, and disseminated disease. The type of infection has significant bearing on treatment decisions.

Skin and soft tissue infections. M. marinum, isolated from fresh- and saltwater, is the prototypic NTM skin infection. The bacteria gain access to the skin through minor wounds from trauma, and the first lesion is an erythematous papule which progresses to a violaceous plaque. Occasionally, the infection spreads along the lymphatic drainage of the initial inoculation site, resulting in a clinical presentation similar to sporotrichosis.

Cosmetic procedures from pedicures to tattooing to liposuction offer the opportunity for NTM to establish in the skin and cause cellulitis and abscesses. Skin and soft tissue infections are often associated with rapid-growing mycobacteria like *M. chelonae*, *M. fortuitum*, and *M. abscessus* [7].

M. ulcerans causes the Buruli ulcer, a slowly developing, ulcerating subcutaneous nodule that is common in many tropical areas. Buruli ulcer can be diagnosed with the help of PCR and newer data supports antibiotic therapy followed by surgical excision [7].

Lymphadenitis. NTM lymphadenitis occurs in children ages 1–5 years old without HIV or known immunosuppressoin. It presents with non-tender, enlarging cervicofacial adenopathy which, left untreated, will form fistulas and drain via sinus tracts. In North America, MAC is the agent most commonly implicated in NTM lymphadenitis [8].

Medical device and nosocomial NTM infections. NTMs have been recognized since 1983 as etiologic agents in peritonitis and exit-site infections in patients receiving continuous ambulatory dialysis through peritoneal catheters [9]. The most common agent in CAPD-related infections is *M. fortuitum* [10, 11],

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_17

but other NTMs have also been documented [12–15]. Since the first description of NTM peritonitis, it has been recommended to include NTM as a possible etiologic agent if peritoneal cultures are negative at 48 h with a clinical syndrome of CAPD-related peritonitis [9, 11].

Mycobacteria have been shown to form biofilms on medical devices including central venous catheters leading to bloodstream infections [16–18]. Biofilm formation offers additional asylum and protection to the opportunistic mycobacteria; therefore, device-related NTM infection usually requires removal of the offending device.

NTMs have been implicated in other nosocomial and healthcare-related infections. Outbreaks of postinjection abscesses have been linked to injections in the Netherlands, New England, Texas, and Colombia [19]. Inadequate sterilization of equipment and contamination of the injected material was implicated in these outbreaks. Surgical operations without implanted medical devices have been complicated by NTM infections. There are case reports of postoperative NTM infections after cardiac surgery, gastric cancer surgery, and Mohs micrographic dermatologic procedures [20, 21].

Pulmonary disease. Pulmonary NTM disease is believed to be increasing in prevalence, at least in the USA [2, 4–6]. Host susceptibility factors include advanced age, certain HLA types, cystic fibrosis transmembrane receptor mutations, chronic obstructive pulmonary disease (COPD), immunomodulatory and steroid drug use, and (among women) thoracic skeletal abnormalities and rheumatoid arthritis [2, 22–24]. As with other NTMs, infection comes mainly from environmental sources, although recent reports raise the possibility of direct or indirect human-to-human transmission of *M. abscessus* among cystic fibrosis patients [25–28]. Recent genotypic studies have identified globally dispersed clinical isolates of *M. abscessus* and *M. avium*, suggesting that certain pathogen strains may be disproportionately associated with human disease [29–31].

The American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA) last released a joint statement reviewing the diagnosis and management of NTM disease in 2007 [32]. Diagnosis of NTM pulmonary disease requires respiratory symptoms associated with radiographic evidence of cavities or nodular bronchiectasis and culture of NTM from more than two sputa or a single bronchoalveolar lavage [32].

In the USA, the most commonly identified etiologic agent of NTM pulmonary infection is MAC, but a survey of cultures from Asia, Africa, Europe, South America, and Australia shows variation in the distribution of various NTM [33]. NTM can present as fibrocavitary lung disease in patients with pre-existing lung disease such a chronic obstructive pulmonary disease, or NTM can complicate established bronchiectatic pulmonary disease as in *M. abscessus* disease in patients with cystic fibrosis [34]. Slow-growing agents like MAC have also been isolated in middle and lingular lobe nodular bronchiectasis in an older, nonsmoking generally female population without prior lung disease [35]. In general, the fibrocavitary presentation has a more aggressive and predictable clinical course of decline. MAC disease presenting with nodular bronchiectasis has a less predictable course and requires clinical judgment on the institution of drug therapy, which is often poorly tolerated [36].

Disseminated disease. In patients with HIV, disseminated infections with slow-growing agents like MAC and *M. kansasii* occur when CD4 counts drop below 100 cells/μL. Up to 40 % of HIV patients with CD4 counts less than 50 cells/μL develop such infections. Disseminated MAC presents with fever, weight loss, diarrhea, adenopathy, and hepatosplenomegaly. Disseminated NTM infections are also seen in immunocompromised patients without HIV [37]. Multiple host factors have been implicated in non-AIDS disseminated NTM infection including iatrogenic immunosuppression in solid organ and hematopoietic stem cell transplants [38], T-cell deficiencies [37], IFN-gamma receptor abnormalities [39], anti-IFN-gamma autoantibodies [40], and IL-12 receptor defects [41, 42].

NTM disease and biologic therapies. Patients receiving anti-TNF alpha therapies as well as other biologic therapies like rituximab for autoimmune diseases like rheumatoid arthritis have been found to have increased risks for both pulmonary and disseminated NTM disease [43–45].

3 Therapy

Drug regimens. The ATS and ISDA have outlined guidelines for NTM therapy and susceptibility testing [32]. Recommended drug regimens and treatment strategies outlined in Table 65.1 are adapted from several sources [6, 7, 32, 36, 46, 47]. Most recommendations are based on retrospective reviews and case studies; therefore, providers should remain vigilant for new therapies as well as multimodal approaches to therapy, such as intraperitoneal streptomycin for refractory CAPD catheters or surgical debridement in conjunction with antimycobacterial therapy [13]. Treatment of NTM disease can be lengthy and expensive [48], and adherence to treatment guidelines has been reported to be problematic [49].

Susceptibility testing. Drug susceptibility testing remains controversial in NTM infection, in part due to a paucity of data related to its efficacy. Evidence supports the use of drug susceptibilities in three specific settings: macrolide sensitivity in new MAC lung disease, rifamycin sensitivity in

Table 65.1 Treatment regimens for NTM disease

Disease state	Common etiology	Therapy	Alternative therapy	Duration	Outcome notes
Pulmonary disease	*M. kansasii*	Isoniazid (300 mg)	Clarithromycin	18 months minimum with 12 months of culture negativity	Relapse rate: 0.8 %
		Rifampin (600 mg)	Moxifloxacin		
		EMB (25 mg/kg) × 2 months then 15 mg/kg)	Surgical resection		
	M. avium complex without HIV disease	C 500–1000 mg QD or AZ	C 1000mg TIW or AZ 250 mg–300 TIW*	1 year after negative culture	Best outcome with therapy following ATS or BTS guidelines
		RIF 450–600 mg QD or RFB	RIF 600 mg TIW*		
	With cavities	EMB (15 mg/kg) QD	EMB 25 mg/kg TIW*		
		Streptomycin 2–3 × week if tolerated	Surgical resection		
Disseminated disease in HIV	*M. avium* complex	C 500–1000 mg QD	AZ 500 mg QD + RFB + EMB	Lifelong if no HAART	High mortality without concomitant HAART
		± RFB 300 mg QD	(RCT with benefit to C over AZ) [57]	12 months if clinical response to HAART [60]	C + RFB + EMB improved survival [113]
		EMB 15 mg/kg QD	Fluoroquinolones		
		HAART	Amikacin		
	M. kansasii	Isoniazid 5 mg/kg (max 300 mg)	Adjust RFB on PI or	Lifelong if no HAART	High mortality without concomitant HAART
		RIF 10 mg/kg (max 600 mg)	Clarithromycin		
		EMB 15 mg/kg	Moxifloxacin		
		HAART			
Disseminated disease in non-HIV	*M. avium* complex	C 500–1000 mg QD	Azithromycin 250–500 mg QD	Consider adjunctive therapies and referral to specialty center	Not well characterized
		± Rifamycin			
		EMB 15 mg/kg QD			
Lymphadenitis	*M. avium* complex	Surgical excision ±	Clarithromycin regimen alone [114]	2–6 months	Good outcome
	M. scrofulaceum	C 500 mg PO BID if refractory or residual disease in parotid gland			
	M. malmoense				
Skin infections	*M. marinum*	C and EMB	Tetracyclines trimethoprim/sulfa	12–24 weeks	No mortality; spontaneous resolution reported
		Add RIF for deep tissue involvement	Surgery for deep involvement	Continue 8 weeks after lesion resolves	
			Amikacin		
	M. ulcerans	Surgical excision	May consider C + RIF post-excision	–	Antibiotics disappointing
					Excision can be deforming
	M. haemophilum	Combination therapy with C + amikacin, ciprofloxacin, and RIF or RFB	Consider surgical debridement	6–9 months	Not well characterized
	M. chelonae	Macrolides, amikacin, cefoxitin (except *M. chelonae*) imipenem-quinolones (*M. fortuitum*), linezolid	Consider surgical debridement	Minimum 4 months	Variable
	M. fortuitum				
	M. abscessus

M. kansasii, and identification of all susceptible agents in rapidly growing mycobacteria (RGM) [32].

Macrolide susceptibility is an important determinant of treatment success and mortality in MAC infections; macrolide resistance without sputum conversion is associated with increased mortality [50]. Macrolide resistance can develop on the recommended multidrug therapy including ethambutol and a rifamycin (4 %), but it is less frequent in this situation than when macrolide monotherapy is given (20 %) [50]. In vitro susceptibility predicted relapses in MAC disease when the MIC increased from ≤4.0 to ≥32 μg/mL [51]. Gardner and colleagues found that 17 % of HIV-associated MAC showed resistance to macrolides, and resistant isolates were more common in patients with prior macrolide exposure [52]. Therefore, susceptibility testing for clarithromycin is recommended in newly diagnosed and relapsed cases of MAC disease [32].

Similarly, resistance to rifamycins predicts treatment failure in *M. kansasii* disease. Resistance can develop on appropriate therapy including rifamycins; therefore, newly diagnosed and relapsed cases of *M. kansasii* should be assessed for sensitivity to rifamycins, and resistant isolates should be tested more broadly to identify other agents for therapy [32]. Drug susceptibility testing should be performed on all rapidly growing NTMs, as susceptibilities can vary intra- and interspecies [36].

Treatment outcomes and prognosis. Few specific NTM therapies have been evaluated in prospective, randomized controlled studies. Most treatment recommendations are derived from uncontrolled prospective studies or retrospective studies.

Prior to the use of rifampin, 4-month sputum conversion rates for *M. kansasii* therapy ranged from 52 to 81 %, with relapse rates of 10 % after completion of therapy [36]. With the addition of rifampin to treatment regimens for *M. kansasii*, sputum conversion rates at 4 months approached 100 % [36]. In 180 patients treated with a regimen containing rifampin, only two patients developed resistance to rifampin while on therapy and had *M. kansasii* reappear in their sputa.

Prior to the era of highly active antiretroviral therapy (HAART), disseminated *M. kansasii* disease was usually progressive and fatal. A retrospective review comparing outcome of disseminated *M. kansasii* in HIV patients between 1991 and 1996 and 1997–2002 revealed a decrease in total number of cases and 100 % survival of patients treated with HAART and a rifamycin plus INH and ethambutol [53]. Similar retrospective findings have been noted [46, 54], and new recommendations regarding length of therapy and prophylaxis have been published [55].

Macrolide therapy, which is ineffective against tuberculosis, has proven far more useful against MAC. In the pre-macrolide era, 4-month sputum conversion rates were dismally low in MAC lung disease, and relapse rates were frustratingly high. With the current recommended regimen of clarithromycin, ethambutol, and a rifamycin, sputum conversion rates of 90 % have been seen [36]. These reflect only the patients who are able to tolerate the regimen, and completion rates of NTM therapy are not well documented.

To improve regimen tolerance in patients with a lower burden of disease, thrice-weekly therapy with a macrolide, a rifamycin, and ethambutol is recommended by the ATS/IDSA for MAC patients with nodular bronchiectatic, non-cavitary disease. Thrice-weekly therapy has been shown to have an acceptable sputum conversion rate in selected patients [32]. A retrospective single-center study of thrice-weekly therapy versus daily therapy showed no difference in sputum conversion rates and no difference in response between treatment with clarithromycin and azithromycin [56] In HIV-related disseminated MAC disease, there is evidence of superiority of clarithromycin over azithromycin. In a randomized open-label study, Ward et al. [57] found that median time to sterilization of blood cultures in HIV patients with disseminated MAC was shorter in a clarithromycin/ethambutol-treated group compared to an azithromycin/ethambutol-treated group (4.38 weeks vs. >16 weeks).

In MAC pulmonary disease with macrolide resistance and disease isolated to individual lobes or subsegments of the lung, emerging data supports combination therapy with injectable aminoglycosides and surgical resection [50]. In 2008, Mitchell and colleagues shared their experience with surgical resection in 236 patients with MAC pulmonary disease in a retrospective review [58]. Surgical resection of NTM lung disease was associated with a mortality rate of 2.6 % with a morbidity rate of 11.7 %. Most notable, their patients had a relapse rate of only 5 % and cleared their sputum 93 % of the time [58].

Surgical excision of affected lymph nodes has been the gold standard in treatment of pediatric NTM lymphadenitis and a recent randomized controlled trial confirmed surgical resection as a more effective therapy than antibiotics alone [47].

Adjunctive therapies. Host defense is an important variable in NTM infections. Human environments are teeming with NTM, and a normal human host can face a daily assault of NTM by showering, inhaling dirt, and eating contaminated foods. NTMs are opportunistic pathogens that exploit known or unrecognized weaknesses in immunity. Therefore, diagnosis and therapy of a patient with NTM disease may require an examination of the host's immunity and inclusion of adjunctive therapies for patients, especially those who are known to be immunodeficient.

Highly active antiretroviral therapy (HAART) is a necessary adjunctive for patients with MAC with HIV coinfections. HAART has sharply decreased AIDS-associated disseminated MAC, which had previously been a leading cause of death in AIDS. Since the institution of HAART, revised guidelines call for the cessation of MAC therapy and prophylaxis in the HIV patient whose CD4 count rises above 100 cells/μL for 6 months or longer [55, 59, 60]. Institution of HAART therapy can uncover previously subclinical MAC in about 3.5 % of HIV+ patients with CD4 counts <100 cells/μL triggering a mycobacterial immune reconstitution syndrome [61].

Cytokines like interferon-gamma are integral in the host defense against mycobacteria. Case studies have reported clinical success using adjunctive therapy with interferon-gamma in non-HIV patients with T-cell deficiencies and disseminated mycobacterial infections, and inhaled interferon-gamma has been used in refractory *M. abscessus* pulmonary disease, resulting in a clearance of the organism from the sputum [37, 62]. Unfortunately, a randomized, placebo-controlled trial of inhaled interferon-gamma-1b failed to show efficacy in pulmonary MAC [50]. Other immunomodulatory agents which have been considered for their role in antimycobacterial defense include TNF-alpha, IL-12, and GM-CSF [59].

Emerging antimicrobials. Multidrug-resistant tuberculosis has driven research in the area of antimycobacterials. Many of the agents discussed here have been used in tuberculous therapy or were developed for antituberculosis therapy. Few have been tested clinically in the treatment of NTM diseases, but many of the agents show promising in vitro data for future therapeutic trials.

Linezolid, which has become an important tool against methicillin-resistant *Staphylococcus aureus*, has been reported to have in vitro activity (MIC ≤ 8 μg/mL) against rapidly growing mycobacteria and some slowly growing mycobacteria [63–66]. In the study reported by Brown-Elliot et al. [65], the species most likely to be susceptible to linezolid in vitro included *M. marinum*, *M. szulgai*, *M. gordonae*, and *M. kansasii*. Unfortunately, most isolates of MAC, the *M. terrae* complex, and *M. simiae* complex lacked susceptibility to linezolid with MIC ≥ 32 μg/mL. Linezolid has been reported clinically as a salvage therapy in an immunosuppressed patient with cutaneous disease due to clarithromycin-resistant *M. chelonae* [67].

Moxifloxacin and other fluoroquinolones have swept into the antimycobacterial armamentarium, and they have activity against many NTMs including MAC and *M. kansasii* (Table 65.1). Levofloxacin has been shown to exhibit synergy in vitro when combined with ethambutol and clofazimine [68], but quinolone therapy combined with a macrolide is insufficient to prevent the development of macrolide resistance in MAC pulmonary disease [50].

The discrepancy between successful in vitro killing of mycobacteria by the emerging antibiotics and the lack of clinical outcomes was further exposed in a recent retrospective review of a Japanese population of pulmonary NTM disease who had refractory disease to the ATS treatment regimen. Only a limited number (15.7 %) had a response to a treatment regimen of clofazimine, moxifloxacin, rifabutin, and linezolid [69].

Drug toxicities and intolerances. Killing NTMs with antimicrobials is only half the battle. Many of the anti-NTM drugs have undesirable side effects and drug interactions. Mild side effects can be tolerated by patients for short courses, but it is difficult to ask a septuagenarian to tolerate daily nausea and vomiting for 12–18 months of treatment for a slowly progressive case of nodular bronchiectasis. Drug toxicities and intolerances are major contributing factors to the failure to complete treatment. This in turn contributes to the development of drug resistance. Research aimed at overcoming these problems may be one way to reduce the problem of drug resistance NTM diseases. A brief summary of documented intolerances and side effects follows.

Ethambutol is recognized to cause retrobulbar optic neuritis, which presents as loss of color discrimination and visual acuity. Griffith et al. noted that 6 % of their study population receiving daily ethambutol (25 mg/kg for the first 2 months, then 15 mg/kg) developed ocular toxicity, compared to none of their patients receiving every other day ethambutol therapy (25 mg/kg) [70]. In the tuberculosis therapy literature, ethambutol ocular toxicity is dose related with an incidence of 5–6 % at dose of 25 mg/kg/day for two months and <1 % at a dose of 15 mg/kg/day [70]. The most recent guidelines have decreased the daily dosage of ethambutol in NTM disease, decreasing the likelihood of toxicity. Current recommendations call for periodic and symptomatic testing and ophthalmologic consultation for any visual complaints.

Clarithromycin and the other macrolides can cause nausea, vomiting, and diarrhea. In 1178 HIV-positive patients enrolled in a study of MAC prophylaxis, 2.5 % of patients taking clarithromycin alone couldn't eat for 3 days or experienced severe GI discomfort. When clarithromycin was combined with rifabutin, complaints of GI distress increased to 4.6 % [71]. Diarrhea occurred at similar frequencies. Clarithromycin inhibits hepatic metabolism of many drugs and may increase arrhythmias and toxicities in conjunction with Seldane™, digoxin, and other drugs [72].

The rifamycins cause orange staining of secretions and urine, which offers an excellent measure of compliance but can be upsetting to patients. Other side effects include hepatitis, nausea, vomiting, and hypersensitivity reactions. The recent ATS/ISDA NTM statement recommends liver function testing (LFT) based on clinical symptoms, but does not endorse regular LFT monitoring while on therapy [32]. The rifamycins can alter hepatic metabolism of many commonly prescribed drugs including clarithromycin and the protease inhibitors that may be part of multidrug therapy for these patients. Rifabutin, often chosen in HIV patients receiving concomitant protease inhibitors, can cause leukopenia, uveitis, arthralgias, and myalgias.

The antimycobacterial aminoglycosides, including amikacin, streptomycin, and tobramycin, are all nephrotoxic and ototoxic. Tetracyclines are not recommended in children under 8 years of age, as they are deposited in calcifying regions like the teeth and bones. They can lead to photosensitivity as well as nausea, vomiting, and diarrhea. Quinolones can also cause GI symptoms as well as the more unusual side effect of tendinopathies, neuropathy, and neuropsychiatric effects. Clofazimine should be considered carefully before use in HIV-infected patients, as increased mortality with clofazimine was seen prior to widespread HAART [73]. Clofazimine can also cause pigmentary changes to the skin which resolves with discontinuation.

4 Prophylaxis and Prevention

Despite decreased mortality with the institution of HAART, NTM infections remain an important cause of HIV-related mortality and morbidity [74]. Prophylactic macrolide therapy is recommended for patients with CD4 counts <50 cells/μL [55].

As noted earlier in this chapter, reported NTM infections appear to be increasing in non-HIV coinfected adults. A recent study on pulmonary MAC highlighted the importance of host susceptibility factors relative to known risk factors for environmental exposure [22]. NTMs have evolved to survive many environmental threats including microbicides, elevations in temperature, and alterations in pH [75–79]. Although elimination of NTM from water supplies can be difficult, viable counts of NTM in treatment effluents are typically very low. Exposure may come about as a result of colonization of downstream sites, including end-user plumbing and taps. In some cases, NTM infections have been linked to inadequate disinfection procedures. At a dialysis center in Louisiana, 25/140 patients developed *M. chelonae* infections before sampling of the water supply identified extensive contamination [80].

5 Mechanisms of Resistance

Primary and acquired resistance associated with genetic alterations of drug targets. Resistance to commonly used antimycobacterial drugs may be primary (meaning that the patient was infected with a drug-resistant strain) or acquired (meaning that resistance developed over the course of the patient's treatment). These mechanisms differ from those associated with intrinsic resistance, defined as the innate characteristics of some *Mycobacterium* species that exclude certain antibiotics from the antimycobacterial armamentarium.

In *M. tuberculosis* resistance usually results from mutations in genes coding for drug targets, or in genes required for the activation of prodrugs [81–84]. For example, resistance to isoniazid can result from mutations in *katG*, which codes for the catalase activity required for INH activation, in *inhA*, a target enzyme in the mycolic acid biosynthetic pathway, or in other genes. Rifampin binds to the β-subunit of RNA polymerase, and resistance almost always results from point mutations in a short section of that protein's structural gene, *rpoB*. Multidrug-resistance results from the accumulation of multiple individual resistance mutations.

Resistance of NTM isolates to individual drugs has been correlated with analogous altered-target phenomena. Rifampin resistance has been correlated with *rpoB* mutations in clinical isolates of *M. kansasii* [85] and, to a more limited extent, in *M. avium* [86]. Similarly, missense mutations in the petidyltransferase region of the 23S rRNA gene have been correlated with macrolide resistance in *M. kansasii* [87], *M. chelonae* [88, 89], *M. abscessus* [89], and *M. avium* [90–92]. Given the importance of macrolides for NTM treatment, it is unfortunate that most slowly growing bacteria have only one copy of the rRNA operon, a characteristic that may make them more susceptible than most bacteria to single-step mutations leading to macrolide resistance [89].

Morphotypic antibiotic resistance of MAC. Among the most clinically significant treatment challenges associated with NTM infection is the multidrug resistance of MAC. Macrolides, fluoroquinolones, rifabutin, ethambutol, amikacin, and clofazimine are effective against primary isolates, but they lose effectiveness relatively quickly unless administered in combinations that often are poorly tolerated by patients.

There is a correlation between multidrug resistance and colony type of MAC. Virtually all isolates form multiple colony morphotypes on laboratory media. Colony types vary with regard to infectivity and drug susceptibility. Reversible morphotypic switches are seen in virtually all isolates of MAC, suggesting that they confer selective advantages. One such switch is opaque-transparent, in which transparent colony-type variants are more resistant to multiple antibiotics than their opaque counterparts. Transparent variants also predominate in patient samples and grow better in animal and macrophage models of disease. Opaque variants predominate after passage in vitro. The molecular basis for the reversible opaque-transparent switch remains poorly understood.

An additional morphotypic switch, termed red-white, is visible among clinical isolates of MAC grown on media containing the lipoprotein stain Congo red (CR) [93, 94]. The red-white switch operates independently of the opaque-transparent switch, such that red-opaque (RO), red-transparent (RT), white-opaque (WO), and white-transparent (WT) morphotypes can be distinguished by CR staining. White variants are more common than red variants in patient samples that have undergone minimal transfer and storage in vitro [94]. White variants also grow better in animal and macrophage models of disease [93, 94]. The white morphotype is expressed during infection and is likely to be relevant to disease and treatment outcomes. However, the red colony type can also be recovered from patient samples [94]. White variants are more resistant than their red counterparts to multiple antibiotics in vitro [93]. The list of affected drugs includes macrolides, rifamycins, penicillins, and quinolones.

The morphotypic multidrug resistance of MAC has been ascribed to the cell wall, although additional factors may contribute. Cell wall factors have been inferred from indirect observations. For example, the genetic markers of rifampin, macrolide, and streptomycin resistance seen in other mycobacteria often are missing in resistant MAC isolates [86, 91, 95, 96]. Conditions that compromise cell wall integrity have been reported to increase the susceptibility of MAC to multiple drugs [97–99]. More recently, mutational analysis identified gene products that are required for the multidrug resistance associated with the white and transparent morphotypes [100, 101].

In order to study the genetics of morphotypic drug resistance in MAC, we have used uptake of the fluorescent nucleic acid stain SYTO16 as a surrogate marker of cell envelope permeability [100, 102, 103]. Cell populations of cultured

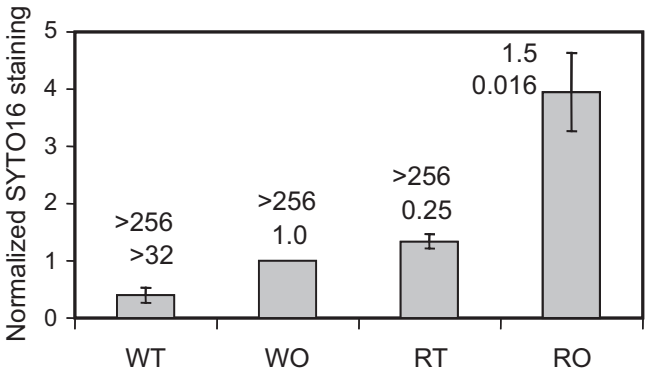

Fig. 65.1 Correlation between SYTO16 permeation and multidrug susceptibility. Naturally occurring WT, WO, RT, and RO morphotypic variants of *M. avium* clinical isolate HMC02 were assessed for SYTO16 uptake as described in the text and in reference [100]. Data were normalized to the WO strain, and means and standard deviations of three measurements are shown. Numbers above each data bar are susceptibility in μg/mL to azithromycin (*upper number*) and ciprofloxacin (*lower number*) by E-test

MAC are morphotypically heterogeneous with regard to permeability, so we quantify staining as the percentage of cells that take up the stain [100]. Mutations leading to loss of morphotypic drug resistance, including those in the genes *mtrAB*, *pks12*, and Maa2520, exhibited increased permeability to SYTO16 ([100] and unpublished results). The two-component regulatory system *mtrAB* was subsequently shown to have broad roles in growth and cell wall homeostasis in diverse *Mycobacterium* species [104, 105].

The correlation between drug resistance and cell envelope impermeability is seen in naturally occurring morphotypic variants of MAC strains, as illustrated in Fig. 65.1. Azithromycin and ciprofloxacin susceptibilities of WO, RO, RT, and WT variants of *M. avium* clinical isolate HMC02 were measured by E-test. MIC values are printed above the bar corresponding to the SYTO16 permeability of each clone in Fig. 65.1 (azithromycin above ciprofloxacin). The multidrug-resistant WT, WO, and RT forms excluded the stain, while the more drug-susceptible RO form was strongly stained. The red-white and opaque-transparent morphotypic switches are reversible and do not require drug selection, enabling these clones to toggle freely between multiresistant/impermeable and pan-sensitive/permeable forms. Morphotypic segregation into multiresistant/impermeable and pan-sensitive/permeable forms has also been observed in *M. abscessus* [106, 107].

It is difficult to conceive of a cell envelope permeability barrier that excludes structurally diverse antibiotics but not beneficial compounds. For MAC and other NTMs, the solution may be their morphotypic switches, which enable the organisms to toggle between permeable and impermeable forms. Such mechanisms may help enable these environmental pathogens to survive and flourish in diverse environments.

A hypothetical permeability barrier is unlikely to be the only mechanism of drug resistance in NTMs. Bacterial drug susceptibility can be impacted in cumulative fashion by multiple resistance mechanisms that function in a given cell. Thus, decreased permeability can function synergistically with increased expression of efflux pumps, resulting in reduced intracellular concentrations of a drug. This in turn can amplify the effects of missense mutations that reduce binding affinities of drug to target [108]. Any of these mechanisms might function in the multidrug resistance of individual NTM strains. However, a full understanding of the problem requires an understanding of how the bacteria regulate and maintain their morphotypic permeability barriers.

Intrinsic drug resistance. Mycobacterium species are innately resistant to many antibiotics that are commonly used to treat other bacterial infections. Penicillins and glycopeptides such as vancomycin are useless against most mycobacteria. NTMs may share environmental niches with related organisms, including the *Streptomyces* species that naturally produce many of the antibiotics that we use in the clinic. These evolutionary roots could have led to the selection of the intrinsic antibiotic resistance seen in many environmental mycobacteria [108].

Mechanisms of intrinsic resistance appear to differ between *Mycobacterium* species. For example, genomic comparisons in silico suggested that *M. tuberculosis* and MAC have different mechanisms of intrinsic resistance to macrolides and penicillins [101]. A 23S rRNA methyltransferase gene, *erm*, functions in the high-level resistance of *M. tuberculosis* to macrolides [109]. Expression of *erm* is controlled by WhiB7, a novel regulatory gene product that controls the expression of multiple genes, including at least some intrinsic drug resistance factors [110]. WhiB7 is found in most or all *Mycobacterium* species, including soil saprophytes, consistent with an ancestral physiological function. Resistance of *M. tuberculosis* to penicillins is thought to be mediated by at least one major β-lactamase, *blaC*, and possibly by altered expression of several penicillin-binding proteins [111, 112]. The genome sequence of MAC strain 104 has homologs to penicillin-binding proteins and putative macrolide efflux pumps found in *M. tuberculosis*, but homologs to *ermMT* and *blaC* were not found in its genome [101]. Conversely, mutational analysis showed that *pks12*, a gene required for morphotypic multidrug resistance in MAC, is not required for intrinsic resistance of *M. tuberculosis* to macrolides and penicillins [101].

6 Concluding Remarks

The prevalence of NTM disease is elevated by its persistent nature and by the challenges associated with treatment in patient populations that often have impaired immune

function. NTM infections are chronic, stubborn, and debilitating. As our population ages, the number of people susceptible to such infections may continue to rise. In order to meet this challenge, new drugs are needed and existing drugs must be preserved. It is also imperative that we improve our understanding of drug resistance in these pathogens.

Part IX

Fungal Drug Resistance: Clinical

The Role of Resistance in *Candida* Infections: Epidemiology and Treatment

66

Jack D. Sobel and R.A. Akins

1 Introduction

During the last three decades, there was a marked increase in the population of immunocompromised and severely ill individuals at risk of developing opportunistic fungal infections [1]. In particular, the increased use of immunosuppressive agents particularly in organ transplant patients, chemotherapy, and lifesaving medical technology resulted in this increase of both superficial and serious invasive fungal infections [2–4]. The initial increase in fungal infections occurred at a time when there were few available, effective, systemic antifungal agents. Parenteral and systemically active oral azoles only became available in the 1980s. Accompanying the introduction of these newer azoles, an explosion in numbers of patients with AIDS at high risk of developing oropharyngeal and esophageal candidiasis was encountered.

It was during the 1990s that drug resistance became an important problem in virtually all populations of patients at risk, but predominantly in patients with AIDS [5, 6]. Reports of resistance to antifungal drugs have appeared with increased frequency. Confusion abounds as to how common *Candida* resistance is and whether fungal isolates should routinely be sent for susceptibility testing. Simultaneously, both clinical resistance and the increased incidence of fungal infections drove the development of new generations and classes of antifungal agents. Although extremely rare prior to the 1990s, antifungal drug resistance has now rapidly become a major problem in certain populations. The highest-risk population has been the most vulnerable, viz., patients with HIV infection. Thus, in the decade of the 1990s, up to a third of advanced-stage AIDS patients had drug-resistant strains of *Candida albicans* isolated from the oral cavities. However, it is no longer HIV-infected patients that demonstrate major clinical problems with antifungal resistance [7]. Nevertheless, occasional cases of clinical and in vitro resistant mucosal candidiasis due to *C. albicans* continue to be reported; however, the availability of new azoles, e.g., posaconazole and parenteral echinocandins, usually resolves the therapeutic challenge. Unfortunately, highly immunocompromised patients following both bone marrow and solid organ transplants have become a focus of rising antifungal resistance to both azole and echinocandin antifungal drugs. The purpose of this chapter is to review the epidemiology, pathogenesis, risk factors, and treatment of resistant candidiasis. Understanding cellular and molecular mechanisms of antifungal drug resistance and associated risk factors is crucial to developing successful prophylactic and treatment strategies to prevent emergence of resistant fungi and is discussed in the subsequent chapters. Management of refractory fungal disease caused by resistant *Candida* species will be reviewed together with methods available to prevent further development of antifungal drug resistance in candidiasis.

2 Epidemiology of Candidiasis

Oropharyngeal candidiasis (OPC) is most prevalent in infants, the elderly, and compromised hosts and also associated with serious underlying conditions including diabetes, leukemia, neoplasia, steroid use, antimicrobial therapy, radiation therapy, and chemotherapy. At least a quarter of cancer patients not receiving antifungal prophylaxis develop OPC, whereas other investigators have observed OPC in more than half of all immunocompromised patients. Prolonged neutropenia appears to be the single most important risk factor for both oropharyngeal colonization with a *Candida* species and subsequent symptomatic disease [8]. Approximately 80–90 % of patients with HIV infection will develop OPC at some stage of the disease [6], and 60 % of untreated patients

develop AIDS-related infection within 2 years of appearance of OPC [9]. *Candida albicans* remains the most common species responsible for OPC [10]. A small unique population at high risk for developing azole antifungal resistance are individuals with immunodeficiency-related chronic mucocutaneous candidiasis [11, 12].

Vulvovaginal candidiasis (VVC) is considered to be the second most common form of vaginitis worldwide affecting millions of immunocompetent women. More than 90 % of infections are caused by *Candida albicans* [13]. The high prevalence of this infection in otherwise healthy females is responsible for significant morbidity and use of antifungal therapy.

During the 1980s, data from the National Center for Health Statistics (NCHS) reported that bloodstream infections (BSIs) were the 13th leading cause of death in the USA. *Candida* bloodstream infection has an attributable mortality of approximately 35 % [1]. Fungal infections, particularly due to *Candida* species, increased dramatically and accounted for 8–15 % of all nosocomial bloodstream infections [14–17]. The National Hospital Discharge Survey (NHDS) reported rates of oropharyngeal and disseminated candidiasis to have increased fourfold and 11-fold, respectively, between 1980 and 1989, a trend that continued over the next two decades [18]. Bloodstream *Candida* infections previously predominantly seen in cancer patients became common in ICUs and pediatric wards [19]. The SCOPE study reported that for the 3-year period ending in 1998, *Candida* species remained the fourth most common cause of nosocomial bloodstream infection [16, 20]. Risk factors for the increased incidence of candidemia have been reviewed [21, 22]. Moreover, candidemia has the highest crude mortality (40–50 %) of all nosocomial bloodstream infections [20, 23, 24]. Autopsy studies have also confirmed the increase in the incidence of disseminated candidiasis. Candidemia is associated with prolongation of hospital stay 70 vs. 40 days compared to matched nonfungemic patients as well as considerable increase in costs of therapy [25].

At present, *C. albicans* accounts for ~40–60 % of all nosocomial invasive *Candida* infections, reflecting a continued shift toward *Candida* species other than *C. albicans* has occurred, and of relevance because of intrinsic or acquired antifungal resistance in several of these species [2, 15, 23, 26–28]. Within the hospital setting, areas with the highest rates of candidemia include intensive care units, surgical units, trauma units, and neonatal ICUs. In fact, 25–50 % of all nosocomial candidemia occurs in critical care units. Neutropenic patients, formerly the highest-risk group, are no longer the most vulnerable subpopulation, likely as a result of the use of fluconazole prophylaxis during neutropenia [29]. In some tertiary care centers, *C. albicans* is no longer the most frequent bloodstream isolate, having been replaced by *C. glabrata*, which in turn replaced *C. tropicalis* as the most prevalent non-*albicans* species, causing 3–50 % of all candidemias. The increased frequency of *C. glabrata* in ICUs is also attributed to fluconazole exposure in ICU patients [30, 31]. There is a wide global variation in the predominance of particular species with *C. tropicalis* common in South America and *C. parapsilosis* common in Europe [32].

3 Mechanism of Action of Antifungal Drugs [33]

3.1 Polyenes [34]

The most important polyenes include amphotericin B and nystatin. Amphotericin B binds to sterol, the primary fungal cell membrane altering membrane permeability and ultimately cell death. Amphotericin B also causes oxidative damage to fungal cells (Vol. 1, Chapter 26).

3.2 Fluoropyrimidines

Flucytosine, or 5-fluorocytosine (5-FC), is a synthetic fluorinated pyrimidine. It is transported into susceptible fungal cells by the action of an enzyme cytosine permease and then converted by cytosine deaminase to fluorouracil. The latter molecule is incorporated into RNA in place of uracil. In addition, flucytosine blocks thymidylate synthetase, an essential enzyme for DNA synthesis (Vol. 1, Chapter 27).

3.3 Azoles

The azole antifungal agents in clinical use contain either two or three nitrogens in the azole rank and are therefore classified as imidazoles (ketoconazole, miconazole, clotrimazole, econazole, and butoconazole) or triazoles (itraconazole, fluconazole, terconazole). The newer azole agents include voriconazole, posaconazole, ravuconazole, and albaconazole. The azoles inhibit ergosterol synthesis in the fungal cell membrane through their action on the cytochrome P450-dependent enzyme lanosterol 14α-demethylase. Differences among various azoles relate primarily to their pharmacokinetics as well as their affinity for the target enzymes. There are also some differences in antifungal spectrum. Voriconazole and posaconazole have activity against many yeasts and filamentous fungi as well (Vol. 1, Chapter 27).

3.4 Echinocandins

This new class consists of parenteral caspofungin, micafungin, and anidulafungin. These agents inhibit fungal cell wall synthesis of an enzyme 1,3-β-D-glucan synthase, preventing the

formation of 1,3-β-D-glucan, an essential component of the fungal cell wall. These agents result in a weakened cell wall resulting in fungal cell lysis and are considered candidacidal [35] (Vol. 1, Chapter 29).

4 Definition of Resistance

4.1 Refractory Candidiasis

This by no means uncommon condition refers to treatment failure of symptomatic patients with antifungal agents. Only one of the many causes of therapeutic failure is due to the presence of in vitro confirmed resistant *Candida* spp. (Box 66.1) (Fig. 66.1). Treatment failure can also be the result of failure of the antifungal agent to reach the target site of infection in sufficient concentrations due to inadequate dosing, impaired absorption (food, gastric pH), poor compliance, and drug interactions. Other causes of treatment failure include local factors that either interfere with drug action, e.g., purulent material in an undrained abscess, or prevent access to organisms seeking refuge in a biofilm, e.g., prosthesis both intravascular and intra-articular [32]. A profoundly depressed immune system may also be responsible for failure. Both adequate numbers of functioning polymorphonuclear leukocytes and cell-mediated immunity are also essential in eradicating *Candida* infection. Clinical resistance refers to treatment failure despite microbial susceptibility in vitro.

Box 66.1. Causes of Treatment Failure Resulting in Refractory Candidiasis

1. In vitro antifungal resistance
   (a) Primary (intrinsic)
   (b) Secondary
2. Failure of drug to reach the site of infection in effective concentration
   (a) Poor adherence
   (b) Inadequate dosing
   (c) Impaired oral absorption
   (d) Drug interactions
3. Failure to drain abscess
4. Local protective mechanisms, e.g., biofilm (catheter, prosthetic valve, device, foreign body)
5. Impaired host immune/defense mechanism
   (a) PMNs
   (b) CMI

*Mechanisms 2–5 result in clinical resistance with failure associated with susceptible microorganisms.

4.2 Primary or Secondary Resistance

An organism that is resistant to a drug prior to exposure is defined as having intrinsic or primary resistance. Examples of primary resistance include *C. krusei* to fluconazole and *C. krusei* and *C. lusitaniae* to flucytosine. Acquired or

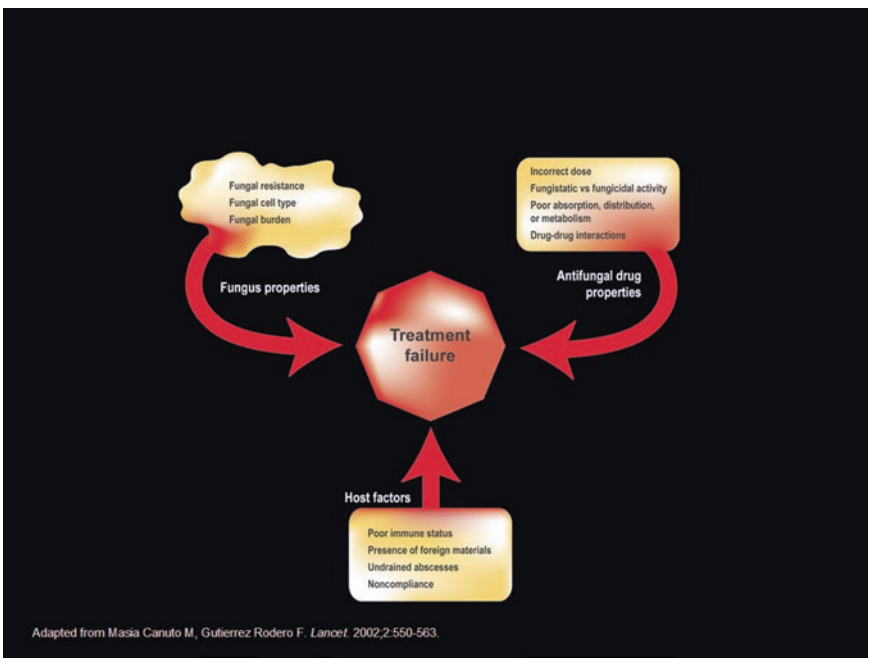

Fig. 66.1 Principal causes of failure of antifungal therapy

secondary resistance develops during or after exposure to an antifungal agent, e.g., HIV-infected patients with fluconazole-resistant OPC and esophageal candidiasis due to *C. albicans*. Cross-resistance refers to multidrug resistance either within the same class or multiple classes. Heteroresistance refers to variable in vitro susceptibility of different colonies of the same isolate obtained from the same agar plate. All forms of in vitro resistance may be temporary, transient, or irreversible.

5 Antifungal Susceptibility Tests

5.1 Methods

Testing methods and breakpoints for antifungal drugs were first suggested by Rex [36–39]. However, considerable change in methods followed to produce standardized, reproducible susceptibility methods for fungi resulting in the Clinical and Laboratory Standards Institute (CLSI) M27-A3 and the EUCAST methodology [40–47]. Accordingly, interpretive breakpoints determined by these methods are available for testing *Candida* species to fluconazole, itraconazole, voriconazole, flucytosine, amphotericin B, caspofungin, anidulafungin, and micafungin [42, 48–53] (Table 66.1). Recently, new interpretative standards have been introduced which profoundly impact upon determination and definition of susceptible and resistance isolates, potentially causing confusion for uninformed clinicians. Firstly, a new epidemiologic cutoff value (ECV) is now available and represents a more sensitive measure of change in susceptibility breakpoints [17, 43, 44]. The ECV method statistically determines the distribution of MICs within a given microbial species and is defined as the MIC value that excludes non-wild-type strains, specifically an isolate likely to contain a resistant mutation. Reliance upon the ECV results in variable breakpoints for different *Candida* species and in many cases a severalfold lowering of the susceptibility breakpoint, e.g., the previous *C. albicans* breakpoint for susceptibility to fluconazole was ≤8 mg/L, but with the new interpretation, this value is reduced to ≤2 mg/L and elevated to ≤16 mg/L for *C. glabrata*. The ECV method is valuable for detecting emergence of resistance in a *Candida* species in an institution. Using this method, most breakpoints have declined, and results of M27-A3 (CLSI) and EUCAST match more frequently. Moreover, as breakpoints decrease more isolates are deemed resistant, but no increased risk of treatment failure has been reported. This conclusion applies to both the triazoles and echinocandins with the new CLSI guidelines (Table 66.1). In the final analysis, therapeutic decisions are always individualized based upon the patient's response to therapy at the time susceptibility results become available.

In general, the susceptibility of the *Candida* isolate to the currently available antifungal agents is generally predictable if the species of the infecting isolate is known. However, individual isolates may not follow this general pattern [17].

In the past susceptibility testing of *Candida* isolates, even blood isolates, was not recommended on a routine basis. Testing was recommended only for persistent disease and failure of organism eradication in symptomatic patients with appropriate antifungal therapy. This principle was based upon the cost and lack of testing facilities available, but also driven by the rarity of in vitro resistance. However, recent surveillance suggests the emergence of reduced susceptibility of some *Candida* species in relation to azoles and echinocandins. Triazole resistance among *C. glabrata* isolates has increased to an extent that it is difficult to rely upon triazoles for therapy without performing susceptibility testing [32]. Unfortunately more recently, a similar trend has begun to emerge for a smaller proportion of *C. glabrata* isolates and the echinocandins [1, 13]. Accordingly, susceptibility testing is now required and recommended to guide the management of candidiasis. It is now recommended the laboratories perform routine antifungal susceptibility testing against both the triazole and echinocandins for *C. glabrata* isolates from blood and sterile sites and for other *Candida* species that have failed to respond to antifungal therapy. Although controversial, based upon the overall infrequency of antifungal resistance in *C. albicans*, routine testing for this species is not indicated in the absence of treatment failure. The value of testing for other *Candida* species is less clear, although occasional resistance among *C. tropicalis* and *C. parapsilosis* has been reported in certain hospitals with high use of antifungals. Hence, some authorities recommend triazole susceptibility testing for all bloodstream and clinically relevant *Candida* isolates, whereas testing for echinocandin susceptibility should be considered in patients who have had prior treatment with an echinocandin.

The objective of susceptibility testing is to differentiate infecting strains that are susceptible and hence likely to respond to a given antifungal drug from those strains resistant and hence more likely to fail therapy. With regard to echinocandins, it is essential that susceptibility tests capture high-MIC strains containing *FKS* mutations. To date the CLSI has used limited clinical data but also microbiologic data to define clinical breakpoint for all three echinocandins against *Candida* spp. [54]. Unfortunately, some resistant *Candida* strains were often misclassified by this breakpoint [55, 56]. As a result, new breakpoints were determined by CLSI that better accounted for *FKS* mutations [32, 47] (see Table 66.1). EUCAST established *Candida* species-specific and echinocandin-specific clinical breakpoints (Vol. 2, Chapter 18).

NCCLS M27-A methodology has only a limited ability to measure MICs of *Candida* isolates to amphotericin B. Rex et al. recommended the use of antibiotic medium 3 broth to measure

Table 66.1 In vitro susceptibility of *Candida albicans* and interpretative breakpoints

	Clinical breakpoints (in μg/mL)			
Organism	Susceptible	Susceptible dose dependent	Intermediate	Resistant
C. albicans				
Caspofungin	≤0.25	–	0.5	≥1

Micafungin	≤2	–	4	≥8

24 h 100 %, MIC end points read as 100 % inhibition at 24 h incubation; 24 h 50 %, MIC end points read as 50 % inhibition at 24 h incubation
[a]Fluconazole breakpoints are not available for *C. krusei* since this species is considered intrinsically resistant to this compound. All strains should be reported as resistant

resistance [48, 57]. In general, current methods are limited to identifying *Candida* isolates associated with clinical failure, although breakpoint minimal lethal concentrations (MLCs) and MICs of ≥1 μg/mL at 48 h have been recommended to more accurately predict mycologic *Candida* spp. failure with amphotericin B [58]. In a multicenter study of candidemia in non-neutropenic patients, all blood isolates demonstrated amphotericin B MICs less than 1.0 μg/mL. As with fluconazole, clinical failures (10–15 %) were all associated with in vitro susceptible isolates with low amphotericin B MICs [50].

The Etest is often used as an alternate to broth dilution methodology and certainly is useful in the setting of refractory clinical disease, and there is no other testing method available. The Etest is considered suitable for testing *Candida* spp. against amphotericin B or flucytosine, but less reliable for azole susceptibility [49, 51–53, 57].

5.2 In Vitro Susceptibility and Resistance of *Candida* Species (Table 66.2)

5.2.1 Azoles

The triazole, voriconazole, posaconazole, and ravuconazole exhibit greater potency and spectrum than either fluconazole or itraconazole but are still essentially fungistatic.

Table 66.2 Susceptibility of *Candida* spp. to antifungal agents

MIC_{50}	Amphotericin B	Fluconazole	Itraconazole	Voriconazole	Flucytosine	Caspofungin
C. albicans	0.5	0.5	0.12	0.03	≤0.25	0.12
C. tropicalis	0.25	1	0.06	0.06	≤0.25	0.25
C. glabrata	0.5	16	0.25	0.25	≤0.25	0.12
C. parapsilosis	0.25	1	0.12	0.03	≤0.25	1.0
C. krusei	0.25	64	0.5	0.5	16	0.5
C. lusitaniae	≥1	2	0.25	0.03	≤0.25	1.0

Shown are typical species-specific MIC_{50}s (μg/mL) adapted from reports describing collections of clinical isolates [50, 59–61]. MICs were obtained by the NCCLS M27 methodology (National Committee for Clinical Laboratory Standards, 1995) for all drugs but amphotericin B. If this method fails to detect amphotericin B-resistant *Candida* [50], then reported amphotericin B MICs were obtained by a more sensitive method based on the use of antibiotic medium 3 in an agar-based testing format

The activity of this broad-spectrum triazole extends to some fluconazole-resistant strains of *Candida*.

Primary and secondary azole resistance is species dependent and also shows marked geographic variation [59, 62]. There is no clear evidence for a correlation between the agricultural use of azoles and an increase in antimycotic resistance in *Candida* species. Primary resistance to azoles remains uncommon in candidiasis, with the exception of *Candida glabrata* and *Candida krusei*. Most acquired azole resistance emerged in AIDS patients with OPC and EC following prolonged azole therapy in the presence of advanced immunodeficiency. Azole resistance in other settings is uncommon [32, 63].

1. *C. albicans*. Primary resistance to fluconazole and itraconazole is extremely rare. Moreover, outside the realm of AIDS, acquired or secondary resistance has likewise remained uncommon especially with regard to bloodstream isolates. Each year, thousands of randomly obtained BSIs isolated from all over the world are tested in a single site (SENTRY), and over several years fluconazole-resistant *C. albicans* remains <5 % and shows no evidence of changing [60, 63, 64]. In contrast, Antoniadou et al. reported that 9 % of bloodstream isolates of *C. albicans* were resistant to fluconazole (MIC > 64 μg/mL) [65]. Spontaneous fluconazole resistance in the absence of prior azole therapy is rare but has been reported in otherwise healthy adults [66]. Based upon molecular modeling studies, it has been reported that certain mutations in *ERG* II result in significant levels of resistance to fluconazole and voriconazole but have less effect on the susceptibility of the organisms to itraconazole and posaconazole, possibly due to the more extensive binding of the latter agents to the target enzymes [67].
2. *C. tropicalis*. Occasional strains of *C. tropicalis* demonstrate azole resistance although MIC_{90} values indicate continued susceptibility. This species has a proclivity to produce trailing grown in vitro often misinterpreted as resistance.
3. *C. parapsilosis* strains are usually highly susceptible to all azoles [67].
4. *C. krusei*. This species is intrinsically resistant to fluconazole and has higher MICs to itraconazole in the S-DD range. Voriconazole is, however, very active against *C. krusei* [60, 68]. *C. krusei* incidence has remained stable over the last decade.
5. *C. dubliniensis*. This species has been increasingly identified and implicated in OPC in HIV-infected agents and is usually identified as *C. albicans*. Most *C. dubliniensis* strains are susceptible to fluconazole although in vitro resistance can be induced. Acquired resistance develops much more rapidly than in *C. albicans*.
6. *C. glabrata*. Among pathogenic yeast species, *Candida glabrata*, which accounts for 5–40 % of all yeast isolates, ranks second in all clinical forms of candidiasis today and in some studies of nosocomial candidemia is more common than *C. albicans* [32, 69]. This opportunistic pathogen is particularly relevant in immunocompromised patients including those receiving cytotoxic chemotherapy, undergoing transplantation, and infected with HIV. This critical *Candida* species represents the Achilles heel of the azole class [70, 71]. *C. glabrata* isolates exhibit bimodal susceptibility to azoles with 10–15 % of bloodstream isolates demonstrating fluconazole resistance (≥64 μg/mL) [60, 64]. Patterns of fluconazole susceptibility vary by geographic area, patient population, risk factors, and azole exposure [72]. In particular, clinical isolates obtained from patients with AIDS and OPC/EC and those with underlying malignancy show reduced susceptibility to fluconazole and itraconazole. Fluconazole resistance is lowest in Asia-Pacific and Latin-American regions (3–4 %) and highest in North America (10–15 %). Both the frequency of *C. glabrata* occurrence and azole susceptibility are profoundly affected by azole exposure, with 30–40 % of isolates being S-DD. International surveillance reveals that recently submitted bloodstream isolates (2001–2005) of *C. parapsilosis* and *C. tropicalis* in contrast to *C. albicans* did reveal a slight increase in fluconazole resistance. A similar increase in resistance was

observed for *C. glabrata* with sustained high rates of fluconazole resistance (14.3–18.3 %) over this period [63]. In general, whereas most *C. glabrata* isolates are still susceptible to voriconazole, most fluconazole-resistant *C. glabrata* isolates are resistant to itraconazole, and half are also resistant to voriconazole and posaconazole [60, 69, 73]. Not surprisingly, several reports of voriconazole-resistant *C. glabrata* breakthrough fungemia in bone marrow transplant recipients receiving long-term voriconazole prophylaxis have been reported [74].

5.2.2 Flucytosine

Intrinsic resistance among *C. albicans* has been described in 6.5–33 % of isolates and is invariably associated with serotype B isolates [75]. More recent studies have shown lower resistance frequency possibly due to infrequent use. Pfaller et al. studying 8803 clinical isolates of *Candida* spp. reported susceptibility as follows: *C. albicans* (97 %), *C. tropicalis* (92 %), *C. guilliermondii* (100 %), *C. dubliniensis* (100 %), *C. parapsilosis* (99 %), and *C. glabrata* (99 %) [64]. The least susceptible species was *C. krusei* (5 % susceptible, 67 % intermediate, and 28 % resistant). A smaller study reported that 82 % of *C. glabrata* were susceptible to flucytosine. The pharmacokinetics and in vitro activity of flucytosine make the agent particularly useful for azole-resistant *Candida* infections in relatively inaccessible sites such as CSF and the genitourinary tract.

Unfortunately, secondary acquired resistance is common (30 %) and acquired rapidly to flucytosine when used as monotherapy. Accordingly, flucytosine is almost always used in combination with other antifungals.

5.2.3 Polyenes

Resistance to amphotericin B may be intrinsic or acquired [76]. *C. albicans* resistance is extremely rare, although the NCCLS M27-A methodology may be underestimating its occurrence. For amphotericin B, NCCLS methodology generates a narrow MIC range limiting its ability to identify isolates likely to cause therapeutic failure [58]. Moreover, more important than resistance is the phenomenon of reduced susceptibility without frank resistance. Powderly et al. reported reduced amphotericin B sensitivity of blood isolates of *C. albicans* in neutropenic patients and correlating higher MICs with poor outcome [77]. Fortunately, such strains are rare and secondary resistance is uncommon [78]. Resistance in *C. parapsilosis* and *C. dubliniensis* but not *C. tropicalis* is rare [79]. Although *C. glabrata* and *C. krusei* isolates are usually considered susceptible to amphotericin B, they tend to have higher MICs, justifying initial empiric use of amphotericin B at a higher dose of 1.0 mg/kg/day. Sterling reported the emergence of resistance to amphotericin B during therapy for *C. glabrata* infection in an immunocompetent host [80]. Many but not all *C. lusitaniae* and some *C. guilliermondii* isolates demonstrate intrinsic resistance to amphotericin B [81]. Acquisition of secondary polyene resistance in species, in addition to *C. albicans*, includes *C. lusitaniae* and *C. guilliermondii* during amphotericin B therapy especially in myelosuppressed patients [78, 82–84]. Rare cases of fatal septicemia reported of amphotericin B-resistant *C. lusitaniae* [85]. Resistance to amphotericin B desoxycholate implies that the organism will be resistant to the various lipid formulations of amphotericin B.

5.2.4 Echinocandins

Early reports of clinical and/or in vitro resistance to any of the echinocandin agents were rare. In 2003, the in vitro activities of caspofungin against 3959 isolates of *Candida* spp. from 95 different medical centers were determined and compared with fluconazole and itraconazole [61]. No resistant strains of *C. albicans* were detected. Against all *Candida* species, 96 % of MICs were ≤2 μg/mL. *C. albicans*, *C. dubliniensis*, *C. tropicalis*, and *C. glabrata* were the most susceptible species, and *C. guilliermondii* was the least susceptible (MIC_{90} >80 μg/mL). *C. parapsilosis* MIC_{90} 2–4 μg/mL was significantly increased versus *C. albicans* 0.25 μg/mL [61]. Echinocandins remain very active against azole-resistant isolates of *C. albicans* and *C. glabrata* (99 % of MICs were ≤1 μg/mL). There is no evidence of a significant impact of azole resistance mediated by CDR pumps on echinocandin resistance in clinical *Candida* isolates.

Similarly, large multinational *Candida* isolate collections have been used to evaluate in vitro resistance to micafungin and anidulafungin, and identical almost universal susceptibility has been reported and once more higher MICs of *C. parapsilosis* emerged [63]. Interestingly, caspofungin is not fungicidal for isolates of *C. parapsilosis* or *C. guilliermondii* [86].

Breakpoints for the echinocandin class of agents were delayed in appearance since in vitro and in vivo analyses were hampered by a dearth of resistant isolates. As a result Kartsonis et al. failed to establish any relationship between baseline caspofungin MICs and clinical outcome with isolates from both mucosal and invasive *Candida* infections [87]. An echinocandin MIC of ≤2.0 μg/mL, a blood concentration easily achievable in vivo under normal dosing, would encompass 99.7 % of all clinical isolates of *Candida* species [63].

While clinical failure due to echinocandin-resistant *Candida* isolates has been rare, acquired in vivo resistance following echinocandin exposure undoubtedly occurs, and resistant isolates have increasingly been reported. All the resistant isolates were shown to have homozygous mutations in the *FKS*1 gene. Clinical failure with all *Candida* species has also increasingly been reported [88–90].

Hernandez et al. in 2004 reported a patient with azole-refractory OPC/EC which in spite of initial improvement

eventually failed on caspofungin [91]. Initial isolates exhibited low caspofungin MICs, whereas a late isolate had higher MIC. The clinical response was reproduced in a murine model correlating MIC with the clinical response to caspofungin. Similarly, a case of progressive loss of echinocandin activity following prolonged use for treatment of *C. albicans* esophagitis was reported [92].

Moudgal et al. in 2005 described a patient with aortic valve endocarditis due to *C. parapsilosis* [93]. After initially responding to combination therapy with caspofungin (MIC 2 μg/mL) and fluconazole, he cleared his fungemia and was discharged on fluconazole only. He returned three months later with recurrent *C. parapsilosis*, now resistant to both fluconazole and caspofungin (MIC > 16 μg/mL) and also voriconazole and micafungin but not anidulafungin. Similar case reports regarding acquired echinocandin resistance in *C. glabrata* are reported more than a decade ago predicting a future likelihood of increased resistance in this species (see Chapter. 29, Volume 1) [94].

5.3 Correlation of In Vitro Susceptibility Testing and Clinical Outcome of Treatment with Antifungal Agents

In vitro susceptibility is only one of the many factors that influence the outcome of therapy of fungal infections [37]. A variety of pharmacokinetic and pharmacodynamic drug factors as well as a multitude of host factors (neutropenia, compliance, catheter presence, APACHE scores, abscess drainage) all interact to impact upon clinical outcome(s). Even the definition of clinical outcome is controversial, ranging from clinical improvement to mycologic evaluation (short or long term) on patient survival (days or weeks). Nevertheless, in vitro susceptibility determination may serve as an objective, reproducible measure that can profoundly influence drug selection with physicians recognizing the limitations of in vitro susceptibility testing.

Establishing that an isolate is resistant to an antifungal agent in vitro is an immensely useful step in selecting therapy. Determining that the isolate is susceptible to antifungal agents in no way predicts survival or fungal eradication. Clinicians should recall the old 90-60 rule in which a clinical response of 90 % or more can be expected when an in vitro sensitive strain is treated with an appropriate antibiotic in comparison to a 60 % response when a resistant strain is treated with drugs showing reduced or no activity in vitro.

With regard to candidiasis, in vitro and clinical outcome correlations have mainly been applied to OPC/EC and candidemia, where the 90-60 rule appears to have been met, recognizing this is merely a minimal standard. The most important principle applied is that organisms deemed resistant in vitro are much less likely to respond in vivo. Yet within the candidemia RCTs involving hundreds of patients, almost all patients failing did so with highly susceptible strains. This emphasizes the principle that susceptibility in vitro does not guarantee successful therapy. Most studies evaluating the 90-60 rule have applied to azoles, specifically fluconazole, and the best correlation was in OPC/EC in AIDS patients. The clinical predictability of amphotericin B susceptibility is less well established. Moreover, Sobel et al. found poor correlation between in vitro MICs and response to fluconazole therapy for VVC [95]. Finally, any discussion of clinical correlation must distinguish resistance developing in a given strain of the same species from the problem of acquiring less susceptible strains from the same or different species.

5.4 Indications for Antifungal Susceptibility Testing in *Candida* Infections

Apart for reasons of periodic epidemiologic surveillance and resistance monitoring, routine susceptibility testing by any of the aforementioned methods is not indicated. Testing is justified for all bloodstream *Candida* isolates, especially if associated with persistent, breakthrough, and recurrent candidemia and also refractory mucosal candidiasis, anticipated prolonged or critical therapy, e.g., endocarditis, osteomyelitis especially with non-*albicans Candida* invasive infections. Also, testing is essential with selected non-*albicans Candida* species, e.g., *C. glabrata*, initially treated by non-azole regimens anticipating a switch to oral therapy with either fluconazole or voriconazole to complete therapy. Given the increase of parenteral echinocandins as first-line therapy for candidemia only to have the remainder of the therapeutic course completed by oral triazoles, the Infectious Society of America now recommends that all first bloodstream isolates should be tested for antifungal susceptibility [96].

6 Epidemiology and Risk Factors for Resistant Candidiasis

Does azole use select for antifungal drug resistance? In this context, clinical resistance is encountered with (a) the presence of organisms with intrinsic, de novo resistance to antifungals usually seen with non-*albicans Candida* and rarely *C. albicans*, (b) alternately, evolution may occur of the initially sensitive strain to an identical strain that has undergone genetic and molecular changes, or (c) there is replacement of the strain with a new resistant strain of the same species or finally replacement with a new strain of a different species.

Evidence links empirical, prophylactic, and therapeutic use of azoles and selection for yeasts other than *C. albicans* that exhibit decreased susceptibility to azoles, e.g., *C. glabrata* and *C. krusei* infections in patients receiving fluconazole prophylaxis [97–99]. Most of the early data came from AIDS patients. The emergence of antifungal-resistant *C. albicans* fungemia has increasingly been reported in bone marrow transplant recipients being administered with long-term fluconazole prophylaxis [100]. Similarly, isolated reports of fluconazole-resistant fungi in surgical ICUs are emerging [101].

While molecular changes in a single strain invariably reflect a single or more usually multiple genetic mutations, the dynamics of acquisition of a new strain or species is less well understood. New more resistant *Candida* strains or species may be acquired during hospitalization from medical staff carriers. This process has been well documented with *C. albicans* and *C. parapsilosis*, but *C. glabrata* is rarely identified on the hands of carriers or in hospital environment. It is hypothesized that patients may be colonized in the gastrointestinal tract simultaneously by multiple strains of *Candida*, including the possibility of multiple species. Routine culture only captures the dominant strain or species. After antifungal drug ingestion or pressure, more susceptible strains are eliminated or so reduced in number so as to allow growth and emergence and recognition of more resistant strains or species that have coexisted long term but were previously not recognized.

6.1 HIV/AIDS

AIDS patients have been the focal point of much of the scientific inquiry into fluconazole resistance. On the one hand, oral and esophageal candidiasis became extremely common as a clinical manifestation of AIDS in the 1980s. The availability of fluconazole as both treatment and subsequently prophylaxis in patients with recurrent disease was an enormous boon to care. Within a few short years, clinical and in vitro fluconazole resistance was widespread and caused major alarm among AIDS practitioners [6, 32, 102]. Several studies, mainly retrospective, identified risk factors for acquisition of fluconazole resistance (Box 66.2). In addition to the status of the immune system (CMI), i.e., CD4 lymphocyte count, most studies concluded that patterns of fluconazole use particularly drug dose were the dominant factors associated with resistance acquisition [103–106]. In the majority of patients, mutation of a previously susceptible strain of *C. albicans* to a resistant strain is likely to have occurred, together with coinfection with *Candida* species resistant to fluconazole, e.g., *C. glabrata* [107].

Box 66.2. Risk Factors for Azole Resistance in Candidiasis

1. HIV/AIDS
   (a) Advanced immunosuppression (low CD4 cells)
   (b) High viral load
   (c) Fluconazole administration
      - Poor compliance
      - Past fluconazole exposure
        – Total dose
        – Intermittent therapy
        – Prophylaxis versus therapeutic
        – Low dose
2. Hematologic malignancy/BM transplantation
   (a) Azole exposure (prophylactic)
3. Prosthetic devices—foreign bodies
   (a) Biofilm

In a prospective, randomized, controlled trial conducted by the Mycoses Study Group, episodic treatment versus continuous prophylaxis with fluconazole was studied. The first conclusion was that overall resistance acquisition was uncommon in this HAART-compliant study population. Secondly, the use of episodic compared to continuous fluconazole prophylaxis was not shown to be protective in preventing emergence of resistance [108]. In general, no pattern of fluconazole prescription or ingestion has been consistently identified as contributing to azole resistance selection, although both dosing and duration have been widely implicated in emergence of resistance. Most importantly, it has not been established whether lower doses used for longer periods of time lead to antifungal resistance and whether intermittent therapy, especially using higher doses for shorter periods, prevents resistance [109]. In contrast to the above, occasionally resistant species were isolated in patients with HIV infection and no prior exposure to fluconazole [110].

It is noteworthy that in the last decade, because of the availability of potent and better tolerated ART, the occurrence of fluconazole-resistant OPC and *Candida* esophagitis has become infrequent.

6.2 Hematologic Malignancies and Transplant Patients

This growing population is the second focus of resistant candidiasis. Empiric systemic antifungals are widely used as empiric therapy for antibiotic-resistant fever in addition to azole prophylaxis both in neutropenic patients (usually fairly short term) and non-neutropenic high-risk posttransplant patients (often long term). Once more, azole exposure both

oral and systemic is recognized as (a) infrequent cause of azole-resistant *C. albicans* and (b) a more frequent and important cause of selection of non-*albicans Candida* species, both colonizing the gastrointestinal tract and as a cause of the ensuing infrequent invasive candidiasis [99, 111]. Primary fluconazole resistance has been reported in patients with severe neutropenia [112, 113]. Candidemia due to *C. krusei* has been associated with prior exposure to fluconazole [94, 114, 115].

6.3 Prosthetic Devices/In Vivo Biofilm

Evidence has been presented based upon in vitro, animal models and clinical studies that *Candida* organisms found in biofilm may show significant reduced susceptibility to azole drugs [116]. The implications are self-evident, since infections involving intravascular catheters and prosthetic valves and devices invariably fail intensive antifungal therapy and require surgical removal for cure. Clinical failure may also be due to failure of the antifungal drug to penetrate the biofilm access of yeast cells found within the biofilm [117]. The most important explanation for biofilm-related resistance appears to be the phenotypic and genotypic changes that are reported in biofilm containing yeast cells demonstrating in vitro antifungal resistance when compared to planktonic isotype cells. Nett et al. reported increased β-1,3-glucan content in *C. albicans* cell walls from biofilm compared to planktonic organisms thought to be responsible for polyene resistance and fluconazole resulting in limited intracellular penetration [118]. Biofilm-associated yeast cells are more susceptible to β-glucan inhibitors, i.e., echinocandins [119].

6.4 Antifungal Drugs

While most of the information available on drug-induced resistance followed the use of fluconazole and ketoconazole, usually as oral agents, little is known about the potential for broader-spectrum (itraconazole, voriconazole, posaconazole, caspofungin, micafungin, anidulafungin) or more active/potent in vitro drugs (voriconazole, posaconazole, echinocandins) or Candidacidal drugs (echinocandin) to select for less susceptible *C. albicans* or non-*albicans Candida* isolates.

Invasive infections due to amphotericin B-resistant *Candida* isolates have infrequently been reported in association with the use of this agent [58, 77, 120]. Many *C. lusitaniae* and some *C. guilliermondii* isolates demonstrated primary resistance to amphotericin B, but secondary resistance to amphotericin B appears to be uncommon. Acquired resistance associated with disseminated infections due to *C. glabrata*, *C. krusei*, and *C. albicans* that developed during therapy is described but is uncommon [121]. Resistance appears to be due to alteration or a decrease in the amount of ergosterol in the cell membrane. Yoon demonstrated in vitro reversible switching of *C. lusitaniae* with acquired amphotericin B resistance [122]. Nystatin-resistant *C. rugosa* was reported a burn unit following extended use of prophylactic topical nystatin [123].

A growing mass of data indicates that frequent and prolonged exposure to azole may influence the emergence of non-*albicans Candida* species especially *C. glabrata* but may also select for acquired resistance in *C. albicans* strains particularly following prolonged exposure to subinhibitory azole concentrations [32, 100, 111, 115]. However, the overall effect of azoles on *Candida* species distribution and resistance development is incompletely understood [124, 125]. Blott et al. reported that over an 11-year period in a single institution, the volume of fluconazole consumption did not correlate with *Candida* sp. distribution [124].

6.5 *Candida* Vaginitis

In spite of widespread use and abuse of over-the-counter (OTC) imidazole antifungals, little evidence has emerged of azole resistance in *C. albicans* or selection of non-*albicans Candida* spp. [126, 127]. However, prolonged use of long-term, low-dose (150 mg/week) fluconazole maintenance prophylaxis, in women with recurrent vulvovaginal candidiasis (RVVC), has recently been reported to contribute to both fluconazole and azole class resistance resulting in refractory vaginitis caused by in vitro resistant *C. albicans* [128, 129]. Moreover, in a study of HIV-positive women with RVVC receiving fluconazole, some evidence did surface of emergence of *C. glabrata* as a more frequent pathogen [130, 131].

6.6 Azole Cross-Resistance

Given that the azole class of antifungal agents share a common mechanism of action and in most cases of resistance, development of cross-resistance is common.

When selecting antifungal treatment, it is essential to establish whether the patient has received previous antifungal therapy because patients may harbor *Candida* species resistant to multiple azole agents [132–134]. Both in vitro and clinical studies have clearly demonstrated high frequency of azole cross-resistance [135]. Several studies indicated cross-resistance to itraconazole, ketoconazole, and other imidazoles in isolates resistant to fluconazole [32, 136]. Most of the strains concerned were fluconazole-resistant isolates of *C. albicans* obtained from patients with advanced AIDS and refractory OPC [137, 138], but others have reported cross-resistance in virtually all species of *Candida* exposed to non-fluconazole azoles, e.g., itraconazole and ketoconazole [132, 133, 139, 140]. Moreover, resistance found to first- and second-generation azoles may

extend, even in the absence of exposure, to newer triazoles, voriconazole and posaconazole, either as absolute resistance or more frequently as higher MIC values [136, 141–144]. In general, fluconazole-resistant strains had higher MICs to voriconazole and posaconazole. Nevertheless, cross-resistance varies considerably among species; hence, some but not all *C. parapsilosis* and *C. albicans* isolates maintain susceptibility to itraconazole, posaconazole, and voriconazole despite fluconazole resistance. Cross-resistance is often more predictable for *C. tropicalis* isolates, and lack of cross-resistance is seen with *C. krusei*. The development of resistance to azoles invariably requires more than one mutation; hence, isolates with resistance to both fluconazole and itraconazole exhibit multiple mechanisms or types of resistance and therefore are more likely to demonstrate resistance or reduced susceptibility to newer azole agents. Cross-resistance is a very common if not universal feature in azole-resistant *C. glabrata* isolates, especially in those that are capable of expressing multiple mechanisms of resistance [145, 146].

Susceptibility testing of 6970 *Candida* isolates from 200 centers worldwide by Pfaller et al. revealed that *C. albicans* and *C. glabrata* strains resistant to both fluconazole and itraconazole were less susceptible to posaconazole, ravuconazole, and voriconazole [60]. Slightly less than 50 % of *Candida* species isolates resistant to fluconazole maintained susceptibility to newer triazole agents [147]. In a study of azole cross-resistance, fluconazole MICs of ≤32 μg/mL predicted susceptibility, and MICs of ≥64 μg/mL predicted resistance of *Candida* spp. to voriconazole and posaconazole [147]. Voriconazole was active against *C. krusei* regardless of azole susceptibility. While much has been written of fluconazole prophylaxis leading to widespread azole resistance, similarly itraconazole prophylaxis was shown to be associated with cross-resistance to fluconazole [133, 148]. While much of the literature on azole cross-resistance has focused on mucosal candidiasis, similarly, large surveillance surveys of *Candida* spp. causing invasive infection including candidemia have shown evidence of cross-resistance.

6.7 Drug Pharmacokinetics, Pharmacodynamics, and Resistance in Candidiasis

Andes et al. reported the impact of fluconazole dosing regimens and pharmacodynamics on resistance development in *C. albicans* [149, 150]. Fluconazole regimens that produced prolonged sub-MIC concentrations were associated with resistance development. The emergence of the resistant phenotype was associated with increased expression of *CDR1*- and *CDR2*-encoded efflux pumps but not *MDR1*-encoded pumps or *ERG II* [149, 150]. In a murine systemic candidiasis model, the more frequently administered dosing regimens prevented the emergence of a resistant cell phenotype.

A correlation between in vitro susceptibility and response to therapy of non-mucosal candidiasis has been demonstrated in some studies [151, 152] but not others. Clancy et al. in 2003 evaluated 32 bloodstream *Candida* isolates and concluded that geometric mean MIC and fluconazole dose/MIC ratio predicted clinical failure [153]. Inadequate dosing of fluconazole (≤200 mg/day) and ratio <50 correlated with therapeutic failure, but not necessarily with resistance development.

6.8 Echinocandin Resistance

Candida sp. isolates resistant to echinocandins were first reported in 2005 [88], but reports of resistance were rare, at <2–3 % with *C. albicans* and most *Candida* species [43, 62, 154, 155]. However with time, reports of clinical failure with isolates demonstrating high MIC were increasingly but still not frequently seen [92, 156–165]. Overall, echinocandin resistance among most *Candida* species has been largely unchanged in the past few years [32]. However, this does not apply to *C. glabrata*, where echinocandin resistance is increasing and there is justifiable concern especially since many isolates also demonstrate azole resistance [166–168]. The SENTRY Antimicrobial Surveillance Program revealed that 8.0–9.3 % of blood isolates of *C. glabrata* from 2006 to 2010 were echinocandin drug resistant [154]. Of concern, Alexander et al. reported an increase in echinocandin-resistant *C. glabrata* bloodstream isolates, in Duke Hospital from 2–3 % in 2001–2006 to more than 13 % in 2009–2010 [166]. This is not widespread throughout the USA in that one recent study showed 3.1–5.7 % resistance in *Candida* isolates [62, 168]. Nevertheless, echinocandin resistance was similarly linked to azole resistance in *C. glabrata*. In this large Pham study, nearly all isolates containing an *FKS* mutation were resistant to at least one echinocandin, and 36 % were also resistant to fluconazole [168].

6.8.1 Mechanism of Acquired Echinocandin Resistance

Echinocandin resistance results from modification of glucan synthase, which is encoded by genes *FKS1* and *FKS2*. Unlike azole drugs, echinocandins are not substitutes for multidrug transporters [169]. Echinocandin resistance is nevertheless well characterized, conferred by restricted mutations in two highly conserved "hot spot" regions of the *FKS* genes [167]. The *FKS* mutations result in amino acid mutations that induce MIC values from 20- to 100-fold and reduced sensitivity of glucan synthase to drug by 50–30,000-fold [170]. These less susceptible fks mutant strains respond poorly to echinocandin drugs in pharmacodynamic models of infection [171, 172] and are associated with reduced clinical response [173, 174]. The *FKS* resistance mechanisms have been observed in many *Candida* species [175]. In all *Candida* species, except *C. glabrata*, mutations occur within two "hot spot" regions of *FKS1* [55] (see Chapter

29, Volume 1). In *C. glabrata* mutations occur in the homologous hot spot regions of *FKS1* and *FKS2* [55, 155, 170].

The echinocandin drugs are highly serum protein bound potentially reducing susceptibility testing. Serum is considered to reduce the fungicidal characters of the echinocandins, resulting in fungistatic activity against certain *Candida* species [175].

Biofilms also play a role in antifungal resistance [176]. Decreasing glucan production, accompanying echinocandin use increases susceptibility of yeast organisms contained within the biofilm to the effects of these drugs [177].

7 Refractory Candidiasis: Clinical Resistance Syndromes and Their Management

7.1 Oropharyngeal and Esophageal Candidiasis

Refractory OPC and EC represent the commonest manifestation of clinical azole resistance and failure that is supported by concomitant in vitro azole resistance. Most patients present with highly symptomatic episodes with oropharyngeal pain and debilitating dysphagia and odynophagia requiring hospitalization. The majority of patients with refractory upper gastrointestinal candidiasis have AIDS and advanced immunodeficiency. In the 1990s, the annual incidence of clinical failure of fluconazole in OPC was approximately 5 % [104–107]. Accordingly, refractory superficial candidiasis peaked and became a major clinical problem during the decades of the 1990s prior to the availability of highly active antiretroviral therapy (HAART) [110, 178, 179]. The majority of these patients have refractory disease caused by *C. albicans* [180]. Only a minority have non-*albicans Candida* spp. usually *C. glabrata*, strains of which are usually resistant in vitro to fluconazole. Resistant strains of *C. albicans* and *C. glabrata* are frequently, but not invariably, cross-resistant to itraconazole and ketoconazole [181]. Refractory mucosal candidiasis has also been reportedly associated with *C. tropicalis* and *C. krusei* [5]. In the absence of coinfection with non-*albicans Candida* species, refractory candidiasis is seen with both in vitro resistant and sensitive *C. albicans*. The reason for treatment failure caused by azole-sensitive *C. albicans* is usually the result of noncompliance with ART therapy, drug underdosing, or drug interactions. Another major factor is simply advanced immunodeficiency. With refractory esophagitis, it is important to exclude concomitant pathology such as CMV or HSV esophagitis. Other explanations for the in vitro-in vivo discrepancy in compliant patients relate to heteroresistance in individual colonies of *Candida*, with chance selection of a "susceptible" colony. Most patients with refractory OPC and EC almost always have usual *Candida* spp. isolates with in vitro resistance.

Finally, some experts have questioned the virulence capacity of non-*albicans Candida* species to induce OPC and EC, let alone refractory disease [5, 182]. It is true that refractory candidiasis in patients with AIDS, from whom NAC strains are isolated, usually represents mixed infections with coexistent *C. albicans*; however, resistant disease due to *C. glabrata* in the absence of *C. albicans* is now widely accepted.

The availability of HAART was rapidly followed by a marked decline in the frequency of refractory OPC and EC [183]. It was assumed that enhanced mucosal immune function was responsible for this phenomenon. However, this issue is more complex in that refractory disease resolved within days and weeks of initiation of HAART, preceding demonstrable improvement or change in CD4 lymphocyte cell count or any other marker of CMI, suggesting that some other beneficial effects might be responsible [184]. Another observation included the disappearance of azole-resistant strains of *C. albicans* and *C. glabrata* with the reappearance of azole-sensitive strains. How was improved mucosal CMI selecting susceptible strains of *Candida*? Another more recent hypothesis relates to a direct effect of HIV structural components in directly influencing genes carried by *Candida* responsible for virulence expression including development of azole resistance. Accordingly, HIV gp 160 and gp 41 may influence *Candida* in vitro, selecting for azole resistance [185]. According to this hypothesis, the mucosal viral load (HIV RNA) would enhance *Candida* virulence in situ and finally induce or select for azole resistance. Introduction of HAART and rapid decrease in viral load, before immune recovery, would explain early resolution of refractory mucosal candidiasis and reemergence of azole-susceptible strains. Therapeutic protease inhibitors may further reduce *Candida* virulence by inhibiting fungal secretory aspartyl proteinases [186].

It follows that in the post-HAART era, the frequency of refractory disease as well as in vitro azole resistance declined substantially. The majority of patients with chronic and refractory disease are usually noncompliant AIDS patients infected with susceptible *C. albicans*. In a study of in vitro susceptibility of oral isolates in the HAART era, Tacconelli showed a reduction in azole resistance from 37 to 7 % [187]. The explanation for the reduced or diminished at-risk population is thought to relate to reduced fluconazole exposure, i.e., fewer low-dose regimens and less continuous long-term therapy; however, this hypothesis is unproven. Barchiesi et al. reported that most patients on HAART are colonized by strains of *C. albicans* susceptible to fluconazole (93 % sensitive) [188]. Most cases of OPC in the HAART era are caused by fluconazole-sensitive *C. albicans*.

A high prevalence of non-*albicans Candida* species (*C. albicans* 49 %, *C. glabrata* 24 %) with frequent resistance to fluconazole and itraconazole has also been reported in patients with advanced cancer, especially head and neck malignancy [189, 190]. Another small but critically important patient population includes patients with the various genetic

forms of chronic mucocutaneous candidiasis such as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) patients [191]. Frequent decreased susceptibility of *C. albicans* to fluconazole is a common complication of prolonged fluconazole use in this population.

Clinical management of refractory OPC requires evaluation and determination of etiological mechanisms responsible for clinical resistance, including CD4 count, compliance with HAART therapy, previous OPC, and exposure to azoles, usually fluconazole [192]. Finally, clinical resistance implies failure to respond despite adequate delivery of a tolerable therapeutic concentration of the drug. Once in vitro resistance is suspected, cultures are obtained and susceptibility determined of the responsible organisms. Most commonly, *C. albicans* is present, sometimes together with a second species usually *C. glabrata*. While awaiting microbiology and susceptibility results, treatment is initiated. Therapeutic strategies are listed in Box 66.3. Initial options include progressive increasing doses of oral fluconazole from 100 to 400 mg/day, including fluconazole suspension [193] or swish-and-swallow amphotericin B suspension (100 mg/mL, taken as 1 mL qid) [194]. Although cross-resistance with other triazoles is common, in the event of retained itraconazole sensitivity, itraconazole suspension (10 mg/mL, taken as 10 mL bid) is often effective, although usually on a temporary basis only [195]. However, the most important advance in therapy of fluconazole-refractory OPC is oral posaconazole. Although initially available only as an oral suspension, it is now prescribed as posaconazole tablet 400 mg bid for 14 days. Given its safety profile, posaconazole is used preferentially to oral voriconazole.

Box 66.3. Therapy of Fluconazole-Refractory Oropharyngeal (OPC) and Esophageal Candidiasis (EC)

OPC

- High doses of fluconazole tablets
- Fluconazole suspension
- Itraconazole capsules/suspension
- Amphotericin B oral suspension
- IV amphotericin B/lipid formulation
- Posaconazole oral/IV
- Voriconazole oral/IV
- IV echinocandin
- Immunomodulation
  - G-CSF
  - GM-CSF
  - α-Interferon

EC

- IV echinocandin
- Fluconazole
- IV lipid formulation of amphotericin B
- IV voriconazole*

*If susceptible in vitro

Parenteral antifungals have become the last resort employing intravenous amphotericin B, echinocandin, or voriconazole [196]. All these options may successfully control and eradicate acute symptomatic infection; however, unless immune reconstitution follows, relapse is inevitable. Potentially, the aforementioned parenteral antifungals could be given on an intermittent maintenance basis; however, maintenance suppressive therapy with oral posaconazole 400 mg per day is effective [197].

While HAART therapy offers a definite solution in AIDS patients, the same cannot be said from CMC patients with progressive azole resistance starting with fluconazole and extending sequentially to itraconazole and then voriconazole with either *C. albicans* or *C. glabrata*. Intermittent parenteral echinocandins or lipid formulation of amphotericin B will be necessary, although the use of oral posaconazole is preferred [198].

7.2 Refractory Esophageal Candidiasis (Box 66.3)

As for refractory OPC, clinically resistant EC is mainly seen in untreated AIDS patients with advanced immunodeficiency, with a history of sporadic previous treatment with fluconazole. Refractory, especially chronic, EC is associated with a profound impact on general health leading to weight loss, malnutrition, and overall reduced general health status. Oral cultures usually reveal the *Candida* species responsible for esophageal disease, recognizing that more than one resistant species may coexist. Most cases of fluconazole-resistant EC are similarly resistant to itraconazole [199]. In a minority of patients still capable of swallowing, oral posaconazole is still a therapeutic possibility. If swallowing is not possible, therapeutic options now include amphotericin B deoxycholate or lipid formulations used parenterally in hospitalized patients, and while widely recognized as efficacious, there are little published data documenting efficacy. Cost with the use of lipid formulations and toxicity associated with conventional AmB remain issues. Regardless of which formulation is chosen, low-dose regimens frequently fail in patients with azole-resistant *C. albicans* and/or *C. glabrata*. Response to IV therapy is frequently slow, and >0.8 mg/kg AmB or 5 mg/kg of lipid AmB should be used.

Fortunately, the drugs of choice are IV echinocandins. Studies confirm similar efficacy with daily IV caspofungins, anidulafungin, and micafungin. Accordingly, caspofungin was found to have ~70 % efficacy rate in treating patients with fluconazole-refractory EC [6, 198, 200–202]. No cross-resistance exists between azoles and echinocandins. Similar efficacy for EC has been observed with parenteral voriconazole, also achieving ~70 % response rates but with little experience published with fluconazole-resistant species [203]. Table 66.1 shows the impact of fluconazole-resistant

C. albicans on susceptibility to voriconazole; hence, higher doses of voriconazole may well be indicated [87, 144]. The recent availability of parenteral posaconazole increases therapeutic options, and oral posaconazole is recommended as de-escalation therapy to complete parenteral echinocandin treatment.

Regardless of the parenteral regimen selected, the dominant issue remains the maintenance antifungal prophylaxis in these severely immunocompromised individuals. It cannot be emphasized sufficiently that the key to preventing further recurrences or inevitable relapses of refractory EC lies with successful initiation of HAART therapy. Noteworthy several studies indicated that relapse rates of EC are higher following initially successful echinocandin treatment [204]. Until HAART therapy reverses susceptibility, maintenance prophylaxis is best afforded with oral posaconazole.

7.3 Refractory *Candida* Vaginitis (VVC)

Two forms of vulvovaginal candidiasis (VVC) exist. In the first place, an individual episode of symptomatic vaginitis may not respond to conventional topical or oral antifungal therapy. The other form of refractory disease is found in a larger population of women with frequently recurring episodes of relapsing symptomatic vaginitis although each individual episode of VVC responds to conventional therapy (RVVC).

Failure to achieve clinical improvement and symptom resolution, i.e., azole-resistant vaginal *C. albicans*, is still uncommon but has increasingly been reported in both HIV-positive and HIV-negative women [205]. It is actually remarkable that resistance is not more frequent given the widespread use of low-dosage fluconazole as single-dose therapy or once-weekly maintenance prophylaxis for RVVC. Nevertheless, any patient with acute *Candida* vaginitis, failing to improve with a standard regimen of oral or topical azoles, with persistent symptoms, positive microscopy, and culture, should be treated with topical vaginal boric acid 600 mg daily for 14 days. At the same time, the *C. albicans* isolate should be sent for azole susceptibility testing. The same cannot be said for acute *C. glabrata* vaginitis which responds to azole agents with a 50 % rate only [206]. Acute *C. glabrata* vaginitis should be treated with topical boric acid 600 mg suppositories daily for 11–21 days with an anticipated clinical and mycological response rate of ~70 % [179]. Higher cure rates (>90 %) can be obtained with topical 17 % flucytosine intravaginal cream, 5 g nightly for 14 days, although the cream must be compounded and is not widely available and hence is expensive [206, 207]. High cure rates also follow daily intravaginal amphotericin B 50 mg suppository for 14 days or in combination with topical flucytosine [208].

Acute vaginitis due to *C. krusei*, although rare, will not surprisingly fail to respond to oral fluconazole, due to innate or primary resistance [209]. Occasionally, patients may respond to oral itraconazole or topical miconazole or clotrimazole prescribed for 14 days. *C. krusei* is also resistant to flucytosine, and hence vaginitis due to this species is often extremely difficult to control.

It should be emphasized that refractory acute vaginitis is extremely rare, although busy practitioners might not agree. This is because of incorrect diagnosis on the part of practitioners who treat vaginitis on an empiric basis, invariably failing to measure vaginal pH, perform microscopy, and obtain a vaginal culture. Several studies have confirmed the poor diagnostic acumen of practitioners. Self-diagnosis by women is no better. Other species of *Candida* can cause vaginitis, but tend to rapidly respond to azole therapy.

Much more common and affecting millions of women, in their childbearing decades worldwide, is recurrent vulvovaginal candidiasis (RVVC) thought to affect 6–8 million women in the USA. Under these circumstances recurring episodes of vaginitis respond appropriately to antifungal therapy regardless of route, only for symptoms and signs to recur within a month or two but rarely monthly [210]. RVVC is mostly caused by azole-sensitive *C. albicans* (>90 %) and less commonly by *C. glabrata* (5 %). RVVC is rarely a manifestation of drug resistance but of host factors that predispose to genital tract yeast colonization and host immune response hyperreactivity to *Candida* antigens [210]. RVVC is best controlled by once-weekly fluconazole maintenance prophylaxis administered for 6 or more months [128], although other forms of suppressive azole therapy are effective but less convenient [211, 212]. Boric acid has also been used effectively [213].

The management of azole-refractory vaginitis due to in vitro confirmed fluconazole-resistant *C. albicans* is initially managed with daily vaginal boric acid for 2 weeks, while in vitro susceptibility tests become available. Acute, nonrecurrent vaginitis may require no additional therapy; however, women suffering from RVVC will of necessity require a maintenance antifungal regimen. Possible alternatives to weekly fluconazole are daily ketoconazole or itraconazole 100–200 mg, provided that susceptibility is confirmed in vitro. As per standard protocols, the maintenance daily regimens are continued for at least 6 months. In the event of frequently reported azole cross-resistance, no oral azoles are likely reasonable safe alternative agents. In this scenario, long-term maintenance therapy can be achieved with topical boric acid or nystatin for the same long-term duration, but little published data are available. Similarly, daily combination therapy with boric acid and nystatin is effective for symptomatic recurrent VVC due to *C. glabrata* although such cases are rare.

Box 66.4. First-Line Antifungal Drug Therapy of Candidemia (Parenteral)

1. Amphotericin B (conventional deoxycholate)
2. Lipid formulation AmB
3. Fluconazole (400 mg/day)
4. Fluconazole (800 mg/day)
5. Itraconazole
6. Voriconazole
7. Caspofungin
8. Amphotericin B + flucytosine
9. Amphotericin B + fluconazole

7.4 Refractory Candidemia and Disseminated Candidiasis

The incidence of bloodstream infections (BSIs) due to *Candida* spp. has increased worldwide, with accompanying significant mortality. Fortunately, in parallel with this increase has been an increase in the therapeutic armamentarium for candidemia (Box 66.4). The purpose of this chapter is not to review management of candidemia (see reviews [96, 114, 214]). Drug resistance is monitored by a variety of study organizations in multiple countries. Perhaps the most comprehensive antifungal susceptibility monitoring organization is the SENTRY system receiving in excess of 2000 bloodstream *Candida* isolates annually from all over the world [63]. Compiled data are shown in Table 66.3. Nevertheless, given the proportional and occasionally found absolute increase in cases of invasive candidiasis and candidemia due to non-*albicans Candida* species especially *C. glabrata*, together with the availability of safe and in the past predictable effective echinocandins, guidelines from national and international infectious disease societies have recently been issued which acknowledge the reduced azole susceptibility of non-*albicans Candida* species. Hence, until information of the identity of the *Candida* species responsible for the bloodstream infection is available, echinocandins are considered drugs of first choice to be prescribed [96].

Table 66.3 Species distribution of *Candida* from cases of invasive candidiasis[a]

	% of total no. of cases[b]					
Species	1997–1998	1999	2000	2001	2002	2003
C. albicans	73.3	69.8	68.1	65.4	61.4	62.3

[c]*Candida* species not otherwise identified

7.4.1 *C. albicans*

Despite the widespread use of fluconazole over the last 15 years, fluconazole resistance in *C. albicans* blood isolates remains below 5 %, with no evidence of a progressive increased resistance with time or associated with a specific geographic area [60]. It is not fear of an azole-resistant strain of *C. albicans* that drives principles of antifungal drug selection. Candidemia due to drug-resistant *C. albicans* is rare, but has been rarely reported in patients with hematologic malignancy [100]. However, *C. albicans* is no longer the most prevalent *Candida* species responsible for BSI, and rarely is drug resistance a management issue. Should an azole-resistant *C. albicans* isolate be responsible for the candidemia, the clinical manifestations include persistent candidemia on fluconazole therapy, relapsing candidemia or possibly increased mortality, and finally breakthrough candidemia. In the last decade, results of at least five randomized prospective controlled studies have been published involving fluconazole and other antifungal drugs [215–220]. Attempts have been made to correlate clinical outcome with in vitro MICs. In none of these studies has *C. albicans* antifungal resistance, specifically fluconazole resistance emerged as a cause of drug failure [216, 217]. The lack of fluconazole resistance in *C. albicans* BSI isolates after all these years remains reassuring, but the altered epidemiology is less so. In contrast to other studies, correlation between in vitro susceptibility and response to fluconazole therapy has been demonstrated, but rarely is persistent fungemia due to azole-resistant *C. albicans* but rather non-*albicans Candida* species [221].

7.4.2 *C. glabrata*

As evident in Table 66.2, candidemia due to *C. glabrata* has increased especially in North America and Europe. Fluconazole resistance in bloodstream *C. glabrata* isolates is evident in 7–10 % of strains, with an addition of 27–30 % of isolates considered S-DD indicating reduced fluconazole susceptibility of *C. glabrata* isolates. Accordingly, only 50–70 % of *C. glabrata* bloodstream isolates are highly susceptible to fluconazole. Several studies involving *C. glabrata* have shown a similar susceptibility pattern [63, 64].

Documented failure or suboptimal response to fluconazole and other antifungals has been forthcoming in some studies and is impressively present in others [221]. When failure was always apparent, this may simply reflect small numbers of patients with *C. glabrata* fungemia, i.e., some published studies have lacked the power to show any differences in outcome by *Candida* species.

Supporting the in vitro data are numerous case reports of fluconazole failure to eradicate *C. glabrata* fungemia subsequently responsive to parenteral polyene or echinocandin therapy as well as retrospective analysis of patients with persistent candidemia [151, 221]. Accordingly, most experts would recommend avoiding any azoles, including voriconazole, initially in patients with candidemia caused by *C. glabrata* and initiate therapy with an echinocandin. Until the *Candida* isolate (species) is identified and species identity is becoming more and more rapidly established, then given the increased likelihood of *C. glabrata* and other reduced fluconazole susceptibilities, selection should include the possibility and commence with an echinocandin. In candidemia patients doing well on azoles, continued therapy with the azole would be perfectly reasonable.

8 Adjuvant Therapy for Resistant Candidiasis

The use of immune and nonimmune adjuvants to treat refractory candidiasis is almost exclusively seen in patients with AIDS or chronic mucocutaneous candidiasis (CMC). Even with the latest generation of azoles (voriconazole, posaconazole) and polyene and echinocandin use, refractory mucosal disease is still reported due to resistant *C. albicans*, *C. glabrata*, and rarely other *Candida* species. There have been anecdotal successes reported with immunostimulators mainly recombinant human granulocyte-macrophage colony-stimulating factor (rhu GM-CSF) [222, 223]. Also, interferon gamma has occasionally been given [196]. Unfortunately, investigators tend to publish only successful therapeutic endeavors and failures are more frequent [224, 225]. Even so, long-term use and success of these growth factors have not been forthcoming especially associated with CMC. The use of these agents, given these expenses, requires the performance of randomized controlled studies which are unlikely given the current infrequency of these refractory cases. The value of GM-CSF in invasive candidiasis has not been demonstrated but may have a role in persistently neutropenic patients. Monoclonal antibodies were shown to prevent disseminated candidiasis in a mouse model and have been the bases for vaccine development. Likewise, the administration of anti-*Candida* heat shock antibodies may have an adjuvant role together with antifungals for resistant or refractory candidemia.

9 Prevention of Antifungal Resistance in *Candida* Species

In general, standard principles of infection control that apply to all microorganisms and particularly nosocomial infections should be applied to prevent antifungal resistance.

Avoidance of prophylactic or suppressive therapy and a preference for repeated short course of azoles for OPC in the late stages of AIDS are an attractive but unproved measure for delaying the appearance of azole resistance. In a study conducted in patients with recurrent OPC and AIDS, episodic fluconazole therapy was compared to continuous fluconazole therapy aimed at evaluating likelihood of inducing fluconazole resistance and refractory oropharyngeal candidiasis [98]. The study failed to show a difference in the two arms with regard to selection or induction of azole resistance. This somewhat disappointing result may reflect the fact that the study was conducted during the HAART era with relatively few individuals presenting with refractory mucosal disease, with advanced immunodeficiency and unavailability of HAART therapy. The study outcome is in sharp contrast to clinical experience obtained in the pre-HAART era.

It goes without saying that all unnecessary use of azoles should be avoided, whether as prophylaxis or therapy. Many clinicians prescribe a lower than recommended prophylactic dose of oral fluconazole in neutropenic patients, i.e., 100 mg vs. 400 mg daily. To date, no evidence has emerged of increased fluconazole resistance as a specific consequence of this reduced daily dose. Nevertheless, many experts advise against the use of azole prophylaxis in neutropenia of short duration. Paterson suggested that combining oral amphotericin B with azoles may prevent the emergence of resistant *Candida* species in neutropenic patients; however, oral amphotericin B is poorly tolerated and noncompliance is common [226].

Studies have indicated that most *Candida* species are carried and readily transferred manually by nursing physicians and other medical personnel [227]. Accordingly, adherence to strict handwashing principles applies equally to *Candida* and specifically the transfer of resistant strains of *C. albicans* and other *Candida* species [228, 229]. In particular, *C. parapsilosis* is frequently isolated from the hands in contrast to *C. glabrata* which appears to be endogenously acquired from GIT carriage only. Isolation of patients with resistant strains of *Candida* is not indicated in this era of universal precautions. Perhaps, the most controversial is the use of antifungal prophylaxis in selected high-risk patients in intensive care units. Several studies suggest limited benefit and only in selected high-risk ICU patients [230, 231, 232].

10 Conclusion and Perspective

During the last two decades, enormous strides have been made in understanding the subcellular, molecular, and genetic basis of antifungal resistance. All in all, clinically refractory candidiasis is uncommon. The explosion in clinically resistant cases of OPC and EC early in the AIDS epidemic has not stood the test of time with the arrival of antiretroviral therapy. Of course, clinically resistant cases still occur and remain a therapeutic challenge, but the majority of cases of mucosal disease are caused by azole-sensitive *Candida albicans*. There has been an increase in non-*albicans Candida* species causing invasive candidiasis. Much, but not all, evidence points to widespread prophylactic, empirical, and therapeutic use of fluconazole. Nevertheless, blood isolates of *C. albicans* remain remarkably and predictably susceptible to fluconazole and other azoles, and this is a worldwide experience. There is no doubt that certain *Candida* species are less susceptible and/or resistant to fluconazole and show cross-resistance to all azoles. This species-specific (*C. krusei*, *C. glabrata*) azole resistance has a major influence in antifungal drug selection. These two species not only expose vulnerability of the azole class but require higher doses of polyenes. As such, fungal susceptibility tests in the past were rarely available and infrequently and selectively used. This however has changed with increased availability. The newer generations of azoles are often active against non-*albicans Candida* species (*C. glabrata* and *C. krusei*) and as such offer early confident broad-spectrum therapy. Moreover, they are frequently active against fluconazole-resistant *C. albicans*. The echinocandins have further eased the concern of azole resistance in candidiasis, but time has yet to determine the potential for echinocandin-acquired resistance in candidiasis.

Antifungal Drug Resistance in *Aspergillus*

67

P.H. Chandrasekar and Elias K. Manavathu

1 Introduction

A recent database search revealed a steady increase in the number of publications (almost 1000 papers) on antifungal drug resistance/lack of drug susceptibility in aspergillus in peer-reviewed scientific journals from 2000 to 2014 (Fig. 67.1). In contrast, about only 57 publications appeared in scientific journals directly dealing with antimicrobial drug resistance in aspergillus prior to 2000. Until recently, unlike in Candida, drug resistance in aspergillus was poorly appreciated. This rapid rise in publications signifies a revitalized interest in aspergillus drug resistance in clinical settings that is augmented by the upward spike in aspergillus infections in humans, primarily in the immunocompromised patient population. Although more than 200 *Aspergillus* species are described in the literature (less than 10 % cause disease in man), more than half (50.63 %) of the published reports deal with drug resistance/lack of drug susceptibility in clinically most common *A. fumigatus* followed by *A. niger* (11.8 %), *A. flavus* (11.3 %), *A. terreus* (7.7 %), and *A. nidulans* (7.0 %) (Fig. 67.1). Approximately 12 % of the publications describe drug resistance/lack of drug susceptibility in other disease-causing *Aspergillus* species. This somewhat skewed distribution of publications on antimicrobial drug resistance in aspergillus is not surprising considering that about 60–70 % of the isolates obtained from clinical specimens are *A. fumigatus*.

Several reasons could be attributed to the increased interest in the area of antimicrobial drug resistance in *Aspergillus* species, namely, (1) effective prophylaxis against *Candida* infections in highly vulnerable immunocompromised patient population (e.g., organ transplant recipients and cancer patients undergoing aggressive chemotherapy) has made the opportunistic *Aspergillus* species a major clinical problem, (2) effective and safer anti-aspergillus drugs have become available, (3) improved modern diagnostic techniques facilitate better identification of aspergillus infection, (4) introduction of standardized susceptibility testing has led to the identification of more drug-resistant clinical strains, (5) introduction of culture-independent molecular techniques to identify potential drug resistance causing gene mutation has enhanced the level of detection of drug resistance, and (6) increased use of antimycotic drugs (e.g., azole derivatives) as agrochemical pesticides has increased the frequency of selection of drug-resistant environmental isolates.

Despite the availability of potent antifungal agents, systemic fungal infections continue to cause significant morbidity and mortality. While *Candida*-related deaths have declined since the late 1980s, those due to aspergillosis remain high. A high percentage of patients continue to die with invasive aspergillosis (IA) despite treatment [1–3]. Scientific discussions regarding unsuccessful treatments reason that susceptible hosts, particularly cancer patients and transplant recipients, are profoundly immunocompromised with neutropenia and/or impaired monocyte/macrophage dysfunction. There is universal agreement that the outcome of IA is largely dictated by the host immune status [4–6]. Regardless of the antifungal drug(s) employed, the poor outcome or failure of antifungal therapy is generally attributed to persistently, compromised host defenses and, in most cases, not considered to be due to drug-resistant fungi. Also, failure of antifungal drugs may be due to inappropriate dose, fungistatic activity, high protein binding, poor absorption/distribution, and metabolism or drug interactions. Until recently, drug resistance in aspergillus was not adequately examined.

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_19

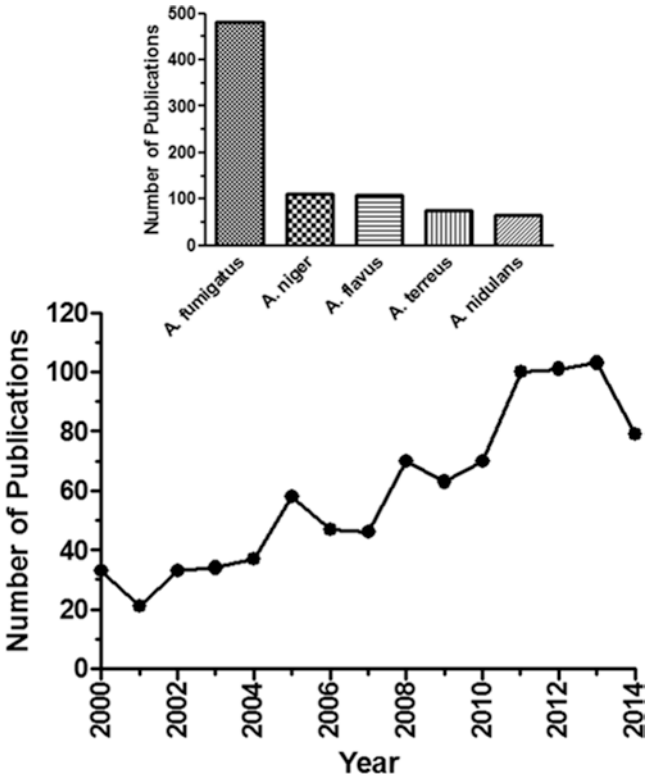

Fig. 67.1 Number of peer-reviewed yearly publications on antimicrobial drug resistance in *Aspergillus* species from 2000 to 2014

In a contrasting argument, azole resistance takes center stage (Fig. 67.2). Availability of better-tolerated effective azoles has led to their widespread and prolonged use for prophylactic or therapeutic purposes, particularly in compromised hosts; as a result, clinically significant azole resistance is increasingly encountered. Failure to available drug therapy can no longer be entirely attributed to the immunocompromised status of the host. Additionally, common use of azoles in agricultural industry in many countries has resulted in the recognition of multi-azole resistance in environmental isolates of aspergillus. Drug resistance in aspergillus is becoming a global phenomenon; strategies and guidelines are urgently needed for the management of suspected or proven drug-resistant aspergillosis.

The cornerstone for the successful management of IA includes decrease in immunosuppression, immune restoration, surgical debridement, and optimal antifungal drug therapy. The antifungal drugs available for therapy of IA are listed in Table 67.1. The most recent addition is isavuconazole, a water-soluble, anti-mold azole available in oral and IV forms. Data on aspergillus exhibiting resistance to drugs listed are limited. This limitation has largely been due to lack of interest in the past as the incidence of infection was low; amphotericin B being the only effective drug, the pathogen not readily recovering from most infected patients; lack of information on resistance to newer drugs; and more importantly, nonavailability of a reliable susceptibility test method to correlate in vitro findings to clinical outcome. The rising incidence of aspergillosis, the recent availability of a standardized in vitro method to test susceptibility of filamentous fungi, and the entry of new drugs have kindled the interest and made it feasible to study drug resistance in aspergillus [7].

2 In Vitro Resistance

2.1 Mechanisms of Antifungal Resistance

Resistance can be described as primary (innate) when a fungal pathogen is intrinsically resistant to the antifungal drug or secondary (acquired) when an organism develops resistance during drug exposure either due to spontaneous mutation or the acquisition of the resistance trait from an external source by genetic transfer. The known cellular and molecular mechanisms responsible for reduced in vitro and in vivo susceptibility to antifungal drugs fall into two broad categories, namely, reduced intracellular accumulation of the antifungal drug compared to that in the susceptible cells and quantitative or structural alteration of the fungal drug target.

The reduced intracellular drug accumulation occurs either due to efflux of the drug from the cell mediated by efflux proteins or due to reduced penetration of the drug into the cell because of selective drug-permeability barrier(s). The efflux proteins belong to two groups, ATP binding cassette (ABC) transporters and major facilitators. The efflux proteins pump out drugs accumulated in the cell at the expense of energy and maintain the concentration of the drug inside the cell below the level normally required for the inhibition of growth. Thus, even in the presence of high concentration of the drug outside the cell, the organism is able to grow and function physiologically more or less normally. The energy required for the expulsion of the drug is generally derived from hydrolysis of ATP. When an organism develops resistance to a certain drug due to efflux, the pump proteins are overproduced compared to the amount present in drug-susceptible cells. In general, the efflux proteins are native to the cell carrying out essential nutrient transport but fortuitously adapted to perform transport of substances toxic to the cell, including antimicrobial drugs.

A second, less well-known mechanism for the reduced accumulation of antifungal drugs inside the fungal cell is diminished penetration of the drug because of selective permeability barrier(s). This type of mechanism is known to be responsible for resistance to antibacterial drugs in Gram-negative bacteria such as *Pseudomonas* species where the outer cell membrane or biofilm acts as a selective permeability barrier [8]. In the case of fungi, the reduced penetration is often associated with other factors such as the chemical

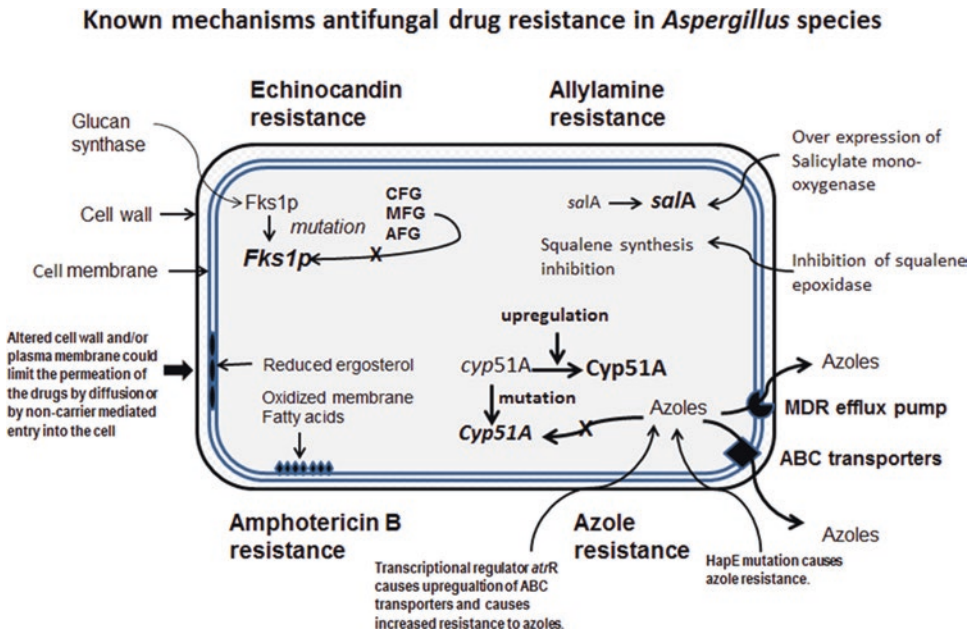

Fig. 67.2 A diagrammatic illustration of the known mechanisms of antimicrobial drug resistance in *Aspergillus* species. See the text for details

Micafungin, Mycamine®
Anidulafungin, Eraxis®

changes in the cell wall and production of hydrophobic compounds such as pigments. Excessive production and incorporation of pigment(s) in the cell wall often act as a barrier for the penetration of toxic substances, including antifungal agents [9]. Since the presence of cell wall pigment provides an added advantage to drug-resistant cells for survival in the presence of antifungal drugs compared to the susceptible ones, the synthesis of cell wall pigment(s) is often considered as a virulence factor [10].

Modification of the fungal drug target (with which the drug molecules interact to bring about their antifungal activity) is a well-known mechanism responsible for the emergence of antifungal drug resistance in medically important fungi. The modification of the drug target is achieved at two levels: quantitative and structural (qualitative). Quantitative drug target modification is obtained by the enhanced production of the drug target by upregulation of its synthesis or by the increased dosage of the gene(s) responsible for the synthesis of the drug target. In either case, the increased amount of the fungal drug target requires higher concentration of the drug to elicit an inhibitory effect. Thus, fungal cells with increased amount of the drug target will survive in the presence of increased amount of the drug compared to a susceptible cell that possesses the base level of the drug target. The structural modification of drug target occurs by the mutational acquisition of genetic variation affecting its synthesis or primary structure (protein). Variation of the primary structure of protein often leads to secondary and tertiary structural changes that affect the binding and processing of drug molecules that mimic the natural substrate (in the case of enzyme target) or ligand (in the case of receptor molecules). Usually, drug target modification-dependent mechanism alone or in combination with other resistance mechanism leads to high-level cellular resistance to the antifungal drug.

2.2 Resistance to Polyenes

Amphotericin B is a typical polyene antifungal drug approved for primary therapy against a wide variety of fungal infections since 1953 [11] and remained as the unchallenged gold standard until recently. It is an amphoteric molecule composed of a hydrophilic polyhydroxyl chain along one side and a lipophilic polyene hydrocarbon chain on the other. It interacts with the fungal membrane-associated ergosterol forming channels or pores spanning across the plasma membrane disrupting the osmotic integrity and the selective permeability of the fungal

plasma membrane. The loss of osmotic integrity and the selective permeability of the membrane result in leakage of essential intracellular cations such as calcium, potassium, and magnesium as well as various metabolites [12]. This indiscriminate massive loss of essential nutrients and ions is believed to be primarily responsible for the death of fungal cells when treated with amphotericin B, although other biochemical reactions such as oxidation of plasma membrane-associated phospholipids and their derivatives affecting the proper functioning of the fungal plasma membrane may also play a major role for the fungicidal activity of amphotericin B [13].

In spite of the extensive use of amphotericin B as the primary antifungal drug against fungal infections over a period of nearly five decades, the emergence of high-level resistance to this compound in clinical isolates of fungi, including *Aspergillus* species, is very rare. The reason(s) for the lack of emergence of resistance to amphotericin B among clinical isolates of fungi is not understood. However, the occurrence of the so-called conventional drug target modification-dependent acquired resistance to amphotericin B requires the synthesis of a modified ergosterol that is biologically functional, but unaffected by the inhibitory action of amphotericin B. The possibility of spontaneous emergence of such a sterol synthetic pathway capable of synthesizing an altered amphotericin B-resistant biologically functional ergosterol in fungi, including *Aspergillus* species, by genetic variation is remote. Hence, it is not surprising that high-level amphotericin B resistance in fungi, including *Aspergillus* species, due to drug target modification is comparatively rare, although other mechanisms of antifungal resistance may occasionally confer reduced susceptibility to this antifungal drug. The clinical and laboratory isolates of *Aspergillus* species showing reduced in vitro or in vivo susceptibility to amphotericin B reported in the literature may belong to this group.

Few reports of low-level amphotericin B resistance among clinical isolates of *Aspergillus* species are available in the literature [14–18]. When attempts were made to evaluate the in vitro resistance (defined as elevated MICs compared to that obtained for the susceptible isolates) to in vivo resistance using animal models, the correlation was poor [15, 16]. On the other hand, when clinical outcome of amphotericin B treatment was retrospectively compared with the in vitro resistance, there was good correlation between amphotericin B failure and elevated MIC of the drug. Because of the paucity of clinical isolates of *Aspergillus* species resistant to amphotericin B, Manavathu et al. [14] have selected *Aspergillus fumigatus* isolates showing low-to-medium-level in vitro resistance to amphotericin B in the laboratory by UV irradiation followed by selection on Sabouraud dextrose agar containing amphotericin B. Using a murine pulmonary aspergillosis model, these investigators have demonstrated correlation between in vitro and in vivo resistance to amphotericin B [19].

Although high-level amphotericin B resistance among clinical isolates of *Aspergillus fumigatus* is rare, *Aspergillus terreus* is inherently less susceptible to amphotericin B, perhaps due to innate resistance to this drug. Exact reason for its reduced susceptibility to amphotericin B is not known. Walsh et al. [18] have investigated the in vitro susceptibility of several clinical isolates of *A. terreus* by the CLSI broth microdilution method M-38A. The MIC of amphotericin B for these isolates ranged from 2 to 4 μg/mL, considerably higher than that of other susceptible *Aspergillus* species such as *A. fumigatus*. Moreover, when tested in an animal model [18], a representative of this group of organisms showed reduced susceptibility to amphotericin B therapy. Therefore, amphotericin B is not the preferred drug for the treatment of aspergillus infection caused by *A. terreus*.

In addition, Seo et al. [17] have selected an *A. flavus* isolate highly resistant to amphotericin B (MIC 100 μg/mL) in the laboratory by sequential transfer of a susceptible strain (MIC ≤ 1 μg/mL) to agar plates containing increasing concentrations of amphotericin B. Further investigation by these authors revealed that the resistant isolate had significant chemical modification to its cell wall which presumably results in poor penetration of the drug to the cell. Balajee et al. [20, 21] have shown that *A. lentulus* and *A. udagawae* previously erroneously identified as *A. fumigatus* are resistant to multiple antifungal drugs, including amphotericin B.

In spite of its high efficacy, a wide spectrum of activity and relatively low cost, conventional amphotericin B deoxycholate is rarely used as the frontline antifungal drug now because of its high potential for toxicity. Liposomal amphotericin B with considerably less toxicity is used as an alternative to treat aspergillus infection. Drugs of the azole and echinocandin classes have considerably diminished the clinical role of amphotericin B.

2.3 Resistance to Triazoles

The triazoles are second-generation members of the azole family of antifungal drugs characterized by the presence of heterocyclic head region carrying three nitrogen atoms instead of two found in imidazole molecule. The addition of an extra nitrogen atom to the imidazole ring moiety not only improved the spectrum of activity but also the potency of the molecule [22–24]. This is not surprising since the heterocyclic ring moiety carrying the nitrogen atoms is the active functional group of the molecule, while the hydrophobic aliphatic chain contributes significantly to the specificity and the pharmacologic properties of the molecule [25]. Itraconazole and newer triazoles such as voriconazole (Pfizer Pharmaceuticals), posaconazole (Schering-Plough Pharmaceuticals, now part of Merck Pharmaceuticals), and isavuconazole (Astellas Pharmaceuticals) possess excellent in vitro and in vivo (clinical and/or animal models) activity against various *Aspergillus* species.

All triazoles are believed to have the same mode of action at clinically relevant concentrations. The primary molecular target of this group of compounds is the cytochrome P450-dependent

14α-sterol demethylase ($P450_{14DM}$), an enzyme responsible for the removal of the methyl group on carbon 14 of 14α-sterol compounds. Although $P450_{14DM}$ is the primary molecular target of triazoles, at high concentrations these drugs may have rather nonspecific effect by directly interfering with the membrane function for which the mechanism is not understood. For instance, it is possible that these molecules, having the capacity to mimic certain sterols, could be randomly inserted into the membranes and as a result affects the function of the plasma membrane. Recently, it was noted that voriconazole has a second target in the sterol synthetic pathway, namely, 24-methylene dihydrolanosterol demethylation [26].

The *cyp*51 gene coding for $P450_{14DM}$ has been characterized from a wide variety of saprophytic and pathogenic fungi, including human pathogens [27–29]. A comparison of the primary structure of $P450_{14DM}$ from various fungal species representing major groups of pathogenic fungi showed six highly conserved regions (CR) arbitrarily called CR1 to CR6 (Fig. 67.3). These conserved regions are known to make important contribution to either the enzyme activity or susceptibility of $P450_{14DM}$ to azole antifungal drugs. In the case of *A. fumigatus* P450 14α-sterol demethylase A protein, these conserved regions are located all throughout the protein sequence (CR1: P38-G89, CR2: V101-S140, CR3: I183-P227, CR4: L267-V315, CR5: V354-V371, CR6: D430-V472). Not

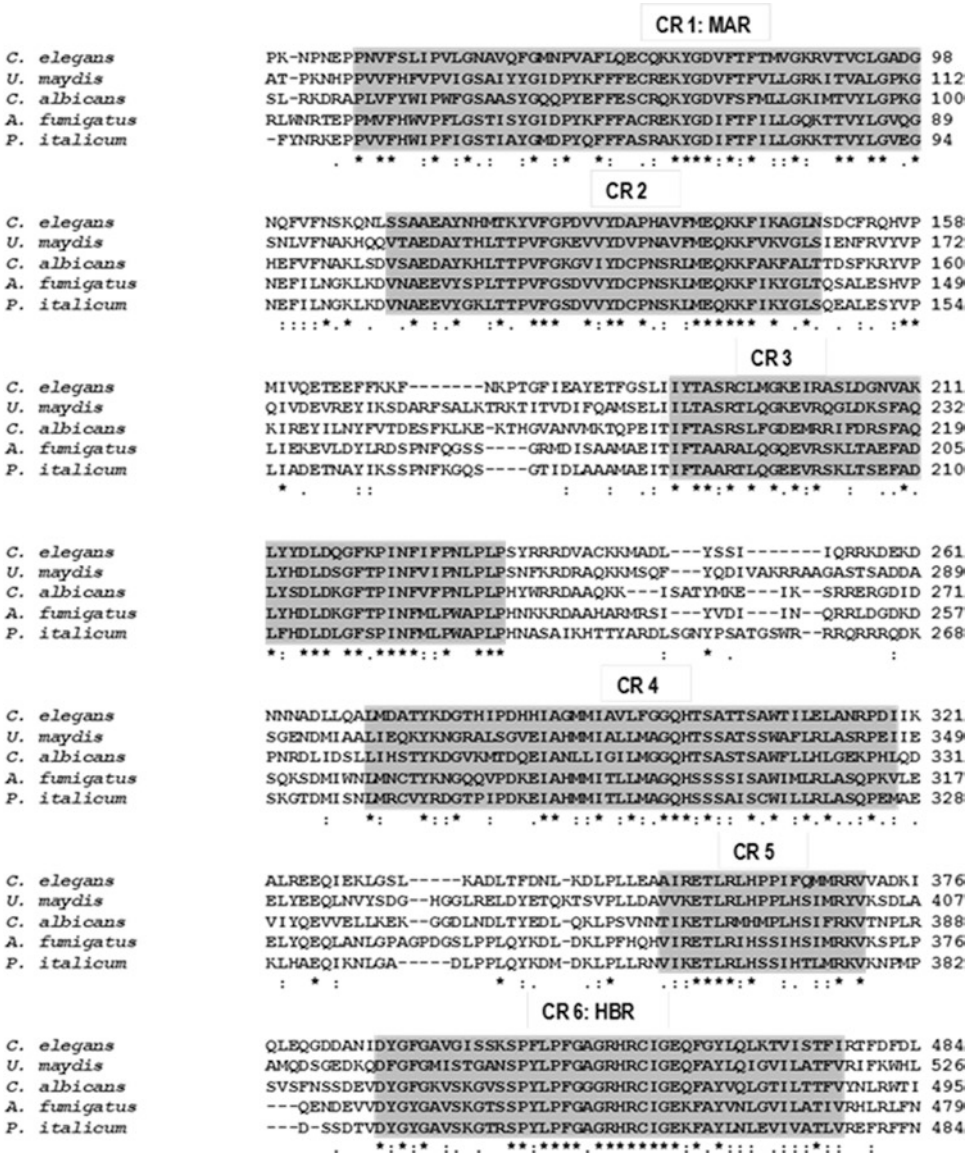

Fig. 67.3 A comparison of the primary structures of P450 lanosterol demethylases ($P450_{LDMs}$) from various fungi. The deduced amino acid sequence of $P450_{LDMs}$ from *Cunninghamella elegans* (Accession AAF20263), *Ustilago maydis* (Accession XM011391846), *Candida albicans* (Accession XP_716761), *Aspergillus fumigatus* (Accession AAK73659), and *Penicillium italicum* (Accession Q12664) was compared by multiple sequence alignment using Clustal Omega as described in Materials and Methods. The highly conserved regions are shaded in *gray*. *CR* conserved region, *MAR* membrane-anchoring region, *HBR* heme-binding region. Asterisks (*) represent identity, colon (:) indicates conserved substitution, whereas period (.) denotes semiconservative substitution

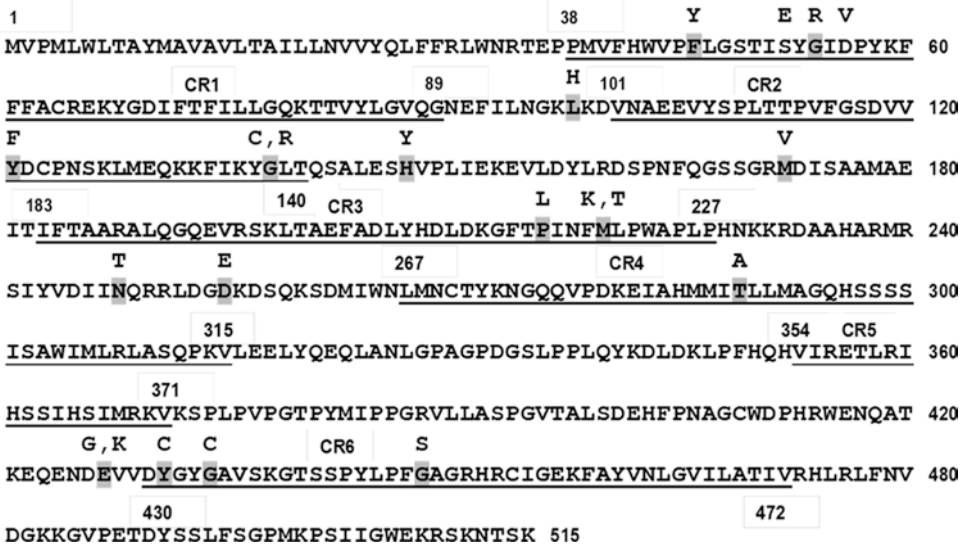

Fig.67.4 Primary structure of *A. fumigatus* Cyp51A protein (Accession AAK73659) showing amino acid substitutions known to affect azole susceptibility in *A. fumigatus*. The highly conserved regions are underlined, and 12 of 16 known substitutions are located in or in close proximity to the conserved regions. Only CR5 is without a known amino acid change affecting azole susceptibility. Among the six conserved domains, the membrane-anchoring (CR1) and the heme-binding (CR6) regions have the most amino acid substitutions and appeared to be the "hot spots" for mutational changes affecting azole susceptibility. The substituted amino acids are shown in *gray*, and the corresponding replacement(s) is shown above. *CR* conserved region

surprisingly, 12 of the 16 loci of *A. fumigatus* P450 14α-sterol demethylase A known to have amino acid substitutions that resulted in azole resistance are located in or in close proximity of these highly conserved regions (Fig. 67.4).

The role of two such highly conserved regions to triazole resistance in *A. fumigatus* has been examined. Proximal to the N-terminus of the protein lies a region starting from amino acid P38 to G89 (CR 1) commonly known as the membrane-anchoring region (MAR) mainly consisting of hydrophobic amino acid residues. It is generally believed that this region of the polypeptide is responsible for anchoring the enzyme to the plasma membrane of the cell. The hydrophobic amino acid residues dominating this region facilitate the insertion of the polypeptide into the lipid bilayer of the membrane. Membrane anchoring places the enzyme molecule in the most favorable position to interact with the incoming substrate (14α-sterol) for binding to the active site for subsequent processing. Thus, plasma membrane-anchored $P450_{14DM}$ will be more efficient for rapid catalysis of the demethylation of 14α-sterol.

The most highly conserved region of the $P450_{14DM}$ is the heme-binding region located at the carboxyl-terminal region from D430-V472 (CR 6) of the protein. Since heme is an essential prosthetic group of all cytochrome P450-dependent enzymes, this region of the polypeptide is highly conserved in all $P450_{14DMS}$. Alignment of 25 $P450_{14DMS}$ from various sources ranging from *Homo sapiens* to the fungus *Cunninghamella elegans* showed that F447, G448, G450, R451, H452, and C454 are perfectly conserved at the core region of the HBR of $P450_{14DMS}$ (Fig. 67.5). Genetic and biochemical studies have shown that C470 in *S. cerevisiae* (C454 in *A. fumigatus*) is involved in substrate binding possibly by providing a sixth coordinate and presumed to be involved in the correct alignment of the incoming substrate molecule for maximum catalytic efficiency [23, 24]. Mutant enzymes carrying variants of this residue lack enzyme activity. Conservation of the critical amino acid residues at the heme-binding region is not only essential for the enzyme function but also necessary for the maintenance of azole susceptibility of the protein. The exact role of each of the highly conserved amino acid residues for the binding and the processing of the substrate is not known at present due to the paucity of adequate X-ray crystallographic data.

In contrast to pathogenic yeasts such as *Candida* species in which a single gene codes for $P450_{14DM}$, in *A. fumigatus*, there are two highly homologous genes *cyp*51A and *cyp*51B coding for P450 14α-sterol demethylases A (Cyp51A) and B (Cyp51B). Several reports of clinical and laboratory isolates of *Aspergillus* species, primarily *A. fumigatus*, showing reduced susceptibility to triazoles have been published recently [21, 30–42]. In several cases, resistance to one member of the triazole group failed to show cross-resistance to other triazole(s) [31, 37, 39, 41]. Amino acid alteration of Cyp51A appears to be the most commonly found mechanism of resistance to triazoles in *A. fumigatus*. Alteration of G54 of Cyp51A to K, E, or R confers resistance to itraconazole and posaconazole [31–33, 36, 41, 42] but not to voriconazole [31, 41]. In contrast, alteration of G448S primarily confers resistance to voriconazole but only a modest reduction of susceptibility to posaconazole and itraconazole

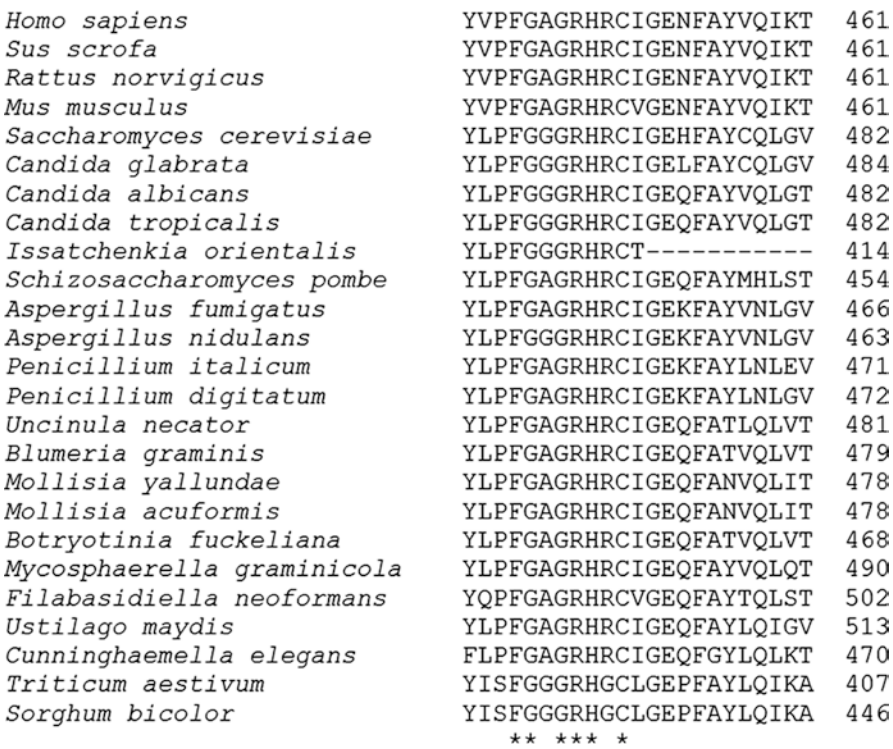

Fig. 67.5 Amino acid alignment of the heme-binding region of 25 $P45014_{DMS}$ from *Homo sapiens* to *C. elegans*. The highly conserved amino acid residues are marked by *asterisks*. The numbers on the right indicate the amino acid residue number. The alignment was done by DNA and protein sequence analysis Program Omiga. The amino acid sequences were obtained from the NCBI protein data bank

[31, 41]. Modeling experiments [43–45] suggest that the heme-binding region is part of the active site of $P450_{14DM}$, and any amino acid change at the active site makes the organism resistant to all triazoles to a lesser or greater degree. In contrast, amino acid variation at the putative membrane-anchoring region confers resistance to triazoles with long aliphatic tail region. These results thus suggest that cross-resistance to triazoles in *A. fumigatus* is at least partly dependent on region-specific amino acid variation of $P450_{14DM}$. On the other hand, alteration of G138 to either C [38] or R [31] confers resistance to multiple triazoles. Initially Mellado et al. [34] and subsequently other investigators [35, 36] have noted that alteration of M220 in Cyp51A to V, K, T [34], or I [35, 36] makes the organism harboring the mutant enzyme resistant to itraconazole. Interestingly, both G138 and M220 are located in CR 2 and CR 3 (Fig. 67.4) of Cyp51A, respectively.

The most widely distributed and frequently reported mechanism of azole resistance in *A. fumigatus* is a combination of *cyp*51A promoter modification coupled with one or more amino acid substitution in Cyp51A protein. The first reported promoter modification involves tandem repeat of a 34 bp (5'GAATCACGCGGTCCGGATGTGTGCTGAGC CGAAT3') nucleic acid sequence (TR34) of the promoter region 288 bp upstream to the ATG codon that specifies the initiation of translation. This promoter modification is often associated with L98H amino acid substitution [40, 46–49], and the TR34/L98H change gives rise to a Cyp51A protein whose activity is relatively unaffected by clinically relevant concentrations of voriconazole, itraconazole, and posaconazole. Hence, the organism that harbors such a variant Cyp51A protein develops pan azole resistance, and the clinician is left with very few options for effectively treating invasive aspergillosis.

A second more recently detected mechanism of azole resistance in *A. fumigatus* involving simultaneous promoter modification and amino acid substitution involves a 46 bp (5'-TCTAGAATCACGCGGTCCGGATGTGTGCTGAGC CGAATGAAAGTTG-3') tandem repeat (TR46) in association with Y121H/T289A amino acid substitutions [50–55]. TR46/Y121H/T289A changes in *cyp*51A/Cyp51A develop high-level resistance to voriconazole but not to posaconazole, although the MIC of posaconazole is slightly elevated [56]. However, there are conflicting reports of the need for the combined presence of TR46/Y121H/T289A simultaneously for the development of azole resistance. For instance, Y121F change alone is able to confer resistance to voriconazole in *A. fumigatus* [57]. Molecular modeling experiments revealed that Y121 is part of a molecular pocket involved in the initial docking of the incoming triazole molecule prior to binding to the active site [58]. Thus, any significant changes in the docking site would have serious implications in the binding of the drug to the target, thus affecting its bioactivity. A comparison of the *cyp*51A promoter regions carrying TR34 and TR46 revealed that the latter is a derivative of TR34 and the two promoters differed by the 12 nucleotide sequence GAAAGTTGTCTA missing from EU626235. If the missing sequence is inserted at the junction of TR34 repeat together with the adjacent flanking sequences, it would generate a perfect 46 bp repeat producing TR46

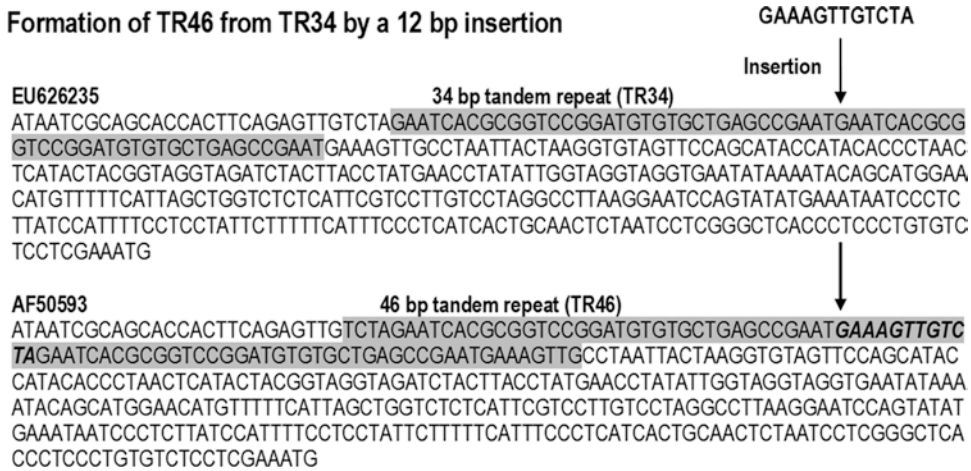

Fig. 67.6 Schematic illustration of the possible formation TR46 from TR34 or vice versa. The TR34/TR46 sequences are highlighted in *gray*. The suspected 12 nucleotide insertion sequence (GAAAGTTGTCTA) is shown in *bold italics*. EU626235 is the GenBank accession number of *cyp*51A gene sequence carrying TR34. AF50593 is an *A. fumigatus* clinical isolate harboring *cyp*51A gene carrying TR46

(Fig. 67.6). Conversely, a deletion of the 12 nucleotide stretch from TR46 would give rise to TR34. Which one of these two possibilities occurred first in nature is unclear.

The TR34/L98H- and TR46/Y121H/T289A-dependent mechanisms of azole resistance have been reported in many regions of Europe and Asia but not in North America. Mutational alteration of critical amino acid residues involved directly or indirectly in the binding of the drug to the target together with alteration of the noncoding regulatory sequences that has the potential to regulate the synthesis of the drug target 14α-sterol demethylase is a powerful mechanism for conferring high-level drug resistance. It is intriguing that the TR46/Y121F/T289A changes on the *cyp*51A gene confer resistance to voriconazole (MIC > 16 μg/mL), yet the organism remains relatively susceptible to itraconazole (MIC 2 μg/mL) and posaconazole (MIC 0.5 μg/mL).

Epidemiological studies have shown that the TR34/L98H and TR46/Y121H/T289A mechanisms of resistance initially emerged in environmental aspergillus isolates probably due to a widespread use of azole-related demethylase inhibitors (DMIs) as pesticides for crop protection in agriculture [59, 60]. The fact that these isolates are widespread and show cross-resistance to currently used azoles jeopardizes their efficacy as antifungal drugs for the treatment of invasive aspergillosis. In the future, patients who demonstrate clinical failure to voriconazole will have to be investigated for the presence of voriconazole resistance in their post-therapy isolates.

Although the efflux-mediated drug resistance is well documented in pathogenic yeasts [61–66], such mechanism of drug resistance in pathogenic filamentous fungi, including *Aspergillus* species, is not well investigated. In *A. fumigatus*, itraconazole is able to induce the expression of an ABC transporter gene called *atr*F, but the role of this gene conferring resistance in clinical isolates to itraconazole is not established. Multiple drug resistance (MDR) membrane proteins called *afu*MDR1 and *afu*MDR2 were previously identified and characterized from *A. fumigatus* [67]. But their actual function or contribution to antifungal drug resistance was not investigated. Nascimento et al. [33] have showed that *Afu*MDR1 and *Afu*MDR2 may not be involved in efflux-mediated triazole resistance in this organism. On the other hand, *Afu*MDR3 and *Afu*MDR4 were overexpressed in *A. fumigatus* resistant to itraconazole, but not *Afu*MDR1 and *Afu*MDR2 suggesting that *Afu*MDR3 and *Afu*MDR4 may play a role in efflux-mediated triazole resistance in *A. fumigatus*. However, these researchers were unable to document the accumulation of itraconazole in the resistant and susceptible isolates of *A. fumigatus*. By itraconazole uptake study in mycelia, Manavathu et al. [68] have previously demonstrated that the intracellular accumulation of radioactive itraconazole was significantly lower in laboratory-selected *A. fumigatus* isolates showing reduced in vitro susceptibility to itraconazole compared to that in the susceptible parent. The efflux of drug in combination with drug target modification has made laboratory-selected *A. fumigatus* isolates highly resistant (MIC ≥ 100 μg/mL) to itraconazole suggesting that multiple mechanisms of drug resistance may coexist in the same cells to make them highly resistant to drug [33]. Through expression of *cyp*51A in an autonomously replicating multicopy plasmid, Osherov et al. [29] transformed an itraconazole-susceptible *A. fumigatus* to a drug-resistant strain.

2.3.1 HapE-Mediated Azole Resistance

Recently, Camps et al. [69] have described a novel mechanism for itraconazole resistance in *A. fumigatus* mediated by the transcription factor HapE by comparative genome analyses of drug-resistant and drug-susceptible *A. fumigatus* serial isolates obtained from a patient suffering from chronic granulomatous disease (CGD). These investigators analyzed the genomes of two drug-susceptible and two drug-resistant isogenic isolates collected serially from the CGD patient in a relatively short period of time (17 weeks apart) by whole genome analysis. By whole genome analysis coupled with sexual crossing and RT-PCR analysis, they identified P88L mutation in the transcription factor HapE subunit. HapE is nucleotide-binding protein which binds to CCAAT sequence

and modulates the promoter activity of a specific gene. Although the exact mechanism by which HapE mutation brings about itraconazole resistance in *A. fumigatus* is unclear at present, two distinct possibilities exit. One, HapE could be a transcription enhancer and by binding to the CCAAT region upregulate *cyp*51A. The increased synthesis of Cyp51A will result in the need of an increased amount of the drug to inhibit the enzyme and sterol synthesis. Two, alternatively, binding of the mutant HapE (or lack of binding) will result in the downregulation of *cyp*51A resulting in the synthesis of less enzyme. Less Cyp51A results in slow rate of sterol synthesis and poor growth. Since most antibiotics are optimally effective against actively growing cells, low growth rate will result in poor killing by the drug, and the organism shows resistance/tolerance to the drug. However, additional investigation is required to pinpoint the exact mechanism of HapE-mediated azole resistance in *A. fumigatus*.

2.3.2 Transcriptional Regulator atrR-Mediated Azole Resistance

Hagiwara et al. [70] have recently identified a new mechanism of azole resistance in *A. fumigatus* which these investigators initially identified and characterized in *Aspergillus oryzae*. This new mechanism of resistance is dependent on the expression level of a crucial transcriptional regulator called *atrR* in aspergillus. *atr*R regulates the level of expression of multiple genes, including *cyp*51A, *cdr*B1, and those genes responsible for *A. fumigatus* to grow under hypoxic conditions. When *atr*R is expressed at normal or elevated level, the expression of azole target gene *cyp*51A and the multidrug efflux pump *cdr*B1 is upregulated producing increased amounts of Cyp51A and CdrB1 proteins. These increases result in elevated MICs for miconazole, itraconazole, and ketoconazole [70], but not for unrelated antifungal drugs such as micafungin and amphotericin B. The reverse situation is also true. In the absence of *atr*R expression, the organism becomes more susceptible to azole antifungal drugs. However, these investigators in their initial investigation did not use newer generation of azole such as voriconazole and posaconazole. So cross-resistance to this newer generation of azoles in the presence of elevated level of *atr*R is not known. In addition, *atr*R regulates the levels of expression of a cluster of genes that enable *A. fumigatus* to grow under hypoxic condition (1 % O_2 level). In contrast, deletion of *atr*R gene results in the loss of hypoxic growth characteristics.

2.4 Resistance to Echinocandins

The echinocandins such as caspofungin, micafungin, and anidulafungin are semisynthetic cyclic lipohexapeptide antifungal drugs designed to render specific interaction with fungal cells with a minimum level of toxicity to host cells at therapeutic doses. The molecular target of echinocandins is believed to be 1,3-β-D-glucan synthase (GS; E. C. 2.4.1.34; UDP glucose: 1,3-β-D-glucan 3-β-D-glucosyltransferase), a multimeric membrane-bound enzyme that catalyzes the synthesis of $\beta(1 \rightarrow 3)$ glucan, even though there is no direct molecular evidence to support this view [71]. However, it is safe to say that these compounds inhibit cell wall synthesis in a wide variety of fungi, and cell wall synthesis is the target of the echinocandin compounds. What distinguishes the members of the echinocandin family of antifungal drugs from the polyenes and the azoles is their specificity against fungi with relatively little mechanism-based toxicity against the host.

Recently, a pair of reports of echinocandin resistance in aspergillus has been published. Gardiner et al. [72] have isolated two classes of *A. fumigatus* mutants in the laboratory showing reduced susceptibility to caspofungin. Site-directed mutation of the target gene coding for glucan synthase Fks1p, including the catalytic subunit, produced mutants showing low-level in vitro resistance (≈16-fold increase of MIC) to caspofungin. Subsequent characterization of one such mutant showed S678P alteration of Fks1p [73].

These investigators also isolated a number of spontaneous mutants of *A. fumigatus* in the laboratory showing a biphasic susceptibility pattern. At low concentrations of the drug (<0.5 μg/mL), these isolates were highly susceptible to the growth inhibitory effect of caspofungin. However, at drug concentrations >0.5 μg/mL but <16 μg/mL, these spontaneous mutant isolates showed near normal growth pattern, whereas at drug concentrations >16 μg/mL, they showed partial susceptibility to growth inhibition. No target gene mutation or upregulation of Fks1p expression was noted in these isolates. These authors speculate that the biphasic pattern of susceptibility to caspofungin is caused by a novel mechanism of echinocandin resistance in *A. fumigatus* perhaps due to the remodeling of cell wall components [72]. In addition to the reports of the acquired resistance to caspofungin in *A. fumigatus* laboratory isolates, Balajee et al. [21] have shown that *A. lentulus* is intrinsically resistant to caspofungin.

2.5 Resistance to Allylamines

Terbinafine (Novartis Pharmaceuticals) is an allylamine antifungal drug that possesses excellent in vitro activity against *Aspergillus* species, including *A. fumigatus*. The MICs of this compound against *Aspergillus* species are in the submicrogram range, usually two- to fourfold lower than that of amphotericin B. Preliminary experiments indicate that terbinafine is a fungicidal agent against *Aspergillus* species [74–78]. Only limited amount of in vivo data (animal models and case reports) is available at present, and the indication is that it is less impres-

sive in vivo than it is in vitro, perhaps because of poor availability of the drug due to the excessive protein binding.

The molecular target of terbinafine is squalene epoxidase (also known as squalene monooxygenase), an enzyme involved in the oxidation of squalene to 2,3-oxidosqualene (also called squalene 2,3-epoxide). The squalene epoxidase, in the presence of NADPH and oxygen, catalyzes the addition of an oxygen atom from molecular oxygen to the end of the squalene chain, forming an epoxide. The cofactor NADPH reduces the other oxygen atom to molecular oxygen and water. The inhibition of 2,3-oxidosqualene synthesis leads to the inhibition of ergosterol synthesis that eventually results in plasma membrane malfunction and fungal cell death.

The investigation of the effect of terbinafine on *Aspergillus* species is at its infancy, and an understanding of the spectrum of terbinafine resistance in *Aspergillus* species will be few years away. To date, there are only three reports of terbinafine resistance in *Aspergillus* species. In all three cases the resistant isolates were either genetically engineered or induced by UV irradiation followed by selection in the presence of terbinafine. Liu et al. [78] have expressed multiple copies of the gene coding for squalene epoxidase in *A. fumigatus* using a multicopy plasmid. Transformants harboring multiple copies of squalene epoxidase gene showed decreased in vitro susceptibility to terbinafine.

Graminha et al. [79] have investigated terbinafine resistance in a laboratory isolate of *A. nidulans*. These investigators generated a number of terbinafine-resistant mutant isolates of *A. nidulans* by UV irradiation followed by selection in the presence of the drug. One such terbinafine-resistant isolate was characterized by molecular genetic techniques. The resistant isolate had multiple copies of *salA*, a gene coding for salicylate 1-monooxygenase, an enzyme known to be responsible for the degradation of naphthalene ring structures in other microorganisms. So it is quite possible that the expression of multiple copies of *salA* may be responsible for the reduced susceptibility of *A. nidulans* to terbinafine.

In contrast to the gene dosage-dependent terbinafine resistance in *A. nidulans* and *A. fumigatus*, Rocha et al. [80] have recently reported terbinafine resistance in a genetically engineered laboratory isolate of *A. fumigatus* harboring an altered squalene epoxidase gene. These investigators genetically engineered replacement of phenylalanine 389 of squalene epoxidase with leucine (F389L). This single amino acid change was sufficient to confer resistance to terbinafine in an isolate carrying the mutant enzyme. Since the terbinafine target is squalene epoxidase, an enzyme involved in the initial stage of ergosterol synthesis, spontaneous mutants resistant to terbinafine will ultimately emerge in nature with the increased use of this drug against aspergillus infection.

3 Stress Response and Antimicrobial Drug Resistance

Aspergillus species are ubiquitous, and as such they are the most widely distributed filamentous fungi pathogenic to man. They are commonly found in the environment and constantly exposed to a wide variety of environmental stress factors. As a group, members of the genus *Aspergillus* successfully adapt to environmental changes such as temperature variations, pH changes, change in osmolarity in the ecological niche, exposure to toxic pollutants, xenobiotics, and antimicrobial drugs. Exposure of aspergillus cells to antimicrobial drugs or other types of xenobiotics induces a tremendous amount of physiological stress, and these organisms are equipped with the necessary tools to successfully cope with such environmental stressors, including exposure to antimicrobial drugs. To effectively prevent from the inhibitory effect(s) of the antibiotics, the organism must develop drug resistance/tolerance. The exposure of an organism to such environmental stressors is often sensed by membrane receptors, and the information is relayed to the intracellular environmental stress response pathway to take appropriate corrective action against the threat. To cope with the life-threatening exposure to antimicrobial drug(s), the organism either develops resistance/tolerance to the antifungal drug utilizing the stress response pathway or adopts other means to nullify the inhibitory effect of the drug [81–89].

The role of stress response pathway on the development of antimicrobial drug resistance has been studied extensively in several saprophytic [90–97] and pathogenic fungi [98–102]. Central to the stress response pathway is a series of mitogen-activated protein kinase cascades commonly known as the MAP kinase (MAPK) pathway. The MAPK cascade is a three-kinase module which receives (sense), transmits (transduces), and regulates the cellular developmental or physiological processes in response to the external signal to counter or nullify the adverse (often deleterious) effect(s) of the external stress [103]. The classical MAPK pathway contains a highly conserved three-tiered module consisting of a MAP kinase kinase kinase (MAPKKK), a MAP kinase kinase (MAPKK), and the final MAP kinase (MAPK). In their inactive form the MAPKs are non-phosphorylated. When sensing extracellular stress signals, the MAPK cascades are activated by sequential dual phosphorylation of highly conserved threonine and tyrosine residues [104]. It is the MAPKKK that usually sense the extracellular stress signal at cell surface level (either cell wall or cell membrane), and signal is relayed (transduced) intracellularly by MAPKK to the nucleus, and activation of MAPK results in activation of transcription factors that regulate synthesis of cellular molecules required to correct or negate the harmful (deleterious) effect of the external stress.

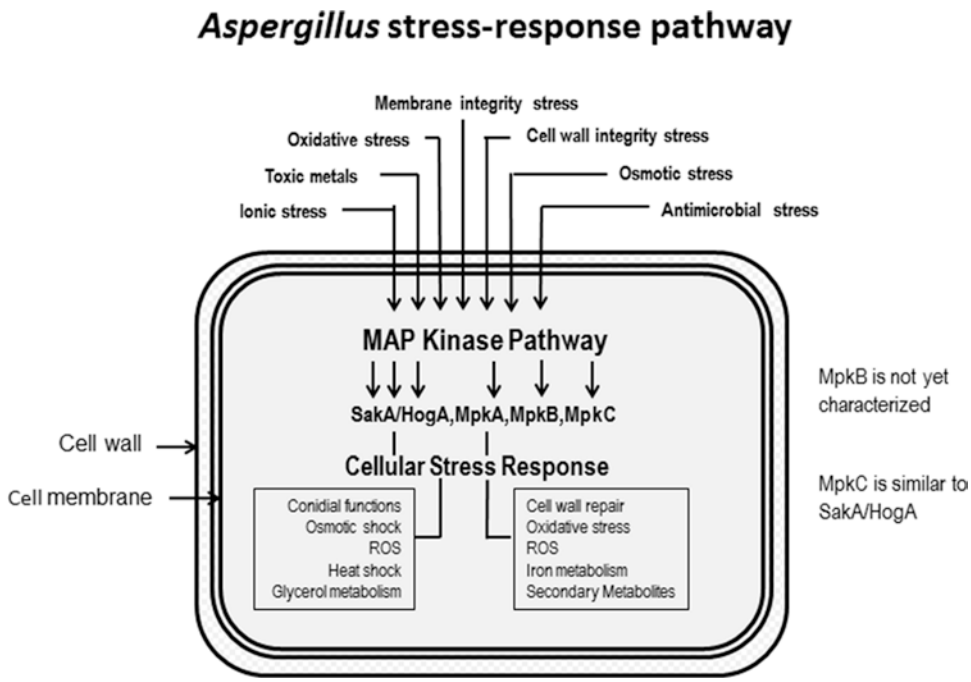

Fig. 67.7 Diagrammatic illustration of the stress response pathway in *Aspergillus fumigatus*. See text for details

The genome of *A. fumigatus* encodes four MAP kinase genes, namely, *sak*A/*hog*A, *mpk*A, *mpk*B, and *mpk*C [105], and their corresponding gene products are designated SakA/HogA, MpkA, MpkB, and MpkC. Of the four MAPKs in *A. fumigatus*, only SakA/HogA and MpkA have been investigated in detail so far. MpkC appears to be very similar to SakA/HogA module, and MpkB has not been characterized yet. A simplified diagrammatic illustration of common external stressors and the known components of the MAPK cascade that respond to stress signals are shown in Fig. 67.7. At times more than one MAPK module is activated in response to the same extracellular stress signal, and this redundancy is to secure added protection to the cell from deleterious stress factors. For example, both the SakA/HogA and MpkA modules in *A. fumigatus* appear to respond when the cell experiences deleterious oxidative stress such as ROS.

SakA/Hog (high-osmolarity glycerol) A module is one of the best characterized well-studied MAPK cascades in fungi, including *A. fumigatus*. It is the primary module of the MAPK pathway that controls transcription, translation, transport, and cell cycle adaptations in response to extracellular stress. Once the osmotic stress signal is received, HogA is activated (phosphorylated) and elicits specific responses for glycerol synthesis and cell cycle arrest [106–109]. In addition to responding to osmotic stress, in *S. cerevisiae* HogA has a broad range of involvement in the responses to UV, heavy metals, heat, citric acid, hypoxia, and oxidative stresses as well as in the response to cell wall-interfering agents. Gene characterization reveals that *A. fumigatus* *sak*A/*hog*A codes for a 366-amino acid protein with a molecular mass of 42 kDa showing high similarity to Hog1p of *S. cerevisiae* (82 % identity), SakA of *A. nidulans* (84 % identity), and Hog1p of *C. albicans* (79 % identity).

A. fumigatus *sak*A/*hog*A regulates the transcription of DprA and DprB involved in eliciting response to osmotic and pH stresses. The response to oxidative stress is a major function of the HOG pathway and is considered playing a key role in resistance to phagocytic killing [110]. Interestingly, amphotericin B and itraconazole are considered to be oxidative stress drugs because of their modes of action mediated by the involvement of the cellular oxidative stress response. The *sak*A/*hog*A deletion mutant of *A. fumigatus* is significantly more sensitive to the cytotoxic effect of these antifungal drugs indicating that it plays a role in antifungal tolerance [111].

The role of MpkA MAPK module in stress response pathway of *A. fumigatus* has been studied by a number of investigators [112–115]. Their results show that MpkA plays a critical role in maintaining the integrity of the cell wall, oxidative stress response, pigment formation by tyrosine degradation pathway, secondary metabolite synthesis (e.g., gliotoxin), iron metabolism by regulating the synthesis of iron-carrying molecule such as siderophore, oxidative stress response (ROS), conidial germination and growth under nutrient deficient/starvation conditions, osmotic shock (hypertonic or hypotonic conditions) response, and in response to temperature variations (heat shock). Preliminary studies have shown that MpkC is able to sense alternate carbon source(s) when the primary carbon source is limited or depleted [116].

The MAPK pathway-mediated antimicrobial drug resistance in *A. fumigatus* appears to be multifactorial and not dependent on any specific resistance mechanism(s) [83, 85,

86, 117–124]. Majority of the reported cases of MAPK-dependent drug resistance in *A. fumigatus* is associated with the cell wall integrity and repair pathway. When the integrity of the cell wall is breached by chemical or mechanical insults, the MpkA module will be activated and repair the damaged cell wall by a rebuilding and restructuring process. The chemical composition and the architecture of the rebuilt wall could be different enough that the cell wall-acting antimicrobial drugs will be rather ineffective.

The cell wall integrity restoration pathway-dependent antimicrobial drug resistance in *A. fumigatus* is often mediated by the molecular chaperone heat shock protein 90 (HSP90). Repression of HSP90 synthesis in *A. fumigatus* not only affects critical cellular process such as conidia formation and cell wall integrity but also potentiates the effects of azoles and cell wall inhibitors such as the echinocandins and Congo red [83, 85, 117, 118]. Similarly, when HSP90 was inhibited chemically, similar results were obtained. Also, HSP90 inhibition either genetically or by pharmacological interaction markedly reduced the high-level resistance of *A. fumigatus* biofilm to azoles and echinocandins [125]. Blum et al. [81, 86, 126, 127] have recently studied the role of HSP90 on *Aspergillus terreus* resistance to amphotericin B (AMB). When HSP90 function was inhibited, both *A. terreus* and *A. fumigatus* became more susceptible to AMB, and the MIC of AMB for *A. terreus* was reduced by 100-fold (32–0.38 μg/mL). Recently, Dirr et al. [128] studied the effect of voriconazole and posaconazole on an *A. fumigatus* mutant lacking *mkk2* (MAPKK) of the cell wall integrity pathway. The mutant strain was significantly more susceptible to voriconazole and posaconazole.

Although research on MAPK pathway-mediated antimicrobial drug resistance in *A. fumigatus* is in its early stages, these results clearly show that MAPK pathway plays a key role in drug resistance/tolerance in fungi, including *A. fumigatus*. Perhaps, this will give an opportunity to explain at least in part the clinical failure of antifungal therapy in the absence of any known mechanism-based resistance to the drug in question in the infecting clinical strain.

4 Animal Models

Animal models have been used extensively to study pathogenesis, host responses, disease transmission, and therapy of aspergillus infection [129]. Animal (mouse, rat, guinea pig, and rabbit) models have been used to evaluate the in vivo efficacy of antimycotic drugs against pulmonary and disseminated aspergillosis caused by drug-susceptible and drug-resistant *Aspergillus* species [130–133]. The selection of a particular animal model suitable for drug therapy study is dependent on the pharmacodynamics of the drug, ideally one that mimics the parameters in human. Most data are from rodent, particularly mouse models of aspergillosis. These models have been critical to the advancement of therapy. Using one or more of these animal models, several investigators examined the efficacy of polyenes, triazoles, echinocandins, and allylamines against aspergillus isolates showing elevated MICs of the drug in vitro.

Using transiently immunocompromised murine [15, 16, 19] and guinea pig [16] models for disseminated [15, 16] and pulmonary [19] aspergillosis, the in vivo efficacy of amphotericin B against *Aspergillus fumigatus* isolates with either elevated amphotericin B MIC or isolate obtained from a patient who failed amphotericin B therapy was examined. No consensus for the correlation of in vitro resistance to in vivo failure was obtained in these studies. For instance, Odds et al. [16] obtained no interpretable relationship either in mouse or guinea pig model when the MIC of amphotericin B was ≥2 μg/mL. In other words, no correlation of in vitro resistance to in vivo resistance was found. On the other hand, Verweij et al. [15] have investigated the efficacy of amphotericin B and caspofungin against two *A. fumigatus* clinical isolates (AF210 and AF65) with more or less similar amphotericin B MICs, although AF65 was obtained from a patient failing amphotericin B therapy. Amphotericin B treatment at doses 0.5, 2, and 5 mg/kg/day failed to improve the survival and reduction of fungal burden in the animals infected with *A. fumigatus* AF65, but not with AF210. On the other hand, anidulafungin (LY303366) treatment at doses of 10 and 25 mg/kg/day was highly effective against AF210 and AF65 infections. These data suggest that even in the absence of elevated MIC, drug failure in the clinical situation is correlated with reduced therapeutic efficacy in the animal model. In contrast, Manavathu et al. [19] have investigated the in vivo efficacy of amphotericin B against a laboratory-selected *A. fumigatus* isolates with elevated amphotericin B MICs in a pulmonary aspergillosis model. Animals infected with the mutant isolate showing in vitro resistance also showed poor survival and increased fungal burden compared to those infected with the drug-susceptible parent. These conflicting limited data suggest the need for additional experiments to establish in vitro-in vivo correlation for amphotericin B resistance in *A. fumigatus* using animal models.

Walsh et al. [18] have examined the effect of conventional and liposomal amphotericin B on *Aspergillus terreus* infection utilizing an experimental invasive pulmonary aspergillosis model in transiently neutropenic rabbit. As mentioned previously, greater than 90 % of the *A. terreus* isolates show high-level in vitro resistance to amphotericin B [134]. Treatment of rabbits infected with *A. terreus* with conventional and liposomal amphotericin B failed to improve survival and reduce fungal burden compared to those obtained for control untreated animals, whereas treatment with posaconazole and itraconazole improved survival with significant reduction of fungal

burden. Thus, for *A. terreus* isolates, their innate in vitro resistance to amphotericin B is well correlated with lack of amphotericin B treatment efficacy in the rabbit model.

Among various triazoles that are effective against *Aspergillus* species, itraconazole was examined to assess the correlation of either in vitro or clinical resistance by an animal model. Denning et al. [30] investigated the susceptibility of a clinical isolate of *A. fumigatus* obtained from an immunocompromised patient with IA who failed itraconazole therapy. The clinical failure of this isolate was associated with elevated MIC for itraconazole with modest rise of MICs for other triazoles. Itraconazole treatment of neutropenic mice infected with this isolate failed to improve survival and reduce fungal burden, whereas the echinocandin anidulafungin was highly effective in prolonging the survival of the animal and significantly decreased the fungal burden. Likewise, micafungin was effective in neutropenic mice infected with an itraconazole-resistant strain of *A. fumigatus* and a strain of *A. terreus* demonstrating in vivo resistance to amphotericin B [135]. In contrast, Odds et al. [16] have obtained no clearly interpretable results showing a correlation between in vitro resistance and failure of drug treatment when the itraconazole MIC of the isolate was greater than 1 μg/mL. Once again, the paucity of sufficient data makes it difficult to draw any conclusion regarding the in vitro-in vivo correlation of triazole resistance in the animal model. In a non-neutropenic murine model of IA using voriconazole-susceptible and voriconazole-resistant *A. fumigatus*, the investigators found the combination of voriconazole and anidulafungin to be synergistic in voriconazole-susceptible IA, but only additive in voriconazole-resistant IA. Survival of 100 % was observed only in groups receiving the highest doses of both drugs [136]. This study suggests the possible utility of combination therapy in azole-resistant IA.

5 Clinical Data: Resistance

A. fumigatus is by far the most common *Aspergillus* species causing human infection. Little is known about the true prevalence of resistant aspergillus infections because there are no national surveillance programs, and most laboratories do not perform susceptibility testing. Primary resistance to antifungal drugs among the isolates of *A. fumigatus*, *A. flavus*, and *A. niger* is infrequent. Among the uncommon species, *A. ustus* is poorly susceptible to all antifungals, and there are case reports of *A. ustus* causing invasive aspergillosis with poor outcome, mostly in allogeneic stem cell recipients [137]. *A. ustus* infection and zygomycosis have emerged as breakthrough infections in stem cell recipients receiving voriconazole and caspofungin [137–139]. *A. ustus* isolates were found resistant to amphotericin B, triazoles, and echinocandins.

5.1 Resistance to Polyenes

A. terreus appears innately resistant to amphotericin B, both in vitro and in animal models [18, 134]. Available clinical data support such observations; in a 12-year retrospective analysis of IA caused by *A. terreus*, infection progressed rapidly resulting in a 91 % mortality despite amphotericin B therapy [140]. Steinbach and colleagues reported a mortality rate of 73 % in patients with *A. terreus* infection and treated mostly with a polyene (amphotericin B or amphotericin B lipid formulation) [141]. The same investigators reported a significantly better survival (56 %) in similar patients treated with voriconazole. Based on in vitro, animal, and limited clinical observations, it appears polyenes are best avoided and azoles are preferred agents in the therapy of *A. terreus* infection. Extremely limited clinical data exist for polyene resistance in non-Aspergillus terreus species. In a retrospective study of 29 immunocompromised patients with IA and treated with amphotericin B, in vitro susceptibility to the drug predicted clinical outcome [142]. Remarkably, 22 of 23 patients infected with aspergillus resistant to amphotericin B (MIC > 2 μg/mL) (both *A. terreus* and non-terreus aspergillus) died, while none of the remaining six infected with susceptible aspergillus died. This study however used "older," nonstandardized methods of susceptibility testing; furthermore, no details of clinical features were provided. Clinical failure with liposomal amphotericin B was noted during the treatment of severe cutaneous aspergillosis in two premature infants with extremely low birth weight; both infants were successfully treated with voriconazole [143].

Verweij et al. [15] described the recovery of amphotericin B-resistant *A. fumigatus* isolates from the lung of a patient with refractory infection treated with the same drug. Introducing the resistant isolate in the animal model, the investigators observed similar poor outcomes in those treated with amphotericin B and untreated controls. Also, a higher inoculum was required to produce disease in the animal model. Of interest, Lionakis et al. [144] found that preexposure of cancer patients to amphotericin B or triazoles was associated with increased frequency of recovery of non-Aspergillus fumigatus species. Moreover, such postexposure isolates were amphotericin B-resistant but not azole-resistant. Since clinical failures are common, emergence of aspergillus resistance to polyenes during therapy of invasive aspergillosis is of interest. Whether resistance to amphotericin B emerges is not clear since most clinical failures have been attributed to poor host factors and perhaps infarcted tissue with poor drug penetration. Unlike with bacterial infections, difficulty in obtaining sequential isolates of the fungus during an episode of infection makes it hard to evaluate emergence of resistance. Available limited data suggest that the emergence of resistance to polyenes during therapy is uncommon [144–146].

5.2 Resistance to Azoles

Azole resistance in aspergillus is increasingly reported and may emerge as a significant problem in the management of aspergillosis. Resistance may be acquired during azole therapy or through environmental exposure to fungicide-exposed strains. Prospective evaluations in several countries suggest prevalence of azole resistance, particularly in *A. fumigatus*, to be around 1–2 % [53, 147–149]. More recent international surveillance data suggest 3–8 % azole resistance among aspergillus isolates [150, 151]. Centers in the UK and the Netherlands have described particularly high frequencies of azole resistance (15 % and 10 %, respectively). Attributable reasons include long-term azole therapy in patients with chronic aspergillosis in Manchester (UK) and high use of azoles in the agrochemical industry in the Netherlands.

Routine susceptibility testing of aspergillus isolates is to be strongly considered in patients with relapsed infection on long-term or subtherapeutic triazole therapy and in other relevant cases. In a recent epidemiological study in lung transplant recipients on long-term azole prophylaxis, Mayo Clinic investigators identified 16.5 % patients with invasive

Table 67.2 Azole resistance in *Aspergillus*—human data

Reference/first author	Clinical data	Comments
154/Chryssanthou	Three of 80 patients: initial ITZ-susceptible, then ITZ-resistant *A. fumigatus* [ITZ use: 5 months–3 years]	No genotyping done (possibly different strains)
30/Denning 155/Oakley	*Patient 1*: Hodgkin's disease—ITZ-susceptible *A. fumigatus* pleuropericarditis. Oral ITZ × 9 months, then sputum: *A. fumigatus* (ITZ MIC > 16 μg/mL)	*A. fumigatus* strains with in vitro ITZ—resistance: good correlation in animal model Mechanism of resistance: primary or secondary
	Patient 2: AIDS—invasive aspergillosis due to *A. fumigatus*; AmB for 3 months; relapsed infection (*A. fumigatus*[1]—recovered from sputum); improved with ITZ. Sputum culture—*A. fumigatus*.[2] Both *A. fumigatus*[1] and *A. fumigatus*[2] had ITZ MIC > 16 μg/mL	
	Animal model: no decreased mortality in animals receiving ITZ for infection with ITZ-resistant aspergillus	
156/Dannaoui	*Patient*: bronchiectasis; sputum, ITZ-susceptible *A. fumigatus*	Pre- and post-therapy Isolates had similar RAPD
	Rx: ITZ × 5 months	Patterns (i.e., same strain)
	Relapse of infection; subsequent *A. fumigatus* ITZ MIC > 16 μg/mL	
	Animal model: poor efficacy of ITZ in animals infected with ITZ-resistant aspergillus	
157/Verweij	1945–1998: collection of clinical isolates of aspergillus in the Netherlands from 114 patients (170 isolates)	Three ITZ-resistant *A. fumigatus* isolates recovered from a lung transplant recipient receiving ITZ
158/Balajee	1991–2000 (Seattle, USA)	Ten patients with ITZ-resistant *A. fumigatus* (no previous exposure to ITZ)
	10 of 128 *A. fumigatus* isolates: ITZ-resistant (MIC ≥ 1 μg/mL)	
	Also, cross resistant with VCZ/caspofungin/amphotericin B	Exact mechanisms of cross-resistance unknown
159/Warris	*Patient*: chronic granulomatous disease	*A. fumigatus* resistant to ITZ/RCZ and reduced susceptibility to VCZ/PCZ
	A. nidulans infection → successful therapy with VCZ; maintenance (6 years) on ITZ; subsequent aspergillosis with *A. fumigatus* (ITZ-resistant)	
	Successful therapy with high-dose VCZ	
37/Howard	*Patient*: sarcoidosis with chronic cavitary aspergilloma (*A. fumigatus*); therapy with ITZ, then VCZ; some response to IV caspofungin	*A. fumigatus* resistant to ITZ/VCZ/PCZ and RCZ Mutation (G138C) in the target gene (CYP51A) encoding 14α-sterol demethylase
38/Dannaoui	*Patient*: sarcoidosis complicated by aspergilloma; ITZ for 3 years; recovery of ITZ-resistant *A. fumigatus*, treated with VCZ (MIC 1 μg/mL) and obtained good response	Mutation (M220L) in CYP51A plus increased expression of multidrug transporters
160/Verweij	Nine patients (13 isolates): four with primary IA and five with breakthrough IA (prior therapy with ITZ or VCZ); two died	Mutation (L98H) in CYP51A with a tandem repeat in the same promoter region. (No clonal spread)
	A. fumigatus resistant to ITZ/VCZ/PCZ/RCZ	
161/van Leer-Buter	*Patient*: oropharyngeal carcinoma with pulmonary cavities	Autopsy: *A. fumigatus* and *A. niger*
	Bronchoalveolar lavage: *A. fumigatus* and *A. niger*. Therapy with VCZ for about 10 days	*A. fumigatus*: azole-susceptible and azole-resistant (L98H in CYP51A and a tandem repeat in the promoter region) phenotypes

VCZ voriconazole, *ITZ* itraconazole, *PCZ* posaconazole, *RCZ* ravuconazole, *AmB* amphotericin B, *MIC* minimum inhibitory concentration

fungal infection. *A fumigatus* was the most common species; of interest, azole resistance was uncommon in these breakthrough cases [152]. Itraconazole, the first triazole effective against aspergillus, became available for clinical use in the mid-1990s. Data on resistance to itraconazole in the clinical context are limited, as shown in Table 67.2 [30, 37, 38, 153–160]. In a nationwide survey of 21 Dutch hospitals, no patients with multiple triazole-resistant *A. fumigatus* were found (0 of 114 patients) during 1945–1998 as compared with 10 of 81 patients with such isolates since 2002 ($P < .001$). Noteworthy is a case report—a patient with chronic granulomatous disease, who, while receiving long-term prophylaxis with itraconazole, developed itraconazole-resistant invasive aspergillosis and required high-dose voriconazole for successful outcome [158]. The *A. fumigatus* isolate had reduced susceptibility to other azoles (voriconazole and posaconazole) as well. High-level panazole-resistant *A. fumigatus* was recovered from four patients with chronic lung disease, one of them developing progressive resistance following long-term azole therapy and switching between antifungal azoles. The phenotypes were not associated with a specific CYP51A gene mutation [161]. Overall, azole-resistant aspergillosis is likely to become a significant clinical issue. No management guidelines exist to guide clinicians encountering or suspecting azole-resistant aspergillosis.

In theory, "clinical resistance" may be anticipated during therapy with a polyene following exposure to azole, because the azole may have depleted the common target (i.e., ergosterol). No clinical study, however, has implicated prior azole exposure (as prophylaxis or therapy) as a cause for subsequent failure with polyene therapy, but such patients may need close observation. This situation may occur with increasing frequency with the standard use of voriconazole as primary therapy of or prophylaxis against aspergillosis. Voriconazole has been used with satisfactory results (~50 % response) as salvage therapy in most patients initially treated with amphotericin B [162].

Given the suboptimal response with single drug use for invasive aspergillosis, particularly in profoundly compromised hosts (e.g., with persistent neutropenia), the strategy of drug combinations is increasingly employed. From previous in vitro observations, clinicians have been concerned about antagonism with the use of drug combinations, leading to clinical failure. However, data from in vitro studies and animal models suggest no antagonistic interactions when azoles are combined with polyenes or echinocandins [163–166]. Experimental and retrospective data suggest synergistic efficacy with combination of azole (voriconazole) plus caspofungin [167, 168]. A prospective clinical study of combination antifungal therapy of voriconazole and anidulafungin for invasive aspergillosis concluded that, in the subgroup of patients with probable aspergillosis (diagnosed by suggestive radiography plus galactomannan positivity), higher survival rate was noted. However, superiority of the combination over monotherapy was not conclusively demonstrated [169]. Azole resistance was not addressed in this paper.

5.3 Resistance to Echinocandins

No clinical data on aspergillus resistance to echinocandins are reported. Susceptibility testing is not routinely performed, and the methods for testing are not standardized. Clinical breakthrough cases have been reported, and resistance has been confirmed in vivo [170]. In high-risk patients treated with caspofungin, 13 cases of breakthrough aspergillosis were noted in a retrospective study. Rate of breakthrough aspergillosis was estimated to be 4.2 % in onco-hematology patients [171]. Emergence of resistance is to be anticipated due to the lack of cytocidal activity of echinocandins against aspergillus and the potential for point mutation resulting in altered glucan synthase. With the increased use of echinocandins for prophylaxis, empiric or definitive therapy, resistance to these drugs in aspergillus isolates needs to be closely monitored.

6 Conclusion

Unlike the situation with candida, data on drug resistance in aspergillus are slow to accumulate. Recent standardization of susceptibility of testing for filamentous fungi has made it possible to study the phenomenon of resistance. Of the four drug classes, aspergillus resistance in azoles is most commonly described; resistance to polyene class has remained remarkably low. Mechanisms of azole resistance in aspergillus are better understood. The widespread nonclinical use of azoles in the agricultural industry appears to be a significant contributor to resistance among environmental isolates. With the increasing incidence of aspergillosis and the widespread use of orally administered anti-aspergillus azoles for prolonged periods in different settings (prophylaxis or therapy), particularly in compromised hosts or in those with a heavy burden of the organism, the emergence of drug resistance in aspergillus is likely to escalate.

Drug Resistance in Cryptococcosis

68

Kimberly E. Hanson, Jelena Catania,
Barbara D. Alexander, and John R. Perfect

1 Introduction

There are over 30 different *Cryptococcus* species (spp.), with *C. neoformans* and *C. gattii* being the two primary human pathogens responsible for the fungal disease, cryptococcosis. These encapsulated basidiomycetous yeasts have important differences in their geographic distribution, ecological niches, and predilection to cause life-threatening disease in immunocompromised as compared to seemingly immunocompetent hosts.

C. neoformans is found throughout the world and primarily causes infection in immunosuppressed patients. Its primary habitat is around pigeon roosts and in soil containing avian droppings. *C. neoformans* strains consist of two varieties and three serotypes that are based on capsular epitopes and five genotypes. Nearly all *C. neoformans* infections in patients with the *human immunodeficiency virus* (HIV) involve *C. neoformans* variety (var.) *grubii* (serotype A), except in Europe, where *Cryptococcus neoformans* var. *neoformans* (serotype D) and some A/D hybrid strains are responsible for clinical disease. *C. gattii* (serotypes B and C with four genotypes) is found in the soil around certain types of trees and has historically been linked to outbreaks in healthy hosts living in tropical and subtropical regions. More recently, *C. gattii* has emerged in temperate portions of the Pacific Northwest (USA and Vancouver, Canada) and has been linked to opportunistic infections in HIV–AIDS patients from southern California.

The two pathogenic cryptococcal species can further be subdivided into nine major molecular types: VNI to VNIV and VNB for *C. neoformans* and VGI to VGIV for *C. gattii*. There is evidence that the various molecular types may actually represent cryptic species, with important differences in virulence and antifungal susceptibility. VNI and VGI molecular types are widespread and cause the majority of disease attributed to *C. neoformans* and *C. gattii*, respectively. In contrast, VGIII, VGIV, and VNIV appear to be geographically restricted, with VGII strains responsible for the Pacific Northwest outbreak.

Cryptococcal infection typically begins after inhalation of the yeast or basidiospores into the lung, which may be followed by hematogenous spread to extrapulmonary tissue, and is usually considered to represent reactivation of a dormant infection [1]. Most patients present for medical attention with subacute signs and symptoms such as fever, headache, lethargy, and/or mental status changes. The five most common anatomic sites of cryptococcal involvement are the lungs, central nervous system (CNS), skin, prostate, and eye. In HIV-infected patients, the two species share similar clinical aspects, but disease manifestations may differ in patients without HIV. *C. neoformans* has a unique predilection for neural tissue and is an important cause of meningoencephalitis. Alternatively, some reports have suggested that *C. gattii* more frequently produces pulmonary infections, but may also involve the CNS [2]. In otherwise healthy hosts, intracranial *C. gattii* infection has a higher propensity to cause focal brain lesions on radiographs than *C. neoformans* and has been associated with a delayed response to therapy as well as more frequent requirements for neurosurgical intervention [3].

Despite serological evidence for widespread infection in select human populations, cryptococcosis is a relatively uncommon disease in individuals with a healthy immune system. Patients with T-cell deficiencies are at the highest risk of developing invasive cryptococcal infection, with a prevalence of up to 30 % in AIDS patients in sub-Saharan Africa. Life-threatening infections caused by this pathogen have been increasingly recognized worldwide, largely due to the AIDS epidemic and the expanded use of immunosuppressive drugs and chemotherapeutic agents. Progress in the

fields of organ transplantation and management strategies in hematology–oncology have led to an increased number of immunosuppressed survivors at risk for invasive fungal infections. Precise estimates of the incidence of cryptococcal disease are not available in the era of antiretroviral therapy (ART). The disease was thought to affect between 6 and 10 % of AIDS patients in the USA, Australia, and Western Europe prior to the advent of ART [4], but its frequency has decreased in the current clinical climate [4].

Cryptococcal disease in both HIV-positive and HIV-negative hosts continues to be associated with significant morbidity and mortality. Successful treatment has historically relied on the use of amphotericin B (AmB), flucytosine (5-FC), and fluconazole. To date, in vitro antifungal drug resistance to amphotericin B is uncommon, and there are geographical differences in rates of fluconazole resistance. Elevated fluconazole MICs have been reported in settings where prophylactic fluconazole use is routine and in cases of relapsed cryptococcal disease after initial fluconazole monotherapy. Despite the availability of antifungal agents with activity against *Cryptococcus* species in vitro and the use of ART to treat HIV, treatment failures continue to occur for a variety of reasons including direct antifungal drug resistance. Recent improvements in antifungal susceptibility testing have allowed for the identification of resistant strains in vitro. However, substantial discrepancies across different susceptibility test methods exist, and the correlation between in vitro drug activity and clinical outcome has not been fully elucidated. AIDS patients with cryptococcal meningitis who survive beyond initial induction therapy may require prolonged maintenance therapy to prevent disease relapse. Secondary prophylaxis or maintenance therapy in conjunction with the prolonged use of antifungal agents for the treatment or prevention of other fungal infections has generated concern that less susceptible cryptococcal strains may emerge.

The potentially devastating clinical ramifications of antifungal drug resistance have led to intensified efforts to better define the scope of the resistance problem. To this end, a significant amount of work has gone toward improving and standardizing systems capable of identifying fungal resistance when it occurs, delineating the molecular mechanisms responsible for the development of drug resistance, and designing new and improved strategies to treat patients with resistant cryptococcosis. The aim of this review is to summarize the current understanding of clinical resistance in *Cryptococcus neoformans* and to discuss future directions for the prevention and management of antifungal drug resistance when it occurs.

2 Definitions

Drug resistance is an important clinical problem in a variety of infectious diseases. Classically, the term resistance is used to describe an in vitro phenomenon in which a microorganism displays relative insensitivity to a specified antimicrobial agent as compared with other isolates of the same species. Resistance can either be primary or secondary. Primary resistance occurs in microorganisms never exposed to the drug of interest. Primary resistance in *C. neoformans* and *C. gattii* is relatively uncommon but has been reported to occur with 5-FC [5] and fluconazole [6]. Secondary resistance, also known as acquired resistance, results from previous drug exposure. This form of drug resistance has been increasingly observed in *C. neoformans* with the azole class of antifungals. Secondary resistance to 5-FC was primarily a concern in the 1970s when this agent was used as monotherapy for the treatment of cryptococcal meningitis [7]; but with the use of the combination of flucytosine and AmB, the development of flucytosine resistance is less common. Intrinsic resistance has been defined as an inherent resistance of all isolates of one species to a certain drug. This type of resistance is observed for the echinocandin class of drugs against both *C. neoformans* and *C. gattii*, and thus, at present, this class of agents has not been useful in treating cryptococcosis.

Lastly, clinical resistance has also been termed clinical failure. Clinical resistance describes an in vivo phenomenon in which a microorganism continues to cause evidence of disease despite therapeutic concentrations of an appropriate antimicrobial at the site of infection. For example, progressive neurologic dysfunction after the initiation of antifungal therapy for cryptococcal meningoencephalitis may result from failure to control intracranial pressure or rapid immune reconstitution and does not necessarily imply underlying antifungal drug resistance.

2.1 Clinical Treatment Failure

Potential reasons for clinical treatment failure are many and include (1) host factors such as immune status and treatment compliance, (2) site of infection, (3) drug characteristics including bioavailability and toxicity profile, and (4) fungal factors such as the virulence of the infecting strain as well as the direct minimum inhibitory concentration (MIC). Arguably, the most important long-term prognostic factor for the successful treatment of cryptococcosis is the ability to treat the patient's underlying disease process as opposed to the organism's MIC.

2.1.1 Clinical Resistance Patterns in Patients Without HIV Infection

Treatment failure as a result of impaired host defenses has been clearly described in the setting of neoplastic disease. In the classic prognostic analysis conducted by Diamond and Bennett in 1974, patients that died on amphotericin B therapy were more likely to have an underlying lymphoreticular malignancy and/or to have received corticosteroid therapy

[8]. Furthermore, patients with cryptococcal meningitis who relapsed after antifungal therapy were more likely to have received 20 mg or more of prednisone a day. Improved clinical outcomes were noted if the corticosteroids were reduced to below 20 mg of prednisone daily.

Outcomes related to invasive cryptococcal disease in HIV-negative patients have been reevaluated in the era of effective azole therapy. Overall mortality was 30 %, and mortality attributable to cryptococcal meningitis was 12 % in a study of 306 HIV-negative patients conducted at 15 US medical centers from 1990 through 1996 [9]. Cause-specific mortality was highest for patients with organ failure syndromes (34 %) and second highest for patients with hematologic malignancies (21 %). Solid organ transplant (SOT) recipients are also at risk for developing cryptococcal disease. Cryptococcosis has been reported to occur in 0.3–5 % SOT recipients, with dissemination beyond the lungs and/or CNS documented in 52–61 % of these patients [10, 11]. Mortality rates have ranged from 15 to 20 % to as high as 40 % in those with CNS infection [10, 11]. Recently, it was shown in one large medical center that mortality was higher in the non-HIV, non-transplant group (31 %) versus the HIV and transplant recipient groups (16 %). These findings likely reflect heterogeneous comorbidities and the fact that the non-HIV/non-transplant groups had substantially longer duration of symptoms prior to diagnosis [12].

2.1.2 Clinical Resistance Patterns in Patients with HIV Infection

Currently recommended antifungal treatment regimens in conjunction with ART have improved the prognosis for patients with HIV-associated cryptococcosis; however, acute mortality remains unacceptably high. Robinson and colleagues [13] reported that 37 % of 204 evaluable AIDS patients with cryptococcal meningitis enrolled between 1986 and 1993 failed to have a negative CSF culture after 10 weeks of combination therapy with AmB and 5-FC. Twenty-nine deaths were reported within the first 2 weeks of the study, and a total of 62 deaths occurred prior to the 10-week assessment. Multivariate analysis identified the CD4 cell count as one of the characteristics associated with treatment outcome at 10 weeks. Furthermore, investigators using quantitative cultures have also shown that an initial high burden of yeasts in CSF during cryptococcal meningitis is associated with a worse prognosis [14]. Both host and yeast factors contribute to final outcome of this disease.

2.1.3 Clinical Resistance and Pharmacologic Limitations

The location of cryptococcal infection in combination with the pharmacologic properties of currently available antifungal drugs also plays a role in clinical outcome. A vivid example of this was the observation that antifungal therapy incompletely eradicated *Cryptococcus* from the genitourinary tract of patients with prostatic involvement and HIV infection [15]. Similarly, ketoconazole with its inconsistent oral absorption and limited penetration into the central nervous system has been shown to be ineffective for treating cryptococcal meningitis in spite of in vitro activity [16]. Drug side-effect profiles and patient adherence are also important considerations in treatment failure. Nephrotoxicity and infusion-related side effects, for example, can limit the clinical effectiveness of amphotericin formulations and have frequently shifted the polyene of primary use from amphotericin B deoxycholate to a lipid formulation of amphotericin B. The development of bone marrow and gastrointestinal side effects has been a problem with flucytosine therapy, and frequently, blood levels of flucytosine are not readily available for adjusting doses.

2.1.4 Cryptococcal Virulence Factors and Clinical Resistance

Cryptococcal pathogenicity also influences clinical resistance patterns. Intrinsic virulence differences among *Cryptococcus* strains have been shown to exist under controlled conditions in animal models, and cryptococcal infection in humans may be linked to the infecting strain's inherent virulence characteristics. It has recently been shown that certain cryptococcal genotypes (i.e., burst groups) were associated with a poorer prognosis in HIV-infected patients [17]. Additionally, Mitchell and colleagues [18] performed a retrospective review of patients with cerebral cryptococcosis in Australia between 1985 and 1992. Infection with *C. gattii* was associated with a poorer prognosis despite prolonged AmB administration and careful management of increased intracranial pressure. Furthermore, the outbreak VGIIa strains from Vancouver Island also appear more virulent than non-outbreak VGIIb strains in macrophage and murine models [19]. In addition to the cryptococcal variety, the yeast's ability to produce a melanin-like pigment in vitro has also been linked to pathogenesis [20]. Melanin may protect the yeast from UV damage, extremes in temperature, oxidative stresses, and host macrophages. Van Duin et al. [21] demonstrated that melanization reduced the susceptibility of *C. neoformans* to AmB and caspofungin using in vitro killing assays. The work of Odom and colleagues [22] has also shown that the calcineurin pathway is required for *C. neoformans* virulence in warm temperatures that mimic the host environment, but not lower environmental temperatures. Lastly, the cryptococcal capsule has also been shown to play a key role in virulence. Acapsular mutants are typically avirulent, whereas encapsulated organisms display varying degrees of pathogenicity. Capsule size has been associated with intracranial pressure and host immune responses [23].

We have highlighted several of the host characteristics, pharmacologic limitations, and fungal virulence factors

thought to be an integral part of cryptococcal clinical resistance. In addition to these variables, the in vitro antimicrobial susceptibility has been shown in animal models and some clinical reports to be an important predictor of outcome in cryptococcal infection. Primary and secondary antifungal drug resistance has become clinically important as the number of immunocompromised patients requiring long-term antifungal therapy has grown. The remainder of this review will focus on the identification of resistant cryptococcal isolates in the microbiology laboratory in addition to a review of the epidemiology and molecular mechanisms of antifungal drug resistance in *C. neoformans*.

3 Susceptibility Testing

Antifungal susceptibility testing has accrued substantial interest in recent years as the incidence of invasive fungal infections and the number of available antifungal agents have increased. A great deal of effort has gone into the development of reproducible and clinically relevant reference methods for yeast susceptibility testing. This collaborative work has promoted standardization across laboratories, and, although imperfect, it has given clinicians an in vitro benchmark to assist in the selection of antifungal therapy.

3.1 Broth Dilution Methods

The internationally recognized reference method for yeast susceptibility testing is broth dilution, a technique that involves serial twofold dilutions of an antifungal drug in a liquid medium that is inoculated with a standardized number of yeast cells and incubated for a prescribed period of time. A substantial body of work has shown excellent correlation between broth macrodilution, which utilizes larger volume individual tubes as compared to microdilution comprised of trays with wells that hold a much smaller volume. The broth microdilution (BMD) adaptation is less labor-intensive and is the broth dilution technique of choice in most microbiology laboratories.

Currently there are two standardized methods for BMD antifungal susceptibility testing of yeast: the Clinical and Laboratory Standards Institute (CLSI documents M27-A3 and M27-S4) and European Committee on Antimicrobial Susceptibility Testing (EUCAST) methods. The two approaches are similar in that they both use RPMI-1640 broth as the base medium and have the same incubation durations and a prominent inhibition endpoint (i.e., 50 % for fluconazole and flucytosine, 100 % for AmB) for MIC determination relative to the growth control. Differences between the methods include the inoculum density, glucose content of the medium, the shape of the microdilution wells, and a visual (CLSI) versus spectrophotometric (EUCAST) endpoint reading. Both methods include guidance for the testing of isolates of *Cryptococcus*, specifically.

3.2 Modifications to the CLSI Broth Microdilution Method

Some cryptococcal isolates grow slowly or suboptimally in the CLSI-recommended RPMI-1640 medium. Therefore, the recommended incubation time for *Cryptococcus* is 70–74 h as opposed to 24–48 h for *Candida*. In addition, the use of Yeast Nitrogen Base (YNB) in place of standard RPMI-1640 media may facilitate the growth of *C. neoformans* and improve the clinical relevance of the MIC, an alteration that was first suggested by Ghannoum et al. [24]. Subsequent multicenter studies have confirmed strong interlaboratory agreement using the CLSI microdilution method combined with YNB [25]. Cryptococcal meningitis, especially in patients with uncontrolled HIV, is a high fungal burden disease; therefore, it has also been suggested that a larger inoculum size improves the predictive value of fluconazole MIC testing. Variation of inocula from 10^3 to 10^5 cells per mL has shown small but significant inoculum effects in determining MICs for fluconazole, AmB, and flucytosine for *C. neoformans* [24]. Therefore, many in vitro studies have used 10^4 colony-forming units/mL (CFU/mL) as the final inoculum for susceptibility testing.

3.3 Disk Diffusion Susceptibility Testing

Both CLSI (Document M44) and EUCAST provide standardized methodologies for disk diffusion testing of *Candida* spp. These methods have also been extended to *Cryptococcus*. Pfaller et al. [26] compared fluconazole disk diffusion zone diameters to MICs determined by M27-A2 using a total of 276 clinical *C. neoformans* isolates. Method comparisons yielded an overall categorical agreement of 86 %, with 0 % very major errors (i.e., the disk diffusion method never indicated that an organism was susceptible when the reference method indicated resistant), 2 % major errors (i.e., disk diffusion suggested that an organism was resistant, but the reference method reported susceptible), and 12 % minor errors.

3.4 The E-test for Antifungal Susceptibility Testing

The E-test method consists of a plastic strip impregnated with a predefined gradient of antifungal drug concentrations that is used to determine an organism's MIC. Several investigators have compared the E-test and CLSI microdilution

methods for determining susceptibility of *C. neoformans* isolates and have observed mixed results. Using RPMI-1640 medium with 2 % glucose (RPG agar) for the E-test, Aller et al. [27] reported that fluconazole and flucytosine MICs measured by the E-test showed good agreement with BMD methods (81.1 and 89.2 % ± one twofold dilutions agreement, respectively). However, only fluconazole showed a statistically significant agreement between methods. Itraconazole and AmB MICs showed poor correlation (54 % and 13.5 % ± 2 dilutions agreement, respectively). No itraconazole- or AmB-resistant isolates were included for analysis. Using the same medium, Maxwell and colleagues [28] showed good agreement between the E-test and BMD for voriconazole (94 %) and AmB (99 %). Similarly, 98 % agreement was observed for isavuconazole, without any significant discrepancies (i.e., >2-well dilution differences) [29]. Lozano-Chiu et al. [30] reported that antibiotic 3 medium was superior to both the YNB and the RPMI-1640 media for consistently identifying AmB-resistant cryptococcal isolates in broth by the M27-A2 method. When these investigators used an E-test agar diffusion method, both the RPMI-1640 and the antibiotic 3 medium allowed ready detection of the amphotericin B-resistant isolates. In addition, the investigators reported a high level of agreement between the broth and E-test methods.

The etiology of discrepancy in AmB results across these studies is unclear. Based on available data, the E-test is likely to be a useful alternative to the M27 microdilution techniques for determining the susceptibility of *C. neoformans* to flucytosine, fluconazole, voriconazole, isavuconazole, and possibly AmB. The E-test may be especially helpful for detecting AmB-resistant isolates.

3.5 Interpretive Breakpoints

Clinical interpretive breakpoints (CBPs) for in vitro antimicrobial susceptibility may be used to identify clinical yeast isolates that are likely to respond to treatment with a given antifungal drug administered using the approved dosing regimen for that agent [31]. Yeast CBPs have only been established for *Candida* and were determined based on extensive clinical experience with mucosal and invasive candidiasis.

Even though recent refinements in susceptibility testing have provided improved standardization, continued technical variability and the lack of data on antifungal PK/PD as well as clinical outcomes relative to MIC have prevented the establishment of CBPs for *C. neoformans* and *C. gattii* by either the CLSI or EUCAST. At this time, there is no exact MIC or zone size endpoint to identify resistant cryptococcal phenotypes. Anecdotally, resistance breakpoints (μg/mL) for *C. neoformans* and *C. gattii* have been proposed and applied in surveys of large collections of isolates. These cutoffs include a MIC (μg/mL) of either ≥16 or ≥64 for fluconazole, ≥1 for itraconazole, ≥2 voriconazole, ≥32 for flucytosine, and ≥1 for AmB. Others have used zone diameters of ≤14 mm as a threshold for non-susceptibility. It is important to note that these breakpoints must be interpreted cautiously in the context of the clinical scenario. Prospective studies are ultimately required to identify accurate CBP determinations for antifungal drug resistance. Furthermore, routine in vitro susceptibility testing is not currently recommended for treatment of cryptococcosis [32].

3.6 Epidemiologic Cutoff Values

Epidemiologic cutoff values (ECVs) potentially represent the most sensitive benchmark for differentiating organisms with decreased antimicrobial susceptibility [33]. ECVs may be useful for identifying isolates that are less likely to respond to treatment due to acquired resistance mechanisms when CBPs have not been established as well as for following in vitro susceptibility trends over time. The ECV is defined as an MIC cutoff value that discriminates wild-type (WT) isolates from non-WT strains (i.e., organisms harboring mutational or acquired resistance mechanisms) [34]. The ECV takes into account the WT MIC distribution, modal MIC, and the inherent variability of the susceptibility test method (±1 doubling dilution). The MIC distribution for WT organisms typically covers 3–5 doubling dilutions surrounding the modal MIC [31, 35, 36]. For most MIC distributions, the ECV occurs at a threshold of approximately two dilutions above the modal MIC and encompasses ≥95 % of the WT MIC distribution [31].

Multiple international studies have determined cryptococcal ECVs using large global collections of isolates tested according to the CLSI M27-A3 method (RPMI-1640 medium and 72 h incubation). The first report focused on the azole class of drugs [37] and included 285 invasive *C. neoformans* clinical isolates. The ECVs (μg/mL), along with the percentage (%) of isolates that had an MIC ≤ ECV for fluconazole, posaconazole, and voriconazole, were 8 (96.9 %), 0.25 (96.5 %), and 0.12 (95.1 %), respectively. Interestingly, temporal trends in fluconazole ECVs between 1996 and 2008 showed a decreasing frequency of non-WT strains. This observation is in agreement with previous surveys from developed countries, which suggest that *C. neoformans* susceptibility to fluconazole has improved with the introduction of antiretroviral therapy.

The second two studies included large numbers of *C. gattii* as well as *C. neoformans* strains and reported ECVs according to molecular type; but not all isolates had genotype determination available [38, 39]. Fluconazole ECVs (μg/mL) for different *C. neoformans* genotypes were 8 (VNI) or 16 (non-typed and VNIII). Fluconazole ECVs for

C. gattii ranged from 8 (non-typed, VGI, VGIIa, VGIII) to 32 (VGII). ECVs for the other triazole drugs also showed genotype-specific differences. Posaconazole ECVs ranged from 0.25 (*C. neoformans* non-typed and VNI) to 0.5 (*C. gattii* non-typed and VGI). Similarly, voriconazole ECVs spanned 0.12 (VNIV), 0.25 (non-typed isolates of both species, VNI, VNIII, VGII, and VGIIa), and 0.5 (VGI). MIC distributions also differed by species and molecular genotypes for AmB and 5-FC. For AmB, the ECVs (with the percentage of isolates for which MICs were less than or equal to the ECV listed in parentheses) were 0.5 μg/mL for *C. neoformans* VNI (97.2 %), *C. gattii* VGI (99.2 %), and VGIIa (97.5 %) and 1 μg/mL for *C. neoformans* (98.5 %), *C. gattii* non-typed (100 %), and VGII (99.2 %) isolates. ECVs for 5-FC were 4 μg/mL for *C. gattii* non-typed (96.4 %) and VGI (95.7 %), 8 μg/mL for VNI (96.6 %), and 16 μg/mL for *C. neoformans* non-typed (98.6 %) and VGII (97.1 %).

These observations suggest that ECVs for the *Cryptococcus neoformans–gattii* species complex should be both species specific and potentially molecular-type specific. Limited sample sizes precluded assessments of ECV differences for molecular types other than those listed here. In general, the triazole ECVs for *C. neoformans* molecular types were lower than those for *C. gattii*, and the frequency of MICs above the ECV (non-WT strains) was higher for fluconazole (1.7–9.5 %) than for the other triazoles (0–5.7 %).

4 Epidemiology of Reduced Cryptococcal Antifungal Susceptibility

Several large studies have examined the prevalence of cryptococcal strains with reduced antifungal susceptibility in vitro.

4.1 Global Surveillance Studies

Using standardized disk diffusion testing, 2230 *C. neoformans* isolates collected from 134 study sites in 40 countries were tested against fluconazole and voriconazole over a 10.5-year period [40]. For study purposes, interpretive breakpoints (zone diameters) for fluconazole were susceptible ≥19 mm and resistant ≤14 mm. For voriconazole, ≥17 mm was considered susceptible and ≤13 mm resistant. Overall, 10.4 % of isolates were resistant to fluconazole while only 1.7 % was resistant to voriconazole. Importantly, a significant proportion of fluconazole-resistant isolates (13.6 %) showed cross-resistance to voriconazole.

4.2 Population-Based Surveys

Brandt and colleagues [41] reported on an active surveillance program conducted by the Centers for Disease Control and Prevention (CDC) in four metropolitan areas of the USA between 1992 and 1994 and 1996 and 1998. A total of 732 isolates from 522 patients were evaluated as part of this surveillance. In vitro susceptibilities for AmB were measured using the E-test and MICs for flucytosine, fluconazole, and itraconazole and were measured by the CLSI broth microdilution method. A broad range of MICs were observed over the study period. Interestingly, the MIC_{50} and MIC_{90} for the four drugs did not change by more than a one log dilution between the first 3 years of surveillance as compared to the follow-up 3-year period. No geographical differences were noted and the AmB MIC was ≥2 μg/mL for just two isolates in the entire study. Both isolates were identified in the 1996–1998 surveillance period. Individual histories of AmB exposure were not described for these isolates. Six isolates (0.6 %) collected between the years of 1992 and 1994, and four isolates (1.6 %) collected between 1996 and 1998, had flucytosine MICs ≥32 μg/mL. The incident isolate MIC for fluconazole was ≥64 μg/mL for 6 of 253 patients (2.4 %) between 1992 and 1994 and ≥64 μg/mL for 2 of 269 patients (0.7 %) between 1996 and 1998. The investigators also compared fluconazole susceptibilities for 172 serial isolates of *C. neoformans* collected at least 1 month apart from 71 patients. Thirteen of the 71 (18 %) patients with follow-up isolates had a fourfold or greater increase in fluconazole MIC as compared with the initial isolate. The remaining 58 patients (82 % of serial isolates) showed either no change in MIC (33 patients) or up to a one log dilution change (25 patients). Clinically, this is an interesting observation given that the group of patients with serial isolates available for comparison had presumably been receiving fluconazole maintenance therapy.

A population-based surveillance program was also conducted in South Africa [42]. In many parts of the developing world, the fungicidal combination of AmB and flucytosine for cryptococcal meningitis is precluded by cost, availability, and difficulties with drug administration and/or monitoring. In these settings fluconazole monotherapy, often administered at a relatively low dose (≤400 mg daily), has been the standard initial treatment for CNS disease. Additionally, long-term fluconazole prophylaxis to prevent and treat HIV-associated mucocutaneous candidiasis is common. To determine whether this practice may contribute to the emergence of cryptococcal isolates with reduced fluconazole susceptibility, cases of laboratory-confirmed cryptococcosis were reported to the Mycology Reference Unit, National Institute for Communicable Diseases in Johannesburg, with

testing performed for isolates from 2002 to 2003 and 2007 to 2008. The MICs for six antifungal drugs (AmB, fluconazole, flucytosine, voriconazole, posaconazole, and itraconazole) were determined for incident isolates using the standard M27-A3 method. An incident case was defined as the first episode of laboratory-confirmed disease in a patient. In addition, serially collected isolate pairs were also tested for susceptibility to fluconazole. Of the 487 incident isolates tested, only 3 (0.6 %) demonstrated a fluconazole MIC of ≥16 μg/mL; all of these were from 2002 to 2003. Three additional isolates from the earlier surveillance period had elevated itraconazole MIC values (MIC ≥ 1 μg/mL). All incident isolates were inhibited by low concentrations of AmB (MIC_{90} = 0.19 μg/mL). The MICs for voriconazole and posaconazole were also low (≤0.25 μg/mL and ≤0.5 μg/mL for voriconazole and posaconazole, respectively). Despite no flucytosine use in South Africa during the surveillance period, 17 of 237 (7 %) isolates had MIC values of 8 μg/mL or 16 μg/mL. There were no differences in MIC_{50} and MIC_{90} between the two surveillance periods for any of the antifungal drugs tested. Lastly, of the 67 cases with serially collected isolate pairs, only one case had a follow-up isolate (collected more than 30 days after the incident culture) with a fluconazole MIC significantly higher than the corresponding incident isolate.

4.3 Studies Involving Patients with Relapsed Meningitis

Bicanic et al. [43] described 32 episodes of relapsed cryptococcal meningitis in 27 HIV-positive subjects after initial treatment with fluconazole at a dose of 400 mg daily. Seventy-six percent of culture-positive relapses (n = 21) were associated with isolates that had reduced susceptibility to fluconazole, and these cases carried a high associated mortality regardless of whether or not the patient was on ART. Interestingly, 44 % of patients infected with fluconazole-resistant isolates had been receiving rifampicin without adjustment of fluconazole dose. Rifampicin is known to induce fluconazole metabolism.

Yildiran et al. [44] also investigated the in vitro susceptibilities of 213 CSF isolates from 192 patients against fluconazole, voriconazole, and posaconazole using the M27-A macrodilution method. This *C. neoformans* collection was comprised of isolates previously submitted to the University of Texas Health Science Center in San Antonio between 1990 and 1999. The MIC_{50} and MIC_{90} for each of the triazoles studied remained essentially unchanged over the 10-year observation period. Overall, posaconazole was the most active triazole (MIC_{90}, 0.06 μg/mL) followed by voriconazole (MIC_{90}, ≤0.125 μg/mL) and then fluconazole (MIC_{90}, 8 μg/mL). Twenty patients with relapsing meningitis who had serial isolates submitted at least 1 month apart were reviewed. Nine patients (45 %) had the same fluconazole MICs (±1 dilution) for the initial as compared to the final isolates; six patients (30 %) had a 4- to 16-fold rise in the fluconazole MIC; and the remaining five patients (25 %) had a 4- to 16-fold decrease in MICs. The voriconazole MICs remained unchanged over time (±1 dilution). Sixteen patients (80 %) had equivalent (±1 dilution) posaconazole MICs for the original and final isolate; two (10 %) patients had a four-fold rise in MICs, and the final two (10 %) had a 4- to 16-fold decrease. The observed changes in fluconazole MICs over time did not necessarily predict the directional changes observed in the posaconazole MIC. Proposed explanations for changes in the posaconazole MICs seen over time in some isolates include speculation that a different cryptococcal strain could be causing relapse. Previous studies, however, have shown that relapses are most often caused by the initial infecting strain.

Taken together, these relatively large studies provide us with some insight into the prevalence of reduced susceptibility to antifungal drugs, over diverse geographic regions and prolonged periods of time. Although the majority of isolates appeared to be susceptible to a variety of antifungal agents in vitro, acquired azole resistance has clearly been demonstrated following fluconazole exposure. Posaconazole appears to be the most active drug in vitro, and some, but not all, studies have observed that elevated fluconazole MICs predict elevated voriconazole MICs. Continued surveillance with documentation of clinical outcomes in relation to MIC is warranted. This is especially important in instances of relapsed cryptococcosis. The IDSA Cryptococcosis Treatment Guidelines have supported the importance of saving all cryptococcal isolates so they can be tested concurrently if there is an apparent relapse. Although empirical as a recommendation, these guidelines suggest a three-tube dilution rise in MIC as a marker for development of direct drug resistance [32].

4.4 Susceptibility Differences Across Cryptococcal Species

There has been significant interest in whether antifungal susceptibility differences exist between *C. neoformans* and *C. gattii* species. *C. gattii* infections are often associated with a delayed response to antifungal therapy [3], but this observation is not necessarily linked to higher MICs. There are conflicting reports comparing MICs between *C. neoformans* and *C. gattii* strains, with some studies reporting similar antifungal MICs among the two species [45], while others show higher azole and flucytosine MICs for *C. gattii* than for *C. neoformans* [46]. It is not clear whether the differences in MICs are truly between the two species complexes or potentially related

to the molecular genotype, as the ECV reports have suggested.

5 Clinical Relevance of In Vitro Fungal Susceptibility Results

Multiple studies have assessed the correlation between susceptibility test results and clinical response in cryptococcal disease. The majority of these reports have focused on the clinical predictive value of fluconazole and/or AmB MICs.

5.1 Correlation Between Fluconazole Susceptibility and Clinical Outcomes

Aller et al. [47] reviewed 25 episodes of predominantly AIDS-related cryptococcal infection in 25 patients from 1994 to 1996 from the USA and Seville, Spain. Therapeutic failure was observed in 5 of 24 patients with AIDS. There was a statistically significant association between elevated fluconazole MICs (≥16 μg/mL) and mortality rate as well as treatment failure. Susceptibility testing in this study was performed following the CLSI guidelines described in document M27-A. Similarly, Menichetti et al. [48] conducted a study of high-dose fluconazole therapy in 14 consecutive AIDS patients with cryptococcal meningitis. The reported median time to first negative CSF culture was 56 days for patients who had an isolate with a fluconazole MIC of 4 μg/mL and 16 days for patients with an isolate MIC of <4 μg/mL. Although the difference in median time to CSF sterilization did not reach statistical significance, 40 days difference may have clinical relevance. An analysis correlating clinical outcome with fluconazole MIC was not conducted in this study.

Witt and colleagues [49], using both BMD with the YNB modification as well as the CLSI macrodilution method, attempted to determine whether in vitro fluconazole susceptibility in conjunction with clinical variables might predict treatment outcome for patients with acute AIDS-associated cryptococcal meningitis. The study population consisted of patients who had enrolled in one of two clinical trials evaluating varying doses of fluconazole with or without flucytosine. Treatment was considered successful if the patient was alive with a sterile CSF culture at the end of 10 weeks of therapy. The mean log MIC for fluconazole was significantly higher for the isolates from patients who failed therapy as compared to those that had treatment success. This was only true, however, when the MIC was measured by the modified BMD method. There was no statistically significant difference in the mean log MIC distribution when the MIC was measured by the standard M27 macrodilution technique. The authors suggested this discrepancy could be due in part to enhanced growth in the YNB medium as compared to the RPMI used for the macrodilution technique.

Although these reports suggest that elevated fluconazole MICs correlate with poorer prognosis, the data are derived from single-center studies with small numbers of patients. It is important to note that fluconazole failures have also been reported with MICs as low as 2–4 μg/mL [50].

5.2 Correlation Between Amphotericin B Susceptibility and Clinical Outcomes

Elevated AmB MICs in *C. neoformans* and *C. gattii* are relatively rare in clinical practice. However, several reports correlating AmB MIC with clinical outcome have been published. Powderly et al. [51] evaluated four serial isolates from a single patient with AIDS-associated cryptococcal meningitis. They reported a rise in AmB MICs from 0.4 to 1.6 μg/mL, which correlated with clinical relapse. Alternatively, others have described susceptibilities of serial *Cryptococcus neoformans* isolates from patients with relapsed meningitis whose isolates showed no decrease in AmB susceptibility relative to the initial isolate [52] and no trend toward higher MICs for strains isolated from patients who failed to respond to antifungal therapy regardless of the drug and susceptibility test method used (i.e., CLSI–RPMI, CLSI–YNB modification, or E-test) [53].

Given the lack of robust correlation between in vitro susceptibility as determined by standard methods and early clinical outcomes, there has been substantial interest in alternative approaches. Larsen and colleagues [54] tested pre- and posttreatment *C. neoformans* CSF isolates from 13 patients using CLSI–RPMI to measure MIC as well as a modified broth macrodilution. In this study, duplicate testing was performed using a standardized inoculum and an inoculum that corresponded to the pretreatment "patient-specific inoculum" as defined by quantitative colony counts per milliliter of CSF. AmB MICs ranged from 0.125 to 0.25 mg/L, a spread too narrow to predict fungal response in culture at day 14 of therapy. Alternatively, a statistically significant association between drug concentration and day 14 quantitative culture was observed when the patient-specific inoculum was used. The authors concluded that assessments of pretreatment fungal burden are required to reliably predict the microbiologic treatment response. These observations were subsequently replicated in an additional independent cohort of AIDS patients [55].

In addition to the patient-specific inoculum approach, there is evidence that minimum fungicidal concentrations (MFCs) may be better predictors of clinical outcome than MICs. In one study, 16 isolates of *C. neoformans* obtained from AIDS patients with meningitis had AmB MIC and MFC testing performed [56]. The MFC was defined as the

concentration of an antifungal agent at which the number of colony-forming units upon subculture in the presence of the drug is essentially zero. An AmB concentration of 1 μg/mL had fungicidal activity against most of the isolates, but four isolates from patients who did not respond to therapy showed a persistent or tolerant antifungal effect. In contrast, the MIC values obtained from all isolates suggested that they were susceptible.

Testing conditions for the reproducible determination of cryptococcal MFCs have not been established. Similarly, a standardized procedure for the quantification of yeast in the initial CSF culture does not currently exist. Both approaches are more labor-intense and technically challenging than the standard BMD methods because they involve meticulous colony counts and therefore may not be practical for most clinical laboratories. However, the current evidence suggests that alternative in vitro approaches are required to optimally predict microbiologic outcomes.

5.3 In Vitro–In Vivo Susceptibility Correlations

There are multiple potential explanations for the lack of reproducible correlations between cryptococcal MICs and clinical outcome. First, it is difficult to directly compare drug susceptibility reports given the heterogeneity of the patient populations studied, differences in testing methodologies, and the variable clinical endpoints used to define treatment success. Another important confounder is the pathobiology of the organism itself. In the environment, cryptococcal strains with different genotypes, serotypes, or mating types are frequently isolated from the same geographic site [57]. Thus, human infection with multiple strains acquired from the environment is plausible. Mixed infections involving different serotypes or genotypes have been reported when single colonies were purified and analyzed due to variable colony morphologies observed in the same culture [58, 59], and molecular analyses of unpurified isolates demonstrated that close to 20 % of cryptococcal infections are actually mixed infections [60]. Microevolution in the host during infection has also been postulated [61–63]. The ability of the organism to undergo recombination with the production of haploid or diploid progeny [64] and the accumulation of translocations, duplications, and even formation of aneuploidy strains is assumed to be a stress response that contributes to genetic diversity and potentially drug resistance. Antifungal therapy may select for the strains that have acquired chromosomal duplications and aneuploidies conferring reduced antifungal susceptibility through duplication of chromosomes or part of chromosomes containing ErgII or drug pumps such as AFR1; but ex vivo, these isolates may then lose their chromosomal abnormalities and thus resistant phenotype when grown on nutrient agar (i.e., non-stress conditions). Going forward, new approaches to susceptibility testing that incorporate direct analysis of CSF (i.e., unpurified isolates) in the presence of drug- or patient-specific inoculum with measurement of antifungal drug effects on fungal viability will likely be required to better replicate in vivo conditions in the laboratory.

6 Molecular Mechanisms of Antifungal Resistance

There are a limited number of antifungal agents available for the treatment of cryptococcosis. The major classes of drugs in use today are the polyenes, azoles, and fluoropyrimidines. Studies have also evaluated the activity of echinocandin analogs alone and in combination with other antifungal agents against *C. neoformans*. The mode of action of the antifungal agents used to treat invasive fungal infections can be divided into three broad categories which include (1) fungal plasma membrane disruption (polyenes and azoles), (2) DNA and RNA synthesis inhibition (fluoropyrimidines), and (3) 1,3-β-D-glucan synthase inhibitors (echinocandins). The development of drug resistance can occur at several sites along the fungal metabolic pathway. Research on the mechanisms of antifungal drug resistance has focused on several areas such as alterations of the drug target, impairment of drug entry into the cell, drug efflux out of the cell, and inactivation of drug within the target cell.

6.1 Polyenes

Amphotericin B deoxycholate (AmB) was first discovered in 1956 in the aerobic actinomycete *Streptomyces nodosus*. AmB was licensed for use in 1959 and is active against a variety of fungi including *Cryptococcus neoformans*. The polyene antifungals, including AmB and the newer less toxic lipid formulations, are fungicidal agents. These drugs work by targeting ergosterol, the principal sterol in most fungal plasma membranes. Ergosterol is important for maintaining structural integrity. It has been hypothesized that 8–10 molecules of drug bind to form a pore within the fungal lipid bilayer, thus promoting spillage of potassium ions and disruption of the cellular proton gradient. In addition to the cell membrane effects, polyenes are also thought to induce oxidative damage in fungal cells [65]. Several investigators have described potential mechanisms for AmB resistance. Kelly et al. [66] described two *C. neoformans* isolates collected from a patient with AIDS-associated cryptococcal meningitis who had failed therapy with AmB and fluconazole. When the pre- and posttreatment isolates were compared, the investigators found the posttreatment isolate to have depleted cell

membrane ergosterol concentrations as a result of a newly acquired defect in sterol delta$^{8\rightarrow7}$ isomerase. This target defect conferred AmB resistance but did not affect the post-treatment isolates' susceptibility to fluconazole.

Ghannoum et al. [67] also described characteristics of cryptococcal sterol composition in relation to AmB and fluconazole susceptibilities. They evaluated 13 isolates from five patients with recurrent cryptococcal meningitis. Strain typing with DNA probes showed that the initial and relapse isolates were identical. All five patients had received fluconazole, and three of the five had also received AmB in the interval between initial diagnosis and relapse of infection. Relapse isolates differed from the initial isolates in sterol composition. None of the relapse isolates had a change in AmB susceptibility, but several relapse isolates did differ in their susceptibility to fluconazole. The investigators concluded that the sterol changes could have been a result of the selective pressure of the antifungal regimen or potentially a result of unidentified in vivo host selection pressures.

The use of azole antifungals, which also inhibit fungal ergosterol synthesis, may theoretically result in a lack of a binding site for AmB. Joseph-Horne and colleagues [68] identified *C. neoformans* mutants that were cross-resistant to azoles and AmB but found that this cross-resistance was not related to sterol biosynthesis. The frequency with which the cross-resistant phenotype was detected in their study was 10^{-8}. The authors suggest that a single mutation may be responsible for the cross-resistance and hypothesized that reduced cellular content of drug could account for the observed multidrug resistance. Unfortunately, no direct measure of AmB drug accumulation could be performed in this investigation. In another study, the same investigators [69] were able to isolate a series of *C. neoformans* mutants resistant to AmB that retained the ability to accumulate ergosterol. They postulated that there are at least several categories of AmB-resistant mutants found among *C. neoformans* isolates. These categories include (1) sterol mutants and (2) mutants with normal sterol biosynthesis with or without cross-resistance to fluconazole.

An animal study conducted by Currie et al. [70] suggested that host factors may also play a role in the development of antifungal drug resistance. In this study, serial passage of five environmental *C. neoformans* isolates in a mouse resulted in statistically significant increases in AmB MIC_{50s} for all isolates, but no significant differences in the fluconazole MICs were noted. Mouse passage was associated with changes in cell membrane sterol content and composition for all five of the passed cryptococcal isolates. Paradoxically, ergosterol content increased in four of the five isolates, all of which were more resistant to AmB after serial passage. This finding highlights the complexity of AmB resistance mechanisms and suggests, at least in the murine model, that drug-resistant variants may arise in vivo without prior drug exposure. As of yet, there has not been a report of primary amphotericin B resistance in a *C. neoformans* strain isolated from a human.

6.2 Fluoropyrimidines

Flucytosine (5-FC) is a fluorinated pyrimidine that was discovered in 1957 as part of a search for novel chemotherapeutics, with subsequent FDA approval in 1971 for the treatment of invasive mycoses. Flucytosine is structurally similar to both fluorouracil (5-FU) and floxuridine and has minimal protein binding and excellent penetration into body fluids. The drug is taken up into fungal cells by a cytosine permease and then deaminated to 5-FU by cytosine deaminase, an enzyme not present in human tissues. The deaminated compound is converted intracellularly to a nucleoside triphosphate termed fluorouridine triphosphate (FUTP) that becomes incorporated into fungal RNA where it causes miscoding and ultimately abnormal protein synthesis. Fluorouracil may also be converted to a deoxynucleoside capable of disrupting DNA synthesis [49, 53].

Inherent resistance to flucytosine has been demonstrated in *C. neoformans* [5] and is thought to result from one of several mechanisms. First, a loss of cytosine permease or deaminase activity may lead to decreased uptake or deamination of the drug. These enzymatic defects confer intrinsic resistance to flucytosine. The next mechanisms of resistance are defects in the activity of uracil phosphoribosyltransferase or uridine-5-monophosphate pyrophosphorylase, enzymes integral to the pyrimidine salvage pathway. Block et al. [7] found that cryptococcal isolates resistant to flucytosine also acquired significant resistance to fluorouracil. This cross-resistance suggested an abnormality in the protein or genes associated with uracil phosphoribosyltransferase or uridine-5-monophosphate pyrophosphorylase.

De novo flucytosine resistance may arise in *C. neoformans* as a result of mutations in either of two non-linked genes. The genes named FCY1 and FCY2 act as simple Mendelian determinants that recombine freely, but have not yet been specifically isolated or sequenced. Studies have examined the frequency of the appearance of flucytosine-resistant mutants within susceptible clinical isolates [71]. In an in vitro experiment, resistant mutants appeared in <0.001 % of randomly selected colonies. The average mutation rate was 70 ± 17.9 mutants per 10^7 cryptococcal cells, suggesting that flucytosine resistance is possibly a single mutational event. These data also suggest that the mutation rate is such that flucytosine resistance could easily be selected for at infection sites such as the CSF, where the burden of yeast can reach 10^7 CFU/mL or greater [71].

Hespenthal and Bennett [72] published their early experience with flucytosine as monotherapy for cryptococcal

meningitis. Their data, collected before the first AmB/flucytosine trials, showed that secondary resistance occurred in 6 of 13 patients who did not respond to therapy or relapsed. In the isolates that developed secondary resistance, flucytosine MICs rose from ≤2.5 to >320 μg/mL and remained at this level for all subsequent testing. The overall treatment failure rate for flucytosine monotherapy in this study was 57 % (13 out of 23 patients).

In a seminal article, the combination of AmB and flucytosine for the treatment of cryptococcal meningitis diminished the frequency of flucytosine resistance in relapse strains [73]. Subsequent clinical experience has shown that flucytosine should always be used in combination with other antifungal drugs such as AmB or fluconazole for the treatment of life-threatening cryptococcosis because of the high rate of secondary drug resistance [73, 74].

6.3 Azoles

Discovery of the azole derivatives in the late 1960s marked a major therapeutic advance for the treatment of invasive mycoses. This class of antifungal agents is totally synthetic and consists of two groups, the imidazoles and the triazoles. The triazoles have three nitrogen molecules within the azole ring, while the imidazoles have two nitrogen atoms. The azoles are fungistatic drugs. The newer azole compounds (voriconazole, posaconazole, and isavuconazole) have a broadened spectrum of antifungal activity including activity against most yeasts as well as some filamentous fungi. Itraconazole, fluconazole, ketoconazole, voriconazole, posaconazole, and isavuconazole have all been shown to have in vitro activity against environmental isolates of *C. neoformans*.

6.3.1 Sterol Biosynthesis

Like the polyenes, the azole class of antifungal drugs acts by interrupting sterol biosynthesis, a multistep process involved in the conversion of lanosterol to ergosterol. Specifically, azoles inhibit lanosterol 14α-demethylase ($P450_{14dm}$), a cytochrome P450-dependent enzyme containing a heme moiety in its active site. Azole compounds function by binding to the iron atom within the $P450_{14dm}$ heme group through an unhindered nitrogen in the azole ring. The azole–heme complex prevents the demethylation of lanosterol required for ergosterol formation. Resultant ergosterol depletion in conjunction with the accumulation of lanosterol and other methylated sterol precursors interferes with fungal membrane structure and function.

Several investigators have attempted to better delineate the mechanisms responsible for azole drug resistance in *C. neoformans*. These appear to be multiple processes that play a role in azole resistance which include changes in the affinity of the target enzyme (sterol 14α-demethylase), inhibition of 3-ketosteroid reductase, drug uptake defects, overexpression of the target enzyme, and genetic mutations encoding for multidrug efflux pumps. Each will be reviewed here.

Venkateswarlu and colleagues [75] evaluated 11 *Cryptococcus neoformans* isolates in an attempt to determine the biochemical basis of tolerance to fluconazole. The investigators focused on variability in sterol composition, inhibition of $P450_{14dm}$ by fluconazole, and the cellular concentration of fluconazole. Sterol analysis was conducted in the presence and absence of fluconazole. Exposure to fluconazole produced a decrease in ergosterol levels to below 20 % of normal in all isolates. All treated isolates accumulated obtusifolione and eburicol, indicative of the inhibition of 3-ketosteroid reductase (a NADPH-dependent enzyme catalyzing C-4 demethylation required for ergosterol biosynthesis) and $P450_{14dm}$, respectively. Eburicol and obtusifolione cannot support cell growth because they are methylated at the C-4 position, and it has been postulated that optimal membrane function requires C-4-demethylation. The investigators suggest that the inhibition of 3-ketosteroid reductase and $P450_{14dm}$ may result from direct azole effects or possibly from the retention of a C14α-methyl group in the substrate. Inhibition of $P450_{14dm}$ was tested by measuring the incorporation of [2-^{14} C] mevalonate into C-14 demethylated sterols in cell extracts. It was noted that only the isolates with low-level fluconazole resistance displayed decreased $P450_{14dm}$ sensitivity to fluconazole. Finally, cellular concentrations of fluconazole were measured using radiolabled drug. The most resistant strains were observed to have a 10- to 20-fold reduction in drug accumulation. The authors hypothesize this could have resulted from the presence of multidrug resistance transporters similar to those found in azole-resistant strains of *C. albicans*. In summary, these data suggest low-level fluconazole resistance may be related to changes in the affinity of the $P450_{14dm}$ target enzyme for fluconazole, while high-level fluconazole resistance may result from decreases in the cellular concentration of fluconazole.

Lamb et al. [76] also studied the P450 system of *C. neoformans* in relation to azole tolerance. In their analysis, sterol composition did not change in the azole-tolerant clinical isolates. All strains accumulated approximately 70 % egosterol, similar to previous sterol analyses of wild-type *C. neoformans*. The investigators also evaluated P450 using microsomal fractions. The specific P450 content was observed to be higher in the azole-tolerant isolates, with approximately twice the P450 content of the susceptible strains. They also noticed that the intracellular concentration of fluconazole was reduced in all of the tolerant isolates, but the drug concentration remained in excess of the microsomal P450 content per cell, suggesting ample drug was available to exert antifungal effect. Lamb's group concluded that alterations in drug target cytochrome P450 may be responsible for azole

tolerance and that this alteration could result in diminished affinity for drug at the enzyme's active site.

6.3.2 14 α-Demethylase (ERG11)

Complimentary to the body of work contributing to an improved understanding of the biochemical basis for azole drug resistance in *C. neoformans*, recent attention has also turned to the potential genetic mechanisms of azole drug resistance in *C. neoformans*. The gene encoding 14α-demythelase (*ERG11*) has been evaluated to determine whether molecular modifications such as mutation or overexpression may lead to antifungal drug resistance in yeasts. The majority of this work has been done with *C. albicans*. The role of *ERG11* alteration in the development of fluconazole resistance in *C. neoformans* was evaluated by examining five isolates from one AIDS patient with recurrent cryptococcal meningitis exposed to fluconazole over a 14-month period [77]. DNA fingerprinting showed that all five isolates were the same strain. Isolates 1–4 were considered susceptible to fluconazole (MIC 1–2 μg/mL), while the fifth isolate showed an MIC of 16 μg/mL and was considered resistant. PCR amplification and gene sequencing of ERG11 for the first four isolates did not show any base changes. The fifth strain displayed a point mutation (g1855t) in a highly conserved region of the *ERG11* protein. An equivalent substitution has been described at the G464S position in *C. albicans* and has been linked previously to fluconazole resistance in this organism. This analysis is one of the first studies to link a point mutation to drug resistance in *C. neoformans*.

6.3.3 Multidrug Efflux Pumps

Posteraro et al. [78] designed a cDNA subtraction library technique to compare gene expression between a fluconazole-resistant mutant and its original azole-susceptible clinical isolate. The azole-resistant mutant was generated by in vitro exposure to fluconazole. The resistant phenotype, with a fluconazole MIC of 64 μg/mL, was stable after 20 consecutive subcultures on drug-free medium. DNA fingerprinting was performed on the two strains, yielding identical RFLP patterns. The investigators then identified cDNA expressed in the resistant mutant but not the fluconazole-susceptible parental strain. Sequence analysis revealed that a portion of cDNA expressed only in the resistant mutant was homologous to known members of the ATP-binding cassette (ABC) transporter superfamily. ABC transporters are groups of genes known to code for multidrug efflux pumps. The unique mutant cDNA was then used as a probe to isolate the entire gene from the *C. neoformans* genomic library. Subsequent sequencing identified an ABC transporter gene that encodes a protein with a significant degree of similarity to other ABC transporters. The researchers named the gene *C. neoformans* Antifungal Resistance 1 (*CnAFR1*, GenBank accession number AJ428201). The *CnAFR1* locus in the resistant isolate was disrupted by homologous recombination to determine whether *CnAFR1* is involved in fluconazole resistance. Disruption of the gene resulted in improved susceptibility to fluconazole in the null mutant. Furthermore, reintroduction of *CnAFR1* led to restoration of the resistance phenotype.

Thornewell et al. [79] also identified a *C. neoformans* gene encoding a protein related to the ABC transporter multidrug resistance proteins. However, the cellular function of this CneMDR1 protein has not been clearly established, and the investigators concluded further experiments are required to determine whether CneMDR1 is actively involved in antifungal drug resistance.

6.3.4 Heteroresistance

Mondonet al. [80] were the first to describe heterogeneity in fluconazole and voriconazole MICs among the clonal subpopulations of a single isolate derived from a HIV-negative man, who had never been treated with antifungal drugs. In addition, these investigators outlined steadily increasing fluconazole MICs among six sequential isolates from an AIDS patient with recurrent meningitis. When single colonies obtained from the isolates of both patients were grown on medium containing 64 μg/mL of fluconazole, a homogeneous population of resistant cells was observed. Upon return to drug-free medium, the majority of these subclones lost their resistance and reverted to the initial phenotype. This pattern of intrinsic azole resistance has been termed heteroresistance and is defined as the emergence of a minor subpopulation of resistant cells, within a single colony of a susceptible strain. The resistant subpopulations can adapt to increasing concentrations of the drug in a stepwise manner. However, repeated transfer on drug-free media causes the highly resistant subpopulation to revert to the original level of heteroresistance. The level of heteroresistance has been defined as the lowest concentration of azole drug at which resistant subpopulations emerge.

Both *C. neoformans* [81] and *C. gattii* [82] strains have been shown to harbor heteroresistance to the triazoles. In one study of clinical and environmental isolates, a considerably higher proportion of *C. gattii* strains (86 %) than *C. neoformans* strains (46 %) exhibited heteroresistance at fluconazole concentrations of ≥16 μg/mL, but there was no apparent correlation between serotype or molecular type with heteroresistance [82]. Yamazumi et al. [83] also investigated the prevalence of heteroresistance in clinical cryptococcal isolates obtained over a broad geographic distribution. In their report, 4.7 % of strains (5 of 107) exhibited heteroresistance to fluconazole.

Comparative genome hybridization and quantitative real-time PCR studies have shown that *C. neoformans* adapts to high concentrations of fluconazole through the duplication of multiple chromosomes [84]. Strains that adapted to fluconazole concentrations higher than their MICs contained

disomies in chromosome 1, with accumulation of additional duplications in several other chromosomes in the presence of increasing drug pressure. Two important determinants of fluconazole susceptibility reside on chromosome 1: *ERG11*, the target of fluconazole, and *AFR1*, the major transporter of azoles in *C. neoformans*. Upon removal of drug exposure, strains returned to their initial level of fluconazole susceptibility and lost the extra chromosomes. Importantly, as proof of principle in subsequent animal model experiments, clones with chromosome 1 disomy emerged in the brain of mice with prolonged fluconazole exposure and biological stress in a strain-dependent manner [85]. Further work is warranted to help determine the clinical significance of fluconazole heteroresistance in human infections, the role it might play in treatment failure, and in ability to develop accurate in vitro susceptibility breakpoints.

6.4 Glucan Synthesis Inhibitors

The fungal cell wall has also been an attractive focus of antifungal drug research and development. Although the composition of the cell wall varies among fungal species, there are common pathways not found in mammalian cells that have been evaluated as potential antifungal drug targets. The general components of these synthesis pathways include chitin, mannoproteins, and 1,3-β-D-glucan. The echinocandins are cyclic hexapeptides that inhibit the biosynthesis of 1,3-β-D-glucan. Specifically, these compounds function as noncompetitive inhibitors of 1,3-β-D-glucan synthase, an enzyme involved in the production of glucan polymers in the fungal cell wall. The current generation of echinocandins includes caspofungin, anidulafungin, and micafungin. These agents have potent activity against a variety of fungi including *Candida* species, *Aspergillus* species, and *Pneumocystis carinii*, but limited activity against *C. neoformans* [86]. It has been hypothesized that the lack of anti-cryptococcal activity displayed by the echinocandins may result from few 1,3-β-D-glucan linkages in the cryptococcal cell wall, absent or low levels of the target enzyme, or limited binding of the synthase inhibitors to the target enzyme. However, the exact etiology of intrinsic resistance has not been definitively established.

Feldmesser et al. [87] undertook an ultrastructural analysis of the cryptococcal cell wall in an attempt to better define glucan linkages and thereby investigate one of the proposed mechanisms of echinocandin drug resistance in *C. neoformans. C. neoformans* cells were grown with and without caspofungin in cell culture. Affinity-purified rabbit antiserum against 1,3-β- and 1,6-β-D-glucan was used to determine whether these epitopes were present in the cell wall of *C. neoformans* cells. Using immunoelectron microscopy and gold particle quantitation, the investigators were able to show that both 1,3-β- and 1,6-β-D-glucan linkages were present in *C. neoformans* cells grown in vitro as well as in infected murine pulmonary tissue. The researchers detected fewer glucan epitopes when the *C. neoformans* cells were grown in caspofungin concentrations typically fungicidal for other fungal species. The group concluded that the absence of 1,3-β-D-glucan linkages does not explain the relative lack of efficacy of caspofungin. They also found that caspofungin partially inhibited the formation of 1,3-β-D-glucan linkages as measured by epitope detection. The authors suggest that *C. neoformans* 1,3-β-D-glucan synthase may be relatively resistant to inhibition by caspofungin and offer this as an explanation for the drug's lack of efficacy against *C. neoformans*.

Previous studies of *C. albicans* and *S. cerevisiae* mutants have identified the transmembrane subunit of the 1,3-β-D-glucan synthase as the target for the echinocandins. The enzyme is a heteromeric complex consisting of two subunits, a large 215-kDa catalytic subunit in the plasma membrane and a small GTP-binding subunit which activates the catalytic portion of the enzyme. Fks1p is the proposed catalytic subunit and is encoded by two homologous genes FKS1 and FKS2. Single disruptions of either gene in *S. cerevisiae* have not been shown to affect fungal viability, however, a double disruption is lethal [88]. Similar FKS genes have been identified in *C. albicans* and *Aspergillus* species [89]. Thompson et al. [90] cloned and sequenced the FKS1 homolog from a *C. neoformans* strain by cross hybridization to *S. cerevisiae*. Sequence analysis of the cryptococcal Fks1p protein was 58% identical to both *C. albicans* and *S. cerevisiae* FKS1 and 62% homologous to *A. fumigatus* FKS1. Only one copy of FKS was found in the *C. neoformans* genome. Amino acid sequences known to be essential for echinocandin susceptibility in *S. cerevisiae* were conserved in the cryptococcal analysis. Thompson's group then disrupted the FKS1 gene in order to evaluate its role in cryptococcal viability. Homologous integrative transformation with a plasmid equally capable of integrating into one of two unique positions within the FKS1 gene was employed to statistically show the essentiality of the gene products for viability. Only one of the two possible integration orientations was capable of disrupting gene function. The demonstration of essentiality derives from exclusive recovery of integrations in the non-disrupting orientation. The investigators observed 23 homologous recombination events in the non-disrupting orientations and no integrations in the disrupting orientation. The probability of this result, assuming an equal chance of recombination in either orientation, is 1.19×10^{-7}. The authors felt this was a strong statistical argument for the essentiality of the FKS1 gene in *C. neoformans*. They also concluded that the gene encoding 1,3-β-D-glucan synthase is present in *C. neoformans* and that glucan synthesis is required for fungal viability.

The relatively low efficacy of echinocandins against *Cryptococcus* also does not appear to result from limited drug activity against the cryptococcal 1,3-beta-glucan synthase [91]. As for the notion that limited drug access to the target enzyme may play a role in echinocandin resistance, it has been demonstrated that acapsular *C. neoformans* strains have caspofungin MICs similar to the capsular isolates described in previous studies [90]. Therefore, the cryptococcal polysaccharide capsule does not appear to play a significant role in the relative lack of efficacy of caspofungin against *C. neoformans*. It is possible that an as of yet undiscovered mechanism of action is operative in other fungal pathogens, but not in *C. neoformans*/*C. gattii*.

7 Strategies to Overcome Drug Resistance in *Cryptococcus neoformans*

Effective strategies to prevent antifungal drug resistance are needed. Plans for the management of existing drug resistance, especially fluconazole resistance, are paramount. This section focuses on six strategies that should be considered in the clinical approach to the prevention and/or management of antifungal drug resistance in *C. neoformans*.

7.1 Primary Prophylaxis

The simplest and most cost-effective strategy to manage cryptococcal drug resistance is to prevent infection entirely. *Cryptococcus gattii* has been found in association with several species of *Eucalyptus* and other trees, while varieties *neoformans* and *grubii* have been isolated from fruit, trees, and bird excreta. Patients at high risk for cryptococcal infection should avoid these environments when possible. Complete elimination of all yeast exposure, however, is highly unlikely. Prevention of the development of cryptococcosis could also involve either chemoprophylaxis or immunization, targeting individuals at the highest risk for disease. Unfortunately, adoption of a prophylactic strategy in high-risk patients has the potential to increase the incidence of drug resistance as a result of prolonged exposure to antifungal drugs, while cryptococcal vaccines await the results of clinical trials in humans.

Several studies have assessed the efficacy of azole prophylactic therapy for the prevention of cryptococcal disease in high-risk AIDS patients. Both fluconazole and itraconazole are effective for preventing cryptococcosis [92, 93]. None of the prevention trials, however, have shown a survival benefit. In addition, the expense, potential for selection of resistant fungi (in both *Candida* and *Cryptococcus* species), and possible drug–drug interactions make most physicians reluctant to use azoles for primary prophylaxis. Also, current use of ART and its associated immune reconstitution have significantly reduced the risk for cryptococcosis in patients with HIV infection. Currently, the recommendations from the Infectious Diseases Society of America (IDSA) and US Public Health Service (USPHS) do not endorse primary prophylaxis for fungal disease in patients with AIDS [94].

A polysaccharide-protein conjugate vaccine composed of cryptococcal capsular glucuronoxylomannan covalently coupled to tetanus toxoid has been developed. Subsequently, the vaccine has been shown to produce a protective antibody response in mice with high levels of capsular antibodies identified after active and passive immunization [95]. The finding that antibodies to the capsular polysaccharide glucuronoxylomannan could mediate protection against infection has led to substantial excitement in the cryptococcal vaccination field. A phase I clinical trial evaluating the safety, pharmacokinetics, and effectiveness on antigen elimination of a protective antibody in humans has been completed [96]. However, currently, there are no fungal vaccines or serotherapeutics available for routine clinical use.

7.2 Host Immune Function Modulation

A significant proportion of the drug resistance problems associated with cryptococcosis are related to clinical resistance. Enhancing the overall immune function of the host with ART or the reduction of immunosuppressive agents when possible for transplant and autoimmune disease patients is also likely the most effective means of preventing cryptococcosis. Effective augmentation of the host immune response along with appropriate fungicidal therapy capable of promoting rapid tissue sterilization is an ideal strategy for preventing antifungal drug resistance.

7.2.1 Cytokine Therapy

A significant amount of work in the last decade has gone toward defining host cell signaling through cytokines in addition to the potential of antibody-based therapies. Commercially available cytokines include granulocyte, granulocyte–macrophage, and macrophage colony-stimulating factors (G-CSF, GM-CSF, and M-CSF), as well as γ-interferon, interleukin 12 (IL-12), IL-18, and IL-2. These agents have produced remarkable results against *Cryptococcus* in vitro, particularly when used in combination with antifungal agents [97–101]. The best studied of the cytokines has been γ-inferferon. A clinical study comparing two different doses of γ-interferon three times per week versus no cytokine treatment as adjunctive therapy in patients receiving standard drugs for cryptococcal meningitis was conducted [102]; a second follow-up study also confirmed the improved killing of *Cryptococcus* with addition of γ-interferon treatment to antifungal drugs [103], but more

studies need to be done using cytokines in the treatment of human cryptococcosis before the clinical utility of these agents can be fully realized.

7.2.2 Antibody Therapy

Casadevall [104] has written a cogent review of antibody-based therapies for emerging infectious diseases. Theoretical benefits of antibody-based therapy include pathogen-specific targeting of therapy, toxin neutralization, the enhancement of host effector cell function, and exploitation of favorable pharmacokinetic profiles as has been seen with human IgG (i.e., long half-life, good tissue penetration, and positive safety and tolerability record). Potential problems with antibody-derived therapy include the emergence of antibody-resistant variants, triggering neutralizing antibody production and/or allergic response, limited CNS penetration, and cost. Several experimental studies have shown that monoclonal antibodies to *C. neoformans* capsular glucuronoxylomannan can enhance the therapeutic efficacy of flucytosine [105], AmB [106], and fluconazole in mouse models. Passive immunization with melanin-binding monoclonal antibodies has also been shown to improve survival and reduce fungal burden in *C. neoformans*-infected mice [107]. Although studies evaluating the safety and kinetics of adjunctive serotherapy with monoclonal antibodies for treatment of human cryptococcosis have been performed [96], human efficacy data are lacking at the present time.

7.3 Pharmacotherapeutic Strategies

Optimal pharmacologic therapy should be individualized, and several variables need to be considered when attempting to curtail the emergence of antifungal drug resistance. These variables include drug selection and dose, drug administration schedule, duration of therapy, site of infection, and host immune status. Although none of these factors have been evaluated specifically for their contribution to antifungal drug resistance in cryptococcosis, we can make some inferences based on our experience with pharmacotherapeutic efficacy and antimicrobial drug resistance in other disease states. The continued use of higher fluconazole doses for cryptococcal meningitis illustrates an attempt at therapeutic drug optimization for dosing.

7.3.1 Drug Dosing

One might hypothesize the use of less toxic antifungal drugs at high doses for as brief a time as possible would optimally reduce the emergence of resistance. AmB has transformed cryptococcal meningitis from a uniformly fatal infection to one that is potentially curable. Recent studies have suggested that treatment regimens containing a higher daily dose of AmB (0.7 mg/kg/day) are associated with more rapid CSF sterilization [13] and may decrease short-term mortality in AIDS patients with meningitis as compared with regimens employing lower doses of the polyene [108].

7.3.2 Drug Selection

One limitation to high-dose AmB has been the increased incidence of toxic side effects. Lipid preparations can be given at higher doses with fewer adverse side effects. Currently, the most clinical experience exists with liposomal amphotericin B (AmBisome) at doses of 3–6 mg/kg/day for the treatment of AIDS-associated cryptococcal meningitis. Liposomal amphotericin B appears at least clinically equivalent to conventional AmB [109].

The favorable therapeutic index of the azoles makes dose escalation an attractive option to promote cure and prevent the emergence of antifungal drug resistance. Although optimal dosing for the acute treatment of cryptococcosis is not precise, fluconazole doses of 800 mg/day for meningitis and 400 mg/day for pulmonary disease are likely to give improved results, and even higher doses of fluconazole (i.e., 1200–2000 mg/day) are being tested. A review by Duswald et al. [110] illustrates that higher daily doses of fluconazole than are currently approved may be well tolerated and improve clinical outcomes in selected patient populations for a variety of indications. Furthermore, as we better understand the relationship between MIC and clinical outcomes, the use of newer azole preparations may become important additions to the armamentarium of anti-cryptococcal agents.

In vitro studies comparing the newer triazoles to fluconazole and itraconazole against clinical isolates of *C. neoformans* have been very encouraging. Independent studies have found that the newer triazoles appear to be highly active in vitro against *C. neoformans*. Pfaller et al. [111] evaluated 566 clinical isolates from the USA and Africa and found voriconazole to be more active against *Cryptococcus* isolates than either fluconazole or itraconazole. As the fluconazole MICs increased in this study, so did the MICs of itraconazole and voriconazole. Despite this finding, 65% of the isolates with fluconazole MICs in the range of 16–32 μg/mL remained highly susceptible to voriconazole (MIC ≤ 0.12 μg/mL), and 99% of isolates with fluconazole MICs ≥ 16 μg/mL were inhibited by ≤1 μg/mL of voriconazole. These results suggest there is no automatic cross-resistance among the azoles for *C. neoformans*. Unfortunately, studies with voriconazole in patients with refractory cryptococcosis have a reported success rate of only 39% [112]. This represents a very select group of patients meeting strict criteria for treatment failure, and it is possible that certain patients are refractory to all azole therapy. Further clinical studies need to be done to confirm the promising in vitro results described with the newer triazoles for cryptococcosis. We need to better define which patients may benefit most from treatment with these agents. Future clinical research efforts should not only evaluate specific

drugs and dosing regimens but also explore the role the host immune status may have in the development of antifungal resistance.

7.4 Combination Therapy

Therapeutic regimens utilizing antifungal drug combinations offer multiple potential advantages: (1) a more rapid fungicidal response, (2) reduced resistance development, (3) enhanced spectrum of activity prior to identification of drug susceptibilities, and (4) reduced relapse rates. Several antifungal combinations have been critically evaluated for the treatment of cryptococcal disease, and the IDSA has published comprehensive practice guidelines which include the currently recommended drug combinations [32].

7.4.1 Amphotericin B Plus Flucytosine

Amphotericin B combined with 5-FC for 2 weeks, followed by 8 weeks of treatment with either itraconazole or fluconazole for the initial treatment of AIDS-associated cryptococcal meningitis, has been evaluated in a randomized double-blind multicenter trial [108]. The addition of flucytosine to induction therapy with AmB followed by fluconazole consolidation was independently associated with CSF sterilization and reduced relapse rates. Another study using quantitative yeast counts in the CSF showed that AmB plus flucytosine more rapidly sterilized the CSF of patients compared with patients receiving AmB alone, AmB plus fluconazole, or all three drugs together [113]. Additionally, a recent study showed the combination not only killed yeast faster than single-drug therapy but also had a survival benefit at 70 days [114].

7.4.2 Fluconazole Plus Flucytosine

Flucytosine plus fluconazole has also been evaluated in human studies. A prospective randomized open-label trial of 58 Ugandan patients with AIDS showed that the combination of fluconazole, 200 mg once a day for 2 months in combination with flucytosine at a dose of 150 mg/kg/day for the first 2 weeks, improved survival at 180 days as compared to fluconazole monotherapy [115]. In a noncomparative prospective open-label pilot study of 32 subjects with AIDS, the clinical success rate of fluconazole combined with flucytosine at 10 weeks was reported to be greater than previous reports of either drug alone [74].

7.4.3 Other Combinations

Amphotericin B and fluconazole given in combination is an alternative recommendation for use set forth in the IDSA treatment guidelines [32]. Recent positive studies with this combination [116] and our personal experience with polyenes and azoles administered concomitantly for the treatment of cryptococcosis have not shown antagonism nor have we noticed an increase in the incidence of antifungal drug resistance. Rex and colleagues have also shown in a well-designed, randomized and blinded multicenter trial that the combination of AmB and fluconazole was not antagonistic for the treatment of candidemia in non-neutropenic adult patients as compared to fluconazole alone [117]. Therefore, the combination of AmB plus fluconazole should be considered in locales without access to flucytosine or when toxicity develops with flucytosine.

Several other interesting drug combinations have been evaluated in vitro. Fugita and Edwards [118] have shown the combination of AmB and rifampin to be synergistic in vitro. The echinocandins have not proven to be effective against *C. neoformans* when used alone, but Franzot and Casadevall [119] showed the combination of caspofungin and AmB in vitro can be strongly synergistic. When fluconazole was combined with caspofungin in this analysis, the effects were less impressive. Barchiesi et al. [120] used checkerboard methodology to evaluate the in vitro interactions of flucytosine and posaconazole in addition to a murine model for in vivo efficacy. In this study, combination therapy with posaconazole and flucytosine was more active in vitro than either agent alone. Although a survival benefit was not demonstrated in vivo, tissue burden experiments showed a reduction in number of cryptococcal cells for those mice receiving combination therapy.

7.5 Surgical Intervention

Another strategy that may be useful, in the appropriate clinical setting, to treat drug-resistant infections is surgical excision or debulking. Surgical intervention has been described for the management of large intracerebral mass lesions >3 cm [121] and large pulmonary cryptococcomas [122], particularly with *C. gattii infections* unresponsive to conventional pharmacotherapy. Continued systemic antifungal therapy is required since surgery alone is unlikely to completely eradicate infection.

7.6 New Drug Targets and Drug Development

The development of new antifungal drugs is likely the most important long-term strategy to manage the problem of antifungal drug resistance. In addition to the agents already mentioned, there are other classes of compounds with demonstrated anti-cryptococcal activity in vitro. These novel agents diversify the range of drug targets and thus broaden therapeutic options. Several of these investigational agents will be discussed here.

7.6.1 Benzimidazole Compounds

In vitro studies have shown *C. neoformans* to be quite susceptible to selected antihelmintic benzimidazole compounds. Benzimidazoles work by binding free β-tubulin, thereby inhibiting polymerization required for the microtubule-dependent uptake of glucose. Cruz and Edlin [123] characterized β-tubulin genes and their expression in *C. neoformans*. They also identified a likely benzimidazole target in this fungal pathogen. Del Poeta et al. [124] have described two bis-benzimidazole compounds with potent in vitro activity against yeast.

7.6.2 Immunophilins and the Inhibition of Signal Transduction Pathways

The immunosuppressants cyclosporin A (CsA), FK506 (tacrolimus), and rapamycin (sirolimus) are natural products that have revolutionized the field of transplantation. These compounds are known to have antimicrobial properties and have been shown to possess activity against *C. neoformans*. Husain et al. [11] have shown that SOT recipients who developed cryptococcosis while receiving tacrolimus were statistically less likely to have CNS involvement as compared to all other transplant recipients not receiving this drug.

The immunosuppressive properties of these agents result from inhibition of cellular signal transduction pathways required for T-cell activation. All three agents diffuse into cells and bind to intracellular immunophilins present in human lymphocytes as well as yeast. CsA binds to cyclophilin A while FK506 and rapamycin bind to FKBP12. The drug-immunophilin complex targets various proteins required for signal transduction and cell proliferation. In humans as well as *C. neoformans*, the cyclophilin A-CsA and FKBP12–FK506 complexes target calcineurin, a calcium-regulated protein phosphatase [22]. Calcineurin has been shown to be essential for the virulence of *C. neoformans* and is required for its growth at 37° [22]. FKBP12–rapamycin does not affect calcineurin. Instead, the FKBP12–rapamycin complex inhibits TOR kinases integral in cell-cycle regulation [125].

Recent work has focused on identifying non-immunosuppressive analogs of these drugs and testing them in vitro against *C. neoformans* [126–128]. The results of these studies have been promising. Novel non-immunosuppressive analogs have been found and appear to retain some anti-cryptococcal activity in vitro. Further examinations of CsA, FK506, and rapamycin analogs are needed. These compounds may have promise for development as antifungal drugs for use either alone or in combination with other agents.

7.6.3 ATPase Activity and H+ Transport

The bafilomycins are a group of macrolide antibiotics that inhibit vacuolar-type proton-translocating ATPases (V-ATPases) with high affinity [129]. Bafilomycin A_1 has also been shown to inhibit plasma membrane ATPase (P-ATPase) as well as the ATP-binding cassette (ABC) transporters [130]. ATPase inhibition reduces cellular ability to withstand cation stress and has been identified as a potential new antifungal target. Manavathu and colleagues [131] examined the in vitro susceptibility of *C. neoformans* to NC1175, a novel conjugated styryl ketone with ATPase inhibitory properties in *Candida* and *Aspergillus* species. The MIC values for NC1175 were threefold to fourfold higher than those of AmB and various azoles (NC1175 $MIC_{90} = 1$ mg/L). The authors state that this compound displays fungicidal activity against *C. neoformans* in vitro, although these data were not shown, and suggest the mechanism of action is at least partly due to inhibition of P-ATPase-mediated extrusion of intracellular protons.

Studies with *Saccharomyces cerevisiae* have shown that mutants with impaired structure or function of V-ATPase were nonviable if the yeast also had cellular defects in calcineurin [132]. Del Poeta et al. [124] have taken this observation a step further and explored the in vitro effects of combining the calcineurin inhibitor FK506 or its non-immunosuppressive analog with bafilomycin A_1 against *C. neoformans*. They found that FK506 in combination with bafilomycin displayed dramatic synergistic antifungal activity. In combination, the dose of both agents could be reduced and still retain an inhibitory endpoint. This is potentially important given the immunosuppressive effects of FK506. The non-immunosuppressive analog combined with bafilomycin was not synergistic against the wild-type *C. neoformans* strains tested. Interestingly, the combination of FK506 plus caspofungin was synergistic in vitro. Again, additional studies in animal models are needed to better define the clinical potential for these novel drugs and drug combinations.

7.6.4 Sordarins

The sordarins are another class of antifungal drugs that selectively inhibit protein synthesis in a variety of yeast. Sordarin derivatives have been reported to show antifungal activity against *C. neoformans* [133]. The mechanism of action is thought to be inhibition of fungal elongation factor 2, an essential step in protein synthesis.

7.6.5 Novel Drug Combinations

Chloroquine at low concentrations has been shown to enhance the activity of human mononuclear phagocytes against *C. neoformans* [134]. The antifungal activity of chloroquine is enhanced at higher concentrations likely to be found within the acidic environment of cryptococcal phagosomes [135]. A related compound, quinacrine, was found to be between 10- and 100-fold more active against *Cryptococcus* than chloroquine on a molar basis [135]. These findings have potential clinical applicability as both drugs have proven to be safe and tolerable when administered orally, and they are available in the developing world.

Furthermore, the benefits of chloroquine in murine models of cryptococcosis have been demonstrated [136]. Experiments examining whether chloroquine and quinacrine have additive or synergistic activity when combined with other agents will bolster our understanding of the utility of these drugs, and possibly other related compounds, for the treatment of cryptococcosis.

8 Conclusions

The last 10 years have seen an explosion in laboratory, and clinical work focused on the medically important fungi, as these organisms have recently emerged as a significant group of opportunistic pathogens. With more widespread use of antifungal therapy for maintenance and/or prophylactic purposes in immunosuppressed patient populations, the problem of antifungal drug resistance is likely to continue to be an important issue. The future of cryptococcal therapy will almost certainly include novel and existing drugs used in combination to maximize fungal killing and minimize the ramifications of antifungal drug resistance. As our understanding of the molecular mechanisms of drug resistance improves, new drug targets will be identified and therapeutic strategies individualized. Conventional antifungal drugs may also eventually be combined with immunoactive cytokines or antibodies to help enhance the host's immune response to cryptococcal disease. Finally, continued clinical laboratory experience, improved microbiologic techniques, and laboratory standardization will enhance our ability to predict clinical outcome based on culture data. The foundations for a productive future in cryptococcal research and clinical care have been firmly established, and we expect the field to continue to flourish in the next few decades.

69 Antifungal Therapy for Histoplasmosis: Focus on Susceptibility, Resistance, and Effectiveness in Humans and Experimental Infection

L. Joseph Wheat

1 Introduction

While effective therapies exist for treatment of histoplasmosis, treatment failure occurs in up to 20 % of cases with disseminated disease. The most common causes for treatment failure include inadequate drug exposure and the presence of far-advanced disease at diagnosis. Antifungal susceptibility testing is rarely performed, and consequently the role of drug resistance as a cause for failure is unknown. Resistance may cause treatment failure with fluconazole and the echinocandins. Resistance should be assessed in evaluation of new agents for treatment of histoplasmosis.

Histoplasma capsulatum var. *capsulatum* is an ascomycete from the *Arthrodermataceae* family and the causative agent of histoplasmosis. The mold form of *H. capsulatum* is found in "microfoci" containing bat or bird guano, in the soil or areas where birds or bats have inhabited. The mold consists of hyphae bearing both macroconidia and the infectious microconidia. The organism is highly endemic to certain parts of North America [1], Central America, and South America [2] and much less so in parts of Asia, Southeast Asia, China, India, Australia, Africa, and Europe.

Infection with *H. capsulatum* is initiated upon inhalation of microconidia, which germinate into yeasts upon engulfment by macrophages. The organism survives within macrophages, which transmit the yeast throughout the body. T-cell immunity is critical in recovery from histoplasmosis.

In the absence of immunocompromising conditions, most infections are asymptomatic and primarily involve the lungs. Symptoms often develop within a few weeks following heavy exposure and involve the lungs diffusely, often causing respiratory difficulty [3, 4]. This form of histoplasmosis is referred to as acute pulmonary histoplasmosis (APH). Chronic pulmonary histoplasmosis (CPH) is progressive and occurs in patients with underlying chronic obstructive pulmonary disease. Progressive disseminated histoplasmosis (PDH) usually occurs in patients with underlying immunosuppressive disorders, some of which are yet to be discovered [5].

2 Treatment

Lipid formulations of amphotericin B are the treatment of choice for more severe cases of histoplasmosis [6–8].

Amphotericin B. The mortality was 83 % in untreated patients with PDH contrasted to 23 % in those receiving amphotericin B [9]. The mortality approached 50 % in patients with the acquired immunodeficiency syndrome (AIDS) that were critically ill who were treated with the deoxycholate formulation amphotericin B [10]. Liposomal amphotericin B was more effective than deoxycholate amphotericin B in a randomized double-blind clinical trial in patients with AIDS [11]. Additionally amphotericin B induces a clinical response more rapidly than itraconazole [12–14]. Treatment usually can be changed to itraconazole within 1–2 weeks [11].

Itraconazole. Itraconazole is the preferred oral agent in patients with milder manifestations who are not felt to require hospitalization and "step-down" therapy following response to amphotericin B. In noncomparative trials itraconazole was successful in 85 to 100 % of cases CPH and APH [8]. Causes for failure of itraconazole therapy include nonadherence to therapy [15], gastrointestinal conditions that impair absorption, interactions with drugs that accelerate its metabolism or interfere with its absorption [16], and

severe disease, due to the delay in achieving therapeutic blood levels of itraconazole [13].

Fluconazole. Fluconazole is less effective than itraconazole in histoplasmosis, based upon data from an experimental model of histoplasmosis [17] and experience in humans [8, 12]. In a study in patients with AIDS, 74 % responded to 800 mg daily, but one-third relapsed over the next 6 months after the dose was reduced to 400 mg daily [18]. Fourfold or greater increases in the minimum inhibitory concentration (MIC) to fluconazole occurred in the isolates from over half of failing patients [18]. Also, the clearance of fungemia occurred more slowly with fluconazole than with itraconazole treatment [12]. Fluconazole may be used in patients who cannot be treated with itraconazole, in whom immunity is not severely reduced.

Posaconazole. H. capsulatum is susceptible to posaconazole [19–21], and posaconazole was as effective as itraconazole and experimental infection [20, 21]. Limited information based on case reports [22, 23] and a small study [24] support these findings. Until recently, the only formulation of posaconazole that was commercially available was the oral suspension, which failed to achieve adequate serum concentrations in many patients [25]. Intravenous [26] and tablet [27] formulations are now available, which achieve therapeutic serum concentrations, overcoming this limitation.

Voriconazole. Voriconazole is active against *H. capsulatum*, but animal studies and clinical trials for treatment of histoplasmosis have not been conducted. Of note is that cross-resistance to voriconazole occurs in fluconazole-resistant strains [28]. Voriconazole has been used successfully in a small number of patients with histoplasmosis [29–32], but prior therapy with amphotericin B or itraconazole compromises assessment of its role. Voriconazole also has been used successfully in a few patients with histoplasmosis of the central nervous system [33–35]. Although voriconazole achieves higher concentrations in the CSF than itraconazole or posaconazole, the role of CSF concentration for treatment of *Histoplasma* meningitis is controversial. For example, fluconazole achieves excellent concentrations in CSF but was inferior to itraconazole and amphotericin in an experimental model of *H capsulatum* meningitis [36].

Ravuconazole. Ravuconazole is highly active against *H. capsulatum* with MICs ranging from less than 0.007 to 0.015 μg/mL [28]. Ravuconazole improved survival and reduced fungal burden to a comparable degree to itraconazole in a murine model of histoplasmosis [37]. Both were more effective than fluconazole. Clinical trials using ravuconazole for treatment of histoplasmosis have not been reported.

Isavuconazole. Isavuconazole also is active against *H. capsulatum* with MICs ranged from less than 0.0004 to 0.0063 μg/mL [38, 39]. Isavuconazole has not been evaluated in experimental models or in humans with histoplasmosis.

Echinocandins. Caspofungin [40], micafungin [41], and anidulafungin (Wheat, unpublished observation, 2004) were not active in vitro or effective treatment for experimental infection in several studies. Others reported greater in vitro susceptibility [19, 42, 43] and a more favorable outcome of experimental infection [42]. Clinical trials evaluating the echinocandins for the treatment of histoplasmosis have not been conducted.

Nikkomycin Z. Variable susceptibility was observed with nikkomycin Z, and its effectiveness in the mouse model correlated with MIC [44]. Other reported greater in vitro activity and in vivo efficacy [45, 46]. Nikkomycin Z has not been studied for treatment of histoplasmosis in humans.

Terbinafine. In vitro activity has been demonstrated with MICs below 0.39 μg/mL in 90 % of strains [47]. In vivo efficacy has been reported in animal models [48] and in patients with African histoplasmosis [49].

Combination therapy. In two studies, antagonism was noted using the combination of amphotericin B and fluconazole [17, 36]. While itraconazole was not antagonistic to amphotericin B, outcome was no better in animals receiving the combination than amphotericin B alone. Nikkomycin Z and fluconazole, used at relatively low doses, exhibited additive activity in an experimental model of histoplasmosis [45]. Micafungin and amphotericin B were evaluated in vitro and in vivo and exhibited no interaction [41]. There is no evidence that combination therapy is more effective than therapy with amphotericin B or itraconazole alone. One reason for administering itraconazole with amphotericin B for a few days before stopping amphotericin B would be to achieve therapeutic itraconazole concentrations before the antifungal effect of amphotericin B dissipated.

3 Resistance

The yeast should be tested as it represents form of the organism found in the tissues, and susceptibility to the mold does not predict susceptibility to the yeast. Susceptibility testing, however, is not available for routine testing. Modifications of the NCCLS method for yeast may be used for susceptibility testing of *H. capsulatum* [50]. Modifications include standardized of the inoculum by comparison to McFarland standard of 5 at 530 nm, which was diluted 1:100, while the *Candida parapsilosis* ATCC 90018 control was prepared according to the NCCLS method, by comparison to a 0.5 McFarland standard, and then diluted 1:2000. A second modification was prolongation of the incubation time from 96 to 120 h at 37 °C. These modifications were required because of the slow growth rate of *H. capsulatum*. Growth of *H. capsulatum* was scored by comparison to controls grown

in the absence of drug. Inhibition of at least 80 % as compared to the no drug control was defined as the MIC for the azoles only.

H. capsulatum yeast is susceptible to amphotericin B and most triazoles [20, 21, 44, 51]. Resistance has been noted with the fluconazole, voriconazole, echinocandins, nikkomycin Z, and 5-fluorocytosine. Susceptibility testing using the yeast correlated with clinical outcome in experimental models of histoplasmosis, while susceptibility using the mold did not [41, 44]. Others, however, using mold have noted greater susceptibility to the echinocandins [19, 42] and nikkomycin Z [45].

Fluconazole. Resistance as a cause for treatment failure with fluconazole has been reported [51, 52]. MICs were significantly lower in isolates from patients who responded to therapy compared to those who did not (Fig. 69.1). The median MICs were 1.0 mg/L for fluconazole, 0.015 mg/L for voriconazole, and ≤0.007 mg/L for posaconazole and ravuconazole. While the MICs to voriconazole were significantly lower than to fluconazole, they were higher than to posaconazole or ravuconazole. Of the 17 posttreatment isolates, 12 (70 %) exhibited a fourfold or greater increase in MIC to fluconazole and 7 (41 %) to voriconazole. MICs did not increase to posaconazole or ravuconazole in these isolates (Fig. 69.2).

The biochemical basis of acquired resistance to fluconazole has been examined in isolates from an AIDS patient who failed fluconazole therapy [52]. The concentration to inhibit 50 % of strains (IC_{50}) for fluconazole was threefold greater for the relapse isolate than the parent isolate. Likewise, with regard to ergosterol content, the IC_{50} for fluconazole was fivefold greater for the relapse isolate than the parent isolate. Differences in inhibition of sterol biosynthesis using [^{14}C] were also observed between the parent and relapse isolate (Fig. 69.3). Ergosterol and erosta-5, 22-diene-3-β-ol remained the predominant sterols formed in the parent and relapse isolates in the absence of drug. Inhibition of ergosterol biosynthesis by both azoles resulted in accumulation of eburicol and obtusifolione in the parent isolate, which were reduced in the relapse isolate. This suggests that the cytochrome P-450-dependent enzymes 14α-demethylase and 3-ketosteroid reductase became less sensitive to fluconazole and more sensitive to itraconazole in the relapse isolate. Comparison of the CYP51Ap amino acid sequences from a fluconazole susceptible pretreatment (MIC 1 mg/L) and a posttreatment isolate exhibiting reduced susceptibility to fluconazole (MIC 16 mg/L) identified a single substitution in the posttreatment isolate; tyrosine at position 136 was replaced by phenylalanine (Y136F) [28].

Nikkomycin Z. Nikkomycin Z was active against some strains of *H. capsulatum* and effective against one susceptible strain in experimental infection [44]. While nikkomycin Z did not prolong survival or reduce fungal burden in experimental infection with an isolate with an MIC of ≥64 μg/mL,

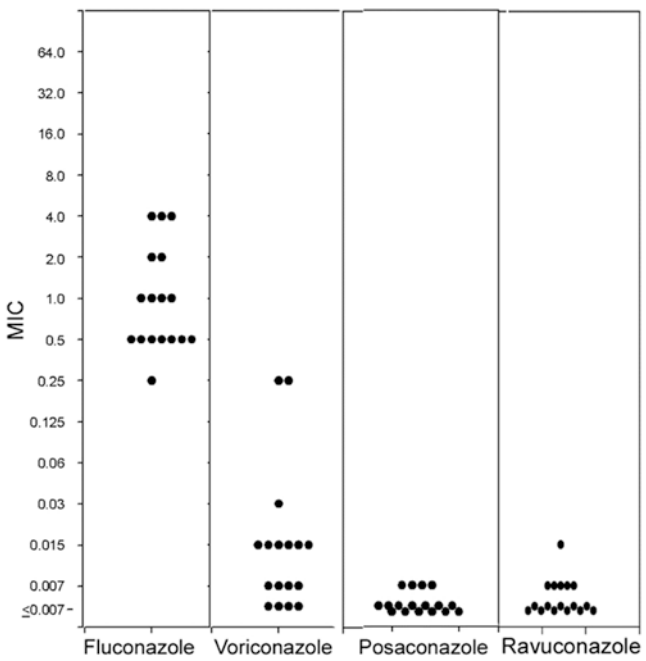

Fig. 69.1 MICs of isolates obtained at baseline before initiating treatment with fluconazole in patients with AIDS and disseminated histoplasmosis. Each *point* represents a single pretreatment isolate from individual cases. Obtained with permission of the publisher [28]

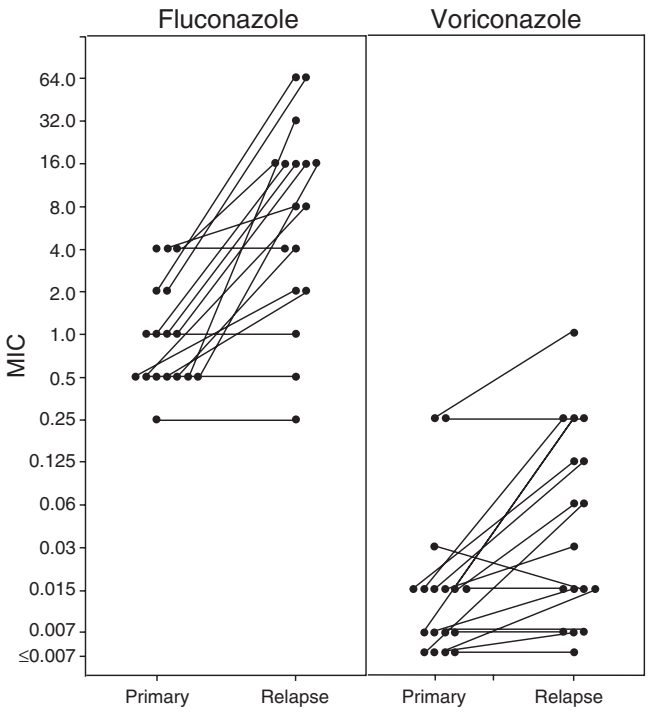

Fig. 69.2 The MIC of the pretreatment and failure isolates are connected by a *line* for each patient that failed fluconazole therapy. Pretreatment and fluconazole failure isolates remain susceptible to posaconazole and ravuconazole, median MICs of 0.007 mg/L or less (obtained with permission of the publisher [28])

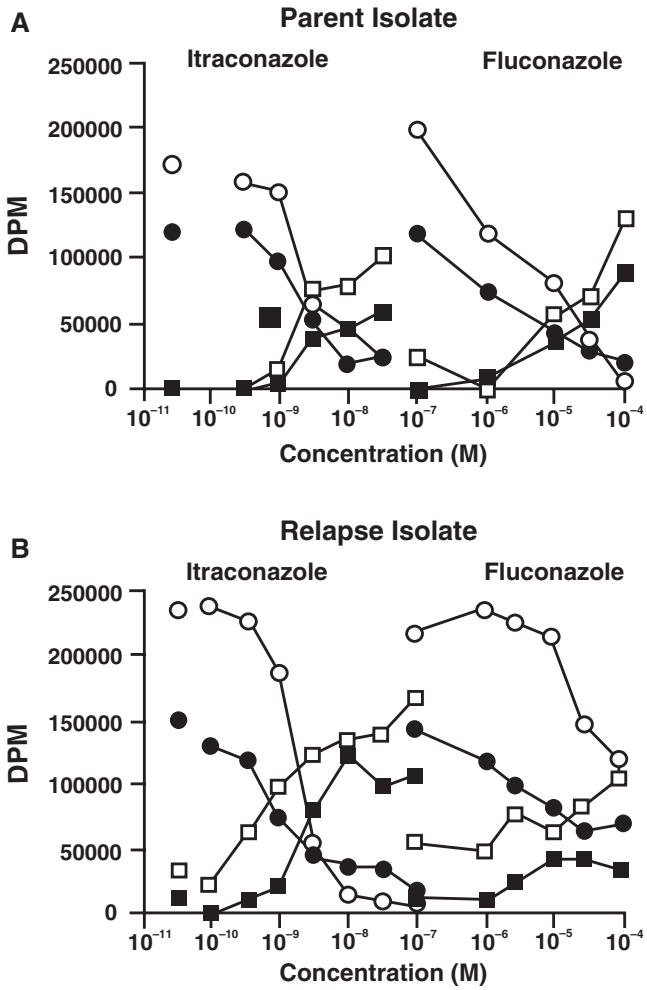

Fig. 69.3 Effects of itraconazole (ITZ) and fluconazole (FCZ) on ergosterol synthesis from [14C] acetate by the parent and relapse isolates. The sterols formed are ergosterol (*circle*), ergosta-5, 22-diene-3-ol (*filled circle*), obtusifolione (*square*), and eburicol (24-methylene-dihydrolanosterol) (*filled square*). Results for controls (ergosterol synthesis in the presence of solvent DMSO) are depicted inside the left-hand margin by the *datum points* that are not connected by *lines*. Results are mean values from four experiments (obtained with permission of the publisher [52])

nikkomycin Z was as amphotericin B against using an isolate with an MIC of 4 μg/mL. In another study using a mold with an MIC of 0.5 μg/mL, nikkomycin Z improved survival and reduced fungal burden [45].

Echinocandins. The activity of the echinocandins against *H. capsulatum* has been inconsistent. In vitro susceptibility testing using the yeast revealed MICs of 16 μg/mL or greater in over 90 % of isolates [40], and therapy was ineffective in experimental infection [40, 53]. Others reported greater in vitro activity [19, 42, 43] and effectiveness in experimental infection [42, 54]. Data on use of the echinocandin for treatment of histoplasmosis in humans is scarce. A patient receiving TNF blocker therapy treated with micafungin for presumed *Candida* sepsis died 4 days later of undiagnosed disseminated histoplasmosis [55].

5-Fluorocytosine. Resistance to 5-fluorocytosine with MICs >64 μg/mL was observed in all 20 strains tested (Wheat, unpublished observation). 5-Fluorocytosine has not been investigated in experimental histoplasmosis or in humans.

Role of melanin in response to antifungal therapy. Melanin plays a role in killing of *H. capsulatum*. Although melanized and non-melanized isolates were susceptible to amphotericin B and caspofungin, melanized strains exhibited reduced killing by these agents [56]. Melanin was postulated to reduce binding of amphotericin B and caspofungin to their targets. One possible role for combination therapy with drugs that inhibit fungal melanization and amphotericin B or echinocandin was proposed.

4 Other Agents with Antifungal Activity

Antibacterial agents. Mycelial and yeast forms were highly susceptible to trimethoprim sulfamethoxazole [57]. Isoniazid derivatives also have shown activity in vitro, including synergy with amphotericin B, which was mediated through inhibition of ergosterol synthesis [58]. Ciprofloxacin exhibited synergy with several antifungal agents for the yeast and mold form of *H. capsulatum* [59]. In vivo studies were not performed, however.

Non-antimicrobial agents. Miltefosine, developed for use in chemotherapy for malignancy, exhibited in vitro activity against the mold and the yeast form of *H. capsulatum* [60]. Maytenin and pristimerin, secondary metabolites of *Maytenus ilicifolia*, a fungus obtained from the roots of *M. ilicifolia* plants, showed antifungal activity for one reference strain and one clinical strain of *H. capsulatum* [61]. Ajoene, isolated from garlic [62], was active against mycelial form of some strains of *H. capsulatum* [63].

5 Conclusion

The liposomal formulation of amphotericin B and itraconazole are the drugs of choice for treatment of histoplasmosis. Considering in vitro susceptibility and potential for development of resistance and the availability of the tablet and intravenous formulation, posaconazole is the most promising alternative to itraconazole. Clinical trials using posaconazole and several newer triazoles for treatment of histoplasmosis are needed. Antifungal resistance limits the effectiveness of fluconazole, and potentially voriconazole, for treatment of histoplasmosis. Echinocandins have no role in treatment for histoplasmosis. Susceptibility testing and evaluation of efficacy in experimental infection are helpful in preclinical evaluation of antifungal agents and investigation of resistance as a cause for treatment failure.
