Drug Resistance in *Pneumocystis jirovecii*

70

Jannik Helweg-Larsen, Thomas Benfield, Joseph Kovacs, and Henry Masur

1 Introduction

Pneumocystis jirovecii (previously known as *Pneumocystis carinii*) is an opportunistic fungus that causes pneumonia, *Pneumocystis carinii* pneumonia (PCP), in immunocompromised individuals. Before 1982 PCP was relatively rare and primarily diagnosed among patients with congenital immunodeficiencies and patients receiving potent immunosuppressive therapy as part of an antineoplastic regimen. However with the AIDS pandemic, PCP emerged as the most common AIDS-defining diagnosis in industrialized countries. The peak incidence of PCP was observed in the late 1980s and early 1990s. Subsequently there has been a decline in the incidence of PCP because of the widespread introduction of PCP chemoprophylaxis and the introduction of increasingly potent HIV-1 antiretroviral regimens. However, PCP remains a serious opportunistic infection among heavily immunosuppressed patients who are not receiving appropriate chemoprophylaxis.

2 The Organism

Pneumocystis were identified early in the last century in guinea pigs by Chagas and in rat lungs by Carini [1, 2]. These investigators mistakenly considered the organisms as a new form of *Trypanosoma cruzi*. In 1912, *Pneumocystis* was recognized as a new species and named in honor of Carini [3]. *Pneumocystis* was first described in humans in 1942 by two Dutch investigators, van der Meer and Brug, who described it in three cases: a 3-month-old infant with congenital heart disease and in 2 of 104 autopsy cases—a 4-month-old infant and a 21-year-old adult [4]. However, *Pneumocystis* was first established as a human pathogen when Vaněk and Jirovec in 1952 identified the organism as the cause of interstitial plasma cell pneumonia among premature or malnourished infants in orphanages [5].

For most of the twentieth century, *Pneumocystis* was considered as a protozoon and single species based on its morphologic features, its resistance to classical antifungal agents, and the effectiveness of certain drugs used to treat protozoan infections. However, in 1988, based on the work by Edman and colleagues [6], phylogenetic analysis of ribosomal RNA (rRNA) sequences and observations of genome size placed *P. carinii* in the fungal kingdom. Subsequent studies including genome sequencing have confirmed that *Pneumocystis* is an *Ascomycete* fungus closely related to *Taphrina deformans* and *Schizosaccharomyces pombe* [7–12].

In contrast to most other fungi, *Pneumocystis* possesses only one copy of the nuclear ribosomal RNA locus, has a fragile cell wall, and contains no ergosterol [13]. Genomic studies suggest that *Pneumocystis* species are obligate parasites, which retrieve energy and compounds from host cells, without free-living forms [14]. During infection, two major stages have been identified morphologically: cysts (asci) and trophic forms (previously called trophozoites). The cyst has a cell wall which primarily consists of β-1,3 glucan, while the trophic form has no detectable β-1,3 glucan [15].

Pneumocystis organisms have been identified in most mammalian species in which it has been searched for. Genetic and antigenic analyses have shown that *Pneumocystis* includes a broad family of organisms, with species specificity among its mammalian hosts [13, 16, 17]. Remarkably, the level of genetic divergence between *Pneumocystis* organisms infecting different mammals is greater than the degree

of divergence observed between certain fungi classified as distinct species [18, 19]. Phylogenetic comparisons of DNA sequences in organisms from 18 different nonhuman primate species have demonstrated that sequence divergence correlates with the phylogenetic difference between the host species, which suggests that *Pneumocystis* species have evolved together with their hosts [20].

Thus unique species of *Pneumocystis* appear to infect each unique mammalian host species. To date, rats are the only species that have been demonstrated to be infected by two unique *Pneumocystis* species. The organism infecting humans has been renamed *Pneumocystis jirovecii*, in honor of Otto Jirovec, who was among the first to describe the microbe in humans [5, 21, 22].

3 Transmission and Infection

Since *P. jirovecii* cannot be cultured in vitro, knowledge about its biology has been difficult to obtain. However, the development of molecular and immunologic techniques, including sequencing the genome from one *P. jirovecii* isolate, has permitted considerable insight into this organism and how it interacts with its host. Based on antibody and PCR findings, primary infection with *P. jirovecii* happens in very early childhood (<1 year of age) with a uniformly high incidence in all geographic areas, which suggests that *P. jirovecii* organisms are ubiquitous [23].

It was previously thought that the infection was carried lifelong and that clinical infection was a result of reactivation in immunocompromised hosts. However, molecular typing studies have questioned this view and support a more complex picture of transmission and infection.

The acquisition of infection in humans is most likely the result of person-to-person spread [24, 25]. When the organism is obtained initially as a primary infection, it is not clear whether an immunocompetent host develops a transient disease. Various investigators have proposed that primary infection might correlate with the development of upper or lower respiratory manifestations, or with the development of sudden infant death syndrome [26–28]. Following primary infection, the presumption, based on murine models, has been that the organism becomes latent, later manifesting clinically if the patient becomes profoundly immunosuppressed.

More recent data, however, suggests that human hosts can be infected with more than one strain of *Pneumocystis jirovecii*, raising the possibility that infection can be acquired on multiple occasions, leading to latency with a variety of distinct organisms [29–35]. Further, typing studies of outbreaks of PCP, especially in renal transplant patients, have provided compelling evidence that a single strain spreading among susceptible hosts can be responsible for such outbreaks. The clinical disease PCP may, therefore, occur as a reactivation of a prior latent organism, or as a result of recent acquisition of an airborne pathogen [36, 37].

Since most infants acquire antibody against *Pneumocystis* during the first year of life, the organism must be ubiquitous. Nonhuman animals are not the source, however, because, as mentioned above, each animal species is infected with a different species of *Pneumocystis*, and there is no cross species infection that has been identified. From PCR-based studies, it is now clear that infants and immunocompetent adults frequently experience colonization and likely constitute the major reservoirs for *P. jirovecii* [38]. Recently, several renal transplant centers have reported rising incidence of PCP with genotype studies showing evidence of patient-to-patient transmission, which suggest that iatrogenic exposure of immunocompromised patients is an increasing problem [39, 40].

Pneumocystis has specific tropism for the lung, where it exists in the alveoli. In rare cases organism has been detected in other organs, but it seldom causes disease at extrapulmonary sites. After inhalation, the organism attaches tightly to the surface of type I alveolar cells [41]. Adherence is potentially mediated by the major surface glycoprotein (MSG) [42, 43]. This protein is the most abundant antigen on the surface of *Pneumocystis* and is encoded by a multicopy gene family. MSG represents a family of proteins that are highly polymorphic, repeated, and distributed among most chromosomes of *Pneumocystis*. MSG provides *Pneumocystis* with a mechanism for antigenic variation by switching the expression of multiple MSG genes, with a system that resembles one used for antigenic variation in *Trypanosoma cruzi* [44, 45]. It is likely that this antigenic variation in MSG serves for avoiding the host immune response [46]. There is no detailed knowledge of the life cycle and the mode of replication has not been definitely established, but both asexual and sexual life cycles have been proposed [47, 48]. Recently, several genes, which in other fungi are involved in mating, pheromone responsiveness, and responses to environmental changes, have been demonstrated in *Pneumocystis*, suggesting that the organism has a sexual replication cycle that responds to environmental changes in the lung [49–51].

4 Drug Treatment

The major drug classes used for treatment and prophylaxis of PCP include antifolate drugs, diamines, atovaquone, and macrolides (Tables 70.1 and 70.2). Most traditional antifungal agents have no activity against *Pneumocystis*, likely due to the absence of ergosterol, which is the target of amphotericin B as well as azoles. As *Pneumocystis* was originally believed to be a protozoon, initial drug testing focused on drugs with activity against protozoan infections.

Table 70.1 Regimens for prophylaxis against *Pneumocystis* pneumonia

Drug	Oral or aerosol dose
First choice	
Trimethoprim-sulfamethoxazole	1 DS or SS daily
Alternatives	
Trimethoprim-sulfamethoxazole	1 DS three times per week
Dapsone	50 mg twice daily or 100 mg daily
Dapsone with pyrimethamine plus leucovorin	50 mg daily 50 mg weekly 25 mg weekly
Dapsone with pyrimethamine plus leucovorin	200 mg weekly 75 mg weekly 25 mg weekly
Pentamidine aerosolized	300 mg monthly via Respirgard II nebulizer system
Atovaquone	1500 mg daily
[a]Pyrimethamine plus	25–75 mg qd
Sulfadiazine	0.5–2.0 g q6h

DS double strength = 800 mg sulfamethoxazole, 160 mg trimethoprim, *SS* single strength = 400 mg sulfamethoxazole, 80 mg trimethoprim
[a]This regimen only for use in case of concurrent toxoplasmosis

In 1958, pentamidine isethionate was the first drug used to successfully treat PCP [52]. In the 1960s, the combination of sulfadoxine and pyrimethamine was used for the prevention of epidemic infantile pneumocystosis in Iran [53]. In 1966, Rifkind treated two patients with sulfadiazine and pyrimethamine: both patients died, but two patients were successfully treated 4 years later [54]. Between 1974 and 1977 studies led by Hughes et al. established that the combination of trimethoprim-sulfamethoxazole (TMP-SMX) is effective for both treatment and prophylaxis of PCP [55–57]. TMP-SMX is as effective as intravenous pentamidine for therapy and is still the treatment of choice. Additionally, TMP-SMX is the most effective chemoprophylaxis for PCP and therefore the standard for prevention.

Other drugs have proven activity for therapy, including sulfadiazine plus pyrimethamine, dapsone plus trimethoprim, atovaquone, clindamycin plus primaquine, and trimetrexate. Dapsone, dapsone-trimethoprim, atovaquone, and aerosolized pentamidine have documented efficacy in prophylaxis in patients at high risk for developing PCP. Clindamycin-primaquine has not been shown to be effective for chemoprophylaxis. Anecdotal reports and case series in pediatric populations suggest that intravenous pentamidine may be effective [58, 59]. There are other drugs that have in vitro activity or anecdotal anti-PCP activity in humans and could have a role in managing human disease if all other alternatives were not feasible. These include azithromycin, doxycycline, and echinocandins; the latter class of drugs, which target beta 1,3-glucan synthesis, have activity against the cyst but not the trophic form in animal models.

5 Prophylaxis

Among HIV-infected patients, the occurrence of PCP is closely related to the CD4 count: the lower the CD4 count, the more likely PCP is to develop. While a count of 200 cells/mm^3 is often used as an indicator or susceptibility, HIV-infected patients do in fact develop PCP at counts higher than 200 cells/mm^3, although at a lower frequency than at 200, 100, or 50 cells/mm^3.

Patients with congenital immunodeficiencies, particularly X-linked immunodeficiency with hyper-immunoglobulin M and SCID, patients receiving long-term and high-dose corticosteroid therapy, and patients receiving certain chemotherapeutic regimens for cancer therapy or transplantation are at risk of developing PCP. Among HIV-negative patients, risk factors for PCP include coexisting pulmonary disease with CMV infection, pre-existing lung disease, the use of certain anti-cytokine antibodies (e.g., adalimumab), and in particular lymphocyte-depleting agents such as alemtuzumab, fludarabine, or rituximab [60–66]. In addition, genetic factors may also contribute to risk. In patients without HIV, CD4 counts are not a reliable marker of susceptibility. Several studies have shown that the occurrence of PCP is not as predictable with these markers in diseases unrelated to HIV [62].

Systemic chemoprophylaxis against PCP was introduced by Dutz in Iran in the early 1960s. He showed that outbreaks of PCP could be aborted with the use of sulfadoxine plus pyrimethamine [67]. Hughes et al. followed this observation with a classic study of children with acute lymphocytic leukemia (ALL); they showed that PCP could be virtually eliminated by TMP-SMX prophylaxis [68]. Subsequently this prophylaxis was used for other populations of cancer and transplant recipients with a very high success rate. With the advent of the AIDS epidemic, PCP prophylaxis was used sporadically in the 1980s. After publication of a convincing study by Fischl et al., PCP prophylaxis became a standard of care for HIV-infected patients with CD4 counts less than 200 cells/mm^3 in 1989 [68]. The identification of additional risk factors for the development of PCP has led to expanded recommendations for the use of PCP chemoprophylaxis—details are provided in Table 70.3. HIV-1-infected patients with oral candidiasis or a CD4 count less than 200 cells/μL should be offered primary prophylaxis. Secondary prophylaxis should be offered to all patients following an episode of PCP. In HIV patients receiving prophylaxis, prophylaxis can safely be discontinued if immune function is improved above a CD4 count of 200 cells/μL for at least 3 months following antiretroviral therapy. If the patient subsequently fails antiretroviral therapy and the CD4 declines to below 200 cells/μL, prophylaxis should be restarted.

In non-HIV-infected individuals, conditions such as organ transplantation, high-dose corticosteroid treatment,

Table 70.2 Drug regimens for the treatment of PCP

Drug	Route	Dose	Toxicity	Advantages	Disadvantages
First choice					
Trimethoprim-sulfamethoxazole	By mouth	2 DS every 8 h	Rash and fever	Superior efficacy	Rash common
			Anemia and neutropenia	Inexpensive	
	Intravenous	Trimethoprim 5 mg/kg with sulfamethoxazole 25 mg/kg every 8 h	Hyperkalemia	Oral and iv	
			Hepatitis	Bacterial and anti-toxoplasmosis activity	
			Nephritis		
			Anaphylactoid reaction		
Alternatives					
Dapsone plus trimethoprim	By mouth	100 mg daily	Rash, nausea and vomiting, fever	Inexpensive	No i.v. formulation
	By mouth	320 mg every 8 h	Methemoglobinemia, leukopenia, and hemolytic anemia		
			Liver function abnormalities, headache		
			Dapsone may cause hemolysis in patients with G-6PD		
Clindamycin plus primaquine	By mouth, intravenous	450–600 mg every 6 h	*Clostridium difficile* diarrhea, nausea and, vomiting. Primaquine may cause hemolysis in patients with G-6PD deficiency		No i.v. formulation for primaquine
	By mouth	30 mg daily			
Pentamidine	Intravenous	4 mg/kg day	High incidence of adverse effects, particularly hypoglycemia and nephrotoxicity	Highly effective	Toxicity common. Only i.v. formulation
			Pancreatitis and dysglycemias		
			Hypotension with short infusion time		
			Pancytopenia, QT prolongation		
Atovaquone	By mouth	750 mg twice daily	Rash, nausea, diarrhea, and headache (20 %)	Well tolerated	Expensive
			Fever, increased transaminases and neutropenia		Useful for mild disease
Adjunctive therapy					
Prednisone in patients with room air $pAO_2 < 70$ mmHg (9.3 kPa)	By mouth, intravenous	40 mg twice daily for 5 days		Standard of care for moderate or severe disease	Metabolic problems especially glucose and electrolyte changes
		40 mg daily days 6–11			
		20 mg daily days 12–21 while on anti-PCP therapy			

and/or high-dose chemotherapy may confer a high risk of PCP. Prophylaxis should be offered as shown in Table 70.3. Several prophylactic regimens are available. The most efficient, cheap, and widely used regimen is daily TMP-SMX. TMP-SMX prophylaxis is relatively well tolerated by most non-HIV patients; in contrast, HIV patients have a high frequency of adverse effects, in particular rash and myelosuppression. Before the advent of antiretroviral therapy, 50 % of patients experienced an adverse effect after 12 months of prophylaxis with double-strength TMP-SMX (160/800 mg), and half would have switched to other types of prophylaxis within 3 years [69]. Fortunately, one single-strength (80/400 mg) TMP-SMX daily appears to be equally effective and is associated with fewer side effects than one double-strength tablet daily [70]. Because of its efficacy, ease of administration, and cost, every effort should be tried to maintain patients at risk of PCP on TMP-SMX. Tolerability may improve with lower-dose or intermittent regimens. For patients who have had nonlife-threatening reactions to TMP-SMX (e.g., not Stevens-Johnson syndrome), it can be safely reintroduced in many patients by dose escalation [71, 72].

Table 70.3 Recommendations for PCP prophylaxis and risk identification in selected diseases

Disease	Risk identification	Duration of prophylaxis	Comment
HIV-1 infection	Prior PCP		Prophylaxis improves survival
	CD4 cell count <200	Lifelong unless CD4 count >200 × >*3 months due to ART*	Restart prophylaxis if CD4 count falls to <200
	Oropharyngeal candidiasis		
	CD4 cell count <14 %		
	Prior AIDS-defining illness		
Organ transplantation		*General: Minimum 6 months after transplantation*	
Kidney	Depends on intensity of immunosuppression and occurrence of graft versus host disease or rejection	At least 6 months	Need for PCP prophylaxis determined by clinical experience. CD4 count is *not* a reliable predictor
Lung		Indefinitely	
Heart/liver		6–12 months	
Autologous BMT		6–12 months	
Allogeneic BMT		Minimum 1 year	
Rejection		Reinstate	
Graft versus host disease		Reinstate	
Malignancy			
Acute lymphoblastic leukemia (ALL)	During and subsequent to combination chemotherapy	During severe immunosuppression	Need for PCP prophylaxis determined by clinical experience with each chemotherapeutic regimen. CD4 count is not a reliable predictor
		Continue during maintenance therapy for childhood ALL	
Chronic lymphatic leukemia (CLL)	Treatment with fludarabine or alemtuzumab (Campath, anti-CD52)	3–6 months post-chemotherapy	
Lymphoma	Certain chemotherapeutic regimens, e.g., R-CHOP14, escalated BEACOPP, nucleoside analogs	Minimum 2 months after discontinuation or until CD4 > 200	

BMT bone marrow transplantation, *ART* antiretroviral therapy

6 Treatment of PCP

Untreated PCP is invariably fatal. In the beginning of the HIV epidemic, the mortality rate of PCP was reported to be 30–40 % [73, 74], increasing to 70–90 % among patients who progressed to respiratory failure [75]. During the 1990s, mortality rates dropped to 5–15 % [76–81]. This appears to be a consequence of earlier recognition of the infection, the introduction of adjuvant corticosteroids to patients with moderate-to-severe PCP as defined by a PaO_2 of less than 70 mmHg, better diagnostic and therapeutic abilities related to concomitant processes, and improved ICU supportive measures.

The importance of educating patients to seek medical attention early, when symptoms are still mild, must be an emphasis of patient management programs. Both patients and health-care professionals must recognize that mild symptoms such as dyspnea, cough, or low-grade fever can be the initial manifestation of PCP, especially in patients with CD4+ T lymphocyte counts below 200 cells/mm^3. Thus, clinicians should not wait for all features of PCP to be present, or for the chest radiograph to be abnormal, before initiating a workup for PCP. Moreover, once there is a high suspicion, therapy should be instituted promptly if the diagnostic procedures will be delayed.

The choice of specific chemotherapy is also important. The most potent drugs for PCP treatment are antifolate drugs, which act by blocking de novo synthesis of folates through inhibition of dihydropteroate synthase (DHPS) or dihydrofolate reductase (DHFR) (Fig. 70.1).

DHPS catalyzes the condensation of p-aminobenzoic acid (PABA) and hydroxymethyl dihydropterin pyrophosphate to produce dihydropteroate, which is later converted to dihydrofolate by dihydrofolate synthase. Subsequently, dihydrofolate is reduced by dihydrofolate reductase (DHFR) into tetrahydrofolate. Sulfa drugs are structural analogs of PABA and inhibit DHPS.

The earliest clinical trials to treat PCP were performed with sulfadiazine plus pyrimethamine on the assumption that

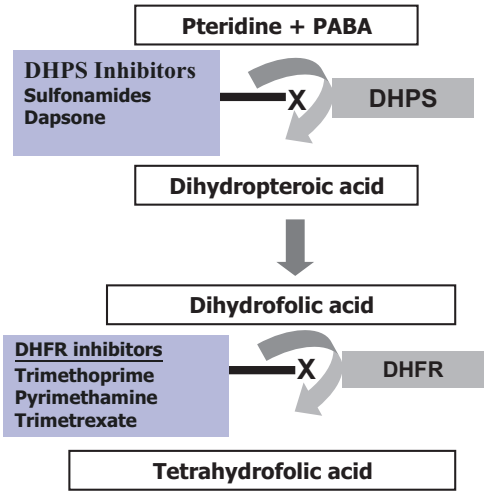

Fig. 70.1 Inhibition of folate synthesis by sulfonamides and DHFR inhibitors. *PABA* paraaminobenzoic acid, *DHPS* dihydropteroate synthase, *DHFR* dihydrofolate reductase

these drugs would have synergistic action against pneumocystis, as against plasmodia. When the commercial combination of sulfamethoxazole plus trimethoprim was developed to treat bacterial infections, this preparation was assessed for PCP therapy and prophylaxis since commercial sponsorship of studies could be obtained. At that time there was no knowledge about the relative potency of various sulfonamide preparations against pneumocystis, nor was there information about the relative potency of various DHFR inhibitors. Subsequently, it was found that sulfamethoxazole is probably as potent as any of the other commercially available sulfonamide preparations as discussed below [82, 83]. However, trimethoprim is not as potent as other available DHFR inhibitors, as also described below.

In Table 70.2, drug treatment options for PCP are listed together with the most important advantages and toxicities of each drug regimen. During the 1980s several trials investigated the efficacy of TMP-SMX compared to pentamidine [84–87]. In the only noncrossover trial ($n=70$) [86], TMP-SMX was associated with a better survival than pentamidine. However, when all trials are considered, TMP-SMX and pentamidine appear to have roughly comparable efficacy [84]. Drug toxicity occurs in 24–57 % of HIV-infected patients treated with TMP-SMX [88].

Adverse effects generally occur after 7 days of therapy and most commonly include rash, fever, and leukopenia. Hepatotoxicity characterized by elevated transaminases also occurs. There are cases of sulfamethoxazole-induced interstitial nephritis, renal calculus formation, anaphylactoid reactions, and pancreatitis reported. Trimethoprim can be associated with hyperkalemia. These toxicities are usually not life threatening, although fatal cases of Stevens-Johnson syndrome have occurred.

Pentamidine is associated with a high frequency of toxicities, some of which are treatment limiting. Early experiences with rapid infusions of pentamidine were associated with hypotension and death, so this route of administration was abandoned. Intramuscular injections were better tolerated in terms of blood pressure, but they caused a high frequency of sterile abscesses. Therapy was then administered by slow intravenous infusion, which is the best tolerated route. Inhaled pentamidine has been used for therapy and is well tolerated, but efficacy is poor. Pentamidine is nephrotoxic and causes predictable glomerular and tubular damage to the kidney. Pentamidine is toxic to the pancreas: its initial effects cause a surge of insulin release that often manifests as hypoglycemia, followed by the development of hyperglycemia. Hypoglycemia can occur days or weeks after starting therapy and may occur many days after stopping therapy. Leukopenia can also occur. Pentamidine prolongs the QT interval, and cases of torsades de pointes have been reported. Treatment-limiting toxicities with pentamidine treatment occur in 13–80 % of patients.

Alternatives for therapy to TMP-SMX and pentamidine include dapsone-trimethoprim, clindamycin-primaquine, and atovaquone (Table 70.2). Trimetrexate has activity but is no longer commercially available. Dapsone has not been studied as a single drug and thus should not be use alone for treatment. Dapsone-trimethoprim is effective, however, and probably has potency that is comparable to TMP-SMX. However, since this combination does not come as a fixed-dose combination, is only available orally, and cross-reacts with sulfa in 50 % of allergic patients, this regimen does not offer many advantages over TMP-SMX.

Clindamycin-primaquine appears to work on a different metabolic pathway than TMP-SMX. Two comparative trials of clindamycin/primaquine with TMP-SMX in moderate-to-severe PCP demonstrated apparent equivalence for clindamycin-primaquine, but both trials were underpowered [89, 90]. A retrospective observational study suggests that this regimen should be preferred for treatment of PCP, if TMP-SMX is not tolerated [91]. Clindamycin causes a relatively high incidence of hepatitis, rash, and diarrhea in HIV-infected patients. Primaquine can only be given orally.

Atovaquone is well tolerated and acts on a different metabolic pathway from TMP-SMX. However, this drug is also only available orally and does not appear to be as effective as TMP-SMX [92]. This is a good alternative for patients with mild disease who cannot tolerate TMP-SMX.

Efficacy of dapsone-trimethoprim has only been demonstrated for mild-to-moderate PCP and for atovaquone only for mild PCP [89, 92–94]. Both must be administered orally.

The optimal duration of therapy for PCP has never been properly studied. Usual recommendations are that HIV-negative patients should receive 2 weeks and HIV-positive patients should receive 3 weeks of drug treatment.

Many patients experience progressive oxygen desaturation during the first 4–5 days of therapy. This deterioration appears to be caused by the drug-induced death of *Pneumocystis* organisms with exacerbation of alveolar inflammation. This inflammation can be reduced by corticosteroids. Four randomized controlled trials demonstrated that corticosteroids could reduce mortality in HIV-infected patients with moderate or severe disease [95–98]. Based upon these results, adjunctive steroids are now recommended for all HIV patients with severe disease ($PaO_s < 70$ mmHg). In non-AIDS patients, the situation is often complicated by prior use of corticosteroids, which are themselves a risk factor for development of PCP. In this setting steroid use must be individualized to balance the beneficial anti-inflammatory effects with the potentially harmful immunosuppressive effects.

7 Sulfonamide Resistance

The widespread use of TMP-SMX and dapsone for therapy and prophylaxis of PCP among HIV patients has led to the concern that sulfa (sulfonamide or sulfone) resistance could develop in *P. jirovecii*.

In many pathogenic bacteria and parasites, resistance to sulfonamides has increased as a consequence of selective pressure and has limited the efficacy of sulfonamides [99]. Widespread use of sulfa drugs for malaria and bacterial infection in Africa has produced high rates of resistance in *P. falciparum* and many bacterial species [100]. In San Francisco, the increasing use of PCP prophylaxis among HIV patients led to a marked increase in trimethoprim-sulfamethoxazole resistance among isolates of *Staphylococcus aureus* and seven genera of *Enterobacteriaceae* [101]. In a retrospective study, trimethoprim-sulfamethoxazole resistance was more than twice as likely in blood culture isolates from HIV patients receiving trimethoprim-sulfamethoxazole compared to patients not receiving this prophylaxis [102].

In pathogens, such as *Escherichia coli*, *Neisseria meningitidis*, *Mycobacterium leprae*, and *Plasmodium falciparum*, sulfonamide resistance is caused by mutations in the primary sequence of the DHPS gene [103–105]. The mutations that confer resistance are localized within a highly conserved active site of the DHPS protein. In *Pneumocystis*, the DHPS protein is part of a trifunctional protein along with dihydroneopterin aldolase and hydroxymethyl dihydropterin pyrophosphokinase, which together are encoded by the multidomain *FAS* gene [106].

In 1997, Lane and co-workers were the first to identify non-synonymous (resulting in changes in the encoded amino acid) DHPS mutations in *Pneumocystis jirovecii* [107]. The most frequent DHPS mutations occur at nucleotide positions 165 and 171, which lead to an amino acid change at positions 55 (Thr to Ala) and 57 (Pro to Ser). The homologous Thr and Pro are highly conserved across species, including *Pneumocystis* infecting other hosts. Thus these variants appear to represent true mutations rather than allelic polymorphisms. The Th55 is homologous to Thr62 of *E. coli* DHPS, which, based on its crystal structure, binds the pterin substrate. It is hypothesized that the Thr55Ala and Pro57Ser affect the position of Arg56 (whose homologue in *E. coli* is involved in binding pterin as well as sulfa drugs), decreasing its ability to bind sulfa drugs and resulting in a consequent reduction in sulfa drug sensitivity [108, 109].

Either mutation can occur alone. However frequently, both mutations are seen in the same isolate. While the association with sulfa exposure is consistent with the concept that these mutations represent resistance that developed under drug pressure, documenting resistance is very difficult, in part because *Pneumocystis* cannot be cultured and in part because functional enzymes (recombinant or native) are not readily available.

Saccharomyces cerevisiae has been used as a model to study *P. jirovecii* DHPS resistance. The DHPS enzyme of *S. cerevisiae* has high functional and genetic similarity to the DHPS of *P. jirovecii*. This enzyme from *Saccharomyces* is also trifunctional. By site-directed mutagenesis, the in vitro effects of mutations identical to the DHPS mutations in *P. jirovecii* can be investigated. Using this model two studies reported that the double DHPS mutations Thr55Ala and Pro57Ser result in an absolute requirement for PABA, consistent with resistance being associated with altered substrate binding [110, 111]. Interestingly, the single mutation Pro57Ser conferred resistance to sulfadoxine, which is supported by clinical observations suggesting a specific association of this mutation with sulfadoxine resistance in PCP [110]. However, one study showed an increase in sensitivity of the double mutations to sulfamethoxazole, suggesting that this approach may not accurately reflect the effect of these mutations in *P. jirovecii*.

Several clinical studies have investigated the frequency and significance of DHPS mutations in *P. jirovecii*. Table 70.3 provides a summary of studies reporting frequencies of mutations in sulfa-exposed and sulfa-unexposed patients. Although the studies vary considerably in size (13–158 patients) and in definitions of sulfa exposure, a clear association between previous exposure to sulfa drugs (primarily for prophylaxis rather than therapy) and DHPS mutations has been shown in most studies. Large geographical variation in the prevalence of DHPS mutations has been reported, ranging from 0 to 100 % of isolates. In the USA, the incidence of mutations was lower in Indianapolis and Denver compared to San Francisco, where one study reported that more than 80 % of patients were infected with mutant strains [112]. Wide variations have also been observed in studies from Europe with a particularly low incidence in Italy: in one study an 8 % frequency of mutations was found among 107

HIV patients with isolates obtained between 1994 and 2001 [113]. Mutations have rarely been found in clinical isolates obtained prior to the early 1990s but seem to have increased in frequency recently presumably as a consequence of increasing selective pressure caused by the widespread use of sulfa drugs for prophylaxis (they were widely used for treatment in the 1980s) of PCP [114–116]. Importantly, DHPS mutations have also been increasingly found in patients without any previous exposure to sulfa drugs, suggesting person-to-person spread of mutant strains.

Based on a genetic analysis of multiple loci, it appears that the mutations arose independently in multiple strains of *Pneumocystis* [117]. In a genotype study of 13 European HIV patients with recurrent episodes of PCP, a switch from wild-type to mutant DHPS occurred in five of seven patients who had a recurrence of the otherwise same molecular type of *P. jirovecii* [118]. All patients had received treatment or secondary prophylaxis with trimethoprim-sulfamethoxazole or dapsone. These findings suggest that DHPS mutants may be selected in vivo (within a given patient) under the pressure of trimethoprim-sulfamethoxazole or dapsone. In addition, recent genotype studies also provide evidence that antibiotic pressure causes changes in DHPS mutant frequency [119]. The emergence of DHPS mutations appears to be specific for *P. jirovecii*, because only wild-type *Pneumocystis* DHPS has been found in other primate species [120].

The clinical significance of DHPS mutations, specifically with regard to response to prophylaxis and therapy using a sulfa-based regimen (primarily trimethoprim-sulfamethoxazole or dapsone), has been controversial. Several studies have reported a significant association of DHPS mutations with failure of low-dose sulfa prophylaxis (Table 70.4). However, the extent to which this association reflects actual drug resistance or failure to comply with prescribed prophylaxis is unknown. Hence, in spite of the emergence of mutant DHPS strains, current clinical experience supports the efficacy of trimethoprim-

Table 70.4 Prevalence of DHPS mutations and association with sulfa exposure

Study	Country (year)	No. of DHPS mutations/no. of PCP episodes	DHPS mutations/ sulfa exposed	DHPS mutations/ no sulfa exposure	Risk ratio (95 %CI)

sulfamethoxazole prophylaxis when taken regularly. However, there is evidence to suggest a contributory role for DHPS mutations in breakthrough PCP in patients using alternative sulfa prophylaxis. Hauser et al. found a significant association with failure of pyrimethamine-sulfadoxine prophylaxis and the Pro57Ser mutation: all 14 patients failing this type of prophylaxis harbored this mutation [124]. Further, relatively high numbers of prophylaxis failures associated with DHPS mutations have been described in patients receiving dapsone prophylaxis. Thus, available data currently suggest that DHPS mutations contribute to low-level sulfa resistance and may be most important in failure of second-line sulfa prophylaxis. However, the major reason for PCP breakthrough continues to be poor adherence to chemoprophylaxis [135].

Studies assessing the impact of DHPS mutations on response to therapeutic, high-dose trimethoprim-sulfamethoxazole have been conflicting, as shown in Fig. 70.2. While initial case reports suggested that patients with mutant DHPS strains had increased risk of failing sulfa therapy or prophylaxis [136], subsequent studies have been more conflicting. A Danish study of 152 patients with AIDS-related PCP found that the presence of DHPS mutations was an independent predictor of decreased 3-month survival, when compared to patients harboring wild-type DHPS [116]. However, several subsequent studies have found no certain evidence for increased mortality when comparing patients with DHPS mutation to wild type [112, 124, 127]. There are several possible reasons for the discrepancy between the studies, including methodological differences in the definitions of survival endpoints or prophylaxis and treatment failures, or other confounding factors related to the difficulties in assessing clinical resistance (see Box 1). Moreover, even in studies reporting an association of DHPS mutations with failure of sulfa therapy, the majority of patients with mutant DHPS strains have been successfully treated with trimethoprim-sulfamethoxazole or dapsone/trimethoprim. These observations suggest that the currently identified DHPS mutations may confer only low-level sulfa resistance, allowing PCP to occur in the setting of prophylactic doses of sulfa drugs, that is overcome by the higher doses used for therapy. Given that *Pneumocystis* has already demonstrated an ability to mutate under antibiotic pressure, a major concern is that additional mutations may develop that produce high-level resistance.

Box 70.1. Limitations to the Study of Drug Resistance in *Pneumocystis*

Compared to other pathogenic fungi, the study of drug resistance in *P. jirovecii* has been and continues to be difficult. In spite of many attempts, there exists no in vitro culture system for propagation of *Pneumocystis*. The absence of a culture system precludes standard susceptibility testing and has greatly limited the understanding of many fundamental aspects of the organism and impeded investigations into mechanisms of drug resistance. Because knowledge of the metabolic pathways is limited, most drug development has been empiric, and the currently available treatment options for PCP have been unchanged during the last 15 years. Experimental systems have mainly relied on immunosuppressed animal, in particular the rat model of *Pneumocystis*.

Another problem is that no consistent definition of clinical failure exists. In other fungal infections, clinical resistance is classically defined as persistence or progression despite the administration of appropriate

(continued)

antimicrobial treatment. However, this definition is problematic when applied to PCP. First, persistence of *Pneumocystis* organisms may happen in spite of a successful treatment response. Studies using repeat bronchoscopy during and immediately after successful treatment of PCP have shown that clearance of organisms is slow, with approximately half of patients still harboring *Pneumocystis* at the end of 3 weeks of treatment in spite of a successful treatment response [137–140]. Although infection is eventually cleared and the viability of organisms detected at end of treatment is uncertain, it is clear that detection of organisms during or at the end of treatment cannot be interpreted as a proxy for resistance. Second, host inflammatory response rather than resistance to antimicrobial drug treatment may cause an apparent absence of response to treatment. PCP is characterized by marked pulmonary inflammation that in severe cases results in alveolar damage and respiratory failure. Although an efficient immune response is required to control the infection, it has also been demonstrated that an excessive inflammatory response, rather than direct effects of *Pneumocystis* organisms, is crucial for the pulmonary injury [141, 142]. Therefore, a severe inflammatory response with respiratory distress, rather than drug resistance, may cause treatment failure. Third, treatment of PCP is associated with a high incidence of adverse effects including fever. In clinical practice it may be difficult to know whether a slow treatment response with continuing fever is caused by the infection or by the treatment. Given the difficulties in defining clinical failure, reported failure rates for primary trimethoprim-sulfamethoxazole treatment in AIDS patients have varied considerably, ranging from 10 to 40 % of cases [53, 76, 78].

In addition, the contribution of non-adherence in presumed failure of prophylaxis may be difficult to assess. The most important reason for prophylaxis failure continues to be non-adherence to prescribed prophylaxis [134, 143, 144]. Clinical resistance has been investigated by genotyping of *P. jirovecii* isolates from patients who develop PCP in spite of prescribed chemoprophylaxis. However, in most studies assessment of adherence to prophylaxis has been based on chart reviews, which may fail to disclose non-adherence to a drug regimen. The likelihood of developing *P. jirovecii* resistance within a patient is likely to be higher with inadequate or interrupted dosing. Hence, in theory resistance mutations could be markers of poor adherence, rather than the direct cause of treatment failure.

8 DHFR Resistance

The diaminopyrimidines, trimethoprim and pyrimethamine, are competitive inhibitors of dihydrofolate reductase (DHFR), which catalyzes the reduction of the biologically inactive7,8-dihydrofolatetotheactive5,6,7,8-tetrahydrofolate in the presence of NADPH and is essential for biosynthesis of purine/pyrimidine nucleotides, thymidylate, and certain amino acids. They are used in combination with sulfonamides.

Interestingly, in animal models trimethoprim does not add any potency to sulfonamides and thus may not be contributing at all to the anti-PCP efficacy of TMP-SMX [145]. The amino acid sequence of DHFR from *P. jirovecii* differs from rat-derived *P. carinii* by 38 %. Ma and Kovacs evaluated the activity of DHFR inhibitors by using a yeast assay expressing *P. jirovecii* DHFR and observed that the human *Pneumocystis*-derived DHFR had a ~tenfold increase in sensitivity to trimetrexate and trimethoprim compared to rat *Pneumocystis*-derived DHFR. For the human *Pneumocystis*-derived DHFR yeast strain, trimethoprim and pyrimethamine were both weak inhibitors, with IC_{50}s in the micromolar range; trimetrexate was about tenfold and 40-fold more potent than trimethoprim and pyrimethamine, respectively (Table 70.5). Given that trimetrexate is much more potent against PCP than trimethoprim in vitro, the combination of trimetrexate and sulfamethoxazole may be a more potent combination than trimethoprim plus sulfamethoxazole. However, there are currently no clinical data to support this, and as noted above, trimetrexate is no longer commercially available.

In several bacterial and parasitic species, resistance to DHFR inhibitors has emerged as a consequence of selective pressure by DHFR inhibitors. In this way, resistance of *P. falciparum* and *P. vivax* to pyrimethamine has emerged and is now widespread [147]. However, despite the widespread use of trimethoprim in combination with sulfamethoxazole for prevention and treatment of PCP, only relatively few DHFR mutations have been identified in *Pneumocystis* DHFR [121, 148–150]. Ma et al. detected only a single synonymous DHFR mutation in specimens obtained from 32 patients, of whom 22 had previous exposure to TMP-SMX therapy or prophylaxis [121]. Takahashi et al. found four mutations in *P. jirovecii* DHFR from 27 patients,

Table 70.5 50 % inhibitory concentrations (IC_{50}) of DHFR inhibitors from a yeast complementation assay [146]

	IC_{50} (nM)	
DHFR inhibitor	Human-derived *P. jirovecii* DHFR	Rat-derived *P. carinii* DHFR
Trimethoprim	5700	81,000
Pyrimethamine	20,500	33,200
Trimetrexate	490	4200

of whom only three had previous exposure to TMP-SMX [148]. Two of these mutations were non-synonymous and were not associated with prior exposure to TMP-SMX. In both studies patients were successfully treated with TMP-SMZ. Nahimana et al. documented non-synonymous substitutions in 9 of 15 patients receiving a DHFR inhibitor as part of their prophylactic regimen compared to 2 of 18 not receiving a DHFR inhibitor [149]. Interestingly, 5 of 7 patients receiving pyrimethamine had non-synonymous substitutions, suggesting a greater selective pressure of this drug. A South African study found non-synonymous DHFR mutations in samples obtained between 2001 and 2003 in 3 of 27 patients. None had long-term exposure to TMP-SMX before developing PCP [130]. Finally, Matos and co-workers from Portugal reported a 27 % rate of DHFR mutations in 128 PCP episodes, without associated failure of PCP prophylaxis [151].

In conclusion, although several studies have reported DHFR mutations, there is so far no evidence that the widespread use of trimethoprim or pyrimethamine has caused emergence of clinical significant resistance to DHFR inhibitors.

8.1 Atovaquone

Atovaquone (2-[*trans*-4-(4′-chlorphenyl)cyclohexyl]-3-hydroxy-1,4-hydroxynaphthoquinone) is used to prevent and treat disease caused by *P. jirovecii*, *Plasmodium* spp., *Toxoplasma gondii*, and *Babesia* spp. [152]. Atovaquone is structurally similar to the mitochondrial protein ubiquinone (coenzyme Q) and competitively binds to the cytochrome bc_1 complex. The bc_1 complex catalyzes electron transfer from ubiquinone to cytochrome c and thereby proton translocation across the mitochondrial membrane resulting in the generation of ATP. Binding of atovaquone to the ubiquinol oxidation pocket of the bc_1 complex and the Rieske iron-sulfur protein disrupts electron transport and leads to collapse of the mitochondrial membrane potential [153]. Eventually, this presumably results in depletion of ATP within *Pneumocystis* and leads to killing of the organism [154]. Mutations of the cytochrome b gene have been identified in *Plasmodium* spp., *Toxoplasma gondii*, and *Pneumocystis*. In vitro studies of *Plasmodium* and *Toxoplasma* show that these mutations confer resistance to atovaquone. Because *Pneumocystis* cannot be propagated in vitro, similar susceptibility testing cannot be done. In vitro studies of the *Saccharomyces cerevisiae* cytochrome bc_1 complex and atovaquone have demonstrated binding to the ubiquinol pocket. Introduction of mutations near the binding pocket led to decreased activity of atovaquone [153]. Introduction of seven mutations observed in isolates of *Pneumocystis* from atovaquone-experienced patients into *S. cerevisiae* cytochrome b increased the inhibitory concentration from 25 to >500 nM [155, 156].

Results from two clinical studies have been published. In the first, sequencing of the cytochrome b gene of *Pneumocystis* from ten patients showed sequence variations in four patients [157]. Three of four patients receiving atovaquone as prophylaxis demonstrated such variations. Notably, two of them had non-synonymous changes leading to amino acid substitutions within the ubiquinol pocket. Similar mutations in other microorganisms are associated with resistance to atovaquone. One patient who had not received atovaquone prophylaxis had a synonymous change that did not confer any change in amino acid sequence. In the second study, a nested case-control study, significantly more patients who previously had been exposed to atovaquone (5 of 15 patients) had mutations than unexposed patients (3 of 45) [158]. Five different mutations near the ubiquinol pocket were described bringing the total number to seven. The high number of mutations is unusual but may be explained by a higher mutational rate and impaired proof-reading of mitochondrial genes. Survival from PCP did not differ between patients with or without mutations. Overall, these findings are consistent with the development of atovaquone resistance after selective pressure is exerted.

8.2 Pentamidine and Clindamycin-Primaquine

Pentamidine and clindamycin/primaquine are used for prevention and treatment of PCP, but possible resistance mechanisms have yet to be discovered and reported.

9 Conclusion

In spite of the inability to culture the organisms, it is now clear that mutations involved in sulfa and atovaquone drug resistance have emerged in *P. jirovecii* as a result of selective pressure by the widespread use of PCP prophylaxis. Currently the clinical effect of the described mutations seems modest. DHPS mutations at codon 55 and 57 are implicated in failure of low-dose sulfa prophylaxis, but there is so far no firm evidence that DHPS mutations result in significant resistance to high-dose sulfa therapy. However, it is possible that if additional mutations arise, then high-level sulfa resistance could emerge and lead to diminished efficacy of TMP-SMX. This would lead to the loss of the most efficient and inexpensive therapy for PCP.

The increasing HIV epidemic and use of TMP-SMX in the third world may significantly increase the risk for development of high-level resistance [129]. Therefore, investigations into the mechanisms of drug resistance and

identification of new molecular targets are continuing. The recent sequencing of the genomes of *Pneumocystis* species, especially *P. jirovecii*, has increased our understanding of the biology of the organism and it's metabolic requirements, and has identified a number of new pathways that appear critical to growth and survival of the organism, which thus are potential new targets for drug development. Better understanding of the organism's biology may eventually also lead to the development of a functional culture system [7, 159].

Part X

Viral Drug Resistance: Clinical

Antiviral Resistance in Influenza Viruses: Clinical and Epidemiological Aspects

71

Erhard van der Vries and Michael G. Ison

1 Introduction

There are three classes of antiviral drugs approved for the treatment of influenza: the M2 ion channel inhibitors (amantadine, rimantadine), the neuraminidase (NA) inhibitors (laninamivir, oseltamivir, peramivir, zanamivir), and the protease inhibitor (favipiravir); some of the agents are only available in selected countries [1, 2]. These agents are effective at treating the signs and symptoms of influenza in patients infected with susceptible viruses. Clinical failure has been demonstrated in patients infected with viruses with primary resistance, i.e., antivirals can be present in the virus initially infecting the patient, or resistance may emerge during the course of therapy [3–5]. NA inhibitors are active against all nine NA subtypes recognized in nature [6], including highly pathogenic avian influenza A/H5N1 and recent low-pathogenic avian influenza A/H7N9 viruses [7]. Since seasonal influenza is usually an acute, self-limited illness in which viral clearance usually occurs rapidly due to innate and adaptive host immune responses, the emergence of drug-resistant variants would be anticipated to have limited effect on clinical recovery in otherwise healthy patients, as has been demonstrated clinically [3, 8, 9]. Unfortunately, immunocompromised or immunologically naïve hosts, such as young children and infants or those exposed to novel strains, are more likely to have mutations that confer resistance emergence during therapy; such resistant variants may also result in clinically significant adverse outcomes [10–13].

Factors that influence the clinical and epidemiologic importance of drug-resistant influenza viruses include the magnitude of phenotypic resistance, its frequency and rapidity of emergence, its stability and ability of resistant variants to compete with wild-type virus in the absence of selective drug pressure, and the effects of resistance mutations on viral replication competence, pathogenicity, and transmissibility in vivo. Prior to being replaced by the pandemic 2009 A/H1N1 virus, most circulating seasonal A/H1N1 viruses in the 2008–2009 season contained the His275Tyr mutation and were therefore highly resistant to oseltamivir while retaining susceptibility to zanamivir. All currently circulating A/H1N1 and A/H3N2 viruses have mutations conferring M2 inhibitor resistance. There is no data to date indicating that M2 inhibitor resistance is associated with worsened viral virulence, atypical influenza, or enhanced transmissibility. Sporadic viruses with primary resistance mutations resulting in neuraminidase inhibitor resistance have been described. Most but not all NA mutations conferring resistance in clinical isolates have been associated with reduced infectivity, replication, and pathogenicity in animal models of influenza. Such features are important not only in clinical management of individual patients but also are key factors that need to be considered by health authorities and governments when making decisions regarding the stockpiling of antivirals for response to pandemics or other influenza threats [14, 15]. Concerns about antiviral resistance, particularly to NA inhibitors, should not dissuade countries from developing adequate antiviral inventories for pandemic response [14, 16].

The frequency of resistance emergence during therapy is higher with M2 inhibitors than NA inhibitors. Development of resistance during the course of therapy was very common among initially M2 inhibitor-susceptible viruses in the past. Mutations in one of five amino acids in the M2 gene result in cross-resistance to both amantadine and rimantadine. Resistance emergence during therapy with neuraminidase inhibitors generally remains rare for circulating strains of A/H1N1, A/H3N2, and B viruses, with higher rates in children

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_23

and immunocompromised patients. A common feature of patients who develop resistance despite ongoing therapy is high-level replication and longer duration of replication in the presence of antiviral therapy. Resistance to neuraminidase inhibitors results from mutations in the neuraminidase gene, the hemagglutinin gene, or both. The specific mutation determines the degree of resistance and which neuraminidase inhibitor has reduced susceptibility. Further, the frequency and magnitude of NA inhibitor resistance vary with drug, virus, and neuraminidase type and subtype. Resistance has been demonstrated to develop during the course of therapy with avian viruses, particularly A/H7N9, with greater frequency than seasonal human viruses. Compensatory mutations may also occur that improve the fitness and transmissibility of resistant viruses and may play a role in establishing persistent transmission, as was demonstrated with the seasonal A/H1N1 during the 2007–2008 and 2008–2009 seasons.

Several new classes of antivirals, many with novel mechanisms of action, are currently undergoing development. Resistance mutations have been identified for many of these agents from in vitro passage experiments, but clinical evidence of resistance emergence is still in its infancy. The following sections review clinical and epidemiological data on antiviral resistance for the three classes of available anti-influenza agents. Information from experimental animal models of influenza is incorporated to supplement the limited data derived from clinical studies.

2 M2 Ion Channel Inhibitors (Amantadine, Rimantadine)

The M2 ion channel allows the influx of protons into the viral particle which, in turn, facilitates uncoating [17]. M2 inhibitors bind to the M2 ion channel and limit the influx of protons resulting in its antiviral effect. Since the M2 protein is present only on influenza A viruses, M2 inhibitors have no activity against influenza B [17]. There are currently two approved M2 ion channel inhibitors, amantadine and rimantadine. Early studies demonstrated that influenza variants with high-level resistance to amantadine and rimantadine could be selected in the laboratory though in vitro and in vivo passage in virus in the presence of the drug [3, 18]. Studies of resistance helped to determine the mechanism of antiviral action of the M2 inhibitors [19].

Mutations in the M2 inhibitor gene at one of five commonly recognized sites (position 26, 27, 30, 31, or 34 of the M2 protein) in human viruses result in reduced binding of the M2 inhibitors or in enlargement of the pore diameter. The function of the M2 pore of viruses with any of the mutations is preserved in the presence of the inhibitor [3, 20, 21]. Resistance mutations do not affect transmissibility or replication fitness as compared to wild-type viruses; documented transmission from person-to-person has been well established [22]. Resistance affects both drugs in the class equally and appears to be persistent over time [3].

During routine treatment with M2 inhibitors for documented influenza, resistant variants emerge frequently. The clinical implications of resistance became apparent in studies during the 1980s of treated children, in whom a high frequency of resistance emergence was documented, and subsequently of households and nursing homes, where transmission of drug-resistant variants was implicated in failures of drug prophylaxis [23–26]. About 30 % of adults treated with M2 inhibitors will have resistant variants detected during the course of their illness with high frequency (up to 80 %) of resistance emergence in immunocompromised patients, patients hospitalized for influenza, and children [8, 23, 25, 27, 28]. Until recently, the frequency of M2 inhibitor resistance among seasonal isolated was low (1–3 %) [29]. Since 2002, though, the prevalence of resistance to M2 inhibitors among circulating influenza A/H3N2 increased globally, and now the majority of A/H3N2 globally is resistant to this class of drugs [29, 30]. Resistance has resulted from the S31N substitution of the M2 inhibitor. M2 inhibitor resistance has also been documented in several important novel strains of influenza: A/H5N1, A/H7N9, and 2009 pandemic A/H1N1 virus [31–36]. Most clade 1 A/H5N1 viruses and all swine-origin A/H1N1 are resistant to the M2 inhibitors as a result of the S31N substitution, while most (~80 %) of clade 2.1 A/H5N1 are resistant secondary to S31N or V27A substitution [31, 32, 37]. Of note, most of the clade 2.2 and 2.3 A/H5N1 viruses remain susceptible to M2 inhibitors [37]. Since most circulating strains of influenza are currently resistant to the M2 inhibitors, this class is not recommended for the prevention or treatment of influenza currently [2].

2.1 Detection of Resistance

There are currently no rapid tests that can screen for and identify the presence of M2 inhibitor resistance. M2 resistance may be diagnosed using phenotypic assays or gene sequencing. Most phenotypic assays, including plaque reduction, yield reduction, and ELISA, utilize the growth of virus in cell culture exposed to a range of concentrations of the drug of interest; these assays are not widely available. Pyrosequencing methods for rapid analysis of mutations in the M2 gene associated with resistance have been described and are used in several reference laboratories [21, 38]. Neither assay is typically available in most clinical labs. As a result, most clinicians rely on data generated from groups

actively monitoring the resistance among circulating strain—in the United States this is actively done by the Centers for Diseases Control and Prevention (http://www.cdc.gov/flu/professionals/antivirals/antiviral-drug-resistance.htm).

Detection of M2 inhibitor resistance has usually relied on virus isolation from respiratory samples and susceptibility testing of virus in cell culture. Several assays have been described including plaque reduction, yield reduction, and ELISA [39]. Following phenotypic analysis, genotypic M2 inhibitor resistance has been confirmed by nucleotide sequence analysis of the M2 gene and detection of the characteristic mutations. Genotypic detection can be accomplished quickly by the use of PCR restriction length polymorphism (RFLP) analysis of RNA extracted from respiratory samples using commercially available endonucleases for discrimination of point mutations in the M2 gene [38, 40]. Greater sensitivity in detecting resistant clones has been described with reverse transcription-polymerase chain reaction amplification of RNA followed by sequencing of multiple clones [4, 38, 41]. Recently, the rapid pyrosequencing technique has been shown to be a reliable, high-throughput method for detecting genotypic resistance in large numbers of community isolates [4, 29, 38].

2.2 Susceptibility of Field Isolates

Historically, human isolates of influenza A/H1N1, A/H2N2, and A/H3N2 were initially susceptible to amantadine and rimantadine [19, 24, 39, 42]. Even after licensure of the M2 inhibitors, there were low levels of primary resistance in community isolates (see Table 71.1). This began to change when field isolates of A/H3N2 viruses from China were noted to have a significant increase in the resistance to the M2 inhibitors, possibly related to increased use of over-the-counter amantadine after the emergence of severe acute respiratory syndrome (SARS) [38]. During the 2004–2005 influenza season, approximately 70 % of the A/H3N2 isolates from China and Hong Kong and nearly 15 % of those from the United States and Europe showed resistance due to a Ser31Asn mutation, and this frequency increased to over 90 % in the United States during the 2005–2006 season [29, 38]. Since then, most clinical isolates of A/H3N2 were noted to have Ser31Asn mutations in the M gene conferring resistance to M2 inhibitors (Table 71.1). This spread occurred despite the absence of sustained selective drug pressure, possibly because the resistant M gene was incorporated into efficiently spreading HA antigenic variants. Phylogenetic

[a]All resistant viruses from family members receiving rimantadine

[b]Over 80 % of tested isolates were H3N2 subtype and all resistant ones were of this subtype. Separate analysis found that 9 (4.5 %) of 198 strains from Australia, 1989–1995, were resistant

[c]In 2004–2005 the frequencies of resistance in H3N2 viruses were 73.8 % in China, 69.6 % in Hong Kong, 22.7 % in Taiwan, 15.1 % in South Korea, 4.3 % in Japan, 30.0 % in Canada, 19.2 % in Mexico, 14.5 % in United States, and 4.7 % in Europe

analyses of the HA1 and M2 genes have suggested a common origin of these viruses [43]. This experience clearly indicates that this resistance mutation does not reduce transmissibility and is stable over time.

The frequency of resistance in seasonal A/H1N1 viruses increased from 2005 to 2007, primarily due to the Ser31Asn mutation [29, 30]. Fortunately, the incidence of primary resistance declined in 2008 and 2009 among seasonal A/H1N1 viruses as oseltamivir-resistant viruses predominated [44]. This seasonal A/H1N1 virus, which was replaced by the 2009 pandemic A/H1N1 virus, was primarily resistant to the M2 inhibitors generally due to the Ser31Asn mutation [44]. As a result, all currently circulating strains of influenza A are primarily resistant to the M2 inhibitors, and this class of drug is not recommended for the prevention or treatment of influenza [2].

M2 proteins show considerable evolution in human and swine viruses, and the H3 and H1 subtype viruses have phylogenetically different M2 proteins [45]. This may influence the mutations that are more advantageous for conferring M2 inhibitor resistance. A characteristic feature of A/H1N1, A/H1N2, and A/H3N2 swine viruses circulating in Europe since 1987 has been the presence of Ser31Asn mutation, as well as Lys27Ala in some isolates, that confers resistance to M2 inhibitors [46]. The postulated role of swine as intermediate hosts in the emergence of some novel human viruses and direct interspecies transmission from birds may be another mechanisms for a reassortment event leading to acquisition of an M gene encoding resistance in a human strain [47, 48].

Although the initial human isolates of highly pathogenic avian A/H5N1 viruses in Hong Kong in 1997 were M2 inhibitor susceptible, resistance to this class of drugs has become more prevalent [32, 37]. Most clade 1 A/H5N1 viruses are resistant to the M2 inhibitors as a result of the Ser31Asn substitution, while most (~80 %) of clade 2.1 A/H5N1 are resistant secondary to Ser31Asn or Val27Ala substitution [32, 37]. Of note, most of the clade 2.2 and 2.3 A/H5N1 viruses remain susceptible to M2 inhibitors [37]. Isolates of A/H7N9 infected humans have also had the Ser31Asn mutation conferring resistance to the M2 inhibitors [49, 50].

2.3 Resistance in Posttreatment Isolates

Studies in experimentally infected animals and treated humans have documented the common emergence of resistant variants as the course of infection progresses over time. Following treatment, approximately 70–90 % of amino acid substitutions in resistant viruses occur at position 31, and about 10 % each are found at positions 27 and 30 [40]. The Ser31Asn mutation has been responsible for the resistant A/H3N2 and A/H1N1 variants recently identified globally [29, 38].

2.3.1 Animal Studies

The rapid emergence of resistant variants in M2 inhibitor-treated patients has been found also in studies of experimentally infected animals. In a study of a chicken A/H5N2 virus, resistant viruses are detectable by 2–3 days after starting drug administration and persisted thereafter [51]. A study in ferrets inoculated with a human influenza A/H3N2 virus detected M2 inhibitor resistance mutations in four of nine amantadine-treated animals by day 6 after inoculation; in each instance two or more M2 gene mutations were identified [52].

2.3.2 Immunocompetent Patients

Resistant variants arise commonly and rapidly in M2 inhibitor-treated children and adults with acute influenza (Table 71.2). One study of adults found that resistant virus could be detected in 50 % of six rimantadine recipients by day 3 of treatment, although the nasal lavage titers were lower than in placebo recipients shedding susceptible virus [27]. Another study found that 33 % of 24 adult and pediatric household members receiving rimantadine shed resistant virus on day 5 of treatment; none were positive when tested 5 days later [27]. A larger pediatric trial found emergence of resistant virus in 27 % of 37 rimantadine recipients, including 45 % of those still virus positive on day 7, compared to 6 % of 32 acetaminophen recipients [23]. Resistant virus was detected as early as day 3 in one child but was usually present on days 5–7. A study of Japanese children treated with amantadine found that 30 % of 81 in the 1999–2000 season and 23 % of 30 during the following season had resistant virus detected on day 3–5 after a 3-day course [53]. Resistant

Table 71.2 Recovery of resistant influenza A during M2 inhibitor treatment

Study	Seasons	Patient group	Treatment	No. treated	No. (%) shedding resistant viruses
Hall et al. [23]		Children	Rimantadine	37	10 (27 %) H3N2
Hayden et al. [25]	1987–1989	Children	Rimantadine	21	6 (29 %) H3N2

Englund et al. [28]	1993–1994	Immunocompromised	Amantadine, rimantadine	15	5 (33 %) H3N2
Saito et al. [53]	1999–2001	Children	Amantadine	111	22 (33 %) H3N2
					9 (20 %) H1N1
Shirashi et al. [41]	1999–2001	Children (hospitalized)	Amantadine	15	8 (100 %) H3N2
					4 (57 %) H1N1

variants were detected more frequently in A/H3N2-infected children (33 %) than in A/H1N1-infected children (20 %). Another study employing sensitive molecular cloning detection methods found mutations conferring resistance in 80 % of 15 hospitalized children during or immediately after amantadine treatment [41]. Nine (75 %) of 12 children had 2–4 resistance mutations detected in clones from a single sample, sometimes mixed with wild-type virus. In a randomized study patients hospitalized with influenza were to receive either rimantadine alone or rimantadine plus nebulized zanamivir [54]. Rimantadine-resistant virus was detected in 2/20 (10 %) of rimantadine monotherapy patients, while non-resistant variants were detected in the 21 patients receiving combination therapy [54].

2.3.3 Immunocompromised Hosts

Resistant influenza A viruses may be shed for prolonged periods in immunocompromised hosts, who can serve as a reservoir for nosocomial transmission. One study of adult bone marrow transplant and acute leukemia patients recovered resistant virus in 5 (33 %) of 15 M2 inhibitor-treated patients and in 5 (83 %) of 6 patients with illness who shed virus for ≥3 days [28]. The median time between the first and last virus isolation was 7 days with range up to 44 days. Death associated with influenza occurred in 2 of 5 (40 %) patients with resistant virus, compared to 5 of 24 (21 %) without, and prolonged illness was noted in several with protracted shedding. Other reports have documented prolonged shedding of resistant variants in immunocompromised hosts with or without continued drug exposure, including one transplanted SCID child who shed for 5 weeks and one adult leukemia patient who shed resistant virus for ≥1 week of therapy [55]. Another case report documented recovery of resistant virus >1 month after cessation of a course of amantadine, as well as shedding of mixtures of wild-type virus and variants with different resistance genotypes [56]. Heterogeneous populations of resistant variants with sequential or dual mutations have been found in several immunocompromised hosts [28, 55]. One stem cell transplant recipient shed dually M2 inhibitor and oseltamivir-resistant virus for at least 5 months and probably over 1 year [57]. The prolonged shedding of resistant variants in immunocompromised hosts is consistent with the genetic stability of such variants observed in experimental animal models [51].

2.4 Transmissibility of Resistant Variants

The transmissibility of M2 inhibitor-resistant viruses has been demonstrated in animal models and in several clinical settings. Competition-transmission studies with an avian A/chicken/Pennsylvania/1370/83 A/H5N2 virus compared the transmissibility of wild-type virus with resistant variants possessing M2 substitutions at positions 27, 30, or 31 [51]. Contact birds shedding resistant virus due to earlier incorporation of amantadine in the drinking water of donors (4 days only) were caged with birds shedding susceptible virus, and the virus was allowed to transmit through three more sets of contact birds in the absence of selective drug pressure. Resistant virus was detected from the final set of contact birds in three of four experiments over four cumulative transmission cycles.

2.4.1 Households

Both amantadine and rimantadine are effective for postexposure prophylaxis of illness due to susceptible strains in household contacts, when ill index cases are not given concurrent treatment (Table 71.3). In contrast, two studies have found no significant reduction in secondary influenza illness in household contacts receiving either amantadine or rimantadine for postexposure prophylaxis, when the ill index cases received treatment with the same drug, and one of these documented failures of prophylaxis due to infection by drug-resistant variants, most likely transmitted from the treated index cases [25]. These findings indicate that the strategy of using M2 inhibitors for both index case treatment and postexposure prophylaxis in households should be avoided.

Table 71.3 Influenza prevention in households with postexposure prophylaxis (PEP)

Study	Drug (age of contacts)	Season (virus)	Index case treated	Influenza A illness in contacts No./total evaluable (%)		PEP efficacy (%)
				Active	Control

[a]Clinical influenza

2.4.2 Chronic Care Facilities

Transmission of M2 inhibitor-resistant viruses is well documented in nursing home outbreaks of influenza A and may be manifested by a persistent or an increasing number of virus-positive patients despite amantadine prophylaxis. The recovery of the same genotype of resistant virus from multiple patients on prophylaxis or from patients or staff not receiving drug indicates ongoing transmission in this setting [26, 58]. This particularly true with multiple isolations of a less commonly observed resistant variant, as was found with nine isolates of a Leu26Phe variant in one nursing home outbreak [58]. The frequency of instances in which amantadine or rimantadine has failed to control outbreaks because of resistance emergence is not well defined, although existing studies demonstrate a range of protective efficacy from 59 to 76 % [59]. Studies have demonstrated patients who developed infections with resistant viruses, typically with the Ser31Asn mutation, in 16–28 % of residents' long-term care where M2 inhibitors were used during an outbreak [40, 60]. Such findings emphasize the importance of proper isolation of treated persons and of using NA inhibitors for treatment of ill persons.

2.5 Pathogenicity

M2 inhibitor-resistant influenza A viruses appear to cause typical influenza illness without obviously enhanced or attenuated symptoms [25, 27]. Illness occurs in both the presence and absence of the drug, a finding that indicates the loss of antiviral effectiveness in vivo. Although severe and progressive infection with resistant virus has been noted in immunocompromised and debilitated elderly patients, this is likely more of a marker of the patients underlying condition than virulence of the resistant virus [57, 61]. In most patients, M2 inhibitor-resistant virus has similar risks of pneumonia, hospitalization, or death compared to those with wild-type illness [39].

While the M gene mutations do not appear to attenuate or potentiate the virulence of human influenza viruses, more subtle effects on biologic fitness cannot be excluded by studies to date. In occasional patients wild-type virus replaces resistant variants after cessation of amantadine [41]. As noted for some avian A/H7 viruses, this reversion in the absence of selective drug pressure suggests diminished replication competence of some resistant genotypes. However, the most common resistant variant with Ser31Asn has no apparent loss of replication competence or transmissibility. In studies in birds and ferrets, influenza viruses with Val27Ala, Ala30Val, or Ser31Asn mutations had no impact of virulence, mortality, febrile responses, peak nasal viral titers, or nasal inflammatory cell counts [22, 51]. In general, it appears that M2 inhibitor-resistant human influenza A viruses that emerge in vivo do not differ substantially in replication ability or pathogenicity from drug-susceptible wild-type viruses, and resistance phenotypes were typically retained in the absence of drug.

In treated patients the emergence of resistant virus may be associated with persistence of viral recovery and in some studies delays in resolution of illness in immunocompetent persons. Although patients who had resistance emergence during the course of therapy had a somewhat longer time to resolution of symptoms, fever, and possibly functional impairment, they still had a more rapid recovery than placebo-treated patients [23, 27]. Patients may have worsening symptoms or viral titers when resistance emerges as well [23].

2.6 Treatment Alternatives

Amantadine and rimantadine share susceptibility and resistance, so that resistance to one M2 inhibitor confers high-level cross-resistance to another one and the entire class of compounds targeting M2 protein. Because of their different mechanism of antiviral action, neuraminidase inhibitors and protease inhibitors (discussed below) retain full activity against M2 inhibitor-resistant viruses and are appropriate choices for both prophylaxis and treatment of suspected M2 inhibitor-resistant infections. Clinical studies suggest that both oseltamivir and zanamivir are successful in terminating institutional outbreaks where amantadine resistance is proven or highly probable [58, 62, 63]. In vitro testing suggests that the synthetic nucleosides ribavirin and favipiravir are also inhibitory for M2 inhibitor-resistant influenza A and B viruses and are a therapeutic consideration [64].

Combination therapy may also be an option. A small study randomized hospitalized adults to rimantadine monotherapy or rimantadine-nebulized zanamivir combination therapy. The combination arm had a trend to less cough and fewer patients with detection of M2 inhibitor resistance mutations over the course of therapy [54]. Recently, a triple combination of amantadine, oseltamivir, and ribavirin has been studied in vitro, in vivo, and in infected patient and appears effective at inhibiting viral replication in vitro and improved outcomes in vivo [65, 66].

3 Neuraminidase Inhibitors

The initial design of the NA inhibitors was accelerated after solving X-ray structures of NA co-crystallized with the chemical compound *2,3-dehydro-2-deoxy-N--acetylneuraminic acid* (DANA) [67, 68]. This transition state

analogue of the NA substrate sialic acid has served as the scaffold for the NA inhibitor derivatives [69]. In vitro studies to determine the genetic antiviral resistance profiles of the NA inhibitors zanamivir and oseltamivir were initiated shortly after their development (reviewed in [70, 71]. Due to differences in drug binding interactions and structural differences in the enzyme active site, NA inhibitors show varying antiviral resistance profiles in NA that depend on virus type and subtype (reviewed in [72–74]). Sequential passage in cell culture to select resistant variants found that changes in HA could confer resistance in vitro also [75–77]. These HA changes are predominately found at the receptor binding site and thought to restore the functional balance between HA receptor-binding and NA receptor-destroying properties [78]. Mechanisms which influence the viral HA/NA functional balance may have played a role in the emergence of oseltamivir-resistant A/H1N1 viruses during the 2007–2008 season [79–82]. The frequency and possible importance of resistance emergence during drug administration have been studied largely in the context of controlled clinical trials conducted in the late 1990s that served as the basis for approval of zanamivir and oseltamivir in 1999 and, more recently, for approval of laninamivir and peramivir [83–87]. Although zanamivir and oseltamivir have been available in many countries since 1999, their use has been quite limited, except in Japan and during the 2009 influenza A/H1N1 pandemic [88]. Clinical importance of antiviral resistance emergence was assessed when comparing clinical outcome of oseltamivir-treated patients infected with a susceptible or oseltamivir-resistant A/H1N1 virus during the 2007–2008 influenza season [89–93]. A retrospective clinical study by Dharan et al. showed that patients infected with an oseltamivir-susceptible virus ($n=182$) had significantly fewer days of fever if treated with oseltamivir ($n=64$) as compared to non-treated patients ($n=93$;$P=0.02$). In contrast, patients infected with an oseltamivir-resistant viruses ($n=44$) did not benefit from oseltamivir treatment ($n=43$; $P=0.5$) [91]. Similar finding was reported in a study by Saito et al. where a reduction of fever on days 3–6 was reported in treated oseltamivir-susceptible A/H1N1-infected patients ($P<0.01$), but not in the patients infected with the oseltamivir-resistant A/H1N1 virus strain [93]. This oseltamivir-resistant A/H1N1 virus variant with an NA H275Y amino acid change emerged first in Norway during the 2007–2008 season and was able to spread rapidly in humans [94, 95]. As it became the dominant variant, it was suggested that the oseltamivir-resistant virus was able to spread more easily in the population than wild type [79, 96]. This was unexpected, as both in vitro and in vivo animal studies had claimed reduced virulence and transmissibility of NA inhibitor-resistant viruses before the beginning of 2007–2008 influenza season [97–99].

3.1 Detection of NA Inhibitor Resistance

Unlike the situation for M2 inhibitors, cell culture-based assays have not been validated for detecting phenotypic resistance in clinical isolates, partly because of the differences in cellular receptor specificity between human respiratory epithelium and available cell culture types (reviewed in [71]). In addition, these types of assays are labor intense and require an additional virus titration step, which make these assays unfavorable for high-throughput surveillance. Humanized Madin-Darby canine kidney (MDCK) cell lines that stably overexpress human 2,6-sialyltransferase (SIAT1) to increase alpha 2,6-linked sialic acids may overcome this first limitation. However, these cells have not been widely utilized to date [100, 101]. Other challenges are the broad variation in morphology of influenza plaques between different influenza types and subtypes and the reduced sensitivity of yield reduction assays. The NA enzyme inhibition phenotypic assays have, therefore, been the preferred assay to screen for clinically relevant NA inhibitor resistance mutations in influenza antiviral resistance surveillance [5, 102, 103]. Both fluorometric (MUNANA) and chemiluminescent (NA-star) type of phenotypic assays are available. Both assays have the same limitations, such as the necessity of a virus propagation step, and may therefore not reliably detect resistant subpopulations and do not detect HA-mediated NA inhibitor resistance [104]. To standardize interpretation and reporting of NA inhibitor susceptibility of influenza viruses, clear definitions were formulated in 2012 using 50 % inhibitory concentration (IC_{50}; the concentration of drug required to inhibit a standardized amount of NA activity by 50 %) fold-change thresholds, compared to the median for viruses from the same type/subtype/lineage showing "normal inhibition" [105, 106].

Besides the phenotypic resistance assay, numerous genotypic PCR-based resistance assays have been developed for detection of previously identified antiviral resistance mutations in NA [107–110]. As compared to the phenotypic assays, these types of assays are rapid and easy to perform, and they allow minor variant detection (~1–5 % of the quasispecies) with no requirement of an additional virus culture step. Unknown resistance patterns in newly emerging influenza subtypes or novel NA inhibitors cannot be identified using PCR-based resistance assays.

The typical NA mutations conferring resistance depends on the drug and NA subtype [72, 74, 111, 112]. For oseltamivir, His274Tyr (based on N2 numbering) confers resistance in N1 [113], whereas Arg292Lys and Glu119Val are the most common antiviral resistance mutations in N2-containing viruses (Table 71.4). Because of the differences in interaction among drugs with the active enzyme site, varying patterns of cross-resistance are found for particular NA mutations.

Table 71.4 Effects of NA mutations that confer oseltamivir resistance on viral fitness measures in clinical isolates of influenza

Virus (ref)	Mutation	Enzyme activity or stability (% of parental virus)	Infectivity in mice/ ferret	Replication in ferret	Transmissibility in ferret

[a]Days of fever in ferrets exposed to the parental A/H3N2 virus was greater than in ferrets exposed to the E119V mutant virus (⩾2 days vs. 1 day, respectively; P > .05).

Importantly, zanamivir and laninamivir retain full inhibitory activity against variants with either the His274Tyr or Glu119Val mutation and partial activity against the Arg292Lys variant [114]. Viruses with a His274Tyr are also cross-resistant to peramivir. Antiviral resistance may be caused by a single resistance mutation or a combination of additional mutations, which may enhance the level resistance and/or causes multidrug resistance [115–117].

HA binding efficiency and associated susceptibility to NA inhibitors are affected by amino acid changes in the receptor binding [112]. Consequently, HA mutations have been looked for in clinical isolates usually by comparing the sequence of pre- and post-therapy isolates and in some instances by examining changes in receptor affinity [10, 11]. HA variants that have reduced receptor affinity show cross-resistance in vitro to all NA inhibitors but in general retain susceptibility to NA inhibitors in vitro and in animal models [118–120].

3.2 Drug Susceptibility of Circulating Viruses

With the exception of the influenza seasons between 2007 and 2009 when the oseltamivir-resistant A/H1N1 viruses were circulating, the global incidence of circulating A and B viruses with de novo resistance to the NA inhibitors has been very low since the approval of these drugs (Table 71.5) [9, 103, 106, 121]. A recent study in which 10,641 viruses were collected globally in 2013–2014 by collaborating National Influenza Centers to determine IC_{50} data for NA inhibitors oseltamivir, zanamivir, peramivir, and laninamivir 172 viruses (1.6 %) showed highly reduced inhibition (>100-fold) against at least one of the four drugs and 32 viruses (0.3 %) with only reduced inhibition (between 10- and 100-fold reduction) [106]. Most of these highly resistant isolates were 2009 pandemic influenza A/H1N1 viruses with a His274Tyr amino acid change ($n = 169$). Only a single resistant A/H3N2 virus was detected, which carried a Glu119Val amino acid change. Two influenza B viruses with and Glu119Gly (B/Victoria) and His273Tyr (B/Yamagata) were detected. In a recent global observational multicenter clinical trial (IRIS) with follow-up sampling of influenza-infected patients after admission to a clinic (2009–2013; $n = 1799$), no genotypic resistance was detected at baseline in respiratory specimens of influenza A or B virus-infected patients apart from the A/H1N1 viruses with an inherited His275Tyr amino acid change [103]. In 19 of 1014 patients (1.9 %) receiving an antiviral, emergence of resistance to oseltamivir could be detected during treatment, in most cases children below the age of 5 ($n = 14$; 74 %). In 17 of these cases, a 2009 A/H1N1 His274Tyr amino acid change was detected. In two oseltamivir-treated children with

[a]One B/Perth/211/2001 isolate had ninefold reduced susceptibility to zanamivir and 14-fold to oseltamivir compared to the mean inhibitory concentrations of influenza B strains and contained a mixed population including resistant variants with a Asp197Glu mutation [79]

[b]Four isolates (0.5 %) with NA deficiency were found to be resistant to NA inhibitors in cell culture-based assays

an A/H3N2 virus infection, an Arg292Lys change emerged posttreatment. Although the incidence of NA inhibitor-resistant viruses is currently low, the occasional clusters of 2009 oseltamivir-resistant influenza A/H1N1 viruses with an His274Tyr are a reason for concern [122–124]. Resistance to zanamivir was reported due to an amino change Gln136Lys [125, 126]. The presence of this mutation, however, may be caused by an artifact propagation of the virus in Madin-Darby canine kidney (MDCK) cell cultures [127]. With regard to the highly pathogenic avian influenza A/H5N1 viruses and low-pathogenic avian influenza A/H7N9 viruses, these are susceptible to the NA inhibitors [128]. Like A/H1N1 influenza viruses, amino acid changes at 119, 274, and 294 were found in 2.4 % of human and 0.8 % of avian A/H5N1 virus sequences, which were deposited to GenBank [33]. Additionally, markers of reduced NA inhibitor susceptibility at amino acid positions 116, 117, 150, 222, and 246 were found in 0.8 % of human and 2.9 % of avian A/H5N1 isolates [129]. Although the His275Tyr change has been the major antiviral resistance pattern found in highly pathogenic avian influenza A/H5N1 viruses [130–133], a A/H5N1 isolate was reported [130], with an Asp295Ser amino acid change causing an 80-fold and sevenfold increase of the IC_{50} for oseltamivir and zanamivir, respectively [134–

137]. This Asn295Ser change has also been observed in A/H5N1 virus isolates. The emergence of an Arg292Lys amino acid change in the low-pathogenic avian influenza A/H7N9 viruses circulating in China since 2013 causes high NA inhibitor resistance to oseltamivir and peramivir and reduced resistance to zanamivir [138, 139]. Unlike A/H3N2 viruses carrying the Arg292Lys amino acid change, A/H7N9 virus does not seem to be much attenuated by this change [128, 140]. Like the influenza A viruses, NA inhibitor resistance in influenza B viruses is currently low [141]. Nevertheless, several oseltamivir-resistant B viruses have been isolated from treated or untreated patients [142–144]. Antiviral resistance to neuraminidase may be caused by changes at residues Asp198 and Ser250. In addition, also influenza B viruses have been found with an Ile221 [144, 145]. These mutations cause only a two- to threefold increase in IC_{50} to oseltamivir, zanamivir, and peramivir.

3.2.1 Immunocompetent Hosts

In natural infections, oseltamivir-resistant variants have been detected much more commonly in treated children than adults (Table 71.6). In the past, analysis of samples from over 2500 influenza patients treated with oseltamivir as outpatients indicated that the frequency of resistance detection is about 0.4 % in adults and about 4.5 % in children [146]. Similar observations were made more recently in the IRIS trial where 14 of 19 oseltamivir-treated outpatients with resistance development were children aged below 5. The higher level of replication with longer duration of virus shedding increases the chance of developing antiviral resistance as compared to adults. Two studies in Japanese children reported high frequencies of 16 and 18 % oseltamivir resistance emergence during oseltamivir therapy [8, 147]. The use of weight-based dosing for children in Japan, as contrasted with unit dosing in most countries, is associated with lower drug exposure in young children. This has been postulated to be a major factor in the higher frequency of resistance detected in these studies. Among 54 volunteers experimentally infected with an A/H1N1 virus, oseltamivir-resistant variants with His274Tyr mutation were detected in two subjects in association with apparent rebounds in viral replication [148]. This study found that oseltamivir-treated subjects were less likely than placebo to have late viral isolates showing reversion of the egg-adapted inoculum virus to a human receptor HA genotype. The His274Tyr finding suggests that HA mutations with reduced affinity for human receptors might have a replication advantage over viruses with human receptor preference during oseltamivir use in humans. Interestingly, amino acid changes in the HA of the influenza A/H1N1 viruses prior to the emergence of the oseltamivir-resistant A/H1N1 virus in the 2007–2008 season have been predicted to have facilitated the emergence of the His274Tyr amino acid change [149, 150].

3.2.2 Immunocompromised Hosts

Immunocompromised individuals tend to suffer from influenza longer with more serious complications than otherwise healthy patients [151–154]. Since immunocompromised patients are more likely to acquire influenza [155], showing relatively high influenza-associated mortality [10, 11, 153], effective antiviral is crucial for these patients. Like with influenza and young children, the higher level of replication with longer duration of virus shedding in immunocompromised patients increases the chance of developing antiviral resistance [156]. Several recent clinical studies have reported that the emergence of antiviral resistance among treated immunocompromised patients is not uncommon [151, 157, 158]. Recently, a prospective clinical study aimed to study antiviral resistance in immunocompromised patients ($n = 24$); a resistance prevalence of 17 % (4/24) was reported [158]. In all four cases the NA His275Tyr was detected by RT-PCR of 2009 influenza A/H1N1 virus-infected patients. In other retrospective studies, similar rates have been reported [151, 157]. The NA His275Tyr amino acid change has been described frequently during the 2009 influenza A/H1N1 virus pandemic in case reports of antiviral-treated immunocompromised patients [117, 159]. Amino acid changes at position 223 have also been reported to cause increased levels of resistance (48-fold) to oseltamivir. The impact on therapy is unclear for such moderate increase in oseltamivir resistance; however viruses with the combination of Ile223Arg and His275Tyr are highly resistant to oseltamivir in vitro (1750-fold) [160]. In the past, emergence of resistance in immunocompromised patients has been also described for influenza A/H3N2 and influenza B virus-infected patients treated with oseltamivir and zanamivir with mutations in both the viral HA and NA glycoproteins [8, 10, 12, 161]. Most fatal cases during influenza pandemics and seasonal epidemics are patients belonging to the traditional high-risk groups for developing severe disease, including the very young children, elderly, and immunocompromised patients [162]. Given the high mortality and morbidity, the moderate effectiveness of current antivirals, and the relatively high prevalence of resistance in immunocompromised patient, better treatment strategies are clearly needed for these patients.

3.3 Pathogenicity and Transmissibility of Resistant Variant

Before the 2007–2008 influenza season, it was thought that NA inhibitor resistance development was to go hand in hand with reduction of virus fitness [97, 163]. Mathematical modeling predicted a 10 % relative transmissibility of oseltamivir-resistant variants would result in low levels of resistant viruses circulating in the community [164]. Based

Table 71.6 Frequency of resistance emergence to oseltamivir or zanamivir during treatment

Drug/study	Population	Assay	Virus type	No. isolates tested	No. (%) resistant	Mutations detected
Oseltamivir

[a]These pediatric studies used a 2 mg/kg dose of oseltamivir that has been shown to give reduced drug exposure because of more rapid clearance in children under the age of 5 years. Insufficient drug exposure may have contributed to resistance emergence in these studies

on animal experiments, the reduced fitness and replication competence of certain NA resistance mutations appeared to be depending on virus subtype and resistance mutation. For instance, an oseltamivir-resistant influenza A/H3N2 virus with an Arg292Lysine amino acid change did not transmit between infected and naïve ferrets and showed a 10–100-fold reduction in nasal virus titers [165]. For the Glu119Val oseltamivir-resistant mutant, however, it was found that the mutant was as transmissible as wild type with comparable nasal virus titers in both donor and recipient animals [98]. An influenza A/H1N1 virus with a His275YTyr mutation required 100-fold higher inoculum to infect the donor ferret, but once infected, they transmitted the virus to contact animals with a delay of 1–3 days compared to wild-type virus. Early after the outbreak of the 2009 pandemic, it was questioned whether a His275Tyr oseltamivir-resistant mutant would be attenuated [13, 166, 167]. In vitro replication and in vivo pathogenicity studies were performed using resistant isolates; however, the answers were conflicting. Some researchers found slight attenuation of the early His275Tyr mutant A/H1N1 viruses [166], while others did not find such differences [167]. At most, from these conflicting data, it can be concluded that the differences between a wild-type 2009 pandemic A/H1N1 virus and its His275Tyr-resistant counterpart are too close to call by means of its pathogenicity and transmissibility [74]. Additional compensatory mutations may facilitate the emergence of NA inhibitor resistance mutations, which cause an initial loss of virus fitness [96]. For instance, for the His275Tyr amino acid change in 2007–2009 A/H1N1 viruses, several permissive amino acid changes have been suggested to have facilitated the emergence of this oseltamivir resistance change. The Asp344Asn amino acid change, which appeared before the 2007–2008 season, had increased the enzymatic properties of NA prior to the introduction of the His275Tyr amino acid change [113, 168]. Amino acid changes Val234Met and Arg222Gln maintained high NA expression in vitro, which was reduced if the single His275Tyr was expressed [80, 169]. In A/H3N2, compensatory roles for amino acid changes at position 222 have been assigned to compensate for the loss of fitness due to the Glu119Val oseltamivir resistance mutation [170, 171]. The observed community clusters of 2009 A/H1N1 viruses with a His275Tyr amino acid change do not seem to be attenuated by the His275Tyr amino acid change either [122]. These viruses contain, in addition to the His275Tyr change, changes at amino acid positions 241, 369, and 386. These mutations may also have permissive effects [122].

3.4 Treatment Alternatives

The patterns of NA inhibitor cross-resistance vary by virus type and subtype, such that zanamivir retains inhibitory activity for the most common resistant variants that emerge during the therapeutic use of oseltamivir or peramivir. Zanamivir is fully inhibitory for oseltamivir-resistant variants possessing the Glu119Val substitution in N2 or His275Tyr or Asn294Ser in N1 [102, 172]. Depending on the virus and assay, zanamivir is partially inhibitory for resistant variants with Arg292Lys substitution in N2, in that the loss of susceptibility is about 5–25-fold compared to the wild type [102, 172–174]. There is controversy about the role of peramivir in the management of variants that are resistant to oseltamivir as in vitro and in vivo models have given conflicting results [175–177]. Oseltamivir is not inhibitory for the Arg152Lys mutation in influenza B NA that confers reduced susceptibility to zanamivir [178].

Given these findings, most experts recommend using zanamivir for the treatment of patients who develop resistance or virologic failure to oseltamivir. Inhaled zanamivir has been utilized in a few patients with variable success but has not been studies systematically in oseltamivir-resistant infections; success is less likely in patients with influenza pneumonia [179–182]. Intravenous zanamivir has been utilized most frequently for patients with proven or suspected resistant influenza; while the therapy is effective for some patients, available data precludes assessing the optimal role of this intervention given the severity of illness of many patients at conversion to therapy and significant prior exposure to numerous interventions [183–186]. Other NA inhibitors and zanamivir dimers that have prolonged duration of antiviral effect after topical application are currently under development [187]. These may provide NA inhibitor prevention and perhaps treatment alternatives in the future.

Ribavirin would also be expected to be inhibitory for influenza A and B viruses resistant to the NA inhibitors, but there are no reports of its use in human influenza infections due to such variants. Ribavirin combined with a NA inhibitor exerts additive to synergistic antiviral activity in vitro [188]. In mice experimentally infected with influenza A, the combination of orally administered ribavirin and peramivir was associated with improved survival relative to ribavirin alone but not to peramivir alone [189]. A more recent study found that a combination of ribavirin and oseltamivir was no more effective than ribavirin alone against a lethal influenza A(H1N1) infection but superior to single agents against influenza B [189]. Further studies of such ribavirin-NA inhibitor or T-705-NA inhibitor combinations (see below) are warranted to determine whether this strategy offers the possibility of treating severe influenza, particularly that due to M2 inhibitor-resistant viruses. Recently, triple combinations of amantadine, ribavirin, and oseltamivir have been studied in vitro, in vivo, and in humans with influenza infection [65, 66, 190]. Given the promise of this combination, a prospective phase 2 study is ongoing to assess the safety and clinical efficacy of this combination for the treatment of influenza. Combination therapy has been demonstrated to reduce the development of resistance in clinical studies and therefore may be of benefit in populations at increased risk of development of resistance emergences [54].

4 Novel Agents

4.1 T705/Favipiravir

Favipiravir (T-705; 6-fluoro-3-hydroxy-2-pyrazinecarboxamide) is an antiviral drug that is phosphoribosylated by cellular enzymes to its active form, favipiravir-ribofuranosyl-5′-triphosphate (RTP), and selectively inhibits the RNA-dependent RNA polymerase of influenza virus [191]. It is highly active against seasonal strains A/H1N1, A/H3N2, and influenza B; the 2009 pandemic A/H1N1 virus; highly pathogenic avian influenza virus A/H5N1 isolated from humans; A/H1N1 and A/H1N2 isolated from swine; and A/H2N2, A/H4N2, and A/H7N2. The antiviral is active against viruses that are resistant to amantadine, rimantadine, oseltamivir, and zanamivir, in addition to dually resistant viruses (M2 and NA inhibitor resistant) [191, 192]. In studies of serial passage of two seasonal (A/Brisbane/59/2007 and A/New Jersey/15/2007) and two 2009 pandemic (A/Denmark/524/2009 and A/Denmark/528/2009) A/H1N1 viruses in MDCK cell lines in the presence or absence of low concentrations of favipiravir, no favipiravir-resistant viruses were phenotypically or genotypically (PB1, PB2, PA, and NP sequencing) detected. Sequence analysis, though, did demonstrate an enrichment of G → A and C → T transversion mutations, increased mutation frequency, and a shift of the nucleotide profiles of individual NP gene clones under drug selection pressure [193]. Few clinical studies have been published with this novel compound, so the frequency of resistance emergence is not fully understood at this point. The drug is currently licensed in Japan for use selectively when approved by the Ministry of Health; studies of efficacy are ongoing in the rest of the world with the goal of seeking regulatory approval in the near future.

4.2 Antibodies

Recent studies have reported the development of neutralizing antibodies to specifically target conserved regions of the virus HA [194, 195]. HA binding of the antibodies was elegantly shown by X-ray crystal structures of HA-antibody protein complexes [196, 197]. These antibodies differ in

their recognition sites: Some are targeted to the sialic acid RBS and globular head, while others bind to the stalk region [195]. As the stalk region is more conserved between different HA subtypes, cross-reactive immunity against several influenza subtypes may be obtained with broadly neutralizing capacities. Although the antibodies are being developed against conserved regions of HA, mutations do arise at the antibody target sites, which may result in viral escape.

5 Implications and Future Research Directions

Currently, circulating strains of influenza are primarily resistant to the M2 inhibitors but are generally susceptible to the clinically available neuraminidase inhibitors. Sporadic cases of neuraminidase inhibitor resistance have been recognized, and limited regional transmission has been demonstrated [4, 44, 198]. Further, resistance in seasonal A/H1N1 became widespread during the 2008–2009 influenza season. Lastly, NA inhibitor resistance has been demonstrated to emerge during therapy in highly pathogenic avian influenza viruses that infect humans, with the highest frequency in A/H7N9 viruses [35, 36, 49]. As such, most regions of the world are currently limited to a single class of drug, the neuraminidase inhibitor, for the management of influenza infections. The risk that resistance could emerge and result in global spread poses a serious threat and requires the development of novel agents and combinations [128, 187].

Lessons learned from the 2009 pandemic suggest that there is a significantly higher frequency of antiviral resistance emergence in the pandemic virus compared to interpandemic influenza. Further, the clinical and epidemiologic implications of antiviral resistance in a future pandemic influenza virus cannot be predicted with confidence. As a result, the great progress made in developing global systems to rapidly monitor the susceptibility patterns of circulating strains needs to be maintained and potentially expanded to include regions with sparse surveillance [106]. Further, surveillance of resistance patterns in animals may give early warnings about future pandemic influenza viruses.

A number of unanswered questions remain regarding antiviral drug resistance in influenza viruses. With contemporary next-generation sequencing, it is possible to understand the kinetics of the emergence of resistance from minor variant populations to the predominant population in a given host. Such data can inform the optimal timing of screening and intervention. Specific risk factors beyond generic concepts, such as immunocompromised and young age, should be identified that predict the emergence of resistance. From a therapeutic perspective, the optimal approach, including the duration of therapy and the benefit of combination therapy in patients with severe illness or who are predicted to have prolonged shedding, needs to be carefully studied. Currently, there is a significant gap in the capacity to test specimens for resistance, and as a result, many patients with potential resistance may be missed. As a result, there is a desperate need for susceptibility assays that can be utilized broadly in the clinical laboratory. Lastly, there is need for ongoing and expanded surveillance of antiviral susceptibility patterns in human and animal influenza viruses, especially community isolates in countries with higher antiviral use, and for resistance transmission in high-risk epidemiologic settings.

Given the current pattern of antiviral susceptibility in circulating strains, M2 inhibitors should not be utilized for the prevention or treatment of influenza, while any of the neuraminidase inhibitors should be considered whenever therapy is indicated. Such therapy should be started as early as possible to improve the benefit obtained from the use of the therapy. Given its slightly broader activity against most oseltamivir-resistant variants, zanamivir would be the preferred therapy for patients with proven or suspected oseltamivir-resistant influenza. Novel agents, optimally with novel mechanisms of action, need to be developed. Drugs in advance stages of development include the polymerase inhibitor favipiravir [191], the receptor-destroying sialidase DAS181 [199], and nitazoxanide [200]. Neutralizing antibodies and convalescent plasma need to be studied further to optimize the treatment of patients, particularly with novel or highly resistant viruses [201]. Lastly, combinations of antivirals should be studied to understand their ability to prevent and overcome resistance clinically [128].

Herpesvirus Resistance to Antiviral Drugs

72

Jocelyne Piret and Guy Boivin

1 Introduction

Herpesviridae is a large family of DNA viruses including nine human viruses which belong to the α-*herpesvirinae* [herpes simplex virus 1 and 2 (HSV-1 and HSV-2) and varicella-zoster virus (VZV)], the β-*herpesvirinae* [human cytomegalovirus (HCMV) and human herpesviruses 6 and 7 (HHV-6 A/B and HHV-7)], and the γ-*herpesvirinae* [Epstein-Barr virus (EBV) and HHV-8] subfamilies. These ubiquitous viruses have the ability to establish latency in specific cell types and to reactivate under certain circumstances. Among members of the *Herpesviridae* family, four of them (HCMV, HSV-1, HSV-2, and VZV) will be discussed in this chapter since they are the main targets of antiviral strategies. HCMV is responsible for mononucleosis-like syndromes as well as systemic and organ-specific diseases in immunocompromised patients. HSV-1 and HSV-2 cause orolabial and genital infections as well as keratitis, encephalitis, and neonatal infections. VZV is the causative agent of varicella and herpes zoster.

The discovery of the nucleoside analogue acyclovir (ACV) was made more than 35 years ago; it represents a milestone in the management of HSV and VZV infections. The modest activity of ACV against HCMV has prompted the development of another nucleoside analogue, ganciclovir (GCV), for the management of systemic and organ-specific HCMV diseases. Clinical use of intravenous GCV began in 1984 for the treatment of life-threatening and sight-threatening HCMV infections in immunocompromised patients. In 1988, strains of HCMV exhibiting resistance to GCV in vitro had been already identified. Second-line antiviral agents such as the pyrophosphate analogue foscarnet (FOS) and the nucleotide analogue cidofovir (CDV) have been approved subsequently. In contrast to ACV and GCV, the latter drugs do not require an initial phosphorylation step by viral protein kinases to be converted into their active forms. However, their use is limited by the absence of oral formulations and their toxicity profiles. As all currently available antiviral agents target the viral DNA polymerase (pol), mutations conferring cross-resistance to two or all drugs emerged. There is thus a need to develop new antiviral compounds with different mechanisms of action, appropriate safety profiles, and good pharmacokinetic properties. In this chapter, we review the antiviral drugs approved for the prevention and the treatment of HCMV, HSV and VZV infections, the laboratory methods for detecting antiviral resistance, the clinical significance of drug-resistant strains, and their management.

2 Antiviral Agents for Herpesvirus Infections

Three antiviral agents and a prodrug are currently available for the systemic treatment of HCMV infections [1]. Ganciclovir (Cytovene®, Roche) is a deoxyguanosine analogue and was the first drug to be approved for this indication in 1988. Since then, it has remained the first-line treatment for HCMV infections in immunocompromised patients. Upon entry in HCMV-infected cells, GCV is selectively phosphorylated by a viral protein kinase homologue (the product of the *UL97* gene, pUL97). Subsequently, cellular kinases convert GCV monophosphate into its triphosphate form, which acts as a potent inhibitor of the HCMV DNA pol (the product of the *UL54* gene) by competing with deoxyguanosine triphosphate on the enzyme binding site (Fig. 72.1). Ganciclovir is also incorporated into the viral DNA where it slows down and eventually stops chain elongation [2]. Ganciclovir formulations are available for intravenous (IV) or oral administration for the treatment of HCMV diseases in

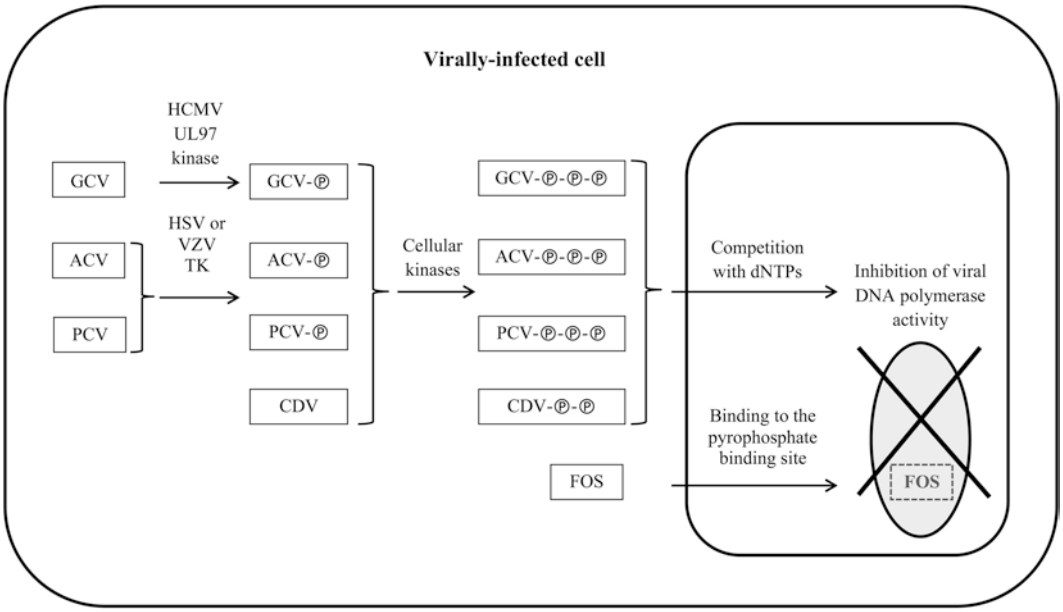

Fig. 72.1 Mechanisms of action of the different classes of antiviral agents. The nucleoside analogues such as ganciclovir (GCV), acyclovir (ACV), and penciclovir (PCV) must be first phosphorylated by the *UL97* protein kinase or viral thymidine kinase (TK) and then by cellular kinases to be converted into their active forms. The acyclic nucleoside phosphonate derivatives such as cidofovir (CDV) must be phosphorylated by cellular kinases only to be active. The resulting triphosphate forms compete with deoxynucleotide triphosphates (dNTPs) to inhibit the viral replication. The pyrophosphate analogue foscarnet (FOS) directly inhibits the activity of the viral DNA polymerase. **Key**: Ⓟ represents one phosphate group

immunocompromised patients as well as ocular implants (Vitrasert, Chiron) for the local treatment of HCMV retinitis. Due to its poor bioavailability (~6 %), efforts were made to develop prodrugs of GCV. Valganciclovir (VGCV, Valcyte®, Roche) is a L-valyl ester prodrug of GCV exhibiting an approximately 10 times improved GCV bioavailability following oral administration compared to the parent drug [3].

The other two compounds approved for systemic treatment of HCMV infections are also potent inhibitors of the viral DNA pol. However, due to their toxicity profiles and the absence of oral formulations, they are usually reserved for patients failing or not tolerating GCV therapy. Cidofovir (Vistide®, Gilead Sciences) is a nucleotide analogue of cytidine (also called acyclic nucleoside phosphonate) that only requires activation (phosphorylation) by cellular enzymes to exert its antiviral activity [4]. Once in its diphosphate form, CDV inhibits the HCMV DNA pol by acting as a chain terminator (Fig. 72.1) [5]. The IV formulation of CDV is indicated for the treatment of HCMV retinitis in patients with the acquired immunodeficiency syndrome (AIDS) and is also occasionally used in transplant patients. Foscarnet (Foscavir®, Astra-Zeneca), a pyrophosphate analogue, differs from the two previous antivirals both by its mechanism of action and by the fact that it does not require any activation step to exert its antiviral activity. Foscarnet binds to and blocks the pyrophosphate binding site on the viral polymerase, thus preventing incorporation of incoming deoxynucleotide triphosphates (dNTPs) into viral DNA (Fig. 72.1) [6]. The IV formulation of FOS is indicated for the treatment of HCMV retinitis in individuals with AIDS and for GCV-resistant HCMV infections in immunocompromised patients.

In addition to the treatment of established HCMV diseases, antivirals have also been used to prevent such symptomatic episodes, especially in transplant recipients. The first strategy, defined as "prophylaxis," consists of administering an antiviral to all at-risk patients during the first 3 months or so after transplantation. However, the occurrence of late-onset HCMV disease which is associated with high rates of graft loss [7] and mortality [8] is an important issue after discontinuing prophylaxis. The second strategy, referred to as "preemptive therapy," consists of using short courses of antivirals only for high-risk patients based on evidence of active viral replication (e.g., detection of early HCMV antigens such as the pp65 protein or a certain assay threshold of viral DNA/mRNA in the blood), optimally before the onset of symptoms [9, 10]. The advantages of preemptive therapy include a lower rate of delayed occurrence of HCMV disease and less drug toxicity [11]. However, patients are more prone to recurrent episodes of DNAemia, and the indirect effects of HCMV infection on graft and patient survival may not be prevented.

Antiviral agents currently licensed for the treatment of HSV and VZV infections include ACV (Zovirax®,

GlaxoSmithKline) and its L-valyl-ester prodrug valacyclovir (VACV, Valtrex®, GlaxoSmithKline), famciclovir (FCV, Famvir®, Novartis) which is the L-valyl-ester prodrug of penciclovir (PCV), and FOS [12, 13]. Acyclovir and PCV are deoxyguanosine analogues that must be phosphorylated by the thymidine kinase (TK) of HSV (encoded by the *UL23* gene) or VZV (encoded by the *ORF36* gene) and then by cellular kinases to exert their antiviral activity [14]. Their triphosphate forms are competitive inhibitors of the viral DNA pol (Fig. 72.1) [15]. In addition, incorporation of ACV triphosphate into the replicating viral DNA chain stops synthesis. Oral ACV, VACV, and FCV are used for short-term therapy of primary and recurrent HSV infections (particularly genital herpes), long-term suppressive therapy of recurrent genital herpes, as well as treatment of herpes zoster. The IV formulation of ACV is indicated for the management of severe HSV (including encephalitis and neonatal herpes) and VZV infections. Topical formulations of ACV and PCV (Denavir®, Novartis) are used for the treatment of herpes labialis and keratitis. The pyrophosphate analogue FOS is usually indicated for ACV- or PCV-resistant HSV or VZV infections [16–18]. Topical and IV formulations of CDV may be used "off label" in the treatment of nucleoside analogues- and/or FOS-resistant HSV infections [13].

3 Human Cytomegalovirus Antiviral Drug Resistance

3.1 Phenotypic and Genotypic Assays to Evaluate HCMV Drug Susceptibility

Two different albeit complementary approaches have been developed to assess HCMV drug resistance. In the phenotypic method, the virus is grown in the presence of various concentrations of an antiviral in order to determine the drug concentration that will inhibit a percentage (more commonly 50 %) of viral growth in cell culture. In this assay, a standardized viral inoculum is inoculated onto susceptible cultured cell lines. The virus is then allowed to grow for a few days (typically 7–10 days) in the presence of serial drug dilutions before staining the cells. The number of viral plaques per antiviral drug concentration is first counted, and the percentage, as compared to control wells without antiviral, is plotted against drug concentrations. The concentration that reduces the number of viral plaques by 50 % (50 % effective concentration or EC_{50}) is then determined. Proposed cutoff values defining resistance to GCV, CDV, and FOS are 6 μM, 2 μM, and 400 μM, respectively [19, 20]. An increase in the EC_{50} value greater than two- to threefold over that of a sensitive reference strain or a baseline isolate is also a widely accepted breakpoint value [21]. Even though efforts have been made to standardize this assay [22], the inter-assay and interlaboratory variability is still problematic. Several phenotypic assays, either based on detection of HCMV DNA by hybridization [23] or quantitative PCR [24] or detection of specific HCMV antigens by ELISA [25], flow cytometry [26–28], immunofluorescence [29], or immunoperoxidase [30], have also been developed to increase the objectivity of the readout. Altogether, these assays are time-consuming, limited by the difficulty of obtaining an appropriate clinical specimen for cell culture, subject to possible selection bias introduced during viral growth of mixed viral populations in cell culture [31, 32] and may lack sensitivity to detect low level of drug resistance or minor resistant subpopulations [31, 33].

In contrast to phenotypic assays, which directly measure drug susceptibility of viral isolates, genotypic assays detect the presence of viral mutations known to be associated with drug resistance. Approximately 80 % of GCV-resistant clinical isolates typically contain one of the seven canonical mutations (M460V/I, H520Q, C592G, A594V, L595S, and C603W) in the *UL97* gene [34]. The limited number of *UL97* mutations responsible for GCV resistance has thus prompted the development of a method based on rapid restriction fragment length polymorphism (RFLP) of PCR-amplified DNA fragments to detect their presence in clinical samples [35, 36]. Typically, the presence of a given mutation will either obliterate an existing restriction site or create a new one. The difference in RFLP patterns can thus be visualized following gel electrophoresis. The major advantages of this assay include its short turnaround time (2–4 days) and its ability to detect as little as 10–20 % of a mutant virus in a background of wild-type viruses [35]. A real-time PCR assay with melting curve analysis using hybridization probes specific for each more common mutations in the *UL97* gene has also been developed [37, 38]. However, melting curves may be affected by natural polymorphisms, and this method does not allow distinguishing different point mutations that occur at the same codon. As GCV resistance mutations also emerge at other codons, DNA sequence of a region typically comprised between codons 400–670 of the *UL97* gene should be determined for a comprehensive analysis. Genotypic analysis of DNA pol mutations can also be performed by sequencing a region of the *UL54* gene typically spanning between codons 300–1000 to cover the large number of mutations reported within all conserved regions of this enzyme [39]. One of the advantages of these assays is that they can be performed directly on clinical specimens [40, 41] thus reducing considerably the time required for data generation (1–3 days). By omitting the need to grow the virus, such methods also minimize the risks of introducing a selection bias. Standard Sanger dideoxy sequencing method can detect an emerging resistance mutation when it exceeds approximately 20 % of the total population. It is thus estimated that a viral load of at least 1000 copies/mL of clinical sample is required

to obtain reliable genotypic profiles [42]. Next-generation sequencing methods use a three-step sequencing process including library preparation, DNA capture and enrichment, and sequencing/detection [43]. Recent advances in high-throughput deep-sequencing technology allows the acquisition of hundreds or thousands reads of gene regions involved in drug resistance and thus improves the detection of emerging mutant subpopulations that are present in less than 10 % of the total viral population [44–46]. Genotypic approaches are objective, but their interpretation is not always straightforward (i.e., discriminating between mutations associated with natural polymorphisms [47–50] and those related to drug resistance). Mutations identified in the *UL97* and *UL54* genes can be linked to drug resistance phenotypes by using a web-based tool (http://www.informatik.uni-ulm.de/ni/staff/HKesler/hcmv) [51]. In order to characterize the role of new mutations not previously linked to drug resistance, recombinant viruses need to be generated by marker transfer experiments of mutated genes in a wild-type virus background [52–54] or by using either overlapping cosmid/plasmid inserts [55] or a viral genome of a susceptible reference strain cloned into a bacterial artificial chromosome [33, 56, 57] prior to testing the phenotypes of mutant viruses in drug susceptibility assays. The introduction of a reporter gene in a permissive cell line [58] or directly in the recombinant virus [59–61] accelerates drug phenotypic testing of mutants and allows a more objective evaluation of viral replication.

3.2 Clinical Significance, Incidence, and Risk Factors for Drug-Resistant HCMV Infections

Shortly after the introduction of GCV, the emergence of drug-resistant HCMV strains was reported particularly in untreated or poorly treated AIDS patients who developed HCMV retinitis at a high frequency (ranging from 20 to 45 %) [62]. Two large studies have evaluated the temporal emergence of GCV-resistant strains during therapy using either phenotypic [63] or genotypic [64] assays. In these studies, GCV resistance (defined by an EC_{50} value ≥6 μM) at the initiation of treatment was a rare event (≤2.7 % of tested strains). Phenotypic evaluation of blood or urine isolates from 95 patients treated with GCV (mostly IV) for HCMV retinitis revealed that 7, 12, 27, and 27 % of patients excreted a GCV-resistant strain after, respectively, 3, 6, 9, and 12 months of drug exposure [63]. On the other hand, a study of 148 AIDS patients treated for HCMV retinitis with oral VGCV has identified the presence of GCV resistance mutations in 2, 7, 9, and 13 % of patients after 3, 6, 9, and 12 months of therapy, respectively [64]. The lower incidence of GCV resistance in the latter study despite the use of sensitive genotypic methods might be explained by differences in the study population, notably improvement in human immunodeficiency virus (HIV) therapy. Due to their less frequent use in clinic, fewer data have been reported on the temporal emergence of FOS- and CDV-resistant HCMV strains in HIV-infected individuals. One small study found an incidence of phenotypic resistance to FOS of 9, 26, 37, and 37 % after 3, 6, 9, and 12 months of therapy using an EC_{50} cutoff value of 400 μM [65], whereas another one reported rates of 13, 24, and 37 % after 6, 9, and 12 months using an EC_{50} cutoff value of 600 μM [66]. The data on CDV resistance (EC_{50} value ≥2–4 μM) are even more limited, but they seem to indicate a resistance rate similar to what has been observed with GCV and FOS [65]. Proposed risk factors for the development of HCMV resistance in this patient population include inadequate tissue drug concentrations due to poor tissue penetration (e.g., the eyes) or poor bioavailability (e.g., oral GCV), a sustained and profound immunosuppression status (CD4 counts <50 cells/μL), frequent discontinuation of treatment due to toxicity, and a high pre-therapy HCMV load [67, 68]. The introduction of highly active antiretroviral therapy (HAART) substantially reduced the incidence of HCMV retinitis in AIDS patients, and this was associated with a concomitant decrease in the rate of GCV resistance from 28 to 9 % evaluated over a period of 2 years in the pre-HAART and HAART eras, respectively [69]. Patients with AIDS, especially those with CD4 counts below 50 cells/μL, remain at risk of developing HCMV retinitis and eventually GCV-resistant infections even nowadays [70].

Thereafter, the more widespread use of oral GCV (with a low bioavailability of 6 %) and the intensification of immunosuppressive regimens resulted in an increased prevalence of HCMV drug resistance in solid organ transplant (SOT) recipients. In this setting, infections caused by HCMV drug-resistant isolates have been associated with an increased number of asymptomatic and symptomatic viremic episodes, earlier onset of HCMV disease, graft loss, and an increased risk of death [71]. Lung transplant recipients appear to have the highest incidence of HCMV resistance development with rates of 3.6–9 % after median cumulative GCV exposures ranging from 79 to 100 days [72–74]. The incidence of resistance increased to 15.8–27 % in seropositive donors (D+)/seronegative recipients (R−) lung transplant patients [73, 74] and occurred as a late complication, i.e., a median of 4.4 months after transplantation [73]. As opposed to what has been reported in lung transplant recipients, the incidence of GCV resistance in other SOT populations has been much lower in D+/R− patients [74, 75] and very occasional in R+ subjects [74]. More specifically, two cohorts of SOT patients including heart, liver, and kidney recipients were evaluated at two US centers [74]. Phenotypic evaluation for HCMV resistance prompted by either clinical suspicion or positive blood cultures indicated that rates of resistance were generally low (e.g., <0.5 %) at one center and varied from 2.2 to

5.6 % at another center depending on the transplanted organ. Another retrospective study evaluated 240 SOT patients including 67 D+/R− patients but excluded lung transplant recipients [75]. In this cohort, GCV-resistant HCMV disease developed only in D+/R− SOT recipients, with resistance rates of 7 % in these patients. HCMV resistance was more frequently seen among recipients of kidney/pancreas or pancreas alone (21 %) than among kidney (5 %) or liver (0 %) recipients. Of note, cases of GCV-resistant HCMV infections occurred at a median of 10 months after transplantation with a median total drug exposure of 194 days (129 days of oral GCV) including 2–3 treatment courses for HCMV disease per patient. Importantly, GCV-resistant HCMV infections accounted for 20 % of HCMV diseases that occurred during the first year after transplantation [75]. Documented risk factors for the emergence of GCV resistance in SOT patients include the lack of HCMV-specific immunity (as encountered in the D+/R− group) [76, 77], lung or kidney/pancreas transplantation, longer drug exposure (prophylaxis > preemptive therapy), suboptimal plasma or tissue drug concentrations (as seen with oral GCV), potent immunosuppressive regimens, a high HCMV viral load, and frequent episodes of HCMV disease [71, 73, 75, 78].

In contrast to GCV, VGCV is highly absorbed after oral administration leading to an improved systemic exposure (about 60 %) that could limit the emergence of drug-resistant HCMV mutants. The clinical efficacy and safety profile of a once-daily (900 mg OD) dose of VGCV were shown to be similar to thrice daily (1 g TID) doses of oral GCV for the prevention of HCMV diseases in high-risk SOT recipients [79]. The first prospective study evaluating the emergence of GCV resistance in SOT recipients used molecular methods to assess the emergence of *UL97* and *UL54* mutations associated with GCV resistance in D+/R− patients (175 liver, 120 kidney, 56 heart, 11 kidney/pancreas, and 2 liver/kidney recipients) receiving HCMV prophylaxis with either oral GCV or VGCV [80, 81]. Among 301 evaluable patients, the incidence of GCV resistance at the end of the prophylactic period (day 100 posttransplant) was very low in both arms (0 % and 3 % for the VGCV and oral GCV arms, respectively). During the first year following transplantation, GCV resistance-associated mutations were found in none compared to 6.1 % of patients at the time of suspected HCMV disease after receiving VGCV and oral GCV prophylaxis, respectively. Of note, however, no lung transplant and a small number of kidney/pancreas recipients were included in this study, which might explain at least partly the low emergence of GCV resistance as compared to previous reports. Interestingly, detection of known GCV resistance mutations was not necessarily associated with adverse clinical outcomes in the latter study [80, 81]. The incidence of drug resistance evaluated by molecular methods in 80 lung transplant recipients who had received IV GCV (D+/R− patients), oral GCV (R+ patients), or oral VGCV prophylaxis was also found to be low [82, 83]. Finally, a low incidence of drug resistance was observed by genotypic testing in adult D+/R− patients (138 kidney, 4 kidney/pancreas, 58 liver, and 25 heart recipients) and pediatric transplant recipients (12 heart, 33 kidney, 17 liver, and 1 liver/kidney recipients) who had received VGCV prophylaxis [84, 85]. The low frequency of drug resistance in SOT recipients receiving VGCV (compared to oral GCV) could be related to an improved GCV exposure and to a better compliance of the patients to the once-daily dosing.

High-risk patients who receive VGCV prophylaxis for 100 days posttransplant might still be at risk of developing late-onset HCMV disease [8]. Extending the prophylactic regimen beyond 3 months may theoretically increase the risk of emergence of drug resistance. Therefore, the impact of extending VGCV prophylaxis from 100 to 200 days on the incidence of resistance was investigated in 318 D+/R− kidney transplant recipients based on genotypic testing [86]. The rates of drug resistance were similar (1.8 % vs. 1.9 %) in patients who had received VGCV prophylaxis for 100 and 200 days suggesting that extending the prophylactic period up to 200 days did not significantly affect the incidence of GCV resistance. Of note, almost all cases of resistance occurred during VGCV prophylaxis and rarely thereafter. Prophylaxis with VGCV for 200 days after transplantation could thus be an interesting option in high-risk kidney transplant recipients.

No clear evidence demonstrates whether a prophylactic or a preemptive approach is more effective in preventing HCMV disease in high-risk transplant patients. Several studies evaluated the effect of these preventive strategies on the emergence of drug resistance based on molecular methods. In a first retrospective study evaluating 1244 renal transplant recipients who had received a once-daily VGCV preemptive therapy, GCV resistance mutations were detected in 2.2 % of the overall population and, more specifically, in 12.5 % of D+/R− patients [87]. Another retrospective study compared the emergence of resistance in D+/R− kidney transplant recipients who had received VGCV prophylaxis for 3 months (32 patients) or VGCV preemptive therapy (80 patients) [88]. HCMV drug resistance was more frequent in the preemptive compared to the prophylactic group (16 % vs. 3 %). The author suggested that, during preemptive therapy, patients may be exposed to suboptimal drug levels which favor an active viral replication state thus increasing the risk of emergence of GCV resistance. It is thus proposed that the prophylactic strategy may be more appropriate than the preemptive therapy in high-risk transplant recipients although further studies are still needed to confirm this point.

Valganciclovir was shown to be noninferior to IV GCV for the treatment of established HCMV disease in SOT recipients [89, 90]. A secondary endpoint of this trial was the

evaluation of the emergence of drug resistance in a cohort including 20 heart, 216 kidney, 23 liver, and 17 lung transplant recipients treated for HCMV disease with a 21-day induction dose of IV GCV or VGCV followed by VGCV maintenance dose for 49 days in both arms [91]. Probable or confirmed drug resistance mutations were low and found to be similar for VGCV (3.6 %) and IV GCV (2.3 %) treatments. Overall, incidence of GCV drug resistance was low in kidneys (3.7 %), intermediate in livers and hearts (4.3–5.0 %), and highest in lungs (17.6 %).

Limited data from small-scale studies suggest that the incidence of GCV resistance in the bone marrow transplant (BMT)/hematopoietic stem cell transplant (HSCT) population might not be as high as observed in SOT recipients and AIDS patients, perhaps because of the more limited immunosuppression exposure. Due to early detection of HCMV reactivation in this setting (prior to engraftment), many centers have adopted a strategy of preemptive therapy in order to reduce morbidity and mortality from subsequent HCMV disease [92]. In a prospective study, molecular methods were used to detect the presence of the most common *UL97* mutations associated with GCV resistance in blood samples of HSCT patients selected on the basis of having a positive HCMV PCR despite ≥14 days of preemptive IV GCV or a second viremic episode within the first 98 days after transplantation. No *UL97* mutations associated with GCV resistance were detected in this cohort of 50 patients (ten of them fulfilling the above criteria for genotypic testing) [93]. However, this was a small study, and resistance would be unlikely after such a short period of preemptive treatment. In another prospective study designed to evaluate risk factors and outcomes associated with rising HCMV antigenemia levels during the first 2–4 weeks of preemptive therapy, 119 HSCT patients receiving preemptive GCV or FOS therapy following a positive pp65 antigenemia test were evaluated [94]. Among these subjects, 47 (39 %) exhibited a significant rise in antigenemia levels despite antiviral administration, and 15 had at least one isolate available for susceptibility testing. Only one GCV-resistant isolate was identified in a patient who had received 4 weeks of GCV therapy [94]. Several other studies [95–97] also reported a low incidence of drug resistance among HSCT recipients who had received preemptive therapy with GCV or VGCV based on genotypic testing. Therefore, the high rate of treatment failure observed in this setting is probably more related to a profound immunocompromised status since immunological reconstitution plays an important role in the final eradication of the infection. In a recent study, a high rate of drug resistance (14.5 %) was exclusively identified in haploidentical-HSCT recipients receiving preemptive therapy with GCV [98]. Ganciclovir resistance appeared after median cumulative treatment duration of 70 days (range 39–330 days) and was associated with severe clinical manifestations. The authors suggested that the continued viral replication may be due to delayed immune reconstitution combined with impaired cross talk between the disparate donor T cells and recipient antigen-presenting cells. Even though short courses of GCV therapy appear to be relatively safe in adult BMT patients, the situation might differ in pediatric patients receiving T-cell depleted unrelated transplants. In a study of 42 such patients [99], 3 showed genotypic evidences of GCV resistance. Of note, in the same study, none of the 37 patients who underwent a similar procedure, but who received their transplant from a mismatched related donor, developed GCV resistance [99]. Rapid emergence of GCV resistance was also documented in 4/5 children with congenital immunodeficiency disorders who underwent T-cell-depleted BMT [100]. In those patients, genotypic evidence of GCV resistance was demonstrated after only 7–24 days (median 10 days) of cumulative GCV therapy.

3.3 Role of UL97 Kinase and UL54 DNA Polymerase Mutations in Drug-Resistant HCMV Clinical Strains

The great majority (>90 %) of drug-resistant HCMV clinical isolates selected from initial treatment with GCV contain one or more mutations in the UL97 kinase, whereas mutations in the UL54 DNA pol are less frequently encountered [101]. The catalytic domain of protein kinases consists of eleven major conserved regions numbered I to XI, with region I having the highest level of homology [102]. The ATP-binding site, the phosphate transfer domain, and the substrate-recognition site correspond to codon ranges located at positions 337–345 (region I), 453–462 (region VIB), and 574–579 (region IX), respectively. Laboratory-engineered UL97-negative HCMV mutant exhibited a severe replicative deficiency compared to the wild-type parental strain highlighting the essential role of this enzyme in the viral replicative cycle [103]. Therefore, only a small number of mutations clustered in a relatively short genomic region of the *UL97* gene have been reported to confer resistance to GCV. Ganciclovir resistance mutations in the *UL97* gene consist in single nucleotide substitutions or in-frame deletions (Fig. 72.2a) [34, 39, 104]. Cumulative analysis of UL97 mutations detected in clinical isolates [74, 105] or in blood samples [64] from 61 AIDS and SOT patients is in general agreement with those of 76 independent UL97 mutants gathered in a single laboratory over years [33]. Those data suggest that mutations A594V (30–34.5 %), L595S (20–24 %), M460V (11.5–14.5 %), and H520Q (5–11.5 %) represent the most frequent UL97 mutations present in GCV-resistant mutants [106]. Additional frequent UL97 mutations associated with GCV resistance include M460I, C592G, and C603W [34, 39, 104]. Other less frequently encountered

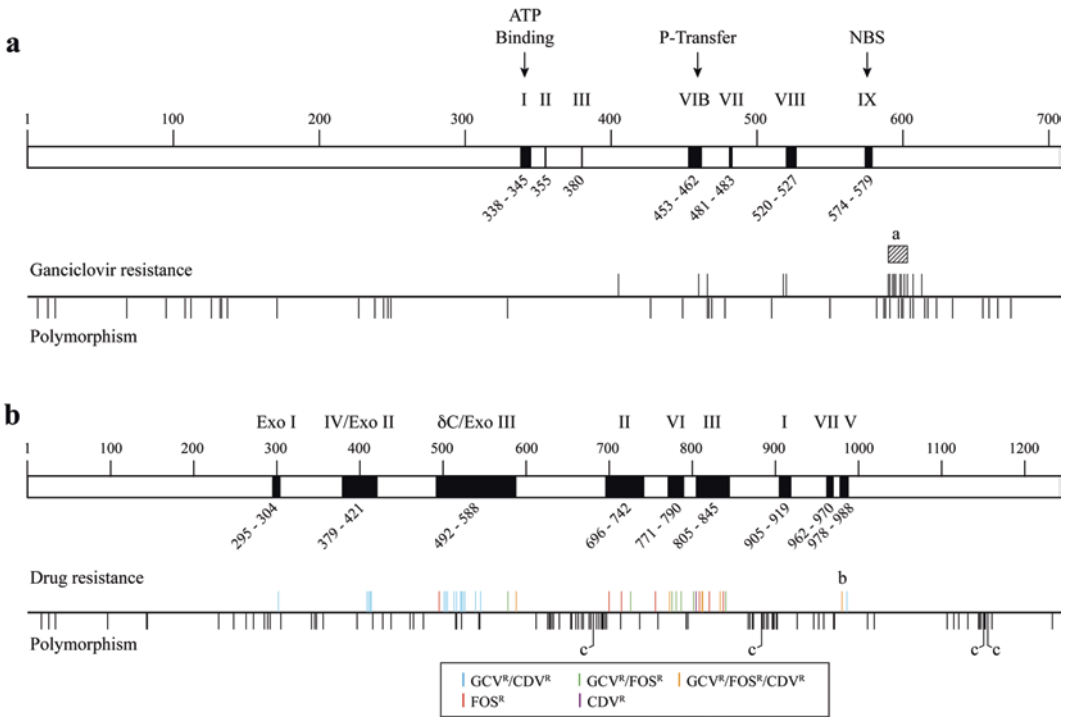

Fig. 72.2 Confirmed drug resistance mutations identified in clinical HCMV isolates. Panel (**a**) shows mutations in the *UL97* gene associated with ganciclovir resistance or natural polymorphism. The ATP-binding site, the phosphate transfer (P-transfer) domain, the nucleoside-binding site (NBS), and some regions conserved among the protein kinase family (i.e., I, II, III, VIB, VII, VIII, and IX) are represented by the *black boxes*. Bars (|) indicate amino acid substitutions associated with ganciclovir resistance (*upper bars*) or with polymorphism (*lower bars*). (*a*) Shaded area corresponds to the codon 590–603 region where different amino acid deletions were identified (i.e., deletions 591–594, 591–607, 595, 595–603, 600, and 601–603). Panel (**b**) shows mutations in the *UL54* gene associated with resistance to ganciclovir (GCV^R), foscarnet (FOS^R), and/or cidofovir (CDV^R) or with natural polymorphism. Conserved regions among the *Herpesviridae* DNA polymerase are represented by the *black boxes*. The roman numbers (I–VII) and δ-region C corresponding to each of these regions are indicated above the boxes. Conserved motifs (Exo I, Exo II, and Exo III) in the exonuclease domain are also indicated above the boxes. Bars (|) indicate amino acid substitutions associated with drug resistance (*upper bars*) or with polymorphism (*lower bars*). (*b*) Amino acid deletion 981–982 that confers resistance to all three antivirals; (*c*) amino acid deletions or insertions associated with polymorphism (i.e., deletions 681–688, 1151, and 1156; insertion 884)

mutations can emerge at codons 460 and between codons 590 and 607 of the UL97 kinase. Based on marker transfer experiments or recombinant phenotyping (Table 72.1), high-level GCV resistance mutations appear to be associated with ≥5-fold increase in EC_{50} values over the parental strain, whereas low-level GCV resistance mutations seem to be associated with <5-fold increase in EC_{50} values. Substitutions or small deletions in the *UL97* gene had no major impact on the viral replicative capacity [33, 110, 114, 115]. Mutation V466G, located outside typical codon ranges, confers a low level of GCV resistance (3.5-fold) and is associated with a significant replicative defect [116]. Amino acid changes associated with natural polymorphisms in the UL97 kinase are mainly clustered in two distinct regions (codons 1–249 and 427–674) [47].

Ganciclovir-resistant HCMV clinical isolates with an altered DNA pol activity result from numerous mutations widely distributed among the different conserved domains of the enzyme, but mostly occur at codons 395–545 and 809–987 (Fig. 72.2b) [34, 39, 104]. The *Herpesviridae* DNA pol belong to the family of α-like DNA polymerases [117] which share regions of homology numbered I to VII. These regions correspond to the degree of conservation among these enzymes, with region I being the most conserved. The *Herpesviridae* DNA pol also contain a δ-region C, which is shared by enzymes related to eukaryotic DNA polymerases δ [118]. Moreover, a 3′-5′ exonuclease domain (containing Exo I, Exo II, and Exo III conserved motifs) maps to the N-terminal region of the herpesvirus DNA pol. DNA pol mutations that emerge under GCV therapy can confer cross-resistance to CDV and, less frequently, to FOS. Cross-resistance to GCV and CDV is associated with mutations located in the exonuclease domains (codons 301, 408–413, 501–545) and in region V (codons 981–987) of the enzyme. Based on marker transfer experiments or recombinant phenotyping (Table 72.2), mutations F412S, D413A, L501I, K513E/N, V526L, and A987G confer a high level of resistance to GCV (≥5-fold increase in EC_{50} values) and cross-resistance to

GCV ganciclovir, *EC_{50}* concentration of antiviral that reduces viral plaques by 50 %, *del* deletion

[a]Fold changes are calculated as the ratio of EC_{50} values of mutant recombinant virus to the wild-type counterpart. An increase in EC_{50} value ≥1.9-fold higher than that of the wild-type strain corresponds to drug resistance

CDV. Other mutations (i.e., D301N, N408D/K/S, N410K, F412C/L/V, D413E/N, T503I, A505V, K513R, L516R, I521T, P522A/S, del524, C539G, and L545S/W) confer a lower level of resistance to GCV (between 1.9- and 5.0-fold increase in EC_{50} values) and are also cross-resistant to CDV. Resistance to FOS is widely dispersed in the conserved domains of the UL54 DNA pol. However, clusters of mutations are mainly found in regions II, VI, and III and are associated with resistance to FOS alone (i.e., N495K, D588E, T700A, V715M, E756D/Q, and T838A) or to both FOS and GCV (i.e., Q578L, I726V, L776M, V781I, V787L, L802M, A809V, and G841S). Mutation K805Q confers resistance to CDV alone. Importantly, some mutations (i.e., Q578H, D588N, E756K, L773V, V812L, T813S, T821I, A834P, G841A, and del981-982) have been associated with resistance to all three antivirals. Contrasting with the situation with UL97 mutants, isolates with UL54 mutations conferring drug resistance usually exhibit an attenuated or slow-growth phenotype in cell culture compared to their wild-type counterpart as assessed in marker transfer experiments. Among those, mutations T700A and V715M (conserved region II) [53], K513N (δ-region C) [123], and D301N (Exo I motif) [56] were shown to significantly reduce the yield of progeny virus in cell culture supernatants, whereas some others (D413E, T503I, L516R, and E756K/D) were only associated with a modest attenuation of viral replication [56]. Finally, the natural polymorphism is more common in the *UL54* gene than in the *UL97* gene and occurs most often at nonconserved residues (between codons 614 and 697) where little homology exists among herpesvirus DNA pol [48, 49]. The high degree of inter-strain variability in the *UL54* gene complicates the interpretation of genotypic testing in the absence of recombinant phenotyping.

In the case of HCMV mutants selected during GCV therapy, it should be noted that UL97 mutations have been generally shown to emerge first and to confer a low level of resistance (EC_{50} < 30 μM), whereas subsequent emergence of UL54 DNA pol mutations usually leads to a high level of GCV resistance (EC_{50} > 30 μM) with potential cross-resistance [133–135]. However, occasional reports have described mutations restricted to the *UL54* gene only after initial therapy with GCV [81, 96].

3.4 When and How to Monitor for HCMV Resistance

HCMV resistance to antivirals should be suspected in patients failing treatment who have been exposed to an antiviral for substantial periods of time (typically >3–4 months in AIDS patients and >6 weeks in transplant recipients), especially if some risk factors are present (i.e., D+/R− SOT, lung or kidney/pancreas transplant, AIDS patients with CD4 counts <50 cells/μL). Resistance should be suspected in pediatric patients with shorter periods of drug exposure if they had T-cell depletion. Clinical resistance is more likely if active viral replication (high or increasing levels of DNAemia/antigenemia or viremia) persists or recurs despite maximum IV doses of the antivirals [68, 78]. On the other hand, rising antigenemia levels during the first 2 weeks of antiviral therapy in HSCT recipients have not been associated with antiviral resistance, but rather with host and other transplant-related factors [94, 136]. Whenever antiviral resistance is suspected, phenotypic and/or genotypic investigation for resistance should be undertaken. As discussed above, genotypic methods are fast,

GCV ganciclovir, *FOS* foscarnet, *CDV* cidofovir, *EC_{50}* concentration of antiviral that reduces the number of viral plaques by 50 %

[a]Fold changes are calculated as the ratio of EC_{50} values of mutant recombinant virus to the wild-type counterpart. An increase in EC_{50} value ≥1.9-fold higher than that of the wild-type strain corresponds to drug resistance (in *bold*)

Regions indicated in brackets are located between conserved regions

more convenient, and provide useful information for selection of an alternative treatment. However, identification of mutations of unknown significance remains problematic, and, for that reason, phenotypic assays may still be necessary. Furthermore, genotypic assays do not quantitate the degree of resistance while phenotypic assays do. The choice of the sample to analyze may also have some importance. Some studies have reported that there is a good correlation between genotypes detected in the eyes and the blood (93.5 %) [137] or between blood and urine isolates (87.5 %) [134] of AIDS patients with HCMV retinitis. However, there have been at least some reports of resistant HCMV strains restricted to specific body compartments [99, 138–140]. This suggests that resistance assessment based solely on blood or urine samples may be suboptimal in some cases [32]. Therefore, genotypic testing of cerebrospinal fluid, bronchoalveolar lavages, or biopsy specimens could be occasionally performed in high-risk patients.

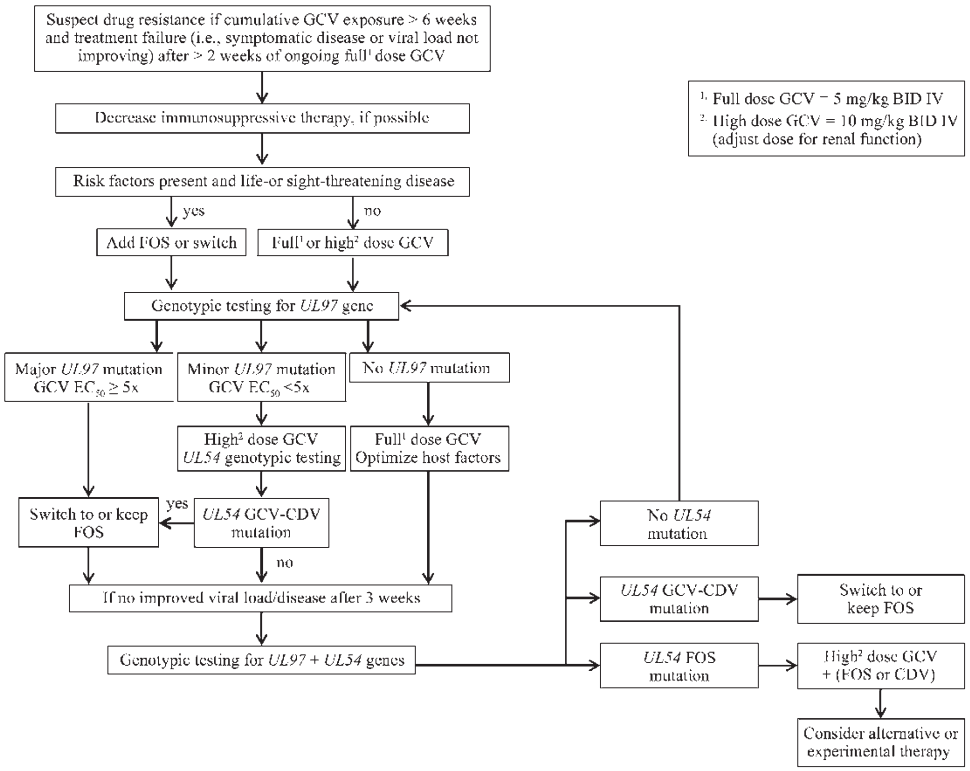

Fig. 72.3 Suggested algorithm for the management of suspected drug-resistant HCMV infections in solid organ transplant recipients. **Key**: *GCV* ganciclovir, *FOS* foscarnet, *CDV* cidofovir, *BID* twice a day, *IV* intravenous, EC_{50} concentration of antiviral that reduces HCMV replication in cultured cells by 50 % compared to the control (without drug) determined in phenotypic assay. Adapted from [141]

3.5 Management of Infections Caused by Drug-Resistant HCMV Strains

Guidelines for the management of GCV-resistant HCMV diseases in SOT have been established during consensus meetings organized by the Transplantation Society International CMV Consensus Group [141] with a suggested algorithm shown in Fig. 72.3. Antiviral drug resistance should be suspected in case of cumulative GCV exposure for more than 6 weeks and stable or rising viral loads (especially DNAemia levels) despite more than 2 weeks after initiating appropriate full dose IV GCV (5 mg/kg of body weight twice daily, adjusted for renal function). Whenever possible, improvement of the patient's immune status (i.e., reduction of immunosuppressive regimen in transplant patients or aggressive antiretroviral therapy in AIDS patients) should be considered. As the modulation of immunosuppression is rarely sufficient to control HCMV, the use of adjunctive immunoglobulins containing HCMV antibodies could be considered, but these agents are expensive, and their supply is limited. At the initial step, a clinical decision about an antiviral switch is empirical but should be based on the evaluation of host risk factors (e.g., D+/R− recipients, lung transplant recipients) and disease severity (sight- or life-threatening disease) [67, 78]. Full or higher doses of IV GCV (5 or 10 mg/kg twice daily, respectively, adjusted for renal function) can be administered to low-risk patients with mild disease [142], whereas FOS alone or combined with GCV can be initiated for high-risk patients with severe disease. Of note, clear evidence of the superiority of GCV and FOS combination over FOS alone has not yet been demonstrated [143]. As resistance mutations to GCV typically emerge in the protein kinase, *UL97* gene sequencing is first recommended. Genotypic assays are performed typically on whole-blood or plasma specimens [144]. Despite the limitations mentioned above, genotypic resistance testing is more practical and rapid than phenotypic assays. Thus, rescue therapy should be ideally based on results of the genotypic assays. In centers where genotypic testing is unavailable or performed infrequently, initial management should avoid the use of drugs with similar pathways of resistance. For instance, patients failing GCV should be given FOS alone or combined with GCV in the absence of any sequencing data due to high frequency of UL54 mutations that confer resistance to both GCV and CDV. If no mutation is identified in the *UL97* gene, full dose of IV GCV (5 mg/kg twice daily, adjusted for renal function) should be continued together with an optimization of host factors. If a high-level GCV resistance mutation (more than fivefold increase in EC_{50} value) is identified in the *UL97* gene, a switch to IV FOS is recommended (or IV FOS should be kept). If a low-level GCV resistance mutation (less than fivefold increase in EC_{50} value) is detected in the *UL97* gene, the patient could be re-induced with higher than normal doses of IV GCV (up to 10 mg/kg twice daily, adjusted for renal function), and drug

resistance mutations should be looked for in the *UL54* gene. If a mutation conferring cross-resistance to GCV and CDV is detected in the *UL54* gene, a switch to IV FOS therapy is recommended (or IV FOS should be kept).

The viral load is typically monitored once weekly by quantitative PCR during the period covering an episode of symptomatic HCMV disease. If there is no improvement in the viral load and a persistence of HCMV disease after a period of 3 weeks, genotypic testing should be repeated to assess the emergence of drug resistance mutations in both the *UL97* and *UL54* genes. If a mutation conferring cross-resistance to GCV and CDV is detected, a switch to IV FOS is recommended (or IV FOS should be kept). If a resistance mutation to FOS is detected, combination of high-dose IV GCV (10 mg/kg twice daily, adjusted for renal function) with IV FOS or CDV (5 mg/kg once a week for 3–4 weeks) should be considered. CDV has a long intracellular half-life that makes infrequent dosing possible. Because of its nephrotoxicity, CDV is routinely administered with probenecid and requires IV hydration. Antiviral therapy is typically continued until viremia is no longer detectable. In case of multidrug-resistant HCMV disease, alternative or experimental therapies should also be considered.

Several nonconventional interventions have been described for the treatment of multidrug-resistant HCMV diseases, although their clinical utility has not been adequately evaluated [145]. Immunoglobulins containing HCMV antibodies and adoptive infusions of HCMV-specific T cells [146] may improve antiviral host defenses. Artesunate, an antimalarial drug, demonstrates in vitro and in vivo activity against HCMV [147] including drug-resistant mutants [148], but its mechanism of action remains unclear. It is suggested that artesunate blocks the synthesis of viral immediate early proteins probably through inhibition of virus-supportive cellular activation pathways [149]. Clinical reports on the treatment of drug-resistant HCMV infections with artesunate are rare and controversial [128, 150, 151]. A recent study indicated that artesunate may be useful for the treatment of mild HCMV diseases due to multidrug-resistant strains but may not be effective against severe HCMV diseases [152]. Leflunomide, a prodrug with immunosuppressive, antiproliferative, and anti-inflammatory properties indicated for the treatment of rheumatoid arthritis, possesses anti-HCMV activity including against GCV-resistant isolates by acting on late-stage virion assembly through the inhibition of viral nucleocapsid and tegument development [153, 154]. Thus, no cross-resistance is expected with the current antiviral agents. The use of leflunomide, alone or in combination with antivirals or HCMV immunoglobulins, has been reported in 17 transplant recipients with complex HCMV syndromes failing to respond to available antiviral agents [155]. Initial clearance of HCMV viremia was observed in 82 % of patients, and 53 % of patients achieved long-term suppression of HCMV recurrences. A review of several case reports shows some efficacy for the use of leflunomide, alone or in combination with standard antiviral agents, particularly in transplant recipients refractory to current therapy [156]. Mammalian target of rapamycin (mTOR) inhibitors are immunosuppressive agents that may affect viral replication by inhibiting cellular pathways critical for HCMV infection and/or by influencing immune-mediated responses [157]. Combination of GCV and sirolimus for the treatment of GCV-resistant HCMV infections has led to favorable outcome with respect to antigenemia level and graft rejection in six kidney and three kidney/pancreas recipients [158]. Salvage therapy with a mTOR inhibitor (sirolimus or everolimus) was effective for the treatment of two SOT recipients with GCV-resistant HCMV infections [159].

4 Herpes Simplex Virus and Varicella-Zoster Virus Antiviral Drug Resistance

4.1 Phenotypic and Genotypic Assays to Evaluate HSV and VZV Drug Susceptibility

Phenotypically, HSV and VZV resistance to ACV is related to one of the following mechanisms: (1) a complete deficiency in viral TK activity (TK-deficient); (2) a decreased production of viral TK (TK low producer); (3) a viral TK protein with altered substrate specificity (TK altered), i.e., the enzyme is able to phosphorylate thymidine, the natural substrate, but does not phosphorylate ACV; and finally (4) a viral DNA pol with altered substrate specificity (DNA pol altered) [160–166]. Both TK and DNA pol mutants resistant to ACV exhibit a decrease in so-called in vivo "fitness" and neurovirulence. Alteration or absence of the TK protein is the most frequent mechanism seen in the clinic, probably because TK is not essential for viral replication in most tissues and cultured cells [161, 164, 167]. However, HSV TK plays an important role in the pathogenesis of infection as demonstrated in animal models [168]. It has been proposed that altered or deficient TK enzyme could not fulfill the greater requirement of thymidine phosphorylation for virus replication in neurons compared to other cells [169]. In this respect, TK low producer mutants show some reduction in pathogenicity compared to wild-type strains but are generally able to reactivate [170]. In contrast, TK-deficient mutants have impaired pathogenicity, establish latency in sensory ganglia with a lower efficiency than wild-type strains, and reactivate poorly [168, 171–174]. However, it has been suggested that some TK-deficient HSV clinical isolates express ultralow levels of enzyme activity that could be sufficient to allow reactivation [170, 175]. Moreover, phylogenetically related strains

sensitive and resistant to ACV can coexist in latently infected trigeminal ganglia of patients which may allow the reactivation of TK-deficient strains [176, 177]. As the HSV DNA pol is essential for viral replication, mutations emerging in this enzyme must be functionally conservative. Mutants with altered DNA pol activity have been less studied, but they seem to exhibit different degrees of attenuation of neurovirulence in mice [178–181].

The TK phenotype can be determined by the selective incorporation of radiolabeled iododeoxycytidine (IdC) and thymidine into infected cells using plaque autoradiography [182]. More recently, a nonisotopic enzyme assay has been developed to assess TK functionality by measuring monophosphate forms of both ACV and thymidine using high-performance liquid chromatography with diode-array detection [162].

Levels of drug resistance (EC_{50} values) are best measured by cell-based (phenotypic) assays. The plaque reduction assay (PRA) is the gold standard phenotypic method to determine the susceptibility of HSV isolates to antiviral drugs and is approved as a standard protocol by the Clinical and Laboratory Standards Institute [183]. Breakpoint values that are widely accepted to define HSV resistance to ACV and FOS are EC_{50} equal to or greater than 9 μM and 330 μM, respectively [183]. No consensus value has been proposed for PCV. Drug resistance can also be defined by an increase in the EC_{50} value greater than three to five times that of the baseline isolate from the same patient.

Susceptibility of VZV to antiviral drugs can be tested in the PRA by using fibroblastic cell lines such as human embryonic MRC-5 fibroblasts [184]. The low rate of VZV isolation from vesicle samples (from 20 to 43 %) and its slow growth in cell culture (typically 5–6 days) limit the use of the PRA in that context [185]. The endpoint for detecting resistance to ACV is a susceptibility index equal to or greater than four times that of a control, known sensitive reference strain such as the Oka strain [186].

An alternative to phenotypic assays is genotyping by sequence analysis. Mutations conferring resistance to nucleoside analogues occur in *UL23* (HSV) or *ORF36* (VZV) gene encoding the TK and/or in *UL30* (HSV) or *ORF28* (VZV) gene encoding the DNA pol. For a comprehensive genotypic analysis, the whole TK gene as well as the conserved regions of the HSV or VZV DNA pol gene sequences should be determined [187]. As some degree of inter-strain variability exists in these genes, mutations conferring drug resistance must be discriminated from natural polymorphisms. In this respect, results of genotypic testing must be interpreted by comparison with mutations already assigned to natural polymorphism or confirmed drug resistance in the literature. Different molecular biology-based systems can be used to generate HSV recombinant viruses and characterize the role of unknown mutations such as the transfection of a set of overlapping cosmids and plasmids allowing rapid site-directed mutagenesis in the gene of interest [188, 189] or the cloning of the viral genome of a control susceptible strain into a bacterial artificial chromosome [190] that can be then manipulated in bacteria.

4.2 Clinical Significance, Incidence, and Risk Factors for Drug-Resistant HSV and VZV Infections

Cases of HSV infections unresponsive to treatment in immunocompetent patients are usually associated with diagnoses of recurrent genital herpes, keratitis, and encephalitis. In general, most unresponsive cases in immunocompetent patients are not due to antiviral drug resistance. Furthermore, the rare instances of resistance in that setting are not associated with prolonged active lesions due to a functional immune system. Studies have shown that 0.1–0.6 % of HSV isolates recovered from untreated, prophylaxed, or treated immunocompetent subjects harbor a resistant phenotype to ACV ($EC_{50} \geq 8.8$ μM) as assessed by a PRA, and this seems to reflect the natural occurrence of TK-deficient mutants in a viral population [191–199]. Except for a few notable cases [200, 201], the occasional recovery of ACV-resistant HSV-2 from immunocompetent hosts has not been associated with clinical failure and proved to be transient [199, 202]. However, a relatively high prevalence (6.4 %) of ACV-resistant HSV-1 isolates has been reported in immunocompetent patients with recurrent herpetic keratitis [203], and some of these cases were clinically refractory to ACV therapy [204–207]. The cornea is an immune-privileged site where a lower immune surveillance could favor the rapid selection of drug-resistant viruses [208]. On the other hand, ACV-resistant HSV strains are more often isolated in immunocompromised hosts, and such isolates have been associated with persistent and/or disseminated diseases [16, 194, 209–214]. Patients with AIDS can develop extensive mucocutaneous lesions usually not associated with visceral or central nervous system infections [215]. In the few clinical surveys reported, the rate of ACV-resistant HSV isolates has varied from 4.3 to 14 % among all immunocompromised groups [194, 195, 198, 211, 215–217]. More specifically, 6.5 % of HSV isolates obtained from patients with cancer were resistant to ACV compared to 10 % from heart or lung transplant recipients and 6 % from AIDS patients [194]. Similarly, 7 % of HSV isolates recovered from AIDS patients were resistant to ACV compared to 5–14 % from diverse SOT and BMT recipients [211]. The prevalence of ACV resistance has ranged from 3.5 to 7 % in HIV-positive patients in several studies [195, 215, 217–219]. Of note, high prevalence rates have been reported in HSCT recipients, with a range of 4.1–10.9 %

[167, 195, 210, 220–224]. An even higher frequency (36 %) of ACV resistance in that population has also been reported [225]. Patients receiving either autologous or allogenic bone marrow have a similar incidence, i.e., 9 %, of HSV infection, but resistance only occurred in allogenic transplants, reaching a prevalence of 30 % in a study [226]. The severity of immunosuppression and the prolonged use of ACV are considered two important factors for the development of drug resistance. The impact of the severity of immunosuppression was underscored in adult patients undergoing lymphocyte-depleted hematopoietic progenitor cell transplant from HLA-matched family donors [225]. All seven evaluable HSV-1 or HSV-2 seropositive patients reactivated at a median of 40 days posttransplant, and the five strains tested were all resistant to ACV. Furthermore, FOS resistance developed rapidly in the three patients treated with this drug [225]. Importantly, the prevalence of ACV-resistant HSV isolates has remained stable in immunocompromised patients over the past two decades [194, 195], and there has been no unequivocal evidence of transmission of a resistant HSV strain from person to person. Drug-resistant HSV mutants have been isolated in some patients in the absence of known history of ACV exposure [227, 228] and likely represent the natural rates of TK mutations.

Only a few FOS-resistant HSV isolates ($EC_{50} \geq 330$ μM or a threefold increase in EC_{50} value compared to the parental susceptible strain) have been reported in the clinic mainly in AIDS patients failing therapy [17, 229–236]. Nine FOS-resistant HSV clinical isolates from HIV-infected subjects for whom ACV and FOS therapy sequentially failed have been described [236]. Interestingly, most of these isolates retained susceptibility or, at the most, borderline levels of susceptibility to ACV and CDV [236, 237].

The emergence of VZV isolates resistant to ACV has not been described in immunocompetent individuals with primary VZV infections or herpes zoster, except for one case report of a patient with an ACV-resistant VZV keratitis [238]. Cases of resistance to ACV have been described in patients with AIDS, SOT, and HSCT recipients as well as hemato-oncological patients with VZV reactivations unresponsive to therapy [184, 239–242]. In these patients, VZV infections not responding to ACV therapy persist in the form of chronic skin lesions and are associated with significant morbidity and mortality due to visceral dissemination. An unusual verrucous form of VZV infections caused by ACV-resistant mutants has also been described in some of these patients [243, 244]. Two cases of immunocompromised children presenting herpes zoster due to the Oka vaccine strain and who developed chronic disseminated drug-resistant VZV infections following ACV therapy have been reported [243, 245]. However, the prevalence of ACV-resistant cases in these different populations is unknown because only case reports have been published so far. In a recent study, it was reported that 27 % of hemato-oncological patients, including HSCT recipients, with persistent VZV infections had mutations probably associated with ACV resistance [246]. Few reports have described the emergence of VZV strains resistant to FOS in immunocompromised patients [17, 229, 231, 242, 247].

4.3 Role of Thymidine Kinase and DNA Polymerase Mutations in Drug-Resistant HSV and VZV Clinical Strains

In HSV clinical isolates, resistance to ACV is mediated in 95 % of the cases by mutations in the *UL23* gene and, in the remaining cases, by mutations in the *UL30* gene [39, 248, 249]. Resistance hot spots in the *UL23* gene consist of either additions or deletions in homopolymer runs of Gs and Cs leading to a premature stop codon [161, 167, 250]. The remaining ACV-resistant clinical isolates have single amino acid substitutions in conserved (especially in the ATP-binding site, the nucleoside-binding site, and at amino acid 336) and nonconserved regions of the TK polypeptide (Table 72.3; Fig. 72.4a) [39, 248, 249]. Globally, each mechanism (additions/deletions or substitutions) accounts for approximately 50 % of ACV-resistant phenotypes in the clinic [161]. However, recent studies reported an increased proportion of additions/deletions which accounts for 62 % [263] or even 80 % [264] of *UL23* gene mutations. Most HSV DNA pol mutations conferring ACV resistance are located in the conserved regions of the enzyme, especially in regions II, III, VI, and VII, the greatest clusters being found in regions II and III (Table 72.4; Fig. 72.4b) [236, 270]. Only a few mutations have been described within the other conserved domains or outside such regions [236]. Most FOS-resistant clinical isolates contain single amino acid substitutions in conserved regions II, III, and VI and in a nonconserved region (between regions I and VII) of the DNA pol [236, 237]. Mutations within conserved regions II and VI are frequently associated with resistance to both ACV and FOS. The mutations S724N (region II) and L778M (region VI) in HSV-1, which confer cross-resistance to ACV and FOS, also cause reduced susceptibility to CDV [188]. Genotypic analyses of drug-sensitive HSV strains reveal a high degree of polymorphism in the *UL23* and *UL30* genes [268, 271, 272].

In VZV clinical isolates, resistance to ACV is mostly associated with mutations in the viral TK (Table 72.3; Fig. 72.4a) and, less frequently, with mutations in the viral DNA pol (Table 72.4; Fig. 72.4b) [39, 249]. The genome of VZV has a lower GC content (46 %) than those of HSVs (68 %), and only a few homopolymer stretches are present in the *ORF36* gene [273]. The string of six cytosines located at codon position 493–498 within this gene emerged as a hot

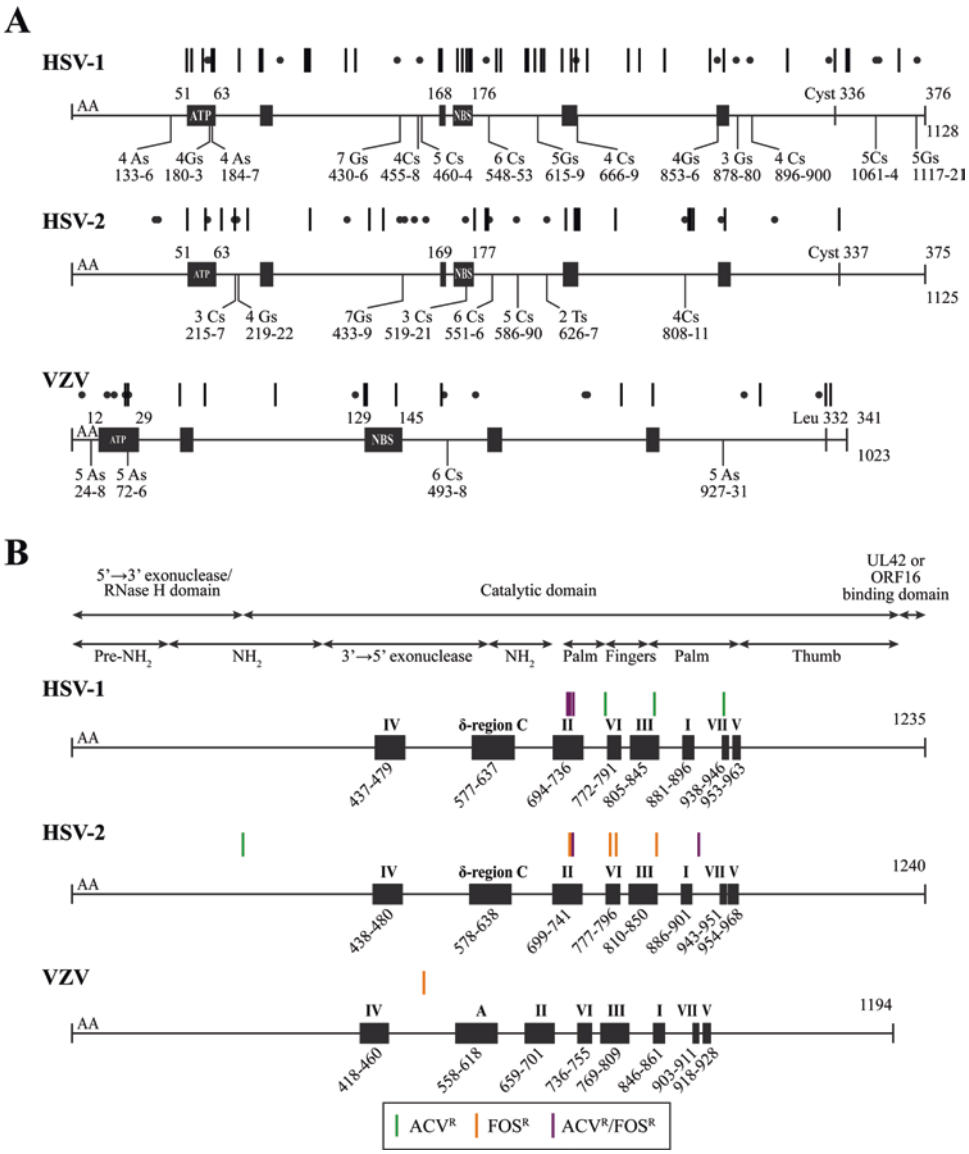

Fig. 72.4 Confirmed drug resistance mutations identified in clinical HSV-1, HSV-2, and VZV isolates. Panel (**a**) shows mutations in the *UL23* gene of HSV-1 and HSV-2 and in the *ORF36* gene of VZV conferring resistance to acyclovir. Conserved regions among the thymidine kinase of *Herpesviridae* including the ATP-binding site (ATP) and the nucleoside-binding site (NBS) are represented by the *black boxes*. Bars (|) indicate amino acid substitutions, whereas dots (*filled circle*) represent nucleotide additions and/or deletions. The homopolymer runs, as well as the nucleotides involved, are indicated below vertical bars. Panel (**b**) shows mutations in the *UL30* gene of HSV-1 and HSV-2 and in the *ORF28* gene of VZV conferring resistance to acyclovir (ACV^R) and/or foscarnet (FOS^R). Conserved regions among the *Herpesviridae* DNA polymerase are represented by the *black boxes*. The roman numbers (I–VII) and δ-region C corresponding to each of these regions are indicated above the boxes. Colored bars (|) indicate amino acid substitutions

spot for the insertion or deletion of nucleotides involved in ACV resistance [239, 240, 246, 273]. Deletions of nucleotides that result in frameshift reading leading to a stop codon at position 231 are often detected in ACV-resistant clinical isolates [240]. In addition, nonsynonymous nucleotide substitutions conferring resistance to ACV are widely dispersed in the *ORF36* gene [184, 186, 239–241, 262, 274]. However, these amino acid changes occur more frequently in the ATP-binding and nucleoside-binding sites of the TK enzyme [240].

A few reports have described ACV-resistant and/or FOS-resistant VZV clinical isolates with mutations in the *ORF28* gene [242, 274, 275]. The amino acid substitutions are mainly found in the catalytic site and in the conserved regions of the DNA pol and may confer cross-resistance to ACV and FOS. The TK and DNA pol of VZV are highly conserved compared with those of HSVs, and only few natural polymorphisms have been identified in the *ORF36* and *ORF28* genes [274].

4.4 Management of Infections Caused by Drug-Resistant HSV and VZV Strains

An algorithm for the management of infections caused by drug-resistant HSV mutants is proposed in Fig. 72.5. The persistence of active lesions due to HSV for 7–10 days after initiation of high-dose oral ACV, VACV, or FCV therapy without appreciable decrease in size, an atypical appearance, or the emergence of satellite lesions is suggestive of treatment failure. When drug resistance is suspected, a change of therapy should be considered depending on the clinical severity of the disease. Most ACV-resistant strains isolated from immunocompromised patients are TK-deficient and are therefore also resistant to VACV and FCV. An initial step in case of treatment failure with oral drugs is to initiate high doses of IV ACV (10 mg/kg of body weight every 8 h adjusted for renal function). If there is no improvement after 7 days, a switch to IV FOS (40 mg/kg every 8 h with reduction in dose for renal

dysfunction) should be considered. In parallel, isolates from the lesions should be submitted for phenotypic susceptibility testing (starting with ACV and FOS and then CDV, if required) and/or genotypic assays of the *UL23*/*UL30* genes if the patient is failing therapy. Standard doses of IV ACV have no clinical benefit if the HSV isolate is resistant to ACV in vitro and IV FOS should be continued. If there is still no improvement of HSV disease after 7–10 days, another option could be to administer continuous infusion of high-dose ACV (e.g., 1.5–2.0 mg/kg per hour) as it is a well-tolerated alternative for severe ACV-resistant or multidrug-resistant HSV infections [276, 277]. Intravenous CDV has shown some efficacy in the treatment of progressive ACV-resistant and/or FOS-resistant mucocutaneous HSV infections in immunocompromised patients [278–281] but is not approved for this indication. A switch to IV CDV (5 mg/kg once a week for 3–4 weeks) could also be considered.

A topical cream containing 1 % FOS was effective in the treatment of mucocutaneous infections unresponsive to ACV [282]. Topical formulations of CDV also demonstrated efficacy in the treatment of drug-resistant mucocutaneous HSV infections [283–286]. Although the use of topical formulations could avoid the adverse effects associated with IV administration of FOS and CDV, they are not commercially

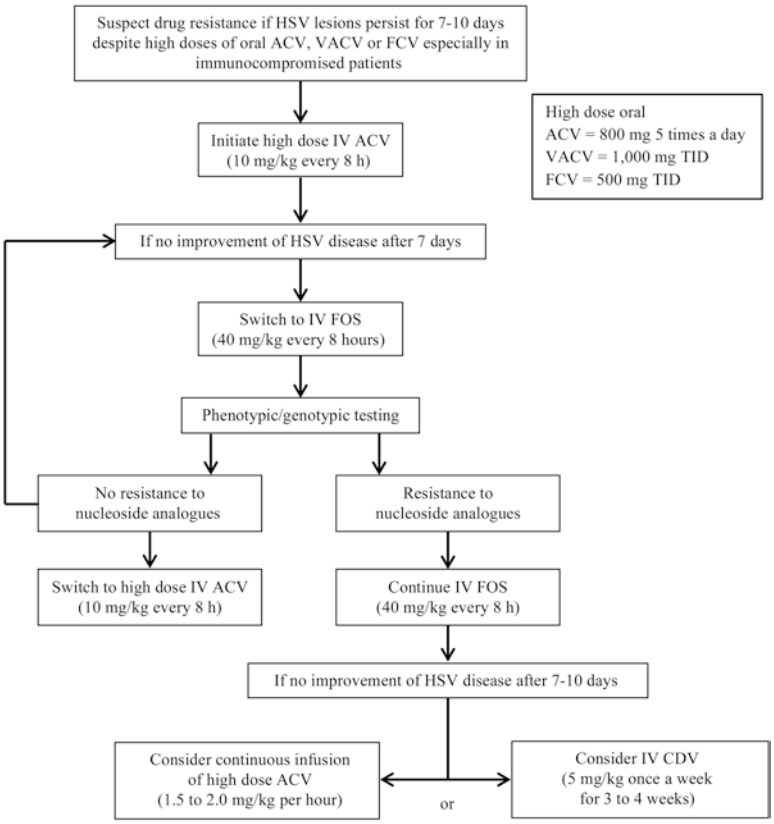

Fig. 72.5 Proposed algorithm for the management of suspected nucleoside analogue-resistant HSV infections. **Key**: *ACV* acyclovir, *VACV* valacyclovir, *FCV* famciclovir, *FOS* foscarnet, *CDV* cidofovir, *TID* thrice a day, *IV* intravenous

available. A topical formulation containing 5 % imiquimod, an immunomodulatory drug, was effective in the treatment of recurrent and severe mucocutaneous lesions due to ACV-resistant and FOS-resistant HSV-2 isolates in HIV-infected individuals [287]. A 1 % topical solution of trifluorothymidine, a fluorinated pyrimidine nucleoside analogue that inhibits thymidylate synthetase, is usually administered in cases of ophthalmic herpetic infections that do not respond to ACV [288].

The persistence of clinical signs of VZV infections for more than 10–14 days after initiation of high-dose oral ACV is suggestive of treatment failure, and it should lead to alternate therapy depending on the clinical severity of the disease [289]. Genotypic testing of the *ORF36* gene encoding for the TK protein could be performed in biopsy of mucocutaneous lesions or other body compartments when necessary [290]. FOS is generally used for the management of VZV infections due to suspected or confirmed ACV-resistant mutants, as described mainly in HIV-infected individuals [17, 291] and some oncology patients [243–245]. The recommended IV dosage is 60 mg/kg every 8 h adjusted for renal function for at least 10 days or until complete lesion healing is observed [289]. Clinical experience with the use of CDV in the treatment of drug-resistant VZV diseases is very limited [292].

5 Conclusions and Future Directions

With the increasing number of immunocompromised subjects and the prolonged administration of antiviral agents, the problem of drug resistance among herpesviruses is not expected to fade. Clearly, some drug-resistant mutants of HCMV and HSV are pathogenic and can result in significant morbidity and mortality among severely immunocompromised patients. The development of fast and efficient methods for detecting viral mutant sequences directly in clinical specimens such as pyrosequencing [293] and ultra-deep pyrosequencing [44–46, 294] will improve the early diagnosis of drug-resistant herpesvirus infections. The use of more powerful recombinant phenotyping techniques [61] and the availability of an Internet database [51] to link individual mutations to their drug susceptibility phenotypes should result in more rational therapeutic strategies.

As all currently available antiviral agents target the viral DNA pol, the development of new anti-herpetic compounds with different mechanisms of action and with adequate safety profiles is an important priority. In that regard, some promising compounds are currently in clinical trials. The orally bioavailable lipid ester prodrug of CDV (i.e., hexadecyloxypropyl-cidofovir; CMX001) could avoid the dose-limiting toxicity of the parent drug and provide a safe alternative

for ACV- and GCV-resistant herpesviruses in immunocompromised patients [295]. Treatment with oral CMX001 (brincidofovir) significantly reduced the incidence of HCMV events in HSCT recipients [296]. Maribavir is a competitive inhibitor of the UL97 kinase [297]. Surprisingly, mutations arising after in vitro selection with this drug most often map to the *UL27* gene and, less frequently, to the *UL97* gene. Of note, mutations found in the *UL97* gene are distinct from those described in GCV-resistant strains [298], and some have been detected outside the conserved kinase domains [19]. Thus, maribavir retains activity against GCV-resistant HCMV mutants. The emergence of resistance to this drug has been reported in some clinical cases [299, 300]. Recently, maribavir faced some limitations in phase III clinical studies [301], but new trials evaluating higher doses are in progress. Letermovir targets the terminase complex of HCMV and interferes with viral DNA concatemer maturation [302, 303]. Accordingly, mutations conferring resistance to letermovir map to the *UL56* gene encoding the HCMV terminase [302, 304]. Successful treatment of a multidrug-resistant HCMV infection with letermovir has been reported in a lung transplant recipient [305]. Preemptive treatment of HCMV infection with letermovir was effective in kidney transplant recipients [306]. Moreover, prophylaxis with letermovir was effective in reducing the incidence of HCMV infection in HSCT recipients [307]. Pritelivir, a potent orally bioavailable helicase-primase inhibitor, reduced the rates of genital HSV-2 shedding and days with lesions in a phase II trial [308]. The bicyclic nucleoside analogue FV-100 and carboxylic nucleoside analogue valomaciclovir were well tolerated and effective for the treatment of herpes zoster in phase II trials [12, 309]. Novel classes of antiviral agents targeting the ribonucleotide reductase, the helicase-primase complex, and the process of viral DNA encapsidation are at earlier stages of development [310].

Clinical Implications of HIV-1 Drug Resistance

73

Douglas L. Mayers and John D. Baxter

1 Introduction

The human immunodeficiency virus type 1 (HIV-1) is a retrovirus that has an error-prone reverse transcriptase enzyme that results in the production of swarms of related viruses called quasi-species in each infected person. This replication strategy involves production of 10^7–10^9 virions per day, each with a half-life of only 1–2 days [1–3]. HIV-1 utilizes an error-prone reverse transcriptase enzyme that lacks proofreading activity and generates 3×10^{-5} errors per base pair per replication cycle [1]. Since there are roughly 9000 base pairs per virion, every possible single- and double-mutant virus is created every day in every patient in the absence of antiretroviral therapy. This strategy allows the virus to escape immune selection pressure and is very efficient at generating drug-resistant viruses in those patients whose drug regimens do not completely suppress viral replication or who are poorly compliant with a fully suppressive regimen.

Since single base drug-resistant mutants preexist in every patient at low frequencies, they can emerge as the predominant circulating virus in as little as 14 days if monotherapy is utilized. This is seen with drugs such as lamivudine (with an M184V mutation) or non-nucleoside reverse transcriptase inhibitors such as efavirenz or nevirapine (with K103N or Y181C mutations) where single-point mutations cause high-level drug resistance. Alternatively some drugs have a higher barrier to resistance due to the need for multiple mutations to cause high-level resistance, which can take months to develop. A small group of drugs develop low levels of resistance slowly, possibly because their primary resistance mutations are associated with low replication capacities (Table 73.1).

The development of drug resistance is associated with rising plasma HIV RNA levels, declining CD4 cell counts, and disease progression. The prevalence of drug-resistant HIV-1 in treated patients with detectable plasma virus is approximately 80 %. Drug-resistant HIV-1 is transmitted to 10–27 % of newly HIV-infected persons. The rapid emergence of NNRTI resistance after use of single-dose nevirapine to block mother-to-child transmission of HIV-1 has impacted treatment options in resource-limited countries.

Additionally, each virion contains two strands of genomic RNA and the reverse transcriptase enzyme can jump from one RNA template strand to the other when replicating the viral genome [4–6]. If two strains of HIV-1, each resistant to one agent, are circulating in a patient the virus can use recombination to generate a new virus resistant to both drugs. The clinical relevance of recombination in generating drug-resistant HIV-1 has not been established although it has been demonstrated in both in vitro experiments and in clinical viruses [7, 8].

Genotypic and phenotypic resistance assays are commercially available to assist in the management of HIV-infected patients. Due to the current prevalence of transmitted HIV-1 drug resistance, resistance testing is recommended when treatment is initiated and prior to switching drug regimens after virologic rebound has occurred. It is critical that patients be given a drug regimen that contains at least two and preferably three active antiretroviral drugs to ensure complete viral suppression. Combining less than three active drugs often leads to rapid viral breakthrough with resistance to the new class of drugs used. Treatment decisions need to take into account prior drug exposure, drug toxicities on prior antiviral regimens, and resistance test results on both prior and the most recent antiretroviral drug regimen. Where available, advice from an expert with experience in treating patients with drug-resistant HIV-1 should be obtained.

		Dolutegravir (DTG)	

[a]Selected viral mutants may have low replication capacities

2 Epidemiology

With the HIV-1 quasispecies replication strategy it is critical that patients be given a drug regimen which is expected to fully suppress all viral replication. This goal was not achievable for most patients in the early years of HIV-1 therapy when regimens containing only nucleoside agents were available. Many patients developed viruses with progressively higher levels of nucleoside resistance and broad resistance to all agents in the nucleoside class. This nucleoside resistance often limited the durability of responses to subsequent combination regimens which combined nucleoside agents with protease inhibitors or non-nucleoside reverse transcriptase inhibitors (NNRTIs) as they became available. Additionally, the early combination regimens were composed of agents with a high pill burden, multiple doses per day, and significant side effects which reduced patients' ability to take medications as prescribed. Thus, a large population of patients with resistance to multiple classes of HIV-1 agents was created in the late 1980s and 1990s. The more recent development of simple, once- or twice-a-day regimens of highly active antiretroviral therapy (HAART) with NNRTIs, boosted protease inhibitors, or integrase inhibitors appears to improve patient compliance and may result in more durable antiviral responses with reduced numbers of patients harboring viruses with resistance to multiple classes of antiretroviral drugs in the future.

3 Prevalence

A series of studies of the prevalence of drug-resistant HIV-1 in treated patients were conducted in North America and Europe between 1996 and 2013 (Table 73.2) [9–12]. Investigators in the United States evaluated a random representative sample of treated patients and estimated that 63 % of treated patients had viremia of >500 copies/mL [9]. Among viremic patients, the overall rate of any drug resistance was very consistent across the cohorts at 69–80 % of treated patients. Rates of resistance to nucleoside reverse transcriptase inhibitors (NRTI) ranged from 64 to 78 %, non-nucleoside reverse transcriptase inhibitors (NNRTI) from 25 to 61 %, and protease inhibitors (PI) from 31 to 62 %. Three classes of drug resistance (multidrug-resistant viruses) were detected in 13–25 % of viremic treated patients. The most common NRTI mutations detected were M184V associated with lamivudine use and T215Y/F associated with zidovudine use. The rates of NNRTI and PI resistance were driven by general use in the treated population with NNRTI resistance increasing from 1996 to 2003 as NNRTI use became more widespread [9–12]. The most common NNRTI mutation was K103N. PI mutations varied with differential use in the different countries.

Factors associated with the development of HIV drug resistance have included host factors such as advanced HIV disease and low CD4 count at the time of initiation of

treatment, viral factors such as high baseline viral load and transmitted drug resistance, and drug regimen factors related to adherence, and the potency and composition of the antiretroviral regimen given [9, 13, 14].

4 Transmission

HIV-1 is transmitted predominantly through sexual contact, due to blood exposure, and from mother to child. Factors associated with the risk of HIV transmission include high viral load, concomitant sexually transmitted diseases, host genetic factors, and high-risk behaviors. Persons with drug-resistant HIV-1 can transmit the virus to their partners.

Interestingly, differential transmission of drug resistance mutations has been observed. Viruses containing the M184V mutation in reverse transcriptase or major protease mutations appear underrepresented in newly infected patients compared to the frequency in prevalently infected populations [12, 15]. This could be due to reduced replication capacity combined with lower viral loads in the potentially transmitting patients with these viruses [12, 16].

The sexual transmission of zidovudine-resistant virus was first reported in 1993 [17]. Surveys of HIV-1 drug resistance have subsequently demonstrated different patterns of transmitted drug resistance over time with some evidence of geographic variability [18–29]. Representative studies where prevalent and incident HIV-1 drug resistance can be compared are presented in Table 73.2. In the period from 1995 to 1998 in North America and Europe, the predominant resistance in transmitted HIV-1 was to nucleoside antiretroviral agents (NRTIs) with rates ranging from 8.5 to 13.4 % and low levels of transmission of viruses resistant to NNRTIs (1.7–2.6 %) or protease inhibitors (0.9–2.8 %). In later surveys in North America and Europe from 1999 to 2002, rates of NRTI resistance ranged from 6.3 to 15.9 %, NNRTIs from 6.6 to 13.2 %, and PIs from 3.2 to 9.1 %. A recent review of global transmitted drug resistance (TDR) prevalence showed that transmitted NNRTI resistance has historically been higher in North America compared to Europe and that rates increased in North America after the year 2003 [30, 139]. The incidence of newly infected patients with drug-resistant virus ranges from approximately 10 to 27 % with multidrug-resistant viruses estimated to be present in 0–4 % [19–21, 23, 31]. As was seen with prevalent HIV drug resistance, transmitted NNRTI resistance has progressively increased from 1996–1997 to 2000–2001 [19–21, 23]. A CDC survey of 1082 treatment-naïve newly diagnosed patients who did not have AIDS showed that 8.6 % of these patients had genotypic evidence of drug-resistant HIV-1 and

1.3 % had MDR virus [32]. A subsequent surveillance study conducted in the United States revealed high percentage of transmitted NNRTI resistance in 7.8 % of newly diagnosed individuals [33].

In recent years, TDR has also been described as an emerging health issue in resource-limited countries, although surveillance data has been lacking [30, 34–36]. In these regions antiretroviral therapy has been introduced more recently and has significantly impacted morbidity and mortality, but access to virologic monitoring techniques is often limited. In the absence of modern laboratory monitoring, there is an increased risk of transmission of drug-resistant HIV-1 in a population given the prolonged time between the onset of initial virologic failure and subsequent clinical consequences. Not surprisingly, TDR prevalence in resource-limited countries is directly correlated with the number of years since ART roll-out programs were initiated [30].

Transmitted drug-resistant viruses can persist for long periods of time in the absence of treatment in comparison to the reversion to wild-type (drug-sensitive) viruses that occurs in patients who develop drug-resistant virus on treatment and then stop therapy [37–41]. It is not clear whether these viruses have altered pathogenicity from the available data [39, 42–44]. Transmitted drug resistance has been associated with an increased risk of suboptimal virologic response to the initial regimen and can also impact future treatment options. The median time to virologic suppression is longer in patients with primary drug-resistant viruses who receive combination therapy than in patients who are infected with drug-sensitive virus [21].

The high prevalence of drug resistance in newly infected patients has led to guideline recommendations that all newly diagnosed HIV-infected patients should have drug resistance testing prior to initiating antiretroviral therapy, if testing is available [45–50].

5 Prevention of Mother-to-Child Transmission

Mother-to-child transmission of HIV-1 remains a major problem in the developing world. Initial studies showed that zidovudine given antepartum, and intrapartum to the mother and to the newborn for 6 weeks, could reduce the rate of mother-to-child transmission by 67 % [51]. Subsequently, the HIVNET 012 study in Uganda showed that single-dose nevirapine given perinatally to mother and child could reduce mother-to-child transmission of HIV-1 to 15.7 % compared to 25.8 % at 18 months of follow-up in a breast-feeding population [52]. The simple, effective single-dose nevirapine regimen has been widely used throughout the developing world. Subsequently, it was shown that single-dose nevirapine would induce NNRTI-resistant virus in 20–25 % of mothers and 46 % of exposed HIV-infected infants using population sequencing [53, 54]. If more sensitive measurements of NNRTI resistance mutations are used, higher levels of NNRTI resistance can be detected. If these mothers require treatment with a nevirapine-containing regimen within 6 months after exposure to single-dose nevirapine, treatment responses to nevirapine-containing regimens are significantly reduced [55, 56]. Longitudinal studies have shown that the prevalence of NNRTI-resistant virus in the mothers exposed to single-dose nevirapine declines over time [54, 57] and mothers who require treatment more than 6 months after prior exposure to single-dose nevirapine have treatment response rates similar to women who have not been previously exposed to nevirapine [56]. The development of drug-resistant virus with regimens to prevent mother-to-child transmission of HIV-1 has driven the use of short-term combination treatment in the developed world. As combination antiretroviral therapy becomes more widely available through roll-out programs in resource-limited countries, the ultimate solution will be to provide chronic fully suppressive combination therapy to all HIV-1-infected mothers.

6 Clinical Significance

The emergence of drug-resistant HIV-1 during treatment has been associated with rising plasma HIV RNA levels, declining CD4 cell counts, and reduced responses to subsequent courses of antiretroviral therapy [58, 59]. Development of multidrug-resistant HIV-1 is associated with disease progression and death [60].

Some patients who develop drug-resistant HIV-1 while on a protease inhibitor-containing regimen can maintain low levels of plasma HIV RNA and stable CD4 cell counts for several years [61]. This may be due to reduced levels of replication capacity (viral fitness) in the viruses that emerge on these regimens. Ultimately, many of these patients will experience CD4 decline and HIV-1 disease progression with multidrug-resistant virus.

7 Resistance to HIV Nucleoside Reverse Transcriptase Inhibitors (NRTI)

HIV nucleoside reverse transcriptase inhibitors (NRTI) block HIV replication by chain termination of the growing DNA strand [62]. Resistance to these agents occurs via mutations which selectively block incorporation of the incoming NRTI, such as L74V for didanosine, V75T for d4T, and M184V for 3TC resistance, or alternatively via thymidine analog mutations (TAMs) associated with zidovudine use at positions M41L, D67N, K70R, L210W,

T215Y/F, and K219Q/E that allow the reverse transcriptase to selectively excise the incorporated NRTI by increased phosphorolysis [63, 64]. Generally increasing numbers of NRTI mutations in the reverse transcriptase enzyme are associated with higher levels of drug resistance and broadened resistance to agents in the NRTI class [65]. Multi-NRTI resistance is most commonly produced by sequential accumulation of TAMs with M184V and additional NRTI-resistance-associated mutations [66]. Less commonly virus can develop the Q151M mutation (often combined with A62V, V75I, F77L, and F116Y) or by amino acid insertion(s) at position 69S combined with multiple TAMs to produce broad resistance to agents of the NRTI class [67–70]. HIV-1 NRTI resistance is reviewed extensively in Chap. 33.

8 Resistance to HIV-1 Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)

HIV-1 non-nucleoside reverse transcriptase inhibitors all bind to a common pocket and block the action of HIV RT in a noncompetitive way [71, 72]. HIV-2 viruses and HIV-1 clade O viruses found in West Africa are naturally resistant to all available NNRTIs [73]. In all other HIV-1 clades, resistance to the first-generation HIV-1 NNRTIs, nevirapine and efavirenz, is generally produced by a single-point mutation at position K103N or Y181C/I resulting in high-level resistance and/or a transient response with rapid viral rebound to these agents [74, 75]. If these agents are continued after viral rebound occurs, additional mutations at positions L100I, V106A/M, V108I, Y188C/L/H, G190S/A, and P225H can be selected [74, 75].

Second-generation NNRTIs, etravirine and rilpivirine, have been introduced into clinical practice to treat patients with NNRTI-resistant virus. These agents are active against viruses with the common K103N mutation. Resistance to etravirine is associated with mutation at positions V90I, A98G, L100I, K101E/P, V106I, V179D/F, and G190S/A, usually in combination with Y181C [76]. Rilpivirine is associated with mutations at positions L100I, K101E/P, E138A/G/K/Q/R, V179L, Y181C/I/V, Y188L, H221Y, F227C, and M230I/L, and interestingly the NRTI M184I mutation can reduce rilpivirine susceptibility when it occurs in combination with either E138K or K101E [77]. Additionally, responses to these agents are reduced when multiple NNRTI-associated resistance mutations are present in the circulating virus. This strongly suggests that patients should not be maintained on a nevirapine- or efavirenz-containing regimen after virologic rebound to prevent development of resistance to the newer second-generation NNRTIs. HIV-1 NNRTI resistance is reviewed extensively in Chap. 34.

9 Resistance to HIV-1 Protease Inhibitors (PI)

HIV protease inhibitors (PI) act by preventing the HIV protease enzyme from cleaving the Gag protein, an essential step of the viral maturation process [78]. Resistance to HIV PIs is a multistep process involving the development of primary mutations in the active site of the protease enzyme responsible for drug resistance and the appearance of secondary compensatory mutations away from the active site which increase the protease enzymatic efficiency [79–81]. Single mutations are generally not sufficient to significantly reduce phenotypic susceptibility for most PIs. Typically, the accumulation of multiple mutations is required to confer resistance to these agents. The accumulation of multiple primary protease resistance mutations (D30N, G48V, I50V, V82A/F/T/S, I84V, or L90M) alters the protease enzyme-binding pocket leading to increasing and broadened PI resistance [82]. Second-generation PIs active against viruses resistant to the first-generation PIs include the agents tipranavir and darunavir.

Mutations can also occur outside of the protease gene contributing to the development of PI resistance. Viral evolution of mutations and insertions at gag cleavage sites may occur after exposure to PIs. These mutations are associated with the restoration of protease enzyme activity and viral replicative capacity that is typically compromised in multi-PI-resistant variants [83–89]. Viruses are able to adapt to the altered drug-resistant protease enzyme by mutating their gag cleavage sites to fit an altered enzyme-binding pocket [90, 91]. When this occurs, the virus becomes "locked" into the altered enzyme configuration since reversion of resistance would require simultaneous reversion of the protease resistance mutations and the gag cleavage site mutations. Gag cleavage site mutations represent another mechanism of PI resistance; however because they occur outside of the protease region they are not generally detected on standard HIV genotypic resistance testing. HIV-1 protease inhibitor resistance is reviewed extensively in Chap. 35.

10 Resistance to HIV-1 Entry Inhibitors

HIV-1 entry inhibitors prevent the HIV envelope proteins gp120 and gp41 from interacting with their cellular receptors and fusing with the host cell membrane.

Enfuvirtide (T-20) blocks the fusion of the viral and host cell membranes mediated by gp41 [92]. The mutations which produce enfuvirtide resistance usually occur at codons 36–45 in the first heptad repeat region (HR1) of gp41 and are not detected with conventional genotypic or phenotypic HIV resistance assays [93]. Patients are generally assumed to have virus sensitive to enfuvirtide if the drug has not been

administered previously and are assumed to have virus with enfuvirtide resistance if they have received enfuvirtide previously and experienced viral rebound on the agent.

Maraviroc, a CCR5 inhibitor, blocks the interaction of the HIV-1 gp 120 envelop protein with the CCR5 molecule on the surface of host cells [94]. The virus gp120 envelope initially binds to CD4 followed by secondary binding to either CCR5 or CXCR4 on the host cell surface. Viruses which are R5-tropic (bind CCR5 to enter host cells) are inhibited by maraviroc while viruses which are X4-tropic (bind CXCR4 to enter host cells) or have a mixed R5/X4 tropism are not inhibited. R5-tropism predominates at the time of infection and during the early stages of HIV disease when patients are asymptomatic. As HIV disease progresses and CD4 cells decline viruses with a mixed R5/X4-tropism or X4-tropism become more common. A tropism assay should be obtained to confirm the presence of R5-tropic virus before maraviroc is given. Viral rebound in the presence of maraviroc therapy is generally assumed to be due to the emergence of X4-tropic virus but this can be confirmed by a tropism assay. Both phenotypic and genotypic tropism assays are currently available. HIV-1 entry inhibitor resistance is reviewed extensively in Chap. 36.

11 Resistance to HIV Integrase Inhibitors

HIV-1 integrase inhibitors block the strand transfer reaction that the HIV integrase uses to insert the HIV genome into host cell DNA [95]. Reduced susceptibility to the first FDA-approved integrase inhibitor, raltegravir, is mediated by two pathways of resistance in the HIV-1 integrase gene: Q148H/K/R combined with either L74M+E138A, E138K, or G140S, or N155H combined with either L74M, E92Q, T97A, E92Q+T97A, Y143H, G163K/R, V151I, or D232N [96]. Integrase mutations associated with elvitegravir resistance include many of the raltegravir-associated mutations and cross-resistance between these agents in common [77]. Additional mutations associated with reduced susceptibility to elvitegravir include S147G and T66I/A/K. Dolutegravir is considered a second-generation integrase inhibitor as it often remains active against HIV-1 strains with reduced susceptibility to raltegravir and elvitegravir. Resistance to dolutegravir is usually associated with Q148H/K/R in combination with G140A/C/S, E138A/K/T, or L74I [77]. Patients experiencing virologic failure while taking integrase inhibitors should have integrase drug resistance testing. In addition, genotypic resistance testing for integrase mutations should be considered in treatment-naïve patients if there is concern for transmitted drug resistance to these agents. HIV-1 integrase inhibitor resistance is reviewed extensively in Chap. 37.

12 Mutational Interactions

Some drug resistance mutations in the HIV genome can interact to result in resensitization of the virus to an antiviral drug to which it was previously resistant. For instance, if a virus is resistant to zidovudine with multiple TAMs and a T215Y/F mutation and develops an L74V mutation due to exposure to didanosine [97] or a Y181C mutation due to nevirapine exposure [98], the virus can show zidovudine sensitivity on a phenotypic sensitivity assay. Viruses with multiple TAMs from nucleoside exposure can demonstrate hypersusceptibility to NNRTI agents and this has been shown to result in better responses to efavirenz-containing regimens when the next round of therapy is given (provided adequate background therapy is available to combine with the NNRTI) [99–102]. Likewise, the M184V mutation enhances susceptibility to tenofovir in the presence or absence of TAMS [77]. Knowledge of mutational interactions can sometimes be used to obtain an enhanced response from a component of a combination regimen in treatment-experienced patients. It should be kept in mind that most of these mutational interactions can be overcome by the virus moving to an alternative resistance pathway so that they are only of clinical benefit if a fully suppressive next regimen can be designed.

13 Viral Fitness (Replication Capacity)

Viral fitness or the ability to replicate in host cells can be reduced due to the presence of drug resistance mutations which decrease a viral enzyme's functional activity as the cost of developing drug resistance. In the patient, the predominant circulating virus is the virus which grows best in the presence of the current drug selection pressure, but this virus can often be rapidly overgrown by wild-type virus if the drugs are stopped. Diminished fitness is seen clinically when a patient's virus rebounds in the presence of a drug regimen but the viral load remains well below baseline levels and the CD4 cell count stays up despite the emergence of drug-resistant virus [61]. Some patients can remain clinically stable for extended periods of time until the virus develops additional mutations which either increase drug resistance or compensate for the drug resistance mutations and allow the virus to replicate more efficiently. When this occurs, CD4 cells will decline and disease progression can occur.

Some drug resistance mutations such as those associated with lamivudine and emtricitabine resistance (M184V in reverse transcriptase) or primary protease inhibitor resistance (D30N) have been associated with decreased viral fitness as manifested by lower viral loads in treated patients who experience viral rebound on therapy and reduced transmission to newly infected patients [12].

Viral fitness or replication capacity is determined by dividing the amount of viral growth of the clinical HIV-1 isolate in the no-drug well of an in vitro drug resistance assay by the amount of growth of the wild-type (drug-sensitive) control virus in the no-drug wells from the same assay. There have been several reviews of the implications of HIV viral fitness on drug resistance, disease progression, transmission, and global epidemic evolution [103, 104].

14 Clades

Most of the current knowledge of HIV-1 drug resistance has been developed from patients infected with clade B virus, which is the predominant strain of virus circulating in North America and Europe [105]. However, most of the patients infected with HIV-1 in the developing world have non-clade B viruses (such as clade A/E viruses in Asia and clade C viruses in sub-Saharan Africa) [105, 106]. The resistance pathways for antiviral drugs are generally similar in non-clade B to those seen in patients with clade B viruses but different primary pathways and profiles can occur [106]. For example, patients exposed to nelfinavir with clade B virus often develop a D30N mutation in their virus whereas those with clade C virus develop an L90M mutation more often than the D30N [107]. Similarly patients who receive nevirapine with clade B virus often develop a secondary V106A mutation whereas those with clade C virus with a 106 mutation usually develop a V106M mutation [108, 109].

The effect of different genetic backgrounds on drug resistance pathways in different regions of the world is currently under investigation. As more information becomes available, resistance algorithms developed in the developed world will need to be expanded to improve interpretation for the non-clade B viruses which predominate in the developing world and now account for up to 24–30 % of new infections in Europe [23, 110–112].

15 Laboratory Diagnosis of HIV-1 Drug Resistance

Zidovudine (AZT)-resistant virus was detected using an MT-2 syncytial assay in 1989 [113]. Soon thereafter, it was shown that phenotypic resistance to zidovudine was associated with mutations in reverse transcriptase at positions M41L, D67N, K70R, T215Y/F, and K219Q/E [114]. As each new antiretroviral drug was developed, viruses with phenotypic drug resistance were detected soon afterwards and the viral genetic mutations associated with drug resistance and/or viral breakthrough were then determined.

Clinical investigators developed a standardized HIV-1 phenotypic drug resistance assay using peripheral blood mononuclear cells which could be applied to the majority of clinical HIV-1 isolates to determine the clinical significance of HIV phenotypic drug resistance [115]. This assay was slow and labor intensive requiring cultivation of HIV-1 in vitro, quantitation of the viral stock to produce a standardized inoculum, and then viral replication in the presence of multiple drug levels to obtain an EC_{50} value (the concentration of drug required to reduce viral replication by 50 % compared to a no-drug control well). The whole process took 4–6 weeks and could only be conducted in a research laboratory. Subsequently, commercial laboratories developed HIV phenotypic resistance assays utilizing recombinant viruses containing PCR-amplified segments of clinical HIV-1 isolates that could be automated and produce highly reproducible results with a 2-week turnaround. Use of HIV-1 phenotypic assays is described in detail in Chap. 35 (Table 73.3).

The development of high-throughput genotypic sequencing allowed the commercial development of sequencing of a PCR-amplified segment containing the HIV-1 protease gene and a portion of the reverse transcriptase gene to detect mutations associated with phenotypic HIV-1 drug resistance and/or viral rebound in the clinic (Table 73.3). Databases of these mutations and listings of these mutations are updated regularly [77, 116, 117]. Interpretative algorithms for resistance resulting from the combinations of drug resistance mutations produced by currently available antiretroviral drug regimens have become complex and are generally generated using computer algorithms. These are then translated into a user-friendly report in which susceptibility to each agent is generally interpreted as sensitive, partially resistant,

Table 73.3 Comparison of genotypic and phenotypic drug resistance testing

	Genotypic drug resistance testing	Phenotypic drug resistance testing
Strengths	Rapid turnaround	Direct measure of drug susceptibility
	Less expensive	Can provide a measure of viral replication capacity
	Widely available	
	Clinically validated in multiple clinical trials	
Weaknesses	Interpretative algorithms are not standardized	Lack of availability of standardized clinical cutoffs
	Indirect measure of resistance	More expensive
	Difficulty interpreting complex mutation patterns	Slower turnaround
	Difficulty interpreting resistance to novel agents	Less widely available
	Cannot detect minority variants (<20 % of all viruses)	Cannot detect minority variants

Table 73.4 Indications for obtaining an HIV drug resistance test

1	Primary/acute or recent HIV infection[a,b,c,d]
2	Initiation of antiretroviral therapy[a,b,c,d]
3	Poor response to initial antiretroviral therapy[a,b]
4	Viral rebound on antiretroviral treatment[a,b,c,d]
5	Pregnancy if detectable plasma virus[a,b,c]
6	Postexposure prophylaxis[c]
7	Pediatric patients initiating antiretroviral treatment[b,c]

or resistant. Use of HIV-1 genotypic assays is described in detail in Chap. 38.

Several groups have provided guidance on the use and interpretation of HIV drug resistance assays [46–48, 118]. The patients for whom resistance testing is recommended are listed in Table 73.4. Numerous websites contain current information on HIV drug resistance [119]. Some useful websites are listed in Table 73.5.

There are several important caveats to the interpretation of HIV-1 drug resistance assays. The assays all report the results for the predominant circulating virus at each time point and will not detect minority viral species that are present at levels below 20–25 %. Additionally, virus populations can turn over rapidly if antiretroviral drugs are discontinued or drug regimens are changed. Thus, patients who are considering switching antiretroviral therapy should have a resistance test performed while on the failing regimen and not after stopping drugs for a period of time. Importantly, when considering drugs to utilize in a new antiretroviral regimen for patients who have received prior antiretroviral therapy, the clinician needs to consider all prior drugs given and all prior antiretroviral resistance results since these earlier viruses will continue to be present as archived viral DNA in HIV-1-infected cells and can rapidly reemerge under the appropriate antiviral selection pressure.

16 Treatment of Drug-Resistant HIV-1

16.1 Initial Treatment of HIV-1

Treatment is initiated for HIV-1 infection with different guidelines in different regions of the world [45, 48, 120, 121]. Most guidelines agree that treatment should be initiated for patients with symptomatic HIV-1 disease or CD4 counts less than 350 cells/μL. In North America and Europe, guidelines have moved to earlier treatment with CD4 cell counts <500 cells/μL or universal treatment of all HIV-infected persons. Initial treatment is typically with two nucleoside drugs in combination with either a non-nucleoside reverse transcriptase inhibitor, a protease inhibitor, or an integrase inhibitor. Data showing that approximately 10–27 % of newly HIV-1-infected persons have a virus with genotypic evidence of drug resistance and up to 4 % of these patients may harbor a multiple drug-resistant (MDR) virus has led to the recommendation that all newly HIV-infected persons should have a resistance test prior to initiating therapy. Patients who do not have a brisk antiviral response in plasma HIV RNA to combination antiretroviral treatment during the first 2 months of treatment should be evaluated for treatment adherence and be considered for genotypic resistance testing at that time.

The goal of combination therapy for treatment of HIV-1 disease is to obtain complete suppression of HIV replication which is measured by a plasma HIV RNA level of less than 20 copies/mL. The challenge for the treating physician and patient is to maintain high levels of adherence to taking the drug regimen over decades of treatment since the most common cause of virological rebound is poor adherence or discontinuation of treatment. If the patient has evidence of a rising plasma HIV RNA value, the clinician should carefully review patient adherence to taking the medications, side effects of treatment that could reduce adherence, concomitant medications such as rifampin which can lower the levels of HIV NNRTI and protease inhibitors, and new-onset gastrointestinal disorders such as nausea, vomiting, or diarrhea to determine if there is any modifiable issue which can be resolved in order to fully suppress the virus. If the plasma HIV RNA remains elevated after these measures are taken, a resistance test should be considered to guide the next round of treatment. Allowing patients to remain on a combination antiretroviral regimen despite active HIV-1 replication manifested by detectable HIV RNA levels will result in increasing levels of resistance to the drugs administered and broadened resistance to the remaining drugs from the classes of drugs used in the regimen [122].

17 Treatment of Drug-Resistant HIV-1

Patients who have experienced virologic breakthrough after initial or early rounds of antiretroviral treatment usually have active drugs available to develop an effective combination treatment regimen. It is critical for each new round of therapy to combine at least two and preferably three active antiretroviral drugs together to ensure that a fully suppressive regimen is used. Adding less than three active drugs often leads to rapid viral breakthrough with resistance to the new class of drugs. HIV drug resistance testing has shown short-term clinical benefit in helping to select active drugs for treatment-experienced patients and should be utilized [123–126]. Treatment decisions need to take into account prior drug exposure, drug toxicities on prior antiviral regimens, prior resistance test results and the resistance data while on the most recent antiretroviral drug regimen, and patient wishes (Table 73.6). Where available, advice from an expert with experience in treating patients with multidrug-resistant HIV-1 should be obtained [124, 126].

18 Salvage Therapy for Drug-Resistant HIV-1

The goals of HIV treatment can change for patients who have virus resistant to most or all currently available drugs. The benefits of drug resistance testing may be limited in this group of patients. These patients should be maintained on antiretroviral treatment since discontinuing all treatment results in disease progression. For patients who are asymptomatic with stable CD4 cell counts, the clinician may elect to continue the current regimen, if it is well tolerated, or switch to a simpler, more easily tolerated combination drug regimen if drug toxicities are present. The goal in these patients is no longer complete viral suppression but to maintain immune status (especially a CD4 count above 200 cells/μL) and patient functioning until active drugs become available to develop a fully active antiviral regimen [60].

Structured treatment interruptions (STI) to allow sensitive virus to reemerge and overgrow the multidrug-resistant circulating virus are not recommended. Studies have shown that reemergence of wild-type, drug-sensitive virus is associated with increasing viral loads and CD4 declines potentially resulting in disease progression events [127–129]. Re-initiation of combination therapy after an STI results in a transient improvement of antiviral responses compared to continued treatment but the decreased CD4 counts can remain depressed for more than a year compared to continued therapy [128]. Discontinuation of antiviral treatment has been associated with increased risk of opportunistic disease or death from any cause including cardiovascular, renal, and hepatic disease [130, 131].

Some investigators have tried "mega-HAART" regimens to treat patients using 5–8 antiretroviral drugs [132–134]. While some short-term antiviral benefits have been observed, the toxicity of these regimens has limited their utility in general practice.

Table 73.6 Factors in choosing drug regimens for treatment-experienced patients

1. Number and duration of prior antiretroviral drugs
2. Toxicity while receiving prior antiretroviral drugs
3. Current and prior HIV drug resistance test results
4. Ability to develop a combination drug regimen with at least two and preferably three drugs active against the current circulating virus
5. Patient desires

19 Newer Classes of Antiretroviral Drugs

The availability of second-generation HIV protease inhibitors (tipranavir and darunavir), second-generation NNRTIs (etravirine and rilpivirine), a CCR5 inhibitor (maraviroc), and HIV integrase inhibitors (raltegravir, elvitegravir, and dolutegravir) has greatly expanded the potential treatment options for patients whose virus is resistant to multiple classes of antiretroviral drugs. Combinations of these drugs have made complete viral suppression possible for patients with the most resistant viruses and have led to a standard goal of therapy to achieve undetectable virus (plasma HIV RNA <20 copies/mL) for all stages of HIV treatment. It is critical in these patients to combine 2–3 active antiretroviral drugs together to ensure that a fully suppressive regimen is used. These decisions in patients with limited options for use of NRTI, NNRTI, PI, and integrase inhibitor classes of drugs may benefit from use of both genotypic and phenotypic HIV drug resistance tests [135]. Advice from an expert with experience in treating patients with multidrug-resistant HIV-1 should be obtained, if possible [135].

20 Prevention of HIV-1 Drug Resistance

The most effective method to prevent emergence of HIV-1 drug resistance and block further transmission of HIV-1 is to fully suppress HIV replication with combination therapy in all HIV-infected persons [136]. Once fully suppressive therapy is given, high patient adherence to the prescribed regimen determines the ultimate durability of each drug regimen. Recent advances utilizing daily fixed-dose combination regimens with well-tolerated agents have significantly increased the success rates and durability of initial antiretroviral treatment.

For patients with multidrug-resistant virus, the availability of second-generation NNRTIs and PIs, entry inhibitors, and

integrase inhibitors offers the potential for patients with HIV-1 resistant to multiple classes of antiretroviral drugs to fashion fully suppressive combination drug regimens and obtain durable treatment responses. This should reduce the potential for transmission of multidrug-resistant viruses to the next generation of HIV-1-infected patients.

Data suggest that the availability of fully suppressive combination therapy for HIV-1 can lower the rates of HIV-1 transmission along with both prevalent and incident HIV-1 drug resistance rates [137]. Additionally, early initiation of antiretroviral therapy as well as prevention programs encouraging safe sex practices and needle exchange should reduce the number of new HIV infections in many communities [138].

Hepatitis B Virus Drug Resistance

74

Apostolos Beloukas and Anna Maria Geretti

1 Introduction

There have been major advances in the prevention and management of antiviral drug resistance in the treatment strategies against HBV infection in the past two decades [1]. Currently, interferon alfa-2b and pegylated interferon-a (pegIFN-α), and several oral inhibitors of the HBV polymerase enzyme are approved for the treatment of CHB [1–5]. Polymerase inhibitors, comprising both nucleoside and nucleotide analogues (NAs), are generally more effective than IFN-based treatment and cause fewer side effects. Whilst current therapeutic options for the de novo treatment of chronic hepatitis B (CHB) carry a low risk of selecting for drug resistance, long-term and indefinite treatment is commonly required to sustain viral suppression. The demand for better treatments heightens with the fact that many patients have accumulated HBV drug resistance and cross-resistance through previous, less efficacious therapy, and have limited treatment options. Even more so, large numbers also continue to be at risk of drug resistance due to limited access to effective antiviral compounds in middle and low-income settings. Several novel compounds are under development that may pave the way for therapeutic regimens of finite duration and, potentially, for HBV eradication [5–7].

The overall short-term and long-term efficacy of NA-based therapy for CHB is influenced by several factors, including drug potency and treatment adherence as key determinants (Table 74.1). Even in optimally adherent patients, some NAs, when used as single agents, can be insufficiently able to suppress virus replication, particularly in the context of a high HBV DNA load. Due to the plasticity of the HBV genome, ongoing virus replication in the presence of drug pressure can lead to the emergence of HBV variants carrying mutations that reduce drug susceptibility. Although some HBV drug-resistant mutants may show a significant loss of fitness and replicative capacity, others replicate efficiently, can cause progression of liver disease, and can be transmitted.

2 Mechanisms of HBV Drug Resistance

2.1 Emergence of Drug Resistance

HBV is a DNA virus that replicates via an RNA intermediate. The viral polymerase enzyme, which also has reverse transcriptase (RT) activity, displays a high error rate and lacks the proofreading function required to repair incorrectly incorporated bases [8, 9]. HBV has a high replication rate, resulting in the production of ~10^{12} virions per day. This combines with a mutational rate of ~10^{-5} substitutions per base and replication cycle [10, 11]. In individuals with ongoing viral replication, approximately $10^{10–11}$ point mutations are estimated to occur per day across the entire viral genome. Some mutations cause a severe loss of function, impairing viral fitness to the extent that the mutant stops replicating. Other mutants display variable degree of fitness impairment. Thus, in an infected host, HBV exists as variety of diverse strains that constitute the *viral quasispecies*. At any given time, and subjected to the influence of modulating factors including immune-mediated and drug-mediated selective pressure, certain mutant species are dominant, whereas others exist only as rarer, low-frequency variants.

HBV mutations that confer reduced drug susceptibility arise spontaneously in the targets of antiviral therapy and circulate within the viral quasispecies prior to the introduction of therapy. Given the overall functional cost, in the absence of drug pressure, HBV drug-resistant variants circulate at low frequency, typically as single mutants, and escape

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_26

detection by both routine and sensitive methods. Under drug-selective pressure, if virus replication continues, the variants acquire a selective advantage and gradually emerge as dominant species. With continued virus replication under drug pressure, the single mutants evolve genetically, acquiring additional primary and secondary mutations, including compensatory changes that restore viral fitness and increase pathogenicity [12–14].

The partially double-stranded circular HBV genome is organized into four overlapping reading frames (ORFs) (Fig. 74.1). Overlapping of the polymerase ORF with the surface ORF has two important consequences. Firstly, there is a reciprocal impact of genetic changes driven by selective pressure, including changes in HBsAg antigenic determinates which create potential for vaccine and diagnostic escape [15, 16]. Secondly, genetic evolution under drug pressure is constrained by the simultaneous impact on polymerase and surface functionality. These constrains are illustrated by comparing the emergence of resistance to lamivudine (LAM) monotherapy in HBV and HIV infection. In HIV-positive subjects, resistant strains emerge as dominant within a few weeks of LAM monotherapy. In contrast, months are required for the emergence of LAM-resistant strains in HBV-positive subjects. Nonetheless, sensitive methodologies have revealed that HBV resistance to LAM can emerge more rapidly than previously appreciated. In a study of patients with HIV and HBV co-infection starting LAM-containing antiretroviral therapy (ART) without additional HBV-active agents, most patients with detectable serum HBV DNA after 6 months had evidence of LAM resistance when evaluated by deep sequencing (Fig. 74.2) [12].

Table 74.1 Determinants of responses to antiviral therapy in chronic hepatitis B

Host	Drug	Virus
Adherence	Potency	HBeAg status
Tolerability	Side effect profile	HBV DNA load
Liver disease status	Genetic barrier	Acquired drug resistance
Immunity	Pharmacokinetics	Transmitted drug resistance
Genetics		

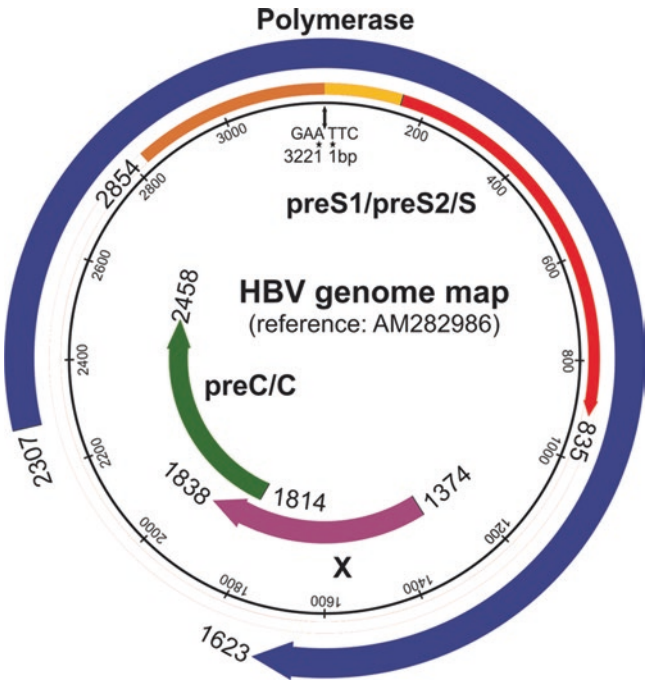

Fig. 74.1 The HBV genome. The relaxed partially double-stranded circular DNA has a size of ~3.2-kilobases and comprises four overlapping reading frames: polymerase (*blue*), surface (preS1, preS2, and S domains; *orange*, *yellow*, and *red*, respectively), X (*purple*), and pre-core/core (*green*). Complete genome numbering starts from TTC and ends at GAA

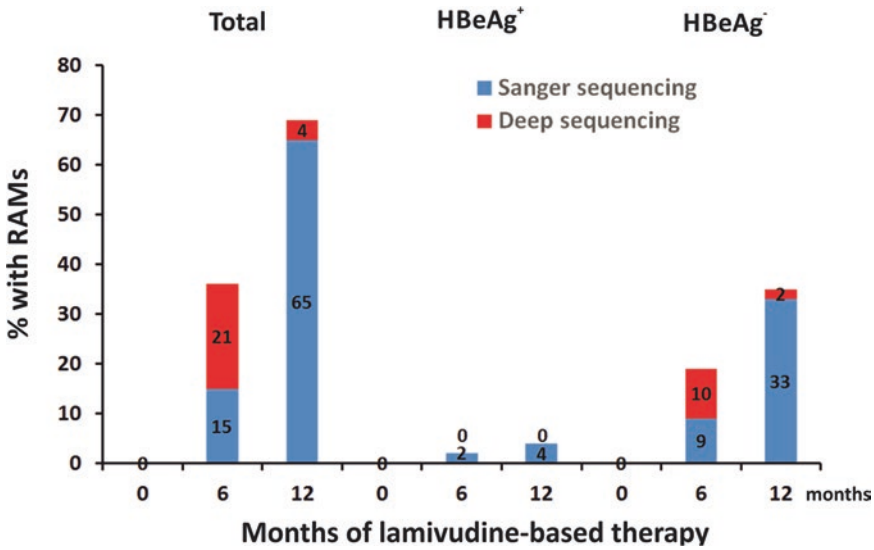

Fig. 74.2 Emergence of HBV drug resistance during lamivudine monotherapy. A total of 133 HIV and HBV co-infected subjects starting lamivudine-containing antiretroviral therapy without additional HBV-active agents underwent testing for the presence of lamivudine resistance-associated mutations (RAMs) in HBV polymerase. Testing was performed at baseline and after 6 and 12 months of therapy using Sanger sequencing and deep sequencing. Resistance rates are presented as total and by baseline HBeAg status (Adapted from [12])

2.2 Persistence of Drug Resistance

HBV RAMs that emerge as dominant during antiviral therapy lose their replicative advantage once therapy is discontinued, and are outgrown by fitter, drug-sensitive ("wild-type") strains. In patients who have discontinued therapy for more than a few weeks, it is usually no longer possible to detect the resistant mutants using routine technology. The disappearance of resistance is only apparent however; treatment-enriched mutants persist as low-frequency circulating variants and rapidly re-emerge if suboptimal treatment is restarted. In addition, HBV establishes an archive of genetic variants within the covalently closed circular DNA (cccDNA) that persists in infected hepatocytes [17]. HBV cccDNA is generated from the relaxed circular DNA genome of incoming virions and persists long-term in episomal form in the nucleus of hepatocytes [18]. Whilst effective in suppressing HBV replication, NAs have limited efficacy in reducing the cccDNA reservoir [19–21]. Current research aims at targeting the reservoir and potentially cure HBV infection [5, 18]. Meanwhile, HBV cccDNA retains a long-term memory of any selected resistant strain, from which new replicating strains can re-emerge [1, 5, 18, 20, 22].

2.3 Nomenclature

A nomenclature for describing HBV drug resistance-associated mutations (RAMs) was established in 2001 [23]. The HBV polymerase gene is divided into four functional units (Fig. 74.3). Resistance is defined by the presence of one or more nucleotide substitutions in the RT domain of the polymerase gene, resulting in amino acid substitutions within the enzyme. Primary or major RAMs play a key role in conferring a drug-resistant phenotype by directly reducing drug susceptibility. Secondary and compensatory RAMs play an accessory role by increasing the level of resistance or restoring the functional defects caused by major RAMs [13]. Mutations are reported with the letters rt followed by the wild-type amino acid, the codon numbered position relative to the start of the rt region, followed by the mutant amino acid. For example, rtM204V describes the major LAM RAM, whereby methionine at RT codon 204 is replaced by valine.

3 Pathways of HBV Drug Resistance

Current treatment strategies for CHB are guided by a number of viral- and host-related parameters and mainly comprise (1) 1 year of treatment with peg-IFN-α or (2) long-term treatment with NAs [1, 2, 4, 5, 24]. Combination strategies of peg-IFN-α plus potent NAs are under evaluation [1]. Peg-IFN-α exerts both direct antiviral and immune modulatory functions by regulating the expression of interferon-stimulated genes (ISGs) [25]. In CHB, IFN-α causes immune activation, inhibition of HBV genome transcription, intracellular destabilization of viral nucleocapsid, and degradation of intracellular cccDNA via APOBEC3A [26–28]. A number of host genetic determinants have been shown to modulate IFN susceptibility, including an effect of viral genotype on the rate and kinetics of HBeAg and HBsAg loss. Generally, patients infected with HBV genotypes A and B show better responses to IFN-based therapy than patients with genotypes C and D, whilst responses to NAs appear to be comparable across different HBV genotypes [29]. Additionally, several mutations in the HBV genome (especially in pre-core and basal core promoter) have been shown to modulate responses to IFN-based treatment [30].

NAs compete with the natural substrate for binding to the active site of the HBV polymerase enzyme [31]. NAs must be phosphorylated to their nucleoside triphosphates or nucleotide di-phosphate derivatives in order to exert antiviral activity. Phosphorylation is mediated by cellular kinases and the initial phosphorylation is the rate-limiting step of the process, considered to modulate some of the differences in efficacy observed among NAs [8, 32]. Once phosphorylated, NAs are incorporated by the viral polymerase in the growing

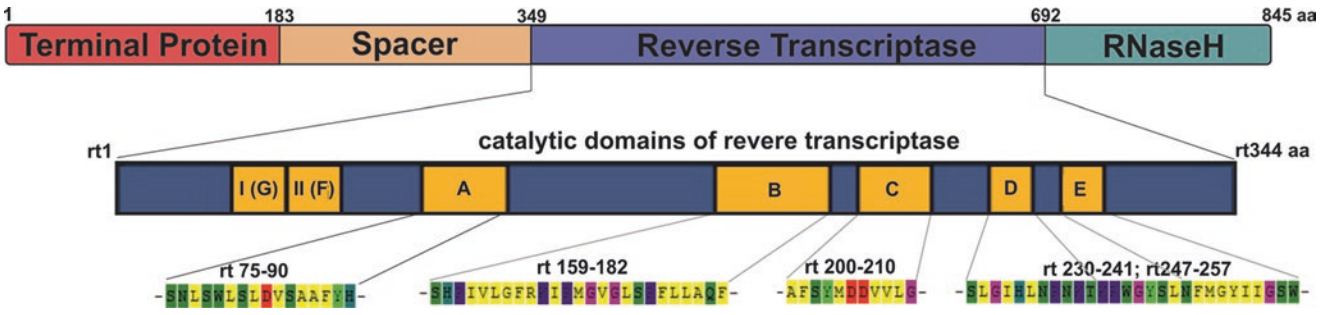

Fig. 74.3 Organisation of the HBV polymerase open reading frame, showing the reverse transcriptase (RT) region and its catalytic domains. The sequence corresponds to HBV genotype A (subtype adw2) (GenBank accession number AM282986); numbering is given according to the standardized nomenclature

Table 74.2 Resistance mutations associated with resistance to nucleoside and nucleotide inhibitors of the HBV polymerase enzyme

Class	Drug	Chemical structure	Genetic barrier	Major or primary RAMs	Compensatory and other RAMs
L-Nucleoside	Lamivudine	2′,3′-Dideoxy-3′-thiacytidine	Low	rtM204I/V/S/Q	rtL80V/I, rtI169T, rtV173L, rtL180M, rtT184S/G, rtS202I, rtQ215S
				rtA181T/V	
	Emtricitabine	5-Fluoro-1-(2R,5S)-[2-(hydroxymethyl)-1,3oxathiolan-5-yl]cytosine	Low		
	Telbivudine	β-L-2′-deoxythymidine	Intermediate		
D-Cyclopentane	Entecavir	2-Amino-9-[(1S,3R,4S)-4-hydroxy-3-(hydroxymethyl)-2-methylidenecyclopentyl]-3H-purin-6-one	High (naïve)	rtL180M + rtM204V + [rtT184A/C/F/G/I/L/S or rtS202I/G or rtM250L/V]	
			Low (LAM resistance)	rtL180M + rtM204V + rtA186T + rtI163V	
Acyclic phosphonate	Adefovir dipivoxil	9-[2-[[Bis[(pivaloyloxy)methoxy]-phosphinyl]methoxy]ethyl]adenine	Intermediate	rtN236T	rtI233V
				rtA181T/V	
	Tenofovir disoproxil fumarate	9-[(R)-2[[bis[[(isopropoxycarbonyl) oxy] methoxy]phosphinyl]methoxy] propyl] adenine fumarate	High	rtA194T (+rtL180M + rtM204V/I)	Precore and basal core promoter mutations
				rtP177G + rtF249A	

RAMs resistance-associated mutations, *LAM* Lamivudine

viral DNA chain, and act as chain terminators, inhibiting negative and positive HBV DNA strand synthesis. Based on the similarities between the HBV and HIV polymerase enzymes, it is not surprising that several NAs have dual antiviral activity [33]. Among available agents, LAM, emtricitabine (FTC), and tenofovir disoproxil (TDF) have significant activity against HIV. Entecavir (ETV) has a low residual antiretroviral activity and potential for selection of HIV drug resistance if used in isolation [34]. Adefovir dipivoxil (ADF) at HBV dosing and telbivudine (LdT) are not thought to exert anti-HIV activity.

NAs are classified into three structural groups: (1) L-nucleosides, (2) D-cyclopentanes, and (3) Acyclic (or alkyl) phosphonates (nucleotides). The classification corresponds to distinct pathways of resistance (Table 74.2) [5, 19, 21, 35]. Four major pathways are recognized: (1) the rtM204 pathway with L-nucleosides; (2) the rtN236T pathway with alkyl phosphonates; (3) the rtA181T/V pathway shared between the L-nucleosides and alkyl phosphonates; and (4) the D-cyclopentante pathway.

3.1 L-Nucleosides

L-Nucleosides comprise LAM and LdT, which are widely available worldwide; FTC, which is available in combination with TDF for the treatment of HIV and HBV co-infection; and clevudine, which is currently available in South Korea and the Philippines. The compounds have a similar molecular structure and bind to the same region of the viral polymerase, which results in shared resistance pathways and extensive cross-resistance [5, 8, 14, 19, 21, 35–50].

Resistant mutants generally remain susceptible to ADV and TDF [37, 51] and may retain partial susceptibility to ETV. The rtA181T/V mutation in domain B can emerge in treated patients and reduce susceptibility to both L-nucleosides and acyclic phosphonates [52–57].

3.1.1 Lamivudine

LAM was the first direct-acting antiviral agent to become available for the treatment of HBV infection. LAM was already used for the treatment of HIV infection and in this context codon M184 in the HIV RT catalytic site (YMDD motif) was identified as the major resistance site. Reflecting sequence homology between the two viral polymerases, the major HBV LAM resistance site is located at the corresponding codon 204 in the catalytic site (C domain) of the RT region of HBV polymerase. A single mutation that results in the substitution in YMDD of methionine by isoleucine (rtM204I), valine (rtM204V), or rarely serine (rtM204S) is sufficient to confer high-level LAM resistance. rtM204Q is an additional LAM RAM, conferring moderate drug resistance and displaying higher replication capacity than rtM204I [58].

During LAM treatment, M204I mutants are typically detected first, and subsequently replaced by rtM204V [12]. The mutants display reduced viral fitness. Molecular modelling indicates that rtM204I/V induce both steric hindrance and electrostatic repulsion for the incoming LAM triphosphate [8, 37, 59–61]. The catalytic activity of the polymerase is also reduced as a result, due to altered alignment of the natural substrate with respect to template and primer. With ongoing virus replication under LAM pressure, compensatory mutations occur in domain A (codon 80), domain

B (codons 169, 173, 180), interdomain B-C (codon 184), and domain C (codons 202 and 215) [14, 21, 35, 38, 45–47, 50]. Compensatory mutations are insufficient to confer LAM resistance in isolation, but combined with rtM204 mutations they enhance resistance and improve enzymatic function and HBV replication. The negative electrical charge of rtL180M/C, for instance, decreases binding affinity for LAM-triphosphate, allowing better discrimination between the drug and the natural substrate [14, 60, 62]. In clonal and single genome sequences, LAM resistance and compensatory mutations typically coexist on the same viral genome [12].

3.1.2 Telbivudine

LdT is more potent than LAM in reducing serum HBV DNA levels in vivo [63, 64] and is also more potent than ADV [65]. LdT has an improved genetic barrier to the emergence of resistance relative to LAM, but shares a similar resistance profile, with rtM204I being the RAM most commonly observed in patients with virological breakthrough [19, 35, 42, 48, 49, 66–69].

3.2 D-Cyclopentanes

ETV, a synthetic analogue of 2-deoxyguanosine, displays a high genetic barrier to resistance in treatment-naïve patients, as resistance requires multiple substitutions to emerge [70–76]. ETV has high potency in both HbeAg-positive and HBeAg-negative treatment-naïve subjects [70, 71, 73, 74]. Due to shared resistance pathways however, ETV activity is reduced in LAM-experienced patients, requiring higher treatment doses and overall reducing the genetic barrier so that evolution of further resistance is facilitated [34, 45, 50, 77–81].

3.3 Acyclic Phosphonates (Nucleotides)

Alkyl nucleoside phosphonates comprise ADV and TDF. These compounds are structurally similar and possess a phosphonate group, requiring two rather than three phosphorylation steps to become intracellularly active [82]. Their structural similarity to the natural substrate deoxyadenosine triphosphate and the small, flexible phosphonate linker favour access to the HBV polymerase active site and high affinity for the enzyme [31, 32, 82].

3.3.1 Adefovir

ADV was initially developed for the treatment of HIV infection, but use was discontinued due to renal toxicity [8]. ADF suppresses HBV replication at significantly lower doses than those required to suppress HIV, and is safe at HBV dosing [83, 84] and putatively inactive against HIV. Development of HBV resistance to ADV occurs more slowly than seen with LAM, and is associated with mutations outside the YMDD motif, most commonly rtA181T (B domain) and rtN236T (D domain) [5, 8, 21, 35, 85–87]. The rtN236T mutant shows 7-fold resistance to ADV in vitro, which increases to 18-fold with the rtA181V + rtN236T double mutant [86]. The N236T mutation also has resistance effects for TDF, but confers no resistance to LAM and ETV. Molecular modelling reveals a possible mechanism of action for rtN236T. In wild-type HBV polymerase, the rtN236 amino acid may be hydrogen bonded to the adjacent rtS85 residue, and may interact directly with the γ-phosphate of ADF di-phosphate. The rtN236T mutation disrupts the hydrogen bond, thereby decreasing the binding affinity for ADF [88].

3.3.2 Tenofovir

The use of ADV for the treatment of CHB is declining, reflecting the superior virological efficacy of TDF in both HBeAg-positive and HBeAg-negative subjects [19, 35, 83, 84, 89–94]. TDF in vivo is converted to tenofovir, an acyclic nucleoside phosphonate (nucleotide) analogue of adenosine 5′-monophosphate. TDF is structurally related to ADV but at the standard dose achieves higher intracellular concentrations and displays higher binding affinity for the HBV polymerase enzyme [95]. This results in a greater virological potency and higher genetic barrier to resistance than ADF. The genotypic resistance profile of TDF remains controversial. The rtA194T mutation has been associated with partial TDF resistance and a negative impact on replication capacity of HBV constructs in vitro [96]. The mutational profile comprising rtA194T plus the LAM RAMs rtL180M + rtM204V/I has been proposed to reduce TDF susceptibility by over tenfold [97], although the finding has not been consistently reproduced [98]. The rtL180M + rtM204V/I + rtA194T mutation profile has a significant fitness cost, reducing replicative capacity by >75 %. The fitness defect of both rtA194T alone and in combination with rtL180M + rtM204V/I however is at least partially compensated through mutations in the precore and basal core promoter regions [96, 98], suggesting that patients with HBeAg-negative CHB may be particularly at risk of TDF resistance. The rt181T/V mutation has been shown to confer low-level resistance to TDF (two- to threefold); resistance levels increase with the combination of rt181T/V + rtN236T, which can be co-localized on the same viral genome [54, 86]. A further proposed pathway comprises rtP177G and rtF249A, which confer enhanced resistance to TDF and reduced replication capacity both in vitro and in vivo [99].

Despite these findings, genotypic HBV resistance to TDF has not been seen to emerge in clinical studies, including subjects with slow HBV DNA kinetics [100–102], and subjects undergoing continued treatment for 6 [91], 7 [89], or 8 [103] years. TDF retains activity in LAM-experienced

[94, 104–106] and ETV-experienced [29] subjects, and is also effective, although less so, in patients with suboptimal treatment responses to ADV [5, 29, 94, 107, 108]. It has been proposed however that the double rtA181T/V + rtN236T mutant in particular is associated with inadequate virological response to TDF [107].

3.4 Genetic Barrier

The genetic barrier to the emergence of drug resistance is the expression of the interaction between multiple factors (Table 74.3) [19, 21, 38, 45, 50, 62, 88, 95, 98, 109, 110]. In general terms, the genetic barrier is low with LAM and FTC, intermediate with LdT and ADV, and high with ETV (in naïve patients) and TDF (Fig. 74.4). With LAM monotherapy, prevalence of RAMs is ~70 % after 4–5 years of treatment [21, 41, 111–114]. The rate of HBV replication is a key modulating factor, with a substantially higher risk of resistance observed in subjects with positive HBeAg status and high HBV DNA levels at start of therapy [12, 106] (Fig. 74.2). LdT resistance emerges more slowly, but rates are substantial, reaching 11 % and 26 % after 2 years in HBeAg-negative and HBeAg-positive subjects, respectively [64]. The cumulative incidence of ADV is 29 % after 5 years [83, 84, 115]. In patients receiving first-line therapy with ETV, rates of resistance are 1.2 % after 5 years for both HBeAg-positive and HBeAg-negative subjects [71, 75], increasing to 2.1 % at 7 years [116]. No resistance has been reported in over 400 patients that received first-line TDF for 7 [89] or even 8 [103] years.

Antagonistic and synergist interactions between the resistance pathways of different drugs modulate the efficacy and genetic barrier of a combination regimen. Emergence of ETV resistance is accelerated by previous LAM exposure, and among subjects with LAM RAMs starting ETV, 51 % have ETV resistance after 5 years [75]. In LAM-experienced subjects with resistance, use of ADV add-on therapy with continuation of LAM shows superior virological efficacy to the use of ADV alone, in part reflecting the antagonism between the main pathways of LAM (rtM204) and ADV (rtN236T) resistance, which result in enhanced susceptibility to ADV, reduced emergence of ADV RAMs, and virological benefit, at least in subjects with low baseline HBV DNA levels [117–121].

Table 74.3 Factors that modulate the genetic barrier to resistance in HBV therapy

Factor
• Drug potency
• Intracellular drug concentration
• Interaction between drug and enzyme (e.g. binding affinity, structural flexibility)
• Phenotypic effect of mutations
• Number of mutations required to compromise drug activity
• Fitness cost of mutations
• Ease of emergence of compensatory mutations that restore viral fitness
• Interactions between resistance pathways
• Viral genome sequence
• Pre-existing selection or transmission of resistance
• Baseline HBV DNA load and kinetics of HBV DNA decline on therapy
• Host genetics and immunity

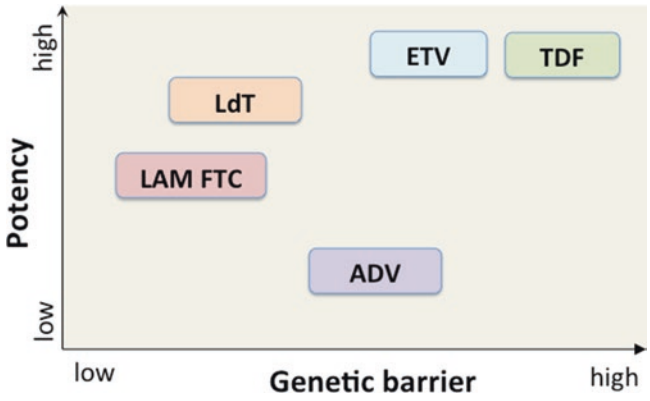

Fig. 74.4 Potency and genetic barrier of available antiviral agents against HBV

4 Tests to Detect Drug Resistance

HBV drug resistance is assessed in clinical practice by demonstrating the presence in the RT domain of the viral polymerase of RAMs that are known to confer a drug-resistant phenotype. Testing is generally recommended in patients experiencing suboptimal treatment responses, as indicated by serum HBV DNA levels [1]. There have been several reports of the transmission of HBV drug-resistant variants; however the prevalence of transmitted HBV drug resistance is too low to support the cost-effectiveness of routine resistance testing prior to starting antiviral therapy [122, 123].

4.1 Genotypic Tests

HBV genotypic tests available for diagnostic use comprise conventional and deep genome sequencing and reverse hybridization mutation-specific assays (MSAs) (Table 74.4). Conventional population (Sanger) sequencing of DNA products amplified by PCR provides accurate results, is widely available, and is applicable to any region of the HBV genome. The method yields a consensus sequence of the dominant quasispecies present in a patient's sample and has a sensitivity ranging from 10 to 20 %. Limitations therefore include

Table 74.4 Methods for detecting HBV drug resistance-associated mutations

Methodology	Detection limit[a]	Target	Advantages	Disadvantages
Population (Sanger) sequencing	10–20 %	Entire gene (RT)	• Current standard of care	• Labour intensive and relatively expensive
			• Both commercial kits and in-house assays available	• Limit of detection leads to underestimation in some patients
			• Moderately portable	• Requires specialized technical skills and laboratory infrastructure
			• Can be performed at low HBV DNA load	
Deep sequencing (e.g. Illumina)	1 %	Entire gene (RT)	• Able to detect low-frequency variants and to estimate the amount (frequency) of variants in a patient's sample	• Assay errors may occur at multiple steps of the process
				• Requires specialized laboratory infrastructure and advanced technical and bioinformatics skills
				• Limited availability in routine care
				• Best suited for centralized testing in high throughput specialist centres
			• Allows simultaneous processing of large number of samples reducing cost	• Testing at low HBV DNA load not generally recommended
Reverse hybridization (INNO-LiPA)	2–10 %	Sentinel RAMs	• Sensitive assay for specific mutations	• Assay development must be tailored for each mutation and across viral genotypes
			• Commercially available and highly portable	• False-positive or false-negative results can occur because of binding site variability
			• Inexpensive and simple to perform	
			• Suitable for resource-limited settings	• Testing at low HBV DNA load not generally recommended

[a]The detection limit describes the sensitivity for low-frequency variants and is a function of the assay and other parameters including HBV DNA load. *RT* reverse transcriptase, *RAMs* resistance-associated mutations

inability to identify linkage of mutations at the individual genome level and limited sensitivity for low-frequency mutants. Deep sequencing is the process of parallel sequencing of millions of individual DNA molecules in a single assay, with thousands of clonal viral sequences being analysed to yield estimates of the number and proportion of unique variants within a sample. Deep sequencing offers increased sensitivity for low-frequency HBV RAMs, providing significant insights into viral kinetics during therapy [12, 124]. Deep sequencing platforms are becoming increasingly affordable and available for routine diagnostic use, although they continue to require extensive expertise in bioinformatics for the analysis of the large sequencing output. Deep sequencing is also vulnerable to errors at various stages of the process [125]. A 1 % interpretative cut-off is generally recommended to distinguish biologically significant findings from spurious detection [126, 127]. In addition, clinical validation studies are required to determine the clinical significance of any low-frequency RAM detected [125].

Among MSAs, the reverse hybridization line probe assay (INNO-LiPA) is commercially available, reliable, relatively inexpensive, and easy to perform. The assay uses a PCR-amplified product for reverse hybridization with specific oligonucleotide probes immobilized on nitrocellulose strips and shows higher sensitivity for low-frequency mutants than Sanger sequencing, generally ranging between 2 and 10 % of the total viral population. INNO-LiPA however remains less sensitive than deep sequencing, and detection is limited to the selected number of targeted RAMs. The major limitation of hybridization-based methods lies in their single-base discrimination. Specificity can be influenced by the sequences neighbouring a polymorphic site, or by interference from secondary structures, and the assay must be tailored for each targeted codon and across viral genotypes. Furthermore, as new RAMs are identified, the assays must be updated accordingly.

In research setting, clonal and single genome sequencing are labour-intensive and costly methods that apply Sanger sequencing to the analysis of single viral genomes [12, 128]. The methods allow detection of linkage of individual mutations on the same viral genome, and the study of the evolutionary pathways of resistant variants. Provided a large number of sequences are analysed, the methods also allow detection of low-frequency variants. Single genome sequencing offers the advantage over clonal sequencing of reducing errors related to in vitro recombination of PCR products.

Restriction fragment length polymorphism analysis and PCR-based methodologies such as allele-specific PCR have been used for research purposes to improve sensitivity of detection of low-frequency RAMs. The methods are generally labour-intensive, technically difficult, and expensive, and only detect known mutations requiring mutation-specific protocols. Assays undergoing development include nanopore and single-molecule long-read sequencing, technologies based on oligonucleotide microarrays (DNA chip) or mass spectrometry, and the amplification-refractory mutation system [129].

4.2 Phenotypic Tests

Phenotypic testing plays a key role in the research of the evolution and significance of HBV drug resistance. The characterization of novel mutations requires in vitro analysis to confirm the effects of the mutation on the viral phenotype, including both drug susceptibility and replication capacity [21, 128]. The methods employ HBV polymerase enzymatic assays and cell-culture methods. Most systems rely on the transfection of recombinant replication-competent HBV DNA into hepatoma cell lines. Testing may be performed with clinical isolates and site-directed mutants, allowing the analysis of the impact of mutations both individually and in combinations.

5 Definition of Virological Responses to HBV Therapy

Based upon the established close relationship between ongoing virus replication and liver disease progression the goal of CHB therapy is to achieve and maintain optimal suppression of serum HBV DNA load, as a key surrogate marker for clinical efficacy, and prevention of disease progression to cirrhosis, liver failure, or hepatocellular carcinoma [1, 4, 5, 130–132]. Further aims, which are difficult to achieve with currently available NA therapy, are to induce loss of HBeAg and anti-HBe seroconversion among HBeAg-positive subjects, and ideally, loss of HBsAg in all treated patients [1, 2, 116, 133]. Patients receiving antiviral treatment undergo regular monitoring of virological responses with HBV DNA assays that are sensitive and specific, offer a wide dynamic range of quantification, and are calibrated to express results in International Units [1, 5, 19, 21, 134].

An optimal virological response (VR) is defined as a serum HBV DNA level below the lower limit of quantification of validated assays, typically <15 or <30 IU/mL. With the highly potent NAs TDF and ETV, rates of virological suppression are >90 % in adherent patients after 3 years [71, 92, 135–137]. In 2006, the National Institutes of Health proposed a set of standardized, HBV-specific definitions to describe suboptimal responses to antiviral therapy, based upon HBV DNA levels measured at key time points after treatment initiation. These definitions remain in clinical use, although they require adjustments when applied to current treatment strategies [1], to reflect differences in antiviral potency and overall resistance risk relative to earlier compounds (Fig. 74.4).

5.1 Primary Non-response

Primary non-response is defined as the inability of treatment to reduce serum HBV DNA levels by ≥1 $\log_{10}$ IU/mL after 12 weeks of treatment or by ≥2 $\log_{10}$ after 24 weeks. It is uncommon with NAs, although seen more frequently with ADV (~10–20 %) than with other NAs because of suboptimal antiviral efficacy [111]. It is recommended that treatment be reviewed promptly, considering adherence as a key determinant, and addressing any concerns related to the anticipated drug efficacy, for instance, in the context of previous drug exposure and likely drug resistance. Patients on ADV monotherapy should be switched to more active therapy. In primary non-responders receiving TDF or ETV who show no evidence of resistance at week 24, continued therapy after 24 weeks may achieve suppression. One study compared the cumulative probability of obtaining a VR in patients with and without primary non-response after 12 or 24 weeks of ETV as first-line. Median time to VR was significantly shorter in primary responders than in non-responders at 24 weeks, but the cumulative probability of achieving a VR at 54 months was similar in the two groups (96 % vs. 100 %) [138]. Time to achieving VR and the cumulative probability of VR over time did not differ between primary responders and non-responders at 12 weeks. A more cautious approach is required when considering continuation of ETV therapy in patients with previous exposure to L-nucleosides due to the risk of resistance.

5.2 Partial Response

A partial response is defined by an initial response as measured at 12 or 24 weeks of therapy, followed by persistently detectable serum HBV DNA levels during continued therapy. Useful reference points include a HBV DNA >2000 IU/mL at 24 weeks or a detectable HBV DNA after 48 weeks of therapy [1]. Review is indicated, and management strategies take into account adherence and anticipated drug efficacy, together with the pre-treatment HBV DNA load, the kinetics of HBV DNA decay after starting therapy, and the likelihood of drug resistance emerging. Patients receiving LAM, LdT, or ADV should be switched to more potent therapy if the response is suboptimal at 24 weeks [1]. Even on potent NAs, some patients with high pre-treatment viral load may need longer to achieve complete HBV DNA suppression. ETV recipients with HBV DNA <1000 IU/mL after 48 weeks of therapy often achieve viral suppression by continuing ETV through at least 2 years total [139]. ETV recipients with higher HBV DNA levels at 48 weeks should be managed by switching to or adding TDF, whereas increasing ETV dose is not usually effective [140, 141]. Management strategies for slow responders to TDF monotherapy are less well defined. A subset of patients may benefit from a change of therapy or treatment intensification, particularly if the treatment history indicates partial resistance is possible, or where immunological function is impaired [101, 142].

5.3 Virological Rebound or Breakthrough

Virological rebound is defined by a confirmed serum HBV DNA increase of ≥1.0 $\log_{10}$ IU/mL relative to the lowest (nadir) level measured during continued treatment in a previous responder. Although the cut-off of 1 $\log_{10}$ is a useful indicator of a significant virological rebound, any HBV DNA increase above the assay quantification limit after achieving suppression should trigger a review. A confirmed viral load rebound typically signals lapses in adherence and drug resistance testing should be considered [5, 19, 21]. Low-level HBV DNA rebound may also reflect poor immunological function. Among HIV and HBV co-infected patients receiving long-term TDF-containing therapy, intermittent HBV DNA rebound is not uncommon; the risk is related to a history of profound immunocompromise as indicated by a low nadir CD4 cell count, but rebound does not appear to result in the selection of TDF resistance [100].

When considering the relevant HBV DNA load cut-off for defining virological breakthrough, it is also important to appreciate that the impaired fitness of emerging variants may initially limit the magnitude of HBV DNA increase. The addition of compensatory mutations that restore replicative capacity is typically signalled by an increase in serum HBV DNA load and serum aminotransferase levels, and potential for progression of liver disease [13, 38, 41].

6 Prevention and Management of HBV Drug Resistance

Development of HBV drug resistance can be largely avoided by starting therapy with drugs that have high potency and a high genetic barrier to resistance—typically TDF or ETV—and with regular monitoring of treatment responses and ongoing re-enforcement of adherence [1, 5, 19, 111, 143, 144]. In a meta-analysis, TDF and ETV as first-line therapy showed no difference in overall virological efficacy and safety over 48 weeks [145]. Long-term data also support the virological efficacy and safety of both treatment options [1, 71, 89, 91, 103, 116, 131]. TDF monotherapy appears to be sufficient even in patients with high baseline HBV DNA load [146], although the combination of TDF plus FTC appears to be more effective than TDF alone in immunotolerant subjects with normal transaminases and high HBV DNA levels (>1.7×10^7 IU/mL) [147]. Combination therapy with TDF and ETV also appears to have a marginal advantage over ETV monotherapy in patients with high HBV DNA levels (≥10^8 IU/mL) [148].

Avoiding the use of LAM, LdT, or ADV as single agents is generally recommended due to the risk of resistance [1, 111, 143]. LdT monotherapy may have a role in selected scenarios, including the prevention of mother-to-child transmission [1]. It has also been argued that LAM monotherapy can be safe and cost-effective as first-line treatment in selected patients with a favourable profile (i.e. low HBV DNA levels, absence of significant fibrosis or cirrhosis), or as a maintenance option after achieving serum HBV DNA suppression with more potent first-line treatment [149, 150]. Further studies are required to provide support for these strategies.

There remain a large number of patients that developed HBV drug resistance prior to TDF or ETV becoming available, and from a global perspective many remain at risk due to regionally limited availability of these more costly compounds [151, 152]. Monotherapy with LAM, ADV, or LdT was frequently prescribed in Europe between 2008 and 2010; among treated subjects undergoing resistance testing monotherapy was frequently associated with the detection of drug resistance, especially HBV RAMs of the rtM204 pathway [151]. The adverse consequences of developing NA resistance have been well documented. Patients treated with LAM or ADV who develop virological breakthrough and emergence of drug resistance frequently experience exacerbation and progression of liver disease [19, 106, 153–157]. In a study of cirrhotic patients treated with LAM, disease progression (as measured by a composite end-point of liver-related complications and mortality) occurred in 13% of patients who developed LAM RAMs compared with 5% of patients who did not develop resistance [158]. Furthermore, sequential rescue therapy increases the risk of developing hard-to-treat multidrug-resistant (MDR) HBV variants [5, 19, 21, 159].

In patients with LAM resistance, add-on therapy with ADV while continuing LAM is superior to switching to ADV alone, and switching to TDF monotherapy is superior to add-on therapy with LAM plus ADV [108] (Table 74.5). TDF alone is as effective for the treatment of patients with the rtM204I/V ± rtL180M as the combination of TDF plus FTC: in a randomized clinical trial, HBV DNA suppression rates over 96 weeks were 89% and 86% with TDF and TDF + FTC, respectively, with no treatment-emergent TDF resistance [105].

TDF is generally less effective for patients with ADV resistance [1, 160]. Patients with the double ADV mutant rtA181T/V + rtN236T may be especially at risk of poor responses [107]. Combination therapy with TDF plus FTC shows superior virological efficacy than TDF monotherapy in this setting [161].

ETV is an alternative treatment option in patients with ADV resistance, with 84% achieving virological suppression after 24 months, although responses are blunted by previous LAM exposure [79, 162]. Whilst ETV use after prolonged LAM therapy failure is not uncommon in clinical practice, ETV monotherapy in L-nucleoside-experienced subjects is associated with a risk of virological breakthrough and evolution of ETV resistance [151] and is not generally recommended [1].

Table 74.5 Treatment strategies for patients with suboptimal responses to HBV therapy

Drug	Strategies
LAM	TDF
	Add-on ADV[a]
ADV (nucleoside-naïve)	ETV
	TDF + FTC
	TDF + ETV
	TDF[b]
ADV (nucleoside-experienced)	TDF + ETV
LdT	TDF
	Add-on TDF
	TDF + FTC
	Add-on ADV[a]
ETV	TDF
	Add-on TDF
	TDF FTC
	Add-on ADV[a]
TDF	Add-on ETV
	ETV

[a]Add-on ADV strategies are generally to be reserved for circumstances when TDF is not available
[b]Reserved for subjects with low HBV DNA load. *LAM* Lamivudine, *TDF* Tenofovir, *FTC* Emtricitabine, *ADV* Adefovir, *ETV* Entecavir, *LdT* Telbuvidine

Combination therapy with ETV and TDF is usually effective in patients with MDR [163]. However combination therapy is not necessarily required in patients with more limited resistance. A multicentre trial investigated patients with ADF RAMs (rtA181V/T and/or rtN236T) randomized to receive TDF monotherapy or TDF plus ETV (1 mg/day) combination therapy [164]. At week 48, the two arms showed similar rates of HBV DNA suppression (62 % vs. 63.5 %; $p=0.88$) and a similar mean change in HBV DNA levels from baseline (−3.03 vs. −3.31 $\log_{10}$IU/mL; $p=0.38$). A second multicentre randomized trial investigated patients with ETV RAMs (rtM204V/I and at least one of rtT184A/C/F/G/I/L/S, rtS202G, or rtM250L/V) randomized to receive TDF monotherapy or TDF plus ETV (1 mg/day) combination therapy [165]. At week 48, the two arms showed similar rates of HBV DNA suppression (71 % vs. 73 %; $p>0.99$) and a similar mean change in HBV DNA levels from baseline (−3.66 vs. −3.74 $\log_{10}$IU/mL; $p=0.81$). In both trials, no patient developed additional RAMs, and safety profiles were comparable in the two groups.

Development of further treatment options is needed to manage certain subgroups of patients. These may include patients with LAM resistance that experience or are at increased risk of TDF toxicity, typically in the form of reduced renal function. These patients are often managed through TDF dose reductions, raising concerns about both ongoing risk of toxicity and sustained virological suppression. There is hope that the novel compound tenofovir alafenamide (TAF) will retain the high efficacy of TDF against HBV combined with an improved renal and bone safety profile. Besifovir is a new nucleotide analogue that has undergone testing in treatment-naïve patients with CHB. Over 96 weeks, besifovir caused over a 5 $\log_{10}$IU/mL decline in HBV DNA levels and suppression rates of around 80 % and similar responses were seen in the comparator arm receiving ETV [166]. There was a low overall incidence of virological breakthrough and no development of drug resistance in both arms. CAdAs (4′-C-cyano-2-amino-2′-deoxyadenosine) are novel compounds that offer hope for the management of drug-resistant HBV [167]. Finally, new treatment strategies are also required to improve long-term control of CHB and allow discontinuation of NA therapy after induction [5–7].

7 The Challenge of HIV-HBV Infection in Resource-Limited Settings

In sub-Saharan Africa (SSA), chronic infection with HBV is an important public health issue characterized by high prevalence, frequent co-infection with HIV, and suboptimally applied ascertainment and management strategies [152, 168]. Among people living with HIV, between 6 and 25 % are co-infected with HBV, and co-infection accelerates fibrosis and increases the risk of liver-related morbidity and mortality. In part as a consequence of reduced HIV-related mortality, cirrhosis and hepatocellular carcinoma (HCC) are increasing in the region. For many years, regimens for first-line ART in SSA have been "HBV-blind" and employed LAM plus zidovudine or stavudine in combination with efavirenz or nevirapine. This approach has led to large numbers of HIV and HBV co-infected patients receiving LAM as the sole HBV-active agent across much of SSA, with the resulting associated risk of drug resistance and liver disease progression. In a typical cohort of HIV and HBV co-infected patients in Ghana, after nearly 4 years of standard LAM-containing ART, over half of patients had detectable HBV DNA, one-third had DNA levels >2000 IU/mL, one-third had HBV LAM resistance by Sanger sequencing, and one in eight had advanced liver fibrosis as determined by transient elastography [106]. In this cohort, the introduction of TDF led to substantial improvements in HBV DNA suppression and promising evidence of reversal of liver fibrosis.

Whilst TDF is now recommended for first-line antiretroviral therapy in all patients with HIV in SSA, availability remains far from universal and much remains to be done to improve the diagnosis and management of CHB in populations with and without HIV. The World Health Organisation [169] has released guidelines for CHB in resource-limited settings that aim to promote the use of simple, non-invasive diagnostic tests to assess the stage of liver disease and eligibility for treatment; prioritize treatment for those with most

advanced liver disease and at greatest risk of mortality; and preferential use of NAs with a high barrier to drug resistance (TDF and ETV). These recommendations provide opportunities to improve the clinical outcomes of persons living with CHB in these settings and reduce HBV incidence and transmission. Implementation remains challenging.

Part XI

Parasitic Drug Resistance: Clinical

Antimalarial Drug Resistance: Clinical Perspectives

75

Bruno Pradines

1 Introduction

Despite efforts to discover new antiplasmodial drugs and to accomplish effective implementation of therapeutic combinations for malaria treatment by health systems, *P. falciparum* fits permanently and develops resistance, including to artemisinin-based combination therapy (ACT). Some mutations allow the parasite to survive in the presence of antimalarial drugs and to become resistant. Thus, other factors favoring the emergence of resistance include the following: (1) misuse of antimalarial drugs by infected people (abusive self-medication, poor compliance) leading to incomplete treatment; (2) unavailability of effective drugs or inadequate deployment of drugs as monotherapies; (3) sub-dosed or counterfeit consumption that allows parasites to survive at suboptimal concentrations of antimalarial drugs and to be selected for their ability to resist; (4) the pharmacokinetics and pharmacodynamics of the antimalarial drugs; and (5) the immunity profile of the community and the individual. Updated epidemiologic data on resistance and the molecular mechanisms involved are presented for each antimalarial drug used. The strategies for delaying the emergence and spread are also presented. The roles of heterogeneous biting and transmission in the establishment and spread of resistance in a population are very important. The role of asymptomatic *P. falciparum* parasites is also important in the evolution of antimalarial drug resistance. Several strategies are considered for controlling the emergence and spread of resistance to antimalarial drugs, such as interruption of asymptomatic carriage with mass drug administration, improvement of surveillance, development of new diagnostics and vaccines, and discovery of new drugs.

2 Malaria Epidemiology

Malaria remains the most important human parasitic disease. It was transmitted in 103 countries inhabited by approximately 3.4 billion people in 2012 [1]. Of this total, 2.2 billion were at low risk (<1 reported case per 1000 population), of whom 94 % were living in geographic regions other than Africa. The 1.2 billion people at high risk (>1 case per 1000 population) were living mostly in Africa (47 %) and Southeast Asia (37 %). In 2012, malaria caused an estimated 207 million cases and 627,000 deaths, meaning that 1300 young lives are lost to malaria every day. More than 85 % of malaria cases and 90 % of malaria deaths occur in sub-Saharan Africa, mainly in children younger than 5 years old (77 %). Malaria is a protozoan disease transmitted by *Anopheles* mosquitoes. Five species of the genus *Plasmodium* cause all malaria infections (*Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and the monkey malaria *P. knowlesi*). Most cases are caused by either *P. falciparum* or *P. vivax*. Almost all fatal cases are caused by *P. falciparum*.

Between 2000 and 2012, estimated malaria mortality rates decreased by 42 % worldwide and by 49 % in Africa; they are estimated to have decreased by 48 % in children younger than 5 years of age globally and by 54 % in Africa. The annual number of reported malaria cases decreased from 1.5 million in 2000 to 627,000 in 2012. Over the same period, malaria-eliminating countries reduced total malaria by more 70 %, with 17 countries reporting a greater than 90 % reduction.

These successes have been driven by several factors, including increased funding, effective vector control, strengthening of health systems, improved case reporting and surveillance, and improved case management with more effective treatment regimens.

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_27

3 Antimalarial Drug Resistance

Despite efforts to discover new antiplasmodial drugs and to achieve effective implementation of therapeutic combinations for malaria treatment by health systems, *P. falciparum* fits permanently and develops resistance, including against artemisinin-based combination therapy (ACT) (Fig. 75.1).

This resistance can be explained by the large genetic diversity of *P. falciparum* due to a high rate of mutations in its genome and the very large parasite biomass carried by infected people. Even if mutations capable of conferring resistance to a new drug are extremely rare and unlikely, the large numbers of parasites infecting humans lead to emergence of these mutations and their selection by drug pressure. Mistakes in DNA replication introduce random mutations into the genome and allow for the process of evolution. These mutations are the cause of the high genetic variability of *P. falciparum*, and when they are not lethal to the parasite, they can lead to a survival benefit by permitting, for example, escape from the host immune system, resistance to toxic molecules or more rapid multiplication than other clones.

Some mutations allow the parasite to survive in the presence of antimalarial drugs and to become resistant. The mutation is then transmitted to descendants, generating a drug-resistant population. The mutation frequency and the speed of the resistance development depend on the characteristics of the drug, the epidemiological context (intensity of transmission), and the manner in which the drug is used. However, the acquired resistance phenotype after mutation is not always an advantage in the absence of drug pressure. These mutations can have a biological fitness cost. When chloroquine was removed from areas where parasites were chloroquine-resistant, susceptible strains were favored, compared with resistant strains, and replaced many of them [2]. Although susceptible populations reappear at the expense of resistant strains in the absence of selection by chloroquine, a new selection of the resistant population should be expected if monotherapy or chloroquine-based combination therapy is used again [3].

Thus, other factors favoring the emergence of resistance are: (1) misuse of antimalarial drugs by infected people (abusive self-medication, poor compliance) leading to incomplete treatment; (2) unavailability of effective drugs or inadequate deployment of drugs as monotherapies; (3) sub-dosed or counterfeit consumption that allows parasites to survive at suboptimal concentrations of antimalarial drugs and to be selected for their ability to resist; (4) the pharmacokinetics and pharmacodynamics of antimalarial drugs; and (5) the immunity profile of the community and the individual. Thus, resistance has emerged against all antimalarial drugs in most endemic areas. This resistance applies both to old drugs that were used as monotherapy for a long time (chloroquine, amodiaquine, sulfadoxine–pyrimethamine, quinine, mefloquine) and to the new molecules used in combination therapy (atovaquone, lumefantrine).

3.1 Chloroquine Resistance

3.1.1 Chloroquine Resistance and *P. falciparum*

Chloroquine is a 4-amino-quinoline that was synthesized after the Second World War. Effective, rapid-acting and inexpensive, chloroquine was a remarkable antimalarial drug. However, in 1957, the first cases of chloroquine resistance emerged in Asia and South America. This resistance spread rapidly across the two continents and then across Africa, and chloroquine resistance now affects all malaria endemic areas. For more than 30 years, chloroquine was the first-line drug for preventing and treating falciparum malaria.

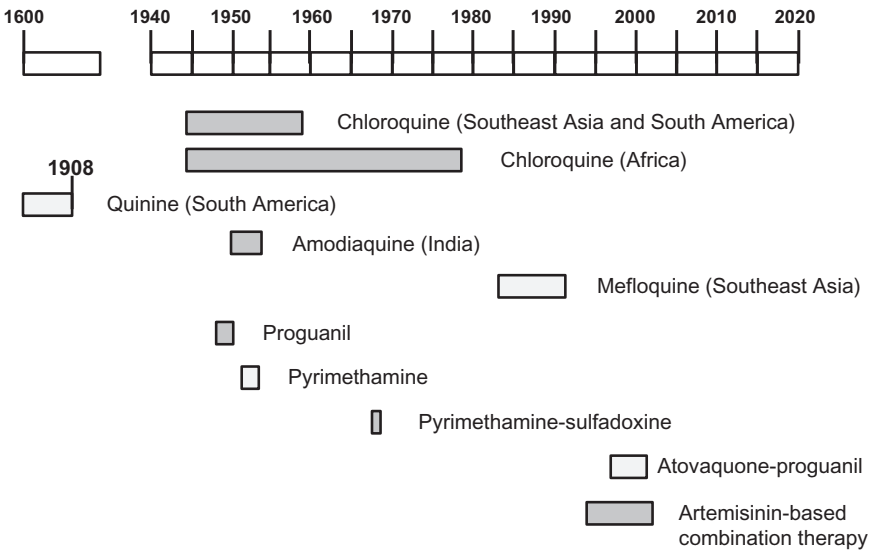

Fig. 75.1 Antimalarial drugs introduction and emergence of resistance in *Plasmodium falciparum*

Chloroquine resistance has been associated with a significant increase in malaria mortality [4, 5]. Chloroquine remains the first-line treatment for vivax malaria.

Characterization of the molecular markers of drug resistance is an important aspect of understanding resistance to antimalarial treatment. Once the genetic changes associated with resistance are identified, drug resistance can be confirmed using molecular techniques. The *pfcrt* gene was first identified in 2000 [6]. To date, at least 20 point mutations have been described, but only one is the reference mutation (K76T), which is a marker of the chloroquine-resistant phenotype [6–9]. This mutation is often associated with other mutations in the *pfcrt* gene, the roles of which have not yet been defined (Cys72Ser, Met74Ile, Asn75Glu, Ala220Ser, Gln271Glu, Asn326Ser, Ile356Thr, Arg371Ile). The odds ratio (OR) for chloroquine failure associated with the K76T mutation was 2.1 (95 % confidence interval [CI]: 1.5–3.0, meta-analysis of 13 studies) over a 14-day follow-up and 7.2 (95 % CI: 4.5–11.5, meta-analysis of 12 studies) over a 28-day follow-up [10]. However, the existence of chloroquine-susceptible strains associated with the K76T mutation suggests that other genes could be involved in resistance to chloroquine. The 76T mutation is necessary, but not sufficient, for influencing chloroquine susceptibility [11].

Polymorphisms within the *pfmdr1* (*Plasmodium falciparum* multidrug resistance 1) gene, which encodes a transmembrane homolog of the PGH1 protein, have been implicated. Field work has shown that the predictive value of chloroquine resistance and of point mutations in the *pfmdr1* sequence resulting in amino acid changes varies depending on the geographic area [12, 13]. Five point mutations have been described: N86Y, Y184F, S1034C, N1042D, and D1246Y. Point mutations, most notably 86Y, have been associated with a decrease in chloroquine susceptibility [14]. However, in some epidemiological studies, the number of chloroquine-susceptible samples has been too limited to provide a statistically meaningful analysis [13, 15]. Using precautions, no relationship or only weak relationships have been established between chloroquine resistance and mutations in *pfmdr1* in *P. falciparum* [12]. However, the risk of therapeutic failure with chloroquine is greater for patients harboring the 86Y mutation, with ORs of 2.2 (95 % CI: 1.6–3.1) over a 14-day follow-up and 1.8 (95 % CI: 1.3–2.4) over a 28-day follow-up [10].

Since the withdrawal of chloroquine, there have been signs of regression of chloroquine resistance in some areas. In China and Vietnam, significant regression of chloroquine resistance has been documented in in vitro and molecular marker studies, while treatment failure rates remain high [16–18]. In Kenya and Malawi, where there is a high level of transmission and almost exclusively infection with *P. falciparum*, there have been signs of a reduction in the prevalence of chloroquine-resistant parasites. Chloroquine was withdrawn from the market in Malawi in 1993 and in Kenya in 1999, when the treatment policies in both countries changed to ACTs. In Malawi, fewer than 10 years after its withdrawal, a re-emergence of chloroquine-susceptible parasites was observed in molecular analyses [19, 20]. Chloroquine was subsequently shown to have 99 % curative efficacy in children with uncomplicated malaria [21]. The prevalence of mutation in the *pfcrt* gene at codon 76 decreased considerably, as did evidence of resistance in vitro [22, 23]. In Kenya, a reduction in resistance to chloroquine was also observed in vitro and with molecular markers, although at a slower rate [24]. It is noteworthy that the prevalence of the Asn86Tyr mutation in the *pfmdr1* gene did not decrease at the same rate as the mutation in the *pfcrt* gene. Decreases in chloroquine resistance have also been observed in vitro and with molecular markers in isolates from Ethiopia, Côte d'Ivoire, and Cameroon [25, 26]. In Senegal, such a decrease was also observed in vitro and with molecular markers in isolates from Senegalese inhabitants in 2009–2011 [27–29], as well as in isolates from travelers returning from Senegal between 2000 and 2011 [25]. However, the chloroquine resistance observed in vitro and with molecular markers is now rising again in Senegal [30–32].

While these results are interesting, caution is nevertheless required. The disappearance of parasites carrying the mutant *pfcrt* gene might be linked to the expansion of wild-type parasites, still present in the subpopulation, replacing the mutant parasites, rather than a reversal of the Lys76Thr mutation [33–35]. Widespread reintroduction of chloroquine is not recommended because it is still too early to predict how long might be needed for chloroquine resistance to reappear or to be reintroduced from neighboring regions. In addition, the rapid dissemination of chloroquine resistance in Dielmo (Senegal), despite strictly controlled antimalarial drug use, argues against the re-introduction of chloroquine, in places where the resistance allele has decreased to very low levels following the discontinuation of chloroquine treatment [3]. Despite the reacquisition of chloroquine susceptibility, any reintroduction would likely result in the rapid re-emergence of resistant strains.

3.1.2 Chloroquine Resistance and *P. vivax*

Chloroquine is the first-line treatment for *P. vivax* in most endemic countries. The clinical efficacy is more difficult to determine in the treatment of *P. vivax* than in *P. falciparum* because recurrent infections can arise from recrudescence, reinfection, or relapses (arising from the dormant liver stages) [36]. Chloroquine-resistant *P. vivax* was first reported in 1989, almost 30 years after chloroquine-resistant *P. falciparum* was first noted, in Indonesia and Papua New Guinea [37, 38]. Papua New Guinea is the epicenter of *P. vivax* chloroquine resistance, and studies conducted there have consistently shown high-grade resistance with early recurrent

parasitemia [39–41]. Treatment failure on or before Day 28 or prophylactic failure have been observed in Afghanistan, Brazil, Cambodia, Colombia, Guyana, Ethiopia, India, Indonesia, Madagascar, Malaysia (Borneo), Myanmar, Pakistan, Papua New Guinea, Peru, the Republic of Korea, the Solomon Islands, Sri Lanka, Thailand, Turkey, Vanuatu, and Vietnam [42]. Several studies in India and Indonesia have shown early treatment failure with rates greater than 10 % and recurrence at Day 28 in between 20 and 100 % of cases [39, 40, 43, 44]. However, antimalarial treatment was not supervised, and drug levels were not measured in several of these studies. True cases of chloroquine resistance (with whole blood concentrations of chloroquine plus desethylchloroquine >100 ng/mL on the day of failure) has been confirmed in Indonesia, Myanmar (Burma), Papua New Guinea, India, and South Korea [45]. The first published reports of chloroquine-resistant vivax parasites in Latin America were from Colombia [46] and Brazil but without blood chloroquine concentration measurements [47]. Consequently, it was only in 1996 that chloroquine resistance was formally documented in a *P. vivax* strain from Guyana [48]. Malaria resistance was then observed in cases from Colombia [49] and was confirmed with chloroquine measurement in two cases from Peru [50]. More recently, two additional reports of in vivo chloroquine resistance in *P. vivax*, with 10.1 and 5.2 % recrudescence despite adequate levels of chloroquine, came from Manaus, a major Brazilian port city in the Amazon Basin [51, 52]. *P. vivax* resistance has also emerged in Ethiopia, with 13 % recurrent parasitemia at Day 28 without chloroquine concentration measurements [53] and between 2.8 and 5.2 % recurrent parasitemia despite adequate levels of chloroquine [54–57].

Parasites carrying the Tyr976Phe mutation of *pvmdr1* showed reduced susceptibility to chloroquine in vitro, compared to wild-type parasites from Indonesia and Thailand [58, 59]. However, this marker was not found to be associated with confirmed clinical chloroquine resistance in Madagascar and Brazil [52, 60, 61].

3.2 Quinine Resistance

Since the adoption of ACTs as the first-line treatment for uncomplicated cases of malaria, quinine has been more commonly used as second-line treatment, and it remains the drug of choice for pregnant women. According to the 2010 *Guidelines for the treatment of malaria*, for the treatment of uncomplicated malaria, oral treatment with quinine should be combined with an antibiotic, such as doxycycline, tetracycline, or clindamycin [62]. Although the World Health Organization (WHO) recommends replacing injectable quinine with injectable artesunate due to the improved efficacy of the latter and higher tolerance of the drug in both adults and children [63, 64], quinine remains a first-line treatment for severe malaria, particularly in Africa. For severe malaria, injectable quinine should be followed by either oral quinine with an antibiotic or artesunate with clindamycin or doxycycline or by a full course of an ACT, once the patient can tolerate oral therapy.

It is difficult to demonstrate resistance to quinine. Despite the efficacy of quinine against chloroquine-resistant *Plasmodium falciparum* isolates, reports of quinine resistance have been increasing. In the 1980s, the frequency of clinical failures increased in Thailand [65–67], Brazil [68], and east Africa [69]. However, the first cases of quinine resistance were described in Brazil in 1908–1910 [70, 71]. Well-documented and confirmed cases have been rare. A few cases were described in French Guiana in 2004 and 2010 [72, 73], in Senegal in 2007 [74], and in Mozambique in 2014 [75].

In the treatment and follow-up of patients, it is important to bear in mind individual differences in the clinical response to quinine. For example, a temporary increase in parasitemia can occur shortly after the first dose, suggesting early treatment failure, although this increase does not tend to affect the treatment outcome [76]. In light of its relatively slow action, as seen by the 48-h parasite reduction rate, the length of treatment should be adjusted to the parasite load [77]. In the event of hyperparasitemia, it might be necessary to extend treatment beyond 7 days or to combine quinine with another antimalarial agent [78].

The in vitro susceptibility of individual *P. falciparum* isolates to quinine has varied widely. Many studies have reported wide ranges of susceptibility to quinine: 25–1253 nM in Comoros [79], 36–1097 nM in the Republic of Congo [80], 5–1291 nM in Senegal [81, 82], and 15–761 nM in Uganda [83]. However, the wide range of quinine susceptibility and recent evidence for quinine treatment failure observed across Africa suggest that the evolution of parasites with reduced susceptibility could contribute to decreased quinine efficacy.

Chromosome 13 in *P. falciparum* contains a candidate gene (*pfnhe-1*), which encodes a putative Na+/H+ exchanger [84]. *Pfnhe-1*ms4760 is highly diverse among parasite isolates. It appears that polymorphisms are more important in Africa and the Indian Ocean region than in India or Asia: in Senegal, 47 different profiles were observed [85]; in the Republic of Congo, 27 different profiles [80]; in Uganda, 40 different profiles [83]; and in the Indian Ocean region, 29 different profiles [86]; whereas in Vietnam, only ten different profiles were observed [87]; in the China–Myanmar border area, ten different profiles [88]; and in India, 16 different profiles [89]. This situation likely reflects the level of transmission in these areas and the level of quinine selection pressure. A repeat polymorphism in *pfnhe-1* microsatellite ms4760 was significantly associated with a poor quinine response, but additional field studies are needed to validate this marker. Conflicting data have been reported regarding

pfnhe-1 polymorphisms. However, investigations of the microsatellite ms4760 polymorphisms in culture-adapted isolates from around the world have shown an association with the quinine susceptibility phenotype [90]. A repetition of the amino acid motif DNNND was associated with decreased susceptibility to quinine, based on the clinical failure of quinine in a traveler from Senegal [74], as well as data from fresh isolates from Vietnam [87] and from culture-adapted isolates from the China–Myanmar border area [88], Asia, South America, and Africa [91]. In cultured-adapted isolates from Kenya [92] and in freshly obtained isolates from Uganda [83], duplication of the DNNND motif was associated with reduced susceptibility to quinine, compared to isolates with one or more than two repeats. Moreover, an increased number of DDNHNDNHNND motifs were associated with increased susceptibility to quinine [84, 87, 88, 90, 91]. Paradoxically, increased numbers of this latter amino acid motif were associated with reduced susceptibility to quinine, based on freshly obtained isolates from Madagascar and 13 other African countries [93]. Moreover, these samples did not exhibit any associations between the number of DNNND repeats and quinine susceptibility. Furthermore, there were no associations between the numbers of DNNND and DDNHNDNHNND repeats and quinine susceptibility, based on freshly obtained isolates from the Republic of Congo [80], Thailand [94], Asia, South America, and Africa [91].

Studies with clones and field isolates have indicated that the *pfmdr1* Asn86Tyr, Ser1034Cys, Asn1042Asp, and Asp1246Tyr mutations might be associated with decreased susceptibility to quinine [95, 96]. Like the response to chloroquine, that to quinine is influenced by mutations in several transporter genes (*pfcrt*, *pfmdr1*, and *pfnhe-1*) [97].

3.3 Amodiaquine Resistance

In the late 1940s and early 1950s, clinical trials for the new and promising 4-aminoquinoline amodiaquine were reported from India, Brazil, the Philippines, Panama, Ecuador, Taiwan, and regions of Africa. Cases of drug resistance were not observed immediately; however, a report of amodiaquine failure was published in 1954 from India [98] and few years later from Colombia [99]. Despite in vivo cross-resistance between chloroquine and amodiaquine [99, 100], amodiaquine is more effective than chloroquine in areas with identified chloroquine resistance [101]. The rates of parasitological or clinical failures with amodiaquine have been lower than those with chloroquine, in Gambia [102], Senegal, Cameroon, Gabon, and Congo [103, 104].

Amodiaquine was therefore chosen by several countries as the first-line drug in combination with artesunate. An amodiaquine failure rate >20 % has been observed in 5 African countries, some of which are currently using artesunate–amodiaquine as the first-line treatment (Burkina Faso, Cameroon, Gabon, Liberia, the Sudan) [105–109]. Parasite strains that are highly resistant to amodiaquine have been reported in Tanzania, and these strains could further compromise the use of artesunate–amodiaquine in Africa [110].

Some chloroquine-resistant isolates have shown cross-resistance with amodiaquine, both in vivo and in vitro. *Pfcrt* and *pfmdr1* alleles interact to yield different levels of resistance to chloroquine and amodiaquine. The *pfcrt* mutations at codons 72–76 observed in South America have been associated with high levels of amodiaquine resistance, whereas *pfcrt* mutations in Southeast Asia and Africa have been linked to greater resistance to chloroquine and moderate resistance to amodiaquine. This difference might be due to the extent of the previous use of amodiaquine in different regions. Amodiaquine resistance might also be modulated by the *pfmdr1* mutations Asn86Tyr and Asn1042Asp [110–112]. However, the role of *pfmdr1* in amodiaquine resistance remains debated. The 86Y mutation was significantly associated with increased in vitro susceptibility to active metabolites of amodiaquine in Senegal [113], while mutant *pfmdr1* 86Y allele showed increased and reduced susceptibility in isolates from Nigeria [114] or no change in isolates from Benin [115].

However, the *Pfmdr1* 86Y mutation has been shown to be associated with treatment failure after monotherapy with amodiaquine [116, 117] or after combination therapy with artesunate–amodiaquine [118]. In a meta-analysis, the *Pfmdr1* 86Y mutation was found to be associated with amodiaquine failure, with an OR of 5.4 [10]. The *pfmdr1* 1246Y mutation has also been found to be associated with in vitro resistance to amodiaquine [119] and with recrudescent infection after treatment with amodiaquine or amodiaquine–artesunate [117, 118].

3.4 Mefloquine Resistance

Mefloquine, an arylaminoalcohol, was discovered at the end of 1970s, and it is still recommended for malaria prophylaxis in areas with multidrug resistance. Mefloquine was widely used to treat uncomplicated malaria as a first line in areas with *P. falciparum* multidrug resistance, such as Thailand [120]. Mefloquine resistance appeared at the Cambodia–Thailand border only a few years after its introduction [121]. There are several probable reasons for this rapid onset. Preexisting strains in the region had markedly reduced susceptibility to quinine. Further, the long half-life of mefloquine might have allowed for exposure to subtherapeutic concentrations. Common use of the low-dose, single-dose regimen (15 mg/kg body weight) in this region might also have contributed to the increase in resistance. The higher dose of 25 mg/kg body weight that is usually recommended

is known to have several adverse effects, particularly vomiting, which can lead to lower blood concentrations and subsequent treatment failure [122].

The *pfmdr1* gene amplification that has been implicated in resistance to mefloquine is acquired relatively rapidly at the Cambodia–Thailand border. Studies conducted in the Greater Mekong subregion (Cambodia and Thailand) showed that increases in copy numbers of this gene were responsible for resistance to mefloquine and to increased risks of treatment failure with artesunate–mefloquine [123]. *Pfmdr1* amplification and deamplification are relatively frequent events related to the rapid evolution of mefloquine resistance when the drug is used as a monotherapy. In vitro susceptibility to mefloquine increased when the *pfmdr1* copy numbers were reduced or when the parasites carried *pfmdr1* mutations [124, 125]. In Southeast Asia, the presence of the Asn86Tyr mutation is a negative marker for gene amplification. It has been shown through heterologous expression that *pfmdr1* mutations at codons 1034 and 1042 abolish or reduce the level of resistance to mefloquine in vitro [126]. Moreover, transfection with a wild-type *pfmdr1* allele at codons 1034, 1042, and 1246 conferred mefloquine resistance to susceptible parasites [95]. However, mutations at *pfmdr1* codons 1034, 1042, and 1246 in *P. falciparum* isolates were not sufficient to explain the variations in mefloquine susceptibility [113, 127]. The significance of the 184F mutation remains less well understood. Indeed, no clear association between the 184F mutation and mefloquine failure has been established. A study showed that Asian isolates with a single 184F mutation exhibited increased resistance to mefloquine [128]. A study from Cambodia demonstrated that isolates with a single 184F mutation had significantly increased IC_{50} values for mefloquine [129]. The *pfmdr1* 86 plus 184 haplotype showed significantly increased in vitro susceptibility to mefloquine in parasites with 86Y plus Y184 from Senegal and Benin [113, 115]. Analyses of *P. falciparum* isolates have shown an association between a mutation at codon 86 and an increase in susceptibility to mefloquine [113, 130–132].

Mefloquine resistance continues to be a concern in the Greater Mekong subregion, particularly in Thailand and Cambodia, where artesunate–mefloquine is still used as a first-line treatment. The national malaria control program in Thailand detected a gradual decline in the efficacy of mefloquine at its sentinel sites, although monitoring of mefloquine monotherapy was last conducted in 2004. Even when the dose was increased from 15 to 25 mg/kg body weight, efficacy increased only temporarily [133]. In Cambodia, after implementation of rapid diagnostic tests and the replacement of artesunate–mefloquine by dihydroartemisinin–piperaquine in Pailin Province, a reduction in mefloquine resistance was detected using molecular markers. The high "fitness cost" linked to mefloquine resistance and the removal of mefloquine pressure led to deamplification of *pfmdr1* copy numbers between 2005 and 2007, resulting in a decrease in the treatment failure rate with artesunate–mefloquine (≤5 %) in 2007–2008 [134–136]. However, a 42-day WHO therapeutic efficacy study, conducted in 2010 in southwest Cambodia, showed 11.1 % late treatment failures with artesunate–mefloquine treatment [137]. In studies from 2008 to 2010, the incidence of Day 3 positive parasitemia among falciparum malaria patients associated with artesunate–mefloquine treatment increased along the Thailand–Myanmar border to surpass 10 % [138]. Approximately 14 % of patients undergoing artesunate–mefloquine treatment remained parasite-positive on Day 3 during 2009–2011 along the Thai–Cambodian border [139].

In Myanmar and Vietnam, the treatment failure rate was as high as 40 % in the late 1990s and early 2000s; however, a low dose of 15 mg/kg body weight was used [140–142]. No recent studies have been reported in which a dose of 25 mg/kg body weight was used.

In Africa, in vitro studies conducted prior to the introduction of mefloquine showed the presence of parasites with reduced susceptibility to mefloquine that were still susceptible to chloroquine [143]. The validation of molecular markers for chloroquine and mefloquine resistance now allows for better understanding of these results. Recently, isolates with increased *pfmdr1* copy numbers have been detected in West Africa and have been associated with mefloquine treatment failure in travelers [144, 145]. However, amplification of *pfmdr1* in Africa has only rarely occurred. Very few isolates with ≥2 copies of *pfmdr1* were identified in Africa in 1993–2014: three in Côte d'Ivoire [145, 146], one in Burkina Faso [145], one in Togo [145], three in eastern Sudan [147], ten in Kenya [148, 149], and ten Senegal [27, 150]. Another isolate was obtained in a patient from Benin who did not respond clinically to mefloquine treatment [144]. In a multicentric study to analyze the polymorphisms in *pfmdr1* after artemether–lumefantrine and artesunate–amodiaquine treatments, amplification of *pfmdr1* was observed in only 2.6 % of isolates from Africa versus 50 % of isolates from Asia [151]. *Pfmdr1* amplification has not been found in many studies in samples collected either before or after treatment for recurring *P. falciparum* infection in Africa. However, the percentage of isolates with increased *pfmdr1* copy numbers increased from 4 % in 2003 to 18 % in 2010 in Ghana [152]. Efficacy studies conducted in Benin (cure rate of 97.5 %) and Nigeria in 2008–2009 (cure rate of 94 %) showed low treatment failure rates [153, 154]. In a multicentric study in Benin, Gabon, Mozambique, and Tanzania of the use of mefloquine as an intermittent preventive treatment in pregnancy (two doses of mefloquine 15 mg/kg), mefloquine reduced the incidence of clinical malaria [155]. In Tanzania between 2004 and 2008, a dose of 125 mg of mefloquine as an intermittent preventive treatment in infancy only protected 38.1 % of infants against malaria [156]. Therapeutic

efficacy in Senegal with mefloquine–artesunate was 96.2 % in children in 2008 and 98.5 % in 2010 [157, 158], compared to 96 % in Mali in 2004–2005 [159]. Selection of the *pfmdr1* N86 mutation was observed in 2009 in Gabon after the introduction of mefloquine–artesunate [160].

Some cases of malaria prophylaxis failures in travelers who correctly took the drug have been observed in Mozambique and Senegal [161, 162].

In South America, mefloquine resistance has remained low, although few therapeutic efficacy studies have been performed. The efficacy of mefloquine at 15 mg/kg was 100 % in 1999–2000 in Peru and in 2001 in Bolivia [127, 163, 164]. The efficacy of mefloquine–artesunate was 98.9 % in the Peruvian Amazon in 2005–2006 [165]. The prevalence of an increased *pfmdr1* copy number was 12 % among 93 samples from Venezuela in 2003 and 2004 [166]. In French Guiana, amplification of the *pfmdr1* gene was associated with in vitro reduced susceptibility to mefloquine, and it was observed at a high rate (mean of 40 %) [167]. However, the proportion of isolates with multiple copies of *pfmdr1* decreased from 2005 to 2008, when in vitro resistance declined, corresponding to the progressive replacement of mefloquine with artemether–lumefantrine in French Guiana [167]. In Suriname, no significant changes in *pfmdr1* copy numbers were observed between 2005 and 2011: 12.5 %, 8.7 %, and 13 % of isolates carried multiple copies of *pfmdr1* in 2005, in 2009, and in 2009–2011, respectively [168, 169].

3.5 Artemisinin and Artemisinin-Based Combination Therapies (ACT)

3.5.1 Artemisinin and Artemisinin Derivatives

In contrast with most previous antimalarial treatments, such as chloroquine and sulfadoxine–pyrimethamine, which are eliminated slowly, artemisinin and its derivatives are eliminated rapidly, and they target all of the blood stages of the malaria life cycle, including early ring forms. This targeting is particularly beneficial for the treatment of severe malaria, when rapid elimination of parasites is critical for patient recovery.

In the 1980s, treatment failures with artemisinin were already reported in China after a 3-day treatment (48 % of recrudescence) [170]. When treatment was extended to 5 and 7 days, the recrudescence rates decreased to 10 % and 2 %, respectively [170]. These data could be explained by the short half-life of artemisinin and its derivatives because not all parasites would necessarily be eliminated after the initial rapid effect of a short treatment with oral artemisinin-based monotherapy. Therefore, monotherapy was not effective unless it was administered over an extended period. In the same manner that parasites that are consistently exposed to a suboptimal dose of treatment develop resistance, incomplete or short treatment with oral artemisinin-based monotherapy could also facilitate the development of resistance, although the short half-lives of these drugs reduce the time window during which resistant parasites can be selected.

In 2007–2008 in Pailin, western Cambodia, where artemisinins have been used for more than 30 years, treatment failure was confirmed in 30 % of patients receiving artesunate monotherapy (2 mg/kg/day for 7 days) and in 5 % receiving artesunate–mefloquine therapy (artesunate at 4 mg/kg/day for 3 days, followed by mefloquine at two doses totaling 25 mg/kg) [135]. This resistance was characterized by slow parasite clearance in vivo. These markedly different parasitological responses were not explained by in vitro *P. falciparum* susceptibility, obtained by a standard 48 h in vitro test. In 2009–2010, in Pursat in western Cambodia, 64 % of the patients treated with artesunate monotherapy (4 mg/kg) had parasite clearance half-lives longer than the geometric mean of the patients in Pailin [171]. Similar parasite clearance half-lives for artemether were found in patients with severe malaria, compared with artesunate in patients with uncomplicated malaria, suggesting that artemether treatment for severe malaria did not accelerate parasite clearance rates, compared with artesunate treatment for uncomplicated malaria [172]. In 2010–2011 in Vietnam, the efficacy of artesunate monotherapy (2 mg/kg/day for 3 days) was 94 %, and 27 % of the patients had a parasite clearance time >72 h [173]. In 2010, artemisinin resistance emerged on the western border of Thailand, with slow parasite clearance half-lives [174]. An open trial of artesunate at a daily dose of either 2 or 4 mg/kg/day for 3 days, followed by a standard 3-day course of ACT, showed that slowly clearing infections (parasite clearance half-live >5 h) were detected throughout mainland Southeast Asia, from southern Vietnam to central Myanmar [175]. No evidence of delayed parasite clearance to artemisinin was shown in Bangladesh or in Africa (Mali, Nigeria, Democratic Republic of Congo, or Kenya) [175, 176]. A method for measuring the parasite clearance in patients was standardized to compare the data and to track artemisinin resistance [177].

P. falciparum isolates with reduced in vitro susceptibility to artemisinin and derivatives were found by 42 h-standard in vitro testing from 2001 in Asia (Thailand, Cambodia, Laos), Africa (Senegal), and South America (French Guiana) [178–180]. However, these in vitro resistance data failed to be associated with in vivo resistance. Artemisinin acts on *P. falciparum* ring stages, which can develop tolerance to artemisinin by a quiescence mechanism [181]. A new in vitro test, the ring stage survival assay, was developed to measure in vitro resistance to artemisinin derivatives manifested by an increase in the ring-stage survival rate after contact with artemisinin [182, 183]. This in vitro resistance was associated with slow in vivo parasite clearance (parasite clearance half-life >5 h) [184–186].

In falciparum malaria, artemisinins are believed to inhibit the sarco-endoplasmic reticulum calcium-ATPase (SERCA)-type, PfATPase 6 protein [187]; however, this protein is unlikely to be the only target [188]. One molecular marker for artemether resistance has been proposed, *pfATPase6* Ser769Asn, but this suggestion was based exclusively on findings from in vitro tests [180], and field studies have not confirmed this hypothesis [189, 190]. In vivo delayed parasite clearance was not associated with *pfATPase6* polymorphisms in artemisinin resistance at the Thai–Cambodian border [191]. Amplification of the *pfmdr1* gene has been associated with significant reductions in susceptibility to artemisinin and derivatives in vitro [123, 124, 150, 192] but not with parasite clearance half-life [193]. So far, none of the known markers, particularly *pfmdr1* copy numbers or mutations, *pfATPase6*, the 6-kb mitochondrial genome (including cytochrome *b*, *COXI*, and *COXIII*) or *pfubp-1* encoding a deubiquitinating enzyme, has been correlated with the artemisinin resistance phenotype observed at the Cambodia–Thailand border [136]. In 2010, a *P. falciparum* strain susceptible to artemisinin became resistant after 3 years of artemisinin pressure [194]. Whole-genome sequences were obtained for both strains. The data indicated that the M476I mutation in the propeller domain of the *Kelch 13* (K13) gene (*PF3D71343700*) was associated with in vitro resistance to artemisinin of this strain [184]. Then, several mutations in K13 (C580Y, R539T, Y493H, and I543T) were associated with in vitro resistance of Cambodian isolates, assessed by ring stage survival assay and delayed parasite clearance half-lives (>5 h) [184]. These mutations were confirmed to be associated with in vitro resistance to artemisinin and with delayed clearance after artemisinin treatment in Southeast Asia [175, 186, 194]. In addition, recent reports have supported a causal role for K13-propeller mutations in conferring resistance to artemisinin and particularly the roles of the C580Y, Y493H, R539T, and I543T mutations due to genome manipulation [195, 196]. These mutations were introduced into the genome of a *P. falciparum* clone and into clinical isolates susceptible to artemisinin, and they consequently increased ring-stage parasite survival in the presence of artemisinin. However, the presence of multiple, population-specific mutations responsible for artemisinin resistance has led to the independent emergence of resistance in multiple geographic locations in Southeast Asia [175, 194].

The polymorphisms associated with artemisinin resistance in Southeast Asia were not detected in other countries in Africa, with the exception of the P553L polymorphism, which was detected in one isolate in Mali [175, 197–200], in Bangladesh [175, 201], in India [202], and in China [203]. In Uganda, the prevalence of K13-propeller polymorphisms was not associated with the persistence of parasites after two days after treatment with artemether–lumefantrine [204]. However, due to the high baseline parasitemia in Uganda, persistent parasitemia two days after the onset of therapy is likely not to be a reliable indicator of resistance in Uganda. No mutations on the K13 gene were detected in parasites from artemether–lumefantrine and dihydroartemisinin–piperaquine failures in Democratic Republic of Congo or Angola [205]. When artemisinin resistance emerges in Africa, it might be due by the spread of resistant parasites imported from Southeast Asia and/or the selection for de novo evolution of resistance (uncommon mechanisms between Asia and Africa). Further studies are needed to characterize better the roles in artemisinin resistance of the mutations in K13 found in Africa, China, Bangladesh, and India.

3.5.2 Artemisinin-Based Combination Therapies (ACTs)

Artesunate–Mefloquine

The artesunate–mefloquine combination was introduced after the spread of resistance to mefloquine in Thailand. It was first available as a co-blister and is now also available as a fixed-dose combination. Currently, eight countries use artesunate–mefloquine as first- or second-line treatment.

In Cambodia in 2000, artesunate–mefloquine became the first-line drug (12 mg/kg artesunate and 20 mg/kg mefloquine given for 3 days). The first report of the emergence of resistance to artesunate–mefloquine was in 2003. Between 2002 and 2004, the efficacy of this combination decreased from 85.7 to 79.3 % in Pailin [206]. Artesunate–mefloquine was introduced in 1995 in Thailand. The efficacy of the same regimen was 78.6 % at the Thai–Cambodian border in 2003 [207]. In Cambodia, after the implementation of rapid diagnostic tests and the replacement of artesunate–mefloquine by dihydroartemisinin–piperaquine in Pailin Province, mefloquine resistance decreased from 9.9 to 14.3 % in 2002–2004 to 0–5 % in 2007–2008 [136]. However, 42-day therapeutic efficacy studies conducted by the WHO in 2006–2008 and 2010 in southern Cambodia showed 18.8 % and 11.1 % failures of late artesunate–mefloquine treatment, respectively [137, 208]. In studies from 2008 to 2010, the proportions of Day 3 positive parasitemia among falciparum malaria patients associated with artesunate–mefloquine treatment increased along the Thailand–Myanmar border to surpass 10 % [138]. Approximately 14 % of patients undergoing artesunate–mefloquine remained parasite-positive on Day 3 during 2009–2011 along the Thai–Cambodian border [139]. In 2008–2009, the 42-day efficacy of artesunate–mefloquine was 72.6 % along the western border of Thailand (Thailand–Myanmar), and parasite clearance was significantly prolonged in patients experiencing treatment failure [2010].

Because of the long half-life of mefloquine, the efficacy of artesunate–mefloquine must be monitored for at least 42 days. Artesunate–mefloquine fails mainly in areas where

mefloquine resistance is highly prevalent. Regardless of whether these failures are due to mefloquine resistance only or to resistance to both mefloquine and artesunate, countries in the Greater Mekong subregion should continue to monitor the efficacy of this combination carefully and should review their treatment policies accordingly. The further spread of mefloquine resistance in areas where there is artemisinin resistance and where artesunate–mefloquine is used as the first-line treatment could jeopardize efforts to contain artemisinin resistance.

Artesunate–Amodiaquine

Amodiaquine was combined with artesunate in clinical trials conducted in Africa [210]. Artesunate–amodiaquine was first available as a co-blister and is now also available as a fixed-dose combination. Currently, 27 countries (25 in Africa) are using artesunate–amodiaquine as a first- or second-line treatment. More than 200 million treatments have been distributed in Africa since the medication became available in 2007 [211].

The efficacy of artesunate–amodiaquine is heterogeneous in Africa, probably due to preexisting amodiaquine resistance [212]. Of the 23 African countries that have adopted artesunate–amodiaquine as the first-line treatment, six (Burkina Faso, the Democratic Republic of the Congo, Eritrea, Gabon, Ghana, and Sierra Leone) have reported a treatment failure rate ≥10 % in at least one study after 28-day follow-up between 1999 and 2009. Overall, 15,017 patients were treated for uncomplicated *P. falciparum* malaria (51 % with artesunate–amodiaquine) at 44 sites in 20 sub-Saharan African countries. The parasite reduction ratio ranged on Day 1 from 77.1 % in Mozambique to 99.2 % in Kenya. The proportion of patients treated with artesunate–amodiaquine who were still parasitemic on Day 3 was 1.5 %, ranging from 0 % at many sites to 55.9 % in the Democratic Republic of Congo. The proportion of patients treated with artesunate–amodiaquine who experienced parasite clearance failure by Day 7 was 0.2 %, mostly from the Democratic Republic of Congo. Studies conducted in Tanzania in 2007 showed that amodiaquine–artesunate had limited clinical efficacy, with 20 % treatment failures after PCR correction [213].

Artesunate–amodiaquine is less effective in Asia than in Africa. In Myanmar, 9.4 % (14 of 155) of patients treated with artesunate–amodiaquine had recrudescent *P. falciparum* malaria in 2008–2009 [214]. In 2005, in rural areas from southern Papua, Indonesia, the cumulative risk of overall parasitological failure by Day 42 was 45 % in patients treated with artesunate–amodiaquine [215]. In 2002–2003, the proportion of late treatment failures with artesunate–amodiaquine was 28.4 % in Afghanistan [216]. However, artesunate–amodiaquine has been effective in Vietnam, with a 2 %, unexpectedly low rate of treatment failure in 2006–2007 and 2008–2009 [217, 218].

Artesunate–amodiaquine was effective in South America, with a 100 % rate of clinical adequate responses in Colombia in 2008–2009 [219].

Artemether–Lumefantrine

In anticipation of the need to protect against resistance to artemisinin and its derivatives, Chinese researchers began studying ACTs in 1981 [220] and registered the first ACT in 1992. This treatment was a combination of artemether and lumefantrine into a single tablet. Currently, 56 countries are using artemether–lumefantrine as first- or second-line treatment.

Artemether–lumefantrine began to lose its efficacy in Africa. In Uganda, the rate of adequate clinical and parasitological response was only 45.4 % in patients treated with artemether–lumefantrine in 2011–2012 [221]. Residual parasitemia, associated with a longer duration of gametocyte carriage, a higher transmission to mosquitoes and a higher risk of recurrence, was detected in 33.3 % of children at Day 3 treated with artemether–lumefantrine in Kenya in 2009 [222]. The proportion of patients with residual parasitemia on Day 1 rose from 81 % in 2005–2006 to 95 % in 2007–2008 in children treated with artemether–lumefantrine on the Kenyan coast [223]. However, by Day 28, the rate of recrudescent primary infection after PCR correction was 1 %, but it rose to 13 % by Day 84. Another study in Kenya showed a cumulative risk of recurrent parasitemia of 20.7 % on Day 42 after the initiation of treatment in 2009 [224]. A proportion of 11.2 % treatment failure was reported in Burkina Faso between 2008 and 2010 [225]. Using intention to treat analysis, the adequate clinical and parasitological response rate was 85.2 % in Malawi in 2004–2006 [226]. Artemether–lumefantrine was efficacious in Ghana, with significant ecologic zonal differences in 2010–2011: the 90.4 % day-28 cure rate observed in the savannah zone was significantly the lowest, compared with 100 % in the forest zone and 93.8 % in the coastal zone [227]. Few cases of clinical failure were reported of artemether–lumefantrine in travelers with imported uncomplicated *Plasmodium falciparum* malaria from Africa: one case in an Italian traveler returning from the Democratic Republic of Congo [228] and one in a Japanese traveler returning from Sierra Leone [229].

The adequate clinical and parasitological response rate was 100 % in Tanzania in 2013 and in Senegal in 2011–2012 after treatment with artemether–lumefantrine [213, 230], compared to 92.3 % in the Democratic Republic of Congo in 2011–2012 [231].

In 2005, the proportion of recrudescence was 17.8 % after artemether–lumefantrine treatment in the western part of Cambodia bordering Thailand [232]. At the Thai–Cambodian border, studies showed a cure rate of only 71.1 % in 2002 and 86.5 % after food supplementation in 2003 [233]. The efficacy of artemether–lumefantrine combination is strongly

influenced by broad variation in the pharmacokinetics of lumefantrine among individuals. Because its absorption is enhanced by concomitant intake of fatty foods [234], treatment failures with this combination might be due to insufficient absorption of lumefantrine. The main determinant of the efficacy of the combination is the area under the curve of the plasma concentration of lumefantrine, or its surrogate, the plasma concentration of lumefantrine, on Day 7 [235]. Even with flavored milk, the treatment failure rate by Day 42 was 25 % after artemether–lumefantrine on the northwestern border of Thailand in 2002 (Karen ethnic group from Myanmar) [236]. Three-day artemether–lumefantrine remained effective in Laos with a 42-day cure rate of 97 % in 2008–2010 [237].

Artemether–lumefantrine remains effective in South America. The clinical adequate response rates were 97.5 % and 99 % in Colombia in 2007–2008 and 2008–2009, respectively [219, 238].

Artemether–lumefantrine remains highly effective in most parts of the world, with the exception of Cambodia. Although no time trends have been observed in any subregions, continuous monitoring is necessary. Artemether–lumefantrine was reported to select for the wild-type *pfmdr1* Asn86 allele in recurrent infections, which could be a marker of reduced susceptibility to lumefantrine. Mutations in *pfmdr1* have also been associated with decreased susceptibility to artemether and lumefantrine drugs separately [160, 239, 240]. The *pfmdr1* N86 allele can predict in vitro decreased susceptibility to lumefantrine, whereas the 86Y mutation was significantly associated with increased susceptibility to lumefantrine [113, 115, 239, 241]. Field studies in east Africa have also shown selection of the 86N allele in recurrent infections after treatment with artemether–lumefantrine, suggesting that 86N could be a potential marker of lumefantrine resistance in vivo [242–245].

Dihydroartemisinin–Piperaquine

Piperaquine is a bisquinoline developed independently in the 1960s by Chinese investigators and the French pharmaceutical company Rhone Poulenc. It was used widely for the treatment and prevention of malaria in China in the 1980s; however, resistance to piperaquine eventually emerged, which led to its use in combination therapy [246]. The most widely studied combination is dihydroartemisinin–piperaquine, which is now one of the five ACTs recommended by the WHO.

Many trials to monitor the safety and efficacy of dihydroartemisinin–piperaquine have been conducted in Africa and Southeast Asia [247–249]. The treatment failure rates in the majority of the studies were <10 %. Dihydroartemisinin–piperaquine began to loss efficacy in Africa. In 2003–2004, the proportion of treatment failures after dihydroartemisinin–piperaquine was 8 % in Rwanda [250]. Residual parasitemia, associated with a longer duration of gametocyte carriage, higher transmission to mosquitoes, and a higher risk of recurrence, was detected at Day 3 in 30.0 % of children treated with dihydroartemisinin–piperaquine in Kenya in 2009 [222]. The proportion of patients with residual parasitemia on Day 1 rose from 55 % in 2005–2006 to 87 % in 2007–2008 in children treated with dihydroartemisinin–piperaquine on the Kenyan coast [223]. However, the adequate clinical and parasitological response rates were 99 % at Day 28 and 96 % at Day 46 in 2010–2011 [251]. In Uganda, the rate of adequate clinical and parasitological response was 87.9 % in patients treated with dihydroartemisinin–piperaquine in 2011–2012 [221]. The risks of treatment failure by Day 28 were 8.9 % and 82.7 % by Day 84 in Uganda in 2009 and 2012, respectively [252]. Recurrent malaria was correlated with low piperaquine concentrations at Day 7 in Burkina Faso [253]. However, the risk of treatment failure with dihydroartemisinin–piperaquine by Day 28 remained low in Burkina Faso in 2005 [254]. Adequate clinical and parasitological responses were observed in 93 % by Day 28 in Zambian children in 2005–2006 [255].

In the brief period since the introduction of dihydroartemisinin–piperaquine, there has been early evidence suggesting declining efficacy in Asia. In 2010, a study conducted in Cambodia showed efficacy of 79 % of dihydroartemisinin–piperaquine [256]. In 2013, at the same location, the efficacy of dihydroartemisinin–piperaquine rose to 65 % [257]. In 2010, the PCR-corrected treatment failure rates for dihydroartemisinin–piperaquine on Day 42 were 25 % in Pailin and 10.7 % in Pursat, while the therapeutic efficacy of dihydroartemisinin–piperaquine remained high (100 %) in Ratanakiri and Preah Vihear provinces, located in northern and eastern Cambodia [258]. PCR-adjusted falciparum efficacy at Day 42 was 75 % on the Thai–Cambodian border in northern Cambodia [256]. In central Vietnam, the efficacy of dihydroartemisinin–piperaquine remained satisfactory (100 % at Day 28 and 97.7 % at Day 42), but the delayed parasite clearance time and rate were indicative of emerging artemisinin resistance [259].

Between 2005 and 2007, the rate of adequate clinical and parasitological response to dihydroartemisinin–piperaquine was 88 % in Papua New Guinea [41].

Dihydroartemisinin–piperaquine remains highly effective in South America. Between 2003 and 2005, the rate of adequate clinical and parasitological response to dihydroartemisinin–piperaquine was 98.4 % in Peru [260].

3.6 Atovaquone–Proguanil

Strictly speaking, atovaquone–proguanil is not a monotherapy but is classified as such because its efficacy relies on the synergistic action of the two components. Early studies of

atovaquone, administered as a monotherapy, showed that resistant parasites were selected rapidly, and the synergistic combination atovaquone–proguanil was developed to delay the emergence and spread of atovaquone resistance [261]. Atovaquone is currently used in combination with proguanil for the treatment and prophylaxis of malaria, but because of its high price, the combination is generally limited to travelers from industrialized countries.

Prophylactic failure with atovaquone–proguanil in travelers has been extremely rare [262–264]. Prophylactic and clinical failures of atovaquone–proguanil against *P. falciparum* have been associated with poor absorption, which can lead to inadequate blood levels. However, resistance can also explain failures of prophylaxis. Few cases of clinical failure of atovaquone–proguanil in travelers with imported uncomplicated *Plasmodium falciparum* malaria have been reported from Africa, including Nigeria [265, 266], Côte d'Ivoire [267], Mozambique [268], Comoros [269], Democratic Republic of Congo [270], Kenya [271], Uganda [264], and Sierra Leone [264]. Treatment failure was confirmed among travelers returning from Nepal [272]. The proportion of treatment failure with atovaquone–proguanil was 1 % in a prospective study of patients treated for uncomplicated malaria in nine travel clinics located in Paris (mostly young men of African origin living in France and infected in West Africa) [273]. This rate was 13.6 % in Israeli travelers [274]. All of these failures were observed in travelers returning from West Africa. In 2004–2005, 97.8 % of Thai patients were cured using a standard 3-day course of atovaquone–proguanil therapy [275].

In previous studies, molecular analysis of recrudescent isolates showed that atovaquone resistance was associated with a single mutation at cytochrome *b* (*cyt b*), which seemed to compromise its efficacy. Mutations in this gene have been reported in Burkina Faso, Cameroon, the Comoros, Côte d'Ivoire, French Guiana, Guinea, India, Kenya, Mali, Mozambique, Nigeria, Senegal, Sierra Leone, and Uganda [276]. A point mutation at codon 268 in cyt b has been linked to atovaquone–proguanil treatment failure [264, 277–281]. This mutation is sufficient for, but not a necessary cause of, atovaquone–proguanil treatment failure [279]. Mutations were also detected among patients who failed treatment due to frequent de novo mutations. Because of the variability in the size of this mutant reservoir, some patients failed to eliminate all of the mutant parasites [282]. In other cases, treatment failures were linked to poor absorption, which could lead to inadequate blood levels [264, 283]. Atovaquone is a lipophilic drug, and its absorption is heavily influenced by the availability of fatty foods.

Atovaquone–proguanil failure requires resistance to atovaquone and to proguanil. Studies of the *pfdhfr* gene have consistently demonstrated the importance of a point mutation at the Ser108Asn codon in the proguanil-resistant phenotype of *P. falciparum*. Additional point mutations at the Asn51Ile, Cys59Arg, and Ile164Leu positions strengthen the resistance of *P. falciparum* to antifolates. The level of resistance increases with the number of mutations [284]. Cycloguanil resistance appeared to be associated with the double mutations Ser108Thr and Ala16Val [285].

The S108N mutation was screened in 71 surveys conducted during or after 2004 from 62 unique sites in 24 countries [286]. Of 9463 samples tested for S108N since 2004, 78 % carried the S108N mutation. Among 62 surveys, only three reported a prevalence of less than 50 % and, like the N51I and C59R mutations, these cases were in Burkina Faso in 2004 [287], Côte d'Ivoire in 2006, and Madagascar in 2006–2008 [288]. There were 24 surveys in which the prevalence was 100 %, and these surveys were conducted in Angola in 2007 [289], Ethiopia in 2004 [290], Kenya in 2004–2006 [291], Malawi in 2005 [292], Rwanda in 2005 [293], São Tome and Principe in 2004 [294], Tanzania in 2004 [295], and Uganda in 2005 [296].

3.7 Doxycycline

Daily administration of doxycycline is currently a recommended chemoprophylactic regimen for travelers visiting malaria-endemic areas with a high prevalence of chloroquine or multidrug resistance [297]. In addition, the French malaria consensus recommends quinine and doxycycline for the first-line treatment of severe *Plasmodium falciparum* malaria in Asia and South America. Doxycycline remains the recommendation for second-line treatment of uncomplicated falciparum malaria or for the treatment of severe malaria, in combination with artesunate or quinine for a 7-day course [298]. Doxycycline in combination with other antimalarial drugs has been studied many times, particularly in areas of multidrug resistance such as Thailand [299–302]. The most described associations have been doxycycline (200 mg)–quinine (10 mg/kg/day) for 7 days, which has been used in Thailand with therapeutic efficacy of 91–100 %.

The main studies of the efficacy and safety of doxycycline prophylaxis were performed in different types of populations that were followed for at least 28 days after the discontinuation of prophylaxis: semi-immune or immune subjects living in endemic areas [303–305] and non-immune travelers, mainly soldiers from different armies [306–308]. The results, which were conclusive, showed efficacy of 91–99 % in semi-immune and immune subjects and 95–100 % in travelers.

Most prophylactic failures of doxycycline against *P. falciparum* have been associated with the use of standard doses, resulting in lower-than-expected serum drug levels [309], inadequately low doses [305], or poor compliance [310–313]. Moreover, doxycycline pharmacokinetic parameters could explain some of these cases. Doxycycline has a short

elimination half-life (16 h), compared to proguanil (24 h), atovaquone (31–73 h), chloroquine (2–3 days), and mefloquine (6–41 days), and a short mean residence time (63 % of the administered dose is eliminated in 27 h) [314]. A surge in the number of malaria cases within 3 weeks after doxycycline prophylaxis discontinuation is often observed after return [303, 314]. Therefore, it is recommended that doxycycline be taken for 4 weeks after returning from an endemic area. However, resistance can also explain failures of prophylactic doxycycline. Cycline resistance in *Plasmodium* was documented as a consequence of drug pressure in a *P. berghei* murine malaria model [315]. The administration of increasing minocycline doses to mice infected with 1×10^7 parasites for 86 successive passages over a 600-day period made it possible to obtain a resistant strain with a median inhibitory concentration (IC_{50}) of 600 mg/kg/day, sixfold greater than that of the susceptible starting strain (100 mg/kg/day).

Although no *P. falciparum* malaria clinical failures with doxycycline have been reported, Bayesian mixture modeling approaches have identified three different phenotypes (low, medium, and high doxycycline IC_{50} phenotypic groups) among clinical *P. falciparum* cases [316, 317]. Using 90 isolates from 14 countries, we demonstrated that copy number increases of *P. falciparum* metabolite drug transporter gene (*pfmdt*, PFE0825w) and *P. falciparum* GTPase TetQ gene (*pfTetQ*, PFL1710c) were associated with reduced susceptibility to doxycycline [318]. This association was later confirmed [317]. In addition, isolates with pfTetQ KYNNNN motif repeats have been associated with in vitro reduced susceptibility to doxycycline and with a significantly greater probability of having an IC_{50} greater than the doxycycline resistance threshold of 35 µM [318, 319].

3.8 Sulfadoxine–Pyrimethamine

Although sulfadoxine–pyrimethamine is actually a co-formulation of two different medicines, it is considered as a monotherapy because the two components act on the same biosynthesis pathway of the parasite. Sulfadoxine–pyrimethamine has been widely used to treat chloroquine-resistant malaria. In contrast to the situation with chloroquine, resistance to antifolates emerged rapidly, after only 1–2 years of intensive use.

In vivo efficacy studies, conducted in 2002 in Benin by the National Malaria Control Programme, according to the WHO protocol, revealed treatment failures rates by region ranging from 3.3 to 45.9 % with sulfadoxine–pyrimethamine, with an overall failure rate of 22.8 % (8.3 % and 24.5 % early and late treatment failures, respectively) [320]. In 2005, Aubouy conducted an in vivo study according to the WHO protocol over 28 days in Benin, showing a very high failure rate of 50 % [153]. In Lambéréné in Gabon, in 2005–2007, 46 % of patients treated with sulfadoxine–pyrimethamine achieved an adequate clinical and parasitological response, and 50 % were late parasitological failures, while 4 % experienced early treatment failure [321]. In two previous studies conducted in 1998 and 2000 in children between 5 and 14 years of age in the extreme south of Cameroon, a clinical and parasitological failure rate for sulfadoxine–pyrimethamine of 13.6 % was reported [322]. In 2003, clinical and parasitological failure rates with sulfadoxine–pyrimethamine of 53.4 % and 56.5 %, respectively, were reported in the west and southwest of Cameroon [323]. In 2004–2006, the clinical and parasitological failure rates on Day 28 for sulfadoxine–pyrimethamine were 29.9 % in north Cameroon and 37.5 % in south Cameroon [106]. In a meta-analysis that included 115 trials of sulfadoxine–pyrimethamine, the treatment failure rates reported from Africa were >20 % in 1999–2002 [324]. In an analysis conducted by the WHO between 2000 and 2007, the median failure rate in eastern Africa (52.8 %) is higher than in the western (18.7 %), central (23.0 %), or southern (23.2 %) subregions.

Since 1978, treatment failures with sulfadoxine–pyrimethamine have been reported in Cambodian refugee camps in southeastern Thailand [325]. In 1979, all 23 patients treated with sulfadoxine–pyrimethamine failed within 21 days at the Thai–Cambodian border [326]. In 1980–1981, treatment failures with sulfadoxine–pyrimethamine ranged from 10 to 68 % in Thailand [327]. In Myanmar in 2002, early treatment failures occurred in 24 % of patients treated with sulfadoxine–pyrimethamine, and treatment failures increased to 81 % by Day 42 [142].

In South America, resistance to sulfadoxine–pyrimethamine was initially observed in few cases in a study of experimentally induced malaria in Brazil [328]. Sulfadoxine–pyrimethamine resistance occurred in 63 % in the Amazon region in the beginning of the 1980s, rising to 90 % at the end of the 1980s in Brazil [329–331]. The first cases of sulfadoxine–pyrimethamine-resistant *Plasmodium falciparum* infection in Suriname were reported in 1981 [332]. In 1982–1983, treatment failures represented 25 % in Colombia [333]. In 2002, in vivo antimalarial drug efficacy studies of uncomplicated *P. falciparum* malaria at an isolated site in the Amazon basin of Peru, bordering Brazil and Colombia, showed >50 % RII/RIII resistance to sulfadoxine–pyrimethamine [334].

In 2002, the WHO recommended the use of ACTs to ensure high cure rates of *P. falciparum* malaria and to reduce the spread of drug resistance. Sulfadoxine–pyrimethamine treatment was gradually abandoned in favor of ACT. In contrast to the situation with chloroquine, resistance to antifolates emerged rapidly, after only 1–2 years of intensive use. Moreover, reductions in resistance have been reported, although they have been rare and poorly documented. The absence of reduction might be a result of cross-resistance between sulfadoxine–pyrimethamine and antibiotics, such as

co-trimoxazole, or of the existence of compensatory mutations in resistant parasites [335]. Furthermore, sulfadoxine–pyrimethamine is still circulating in large quantities in the informal sector, which maintains the drug pressure on the regional parasite populations. After 2 years of use of insecticide-treated nets in a village in Tanzania, the prevalence of wild-type strains was higher than in a nearby control village [336]. Confounding and other factors, such as migration of sensitive parasites into study sites, have weakened the conclusions of such studies [337]. In Peru, the frequency of mutations conferring sulfadoxine–pyrimethamine resistance appeared to decline between 1997 and 2006; however, the studies were not conducted at exactly the same sites or in the same epidemiological setting; e.g., a study in 1997 was undertaken during an epidemic outbreak [338, 339]. Additional field studies are needed to confirm the regression of antifolate resistance [340].

The S108N mutation in the *pfdhfr* gene has been associated with resistance to antifolate drugs [341]. The OR for sulfadoxine–pyrimethamine failure associated with S108N was 3.5 (95 % CI: 1.9–6.3, meta-analysis of ten studies) over a 28-day follow-up [10]. The additional mutations N51I, C59R, or I164L increased the level of in vitro resistance to antifolate drugs and sulfadoxine–pyrimethamine. The OR values for single mutations at codons 51 and 59 were 1.7 (95 % CI: 1.0–3.0) and 1.9 (95 % CI: 1.4–2.6), respectively [10]. A triple mutation (51 + 59 + 108) increased the risk of in vivo resistance to sulfadoxine–pyrimethamine by 4.3 (95 % CI: 3.0–6.3, meta-analysis of 22 28-day studies) [10].

Sulfones (dapsone) and sulfonamides (sulfadoxine) are inhibitors of the *P. falciparum* DHPS [342]. The mutations S436A, S436F, A437G, and K540E are involved in resistance to sulfadoxine [343]. Mutations at 437 and 540 confer some degree of resistance; the 436, 581, and 613 mutations all contribute to a higher degree of resistance [285]. The single mutation A437G and the double mutation A437G + K540E increased the risk of in vivo resistance to sulfadoxine–pyrimethamine by 1.5 (95 % CI: 1.0–2.4, meta-analysis of 12 studies) and 3.9 (95 % CI: 2.6–5.8, meta-analysis of 10 studies), respectively [10].

Several mutations in both the *pfdhfr* and *pfdhps* genes are necessary to induce treatment failure with the sulfadoxine–pyrimethamine combination, such as triple mutations at codons 108, 51, and 59 of the *pfdhfr* gene and double mutations at codons 437 and 540 of the *pfdhps* gene [344]. In population studies, mutations at codon 59 of the *pfdhfr* gene and at codon 540 of the *pfdhps* gene have been strongly predictive of treatment failure. A quintuple genetic mutation could create the conditions needed for the emergence of the *pfdhfr* Ile164Leu mutation and the *pfdhps* A581G mutation [296]. The quintuple mutant of *pfdhfr* (codons 51 + 59 + 108) plus *pfdhps* (codons 437 + 540) increased the risk of in vivo resistance to sulfadoxine–pyrimethamine by 5.2 (95 % CI: 3.2–8.8, meta-analysis of three studies) [10].

The relationship between the parasite genotype and the therapeutic response to sulfadoxine–pyrimethamine is influenced by the parasite, pharmacokinetics, and human factors. When a parasite has wild-type *pfdhfr* without a mutation, the risk for failure is trivial, regardless of the *pfdhps* alleles. In contrast, the risk increases with the number of mutations in the *pfdhfr* gene, particularly when there is an additional mutation in the *pfdhps* gene or when immunity is lacking [341, 345]. Cumulative mutations in the *pfdhfr* gene increase parasite clearance time and the risk for gametocyte carriage. As a result, although sulfadoxine–pyrimethamine remains effective, the emergence of one or two mutations could increase the transmission of malaria and the spread of resistance [346].

The major resistance mutations in *pfdhfr* are widespread and have been thoroughly established throughout Africa. Very few sites found prevalence rates of S108N, N51I, and C59R less than 50 %, and these were Burkina Faso in 2004 [287], Ivory Coast in 2006, and Madagascar in 2006–2008 [288]. Elsewhere in Africa, all recent surveys have recorded a prevalence exceeding 50 % because sulfadoxine–pyrimethamine was used as the first-line treatment for clinical malaria for many years, exerting strong selection on these mutations [286]. The prevalence of the N51I/C59R/S108N triple mutation in *pfdhfr* and the *pfdhfr* N51I/C59R/S108N and a *pfdhps* A437G quadruple mutation was high in all of the areas with *P. falciparum*, even after sulfadoxine–pyrimethamine treatment was gradually abandoned in favor of ACT. The prevalence of the N51I/C59R/S108N triple mutation in *pfdhfr* increased from 40 % in 2003 to 93 % in 2011 in Senegal [347]. Furthermore, the prevalence of the *pfdhfr* N51I/C59R/S108N and *pfdhps* A437G quadruple mutation increased, from 20 to 66 %, over the same time frame, then decreasing to 44 % by 2011. The double mutants *pfdhfr* 108Asn/51Ile were detected at rate of 98.4 % in 2005 and 98.7 % in 2008, 3 years after the withdrawal of sulfadoxine–pyrimethamine in Ethiopia [348]. A significant decrease in the triple *pfdhfr* (108Asn/51Ile/59Arg) mutation was observed from 2005 (78.6 %) to 2008 (56.4 %). The quadruple mutations of *pfdhfr* (108Asn/51Ile/59Arg)/*pfdhps* 437Gly significantly decreased from 78.6 % in 2005 to 53.8 % in 2008; however, this rate remains high. There are eight countries in east Africa where the "quintuple mutant" (*pfdhfr* (108Asn/51Ile/59Arg)/*pfdhps* (437Gly/540E)) has been consistently reported at a prevalence exceeding 50 % [349]: Kenya (nine surveys since 2004), Uganda (three surveys since 2004), Tanzania (seven surveys since 2004), Zambia (five surveys since 2004), Malawi (six surveys since 2004), Ethiopia (three surveys since 2004), Rwanda (two surveys since 2004), and Mozambique (five surveys since 2004).

An increase in the prevalence of the resistance haplotypes DHFR 51I/59R/108N and DHPS 437G/540E occurred under sustained drug pressure, with no change in haplotype prevalence 5 years after a reduction in sulfadoxine–pyrimethamine pressure in Malawi [350]. The DHPS 437G/540E/581G haplotype was observed in 2007, and it increased in prevalence during a period of reduced sulfadoxine–pyrimethamine pressure in 2012.

Sulfadoxine–pyrimethamine has been now used as an intermittent preventive treatment (IPT), given to all children and pregnant women once per month during the transmission season, and it can provide a high degree of protection against malaria. Guidelines for the use of sulfadoxine–pyrimethamine in IPT must consider resistance, and molecular markers came into use in policy for the first time in 2010, when the WHO technical consultation on IPT in infants recommended that the prevalence of the *pfdhps* K540E mutation (indicating presence of the "quintuple mutant" or "fully resistant" genotype) be used as the basis for deciding where to implement sulfadoxine–pyrimethamine-IPT in infants [351]. The WHO recommendation was that where the prevalence of *pfdhps* K540E exceeded 50 %, sulfadoxine–pyrimethamine-IPT in infants should not be implemented.

4 New Strategies Do Delay Emergence and Spread

The emergence and spread of resistance to former first-line antimalarial drugs lead to defining new strategies. Resistance is the result of two processes: (1) drug selection of resistant parasites and (2) spread of resistance.

4.1 Drug Selection of Resistant Parasites

Antimalarial drug resistance is mediated by two processes: (1) the rate at which de novo mutations conferring resistance appear and are selected through drug use within an individual and (2) the spread of these resistant alleles to other individuals. For chloroquine and, more recently, the artemisinin derivatives, unlike other drugs, such as atovaquone and pyrimethamine (when not combined with sulfadoxine), the rate at which de novo mutations confer resistance occur is low. Heritable drug resistance is the result of mutations that can be single point mutations, alterations to multiple loci, or the result of gene duplication [352].

The likelihood that a specific mutation conferring resistance will be present in a treated individual is a function of the mutation rate and the biological fitness cost of the mutation [353]. If the frequencies of two necessary resistance-conferring mutations are both 0.01 %, then parasites with both mutations will have an initial frequency among infections of 0.0001 %. This process underlies the recommendation that all malaria infections should be treated with combinations of two or more drugs.

The total parasite load also plays an important role in the drug selection of resistant parasites. Although the density at which symptoms occur can vary widely, depending on the immune status of the individual, they are generally associated with blooms in parasite biomass. In non-immune individuals, symptoms can occur at densities of 50 parasites/L of blood or between 10^8 and 10^9 asexual parasites [354]. Clinically immune individuals may tolerate higher parasite loads, but parasite loads greater than 10,000 parasites/L or 10^{11} parasites are typically symptomatic regardless of immune status [354]. Most individuals harboring parasites at any one time are asymptomatic, with low levels of parasitemia. However, because individuals who are symptomatic have such high levels of parasitemia, the majority of malaria parasites in the world at any one time are likely to occur in individuals who are symptomatic [355], suggesting that symptomatic individuals are more likely to harbor resistant parasites [356].

The appearance of de novo mutations is only important for drug selection if individuals harboring these mutants use drugs. Increased drug use within a population thus leads inexorably to a greater probability of resistant mutants being drug-selected (i.e., all of the sensitive parasites being eliminated, leaving only resistant parasites), and this relationship has been well documented both in models and experimentally [357]. However, the widespread use of drugs has significant benefits both for the individual (reduced likelihood of morbidity and mortality) and the population.

Drug selection for resistant mutants at the individual level depends on the concentration of drug over time in the blood (pharmacokinetics) and on the inhibitory effects on the malaria parasite at these concentrations (pharmacodynamics). Together, the pharmacokinetics and pharmacodynamics yield the concentration and length of exposure to a drug that will be in contact with parasites; however, antimalarial drugs differ significantly in the lengths of time that they are maintained in the body. Some drugs have short elimination half-life, such as artemisinin (1 h) or doxycycline (16 h), compared to proguanil (24 h), atovaquone (31–73 h), chloroquine (2–3 days), or mefloquine (6–41 days). As the concentration of a drug falls, its therapeutic efficacy also falls. If the dosing is incomplete, meaning that it fails to eliminate all of the parasites effectively, either because of non-compliance or a dosage that is too low (due to misuse of antimalarial drugs, inadequate dosage in obese, abnormal metabolism or counterfeit drugs), parasites that might be inhibited at higher concentrations could survive and recrudesce. Alternatively, new infections can be exposed to sub-therapeutic levels of drugs due to a long drug half-life [77] or because of prophylactic use [358]. At low drug concentrations, parasites with resistance

mutations are able to survive and, over time, to increase their fitness through compensatory mutations [359]. However, there have been some cases of high-level drug resistance arising in individual infections during therapy [360].

4.2 Spread of Resistance

4.2.1 Emergence

Once the susceptible parasites have been eliminated from a patient after antimalarial drug treatment, the resistant parasites must be transmitted to become a problem. The parasites first must survive the immune response for a sufficiently long duration to produce infective gametocytes that will be transmitted to a mosquito vector. Then, the resistant mutation must not be lost during meiosis in the mosquito. In addition, the mosquito must survive sporogony and transmit a viable infection to a new individual.

The rate at which resistance emerges defines the time after a drug is introduced into a population until a specific proportion of clinical infections is caused by resistant parasites.

This measurement implicitly assumes both the initial drug selection of resistance mutations and their subsequent spread within a population. The rate at which resistance emerges depends in part on how resistance is encoded. Resistance due to only one mutation (*pfdhfr* 108Asn) or multigenic resistance, in which each subsequent additive mutation increases the tolerance of the parasite (*pfdhfr* 51I/59R/108N), leads to resistance that emerges more rapidly than if every mutation is needed for resistance [361–363].

The roles of heterogeneous biting and transmission in the establishment and spread of resistance in a population are very important. Heterogeneous biting plays a more significant role than transmission in the emergence of resistance [364]. Individuals and mosquitoes are distributed nonrandomly across the landscape [365], generating spatially heterogeneous biting patterns. These differences in biting patterns are further localized by the movement patterns of both mosquitoes and humans [366]. In addition, mosquitoes are differentially attracted to some individuals [367], and they are more likely to feed on larger individuals (i.e., adults versus children) because they have more surface area for biting [368]. Thus, it is likely that the multiplicity of infection (MOI) is highly variable across a spatial landscape, even at the scale of a village, which could result in differential levels of competition, depending upon the rate at which a host is bitten. Once the resistant parasites are established, the rate at which resistance increases from its establishment level is more rapid when heterogeneous biting occurs, regardless of transmission rate [364]. Heterogeneous transmission slows the establishment of resistance in the populations, but once resistance is established, it expedites the spread of resistance through the population because once resistance becomes established: (1) individuals with low probabilities of being bitten by mosquitoes are less likely to become reinfected with susceptible parasites when they are infected, which generates a reservoir of resistance and (2) individuals with higher transmission rates will quickly spread resistant parasites due to their high rates of being bitten. However, this point is in contrast with other models discussing the role of transmission in the initial emergence of resistance, which have generally suggested that resistance is more likely to emerge in low transmission areas. First, resistance likely emerges in high biomass infections [355] because of the lower levels of clinical immunity in these areas; thus, each infection is more likely to result in a higher parasite load. Second, because immunity is less developed in low transmission areas, mutant parasites are more likely to survive the host immune response and subsequently to be spread [369, 370]. Third, there is more drug treatment per parasite in low-transmission areas than in high-transmission areas [370]. Because individuals in low-transmission areas are less likely to develop immunity, they are more likely to become symptomatic and to treat each infection; it is thus more likely that a resistant parasite will encounter drugs. Fourth, in low-transmission areas, individuals tend to be infected concurrently by fewer genetically distinct parasites, so resistant parasites face less competition within the host and an increased probability of transmission success. Fifth, the higher the transmission rate is, the shorter the period is during which individuals with resistant parasites will harbor them without competition after drug treatment. Chloroquine resistance, as well as resistance to sulfadoxine–pyrimethamine, mefloquine, and artemisinin, arose in low-transmission areas of Southeast Asia.

4.2.2 Spread of Resistance Between Populations

The rate at which drug resistance will spread between populations is a function of the frequency with which resistance is introduced into new populations (exchange between populations, travel), associated with the probability of the resistant parasite becoming established, which is determined by the drug usage and transmission rates. The common hypothesis is that resistant parasites will emerge in a low-transmission area and spread to a high-transmission area. However, because the transmission rate is higher, once parasites have acquired compensatory mutations, allowing them to compete more effectively within the host, drug resistance will spread through the population much more rapidly than in a low-transmission setting [371]. However, in Klein's model, heterogeneous transmission slows the establishment of resistance in the population, but once resistance is established, it expedites the spread of resistance through the population [364].

The role of asymptomatic *P. falciparum* parasites is also important in the evolution of antimalarial drug resistance [372]. Malaria parasites are often carried as asymptomatic infections with no defined clinical symptoms. This asymptomatic parasitemia can exist at microscopically detectable levels; however, it often persists at less than this threshold [373, 374]. In areas with low levels of transmission, the use of ACT in association with the use of insecticide-impregnated bednets has brought the incidence of symptomatic malaria to very low rates [375]. However, attempts to eliminate asymptomatic parasitemia have failed to interrupt the regular malaria outbreaks that follow annual rains [376, 377]. In addition, the widespread use of asymptomatic-targeted therapy carries the risk of selecting resistant parasites that might exist at a low prevalence but that have a survival advantage under such uniform drug pressure. Epidemiological and laboratory experimental evidence has suggested that the therapy-free environment that prevails among asymptomatic parasite carriers can favor wild-type, drug-susceptible parasites and can disadvantage mutant, drug-resistant lineages [19, 378, 379]. Asymptomatic parasites have been observed at higher rates in children [380] and across different endemic settings with low- and high-transmission intensity in Africa [380, 381], Asia [382], and South America [383]. When drug-susceptible and -resistant parasites coexist and persist in asymptomatic individuals, their relative frequencies can be affected by factors such as their relative growth rates (fitness costs of resistance), as well as any competitive interaction between the genotypes.

4.3 Controlling the Emergence and Spread of Resistance

4.3.1 Interruption of Asymptomatic Carriage with Mass Drug Administration

Attempts to use therapy to interrupt asymptomatic carriage can enhance the selective advantage of resistant lineages. In turn, this enhancement can lead to subsequent rounds of selection in the transmission season, when clinical malaria and drug pressure prevail, resulting in a more rapid increase in the frequency of drug-resistant parasites. Such a pattern has been observed with the initial spread of resistance when it first appears, when repeated attempts to clear resistant parasites can lead to intense drug pressure, the acquisition of additional mutations, and increased levels of resistance [384]. Epidemiological and laboratory experimental evidence suggest that the therapy-free environment that prevails among asymptomatic parasite carriers can favor wild-type, drug-susceptible parasites and can disadvantage mutant, drug-resistant lineages [19, 378, 379]. The widespread use of therapy to eliminate asymptomatic parasitemia would not only favor the selection of drug-resistant lineages, but it would also reduce within host multiplicity and limit the expansion of wild-type parasites. Using this viewpoint, Read et al. recently suggested that the use of subcurative malaria therapy that retains some wild-type parasites could lead to a reduction in the resistant genotypes in the field [385]. The risks and benefits of subcurative treatment warrant further assessment. In the absence of obvious ethical concerns with this evolutionary approach, stringent guidelines to decrease the use of malaria therapy for asymptomatic infections should be urgently considered.

4.3.2 Improvement of Surveillance

In countries where malaria is controlled, passive surveillance systems are the cornerstone of detection, providing a standardized method for tracking progress, gathering demographical and epidemiological data, and enabling rapid investigation and appropriate response [386, 387]. When malaria is eliminated, passive surveillance is the frontline method for the detection of importation and local transmission. When reliable, passive surveillance data can be linked to remote sensing data, including altitude, population, weather, and wetness, to produce risk maps to guide the implementation of control and elimination measures [388].

During the elimination phase, active case detection, in which malaria programs are used to determine infections in high-risk groups, becomes crucial for targeting of the asymptomatic parasite reservoir in hotspots and hot-pops. Analysis of the complex interplay of factors (de novo mutations, drug use, malaria transmission intensity, human population, and infection among migrants) for the emergence and spread of resistance might provide evidence of a confluence in areas that we might regard as hotspots, which could serve as sentinel sites for surveillance or could be targeted for comprehensive clinical trials that include pharmacological measurements and molecular surveillance [389]. Operational research should be developed around simple models of detecting treatment failure, including institutional collection and the reporting of posttreatment review outcomes, if feasible.

The objectives of monitoring antimalarial drugs must be: to rationalize the distribution of surveillance sites on the basis of up-to-date malaria risk mapping; to conduct regular, standardized therapeutic efficacy studies and encourage capacity building for antimalarial drug resistance surveillance; to establish a mechanism for the exchange of data, the sharing of expertise and best practices, and the dissemination of the results of therapeutic efficacy studies and their implications; to identify and promote important research, support the collation of research evidence, and disseminate results to inform policy and practice; and collectively to address transnational issues and harmonize efforts within and between countries and to collaborate with other regional and subregional groups and broader global networks.

During the era of failing monotherapy, regional and subregional networks were established to monitor the efficacy of antimalarial treatment in Africa routinely. These networks were useful for the development of standard approaches, maintenance of cross-country quality assurance, and provision of a platform for dialogue between national malaria control programs and regional research groups (with a focus on drug resistance and its monitoring) to change policy effectively. Crucial to the success of drug resistance surveillance is communication between national control programs and research groups. The changing technical needs of efficacy studies include the use of molecular techniques to distinguish recrudescence from new infections, which in most settings requires a technical partnership between regional or national research groups and ministry of health staff, either as a long-term sustained relationship or as a provisional step toward building modern epidemiological competencies within ministries of health. Many stakeholders in Africa agree that malaria drug resistance surveillance should be a long-term, national commitment with common national and international goals [390]. Furthermore, investment in technology is needed to enable increased numbers of studies with pharmacokinetic and pharmacodynamic components. Such investment will require a long-term vision and should be integrated with capacity improvements, particularly of human resources, diagnostic techniques, and infrastructural capacities.

The organization of networks is crucial. For example, artemisinin resistance in Africa is initially likely to occur as a rare event, and individual patient-level pooled analysis across several sites could greatly increase the likelihood of detection. This method is frequently used in epidemiology when single studies are too small to allow for any definite conclusions. In an endeavor to encourage pooled analysis, the Worldwide Antimalarial Resistance Network has called for the formation of study groups on ACT in Asia and Africa. In 2011, the WHO introduced the TRAC project (Tracking Resistance to Artemisinin Collaboration).

4.3.3 Diagnostics

Although microscopy and rapid diagnostic tests (RDTs) are the standard methods for diagnosing malaria at health facilities, new and more sensitive methods are needed to screen populations for the identification of low density sub-patent infections [391]. Ideally, these new diagnostic tests would detect all plasmodia species infections at low density and would combine high throughput and low cost with delivery at the point of care.

Malaria antibody-based surveillance has been increasingly recognized as a valuable complement to classic methods for the detection of infection, especially at low transmission levels [392]. Serological tests could identify areas of persistent malaria transmission, even where parasite-infected individuals are undetected by routine tests.

4.3.4 Vaccines

The development of a malaria vaccine is considered to be one of the most cost-effective measures to counter malaria. The goal of malaria vaccine has been to save lives in the highest-risk groups: young children and pregnant women. In a seasonal setting, if the vaccine could induce sufficient immunity to reduce the basic reproductive rate to less than one member of the population at risk for the duration of the malaria season, and it could be administered in conjunction with other control measures, it might interrupt transmission. Valuable progress has been achieved over the last 30 years in the development of *P. falciparum* subunit vaccines [393]. Seventeen vaccines are currently in clinical trials, but the most advanced malaria vaccine candidate, the RTS,S vaccine based on the *P. falciparum* circumsporozoite (CS) protein, has undergone extensive testing in Africa, where a recent phase 3 trial showed 27 % and 46 % protection against clinical malaria in African infants and children, respectively, but unfortunately, its efficacy waned in a relatively short time [394]. Its efficacy was different, depending on the location and transmission rate. The homologation of the RTS,S vaccine might also pose a challenge to the development of alternative vaccines to increase the efficacy of RTS,S, either in combinations of RTS,S with new antigens or in totally new formulations [395]. It is possible that the most effective combinations might derive from mixing vaccines that are found to be efficacious when tested alone, that target different stages of parasite life and/or that are based on different mechanisms. In particular, one might speculate adding the RH5 antigen or antigens acting in opsonization, such as fragments from MSP2, MSP3, GLURP, and PFF0165, to RTS,S. Although single antigens might be only weakly effective, their combination together with RTS,S is expected to be more effective in controlling the disease and, as a result, reducing transmission by mosquitoes.

4.3.5 Drug Discovery Strategy

Since the discovery in 1891 of methylene blue, the first synthetic antimalarial, multiple chemical classes of molecules have been shown to clear blood-stage parasitemia efficiently in humans. As a consequence of resistance to the existing antimalarial drugs, new drugs are needed, and treatments must consist of combinations of two or more active compounds such that no compound is exposed as a monotherapy to high levels of parasites. During the past decade, new potential antimalarial targets have been proposed, based on the increasing number of plasmodial genomes that have been successfully sequenced [396, 397]. New screening and imaging technologies have generated thousands of new active drugs against Plasmodium asexual blood stages. Some of these drugs are currently in clinical development. However, despite this progress and given the increasing effectiveness and safety of current antimalarial drugs, simply curing

malaria rapidly and efficiently with new candidate drugs is no longer sufficient. There is a crucial need for therapeutics that exceed the treating of acute infections and that have the potential to eradicate the disease [398]. Accordingly, four major goals have been identified: (1) efficient elimination of all human parasites that populate the liver as dormant hypnozoites, notably those of *P. vivax* and *P. ovale*; (2) blocking of disease transmission by targeting parasite sexual stages in human blood; (3) identifying and developing new chemical entities that overcome all known cross-resistance and that minimize the risk of resistance emerging; and (4) delivering molecules that protect vulnerable populations. Future antimalarial combination treatments will need to cure the disease efficiently, by rapid clearance of parasitemia in patients, thereby reducing the risk of resistance and preventing recrudescence. In addition, these new medicines will be expected to block transmission and to eliminate all liver forms of the parasite, including dormant hypnozoites. A selection of these antimalarial drugs is described below.

Tafenoquine

Tafenoquine, an 8-aminoquinoline, is the only anti-relapse drug presently in clinical development. Tafenoquine recently completed a pivotal Phase II trial and demonstrated excellent anti-relapse efficacy from a single 300 mg dose; a Phase III trial has been initiated. This latter clinical trial is a randomized, double-blind treatment study to evaluate tafenoquine in adult patients infected with *P. vivax*. The efficacy, safety, and tolerability of tafenoquine to achieve a radical cure when coadministered with chloroquine were analyzed [399]. A single dose of tafenoquine plus 3-day chloroquine was assessed in patients with *P. vivax* from Brazil, Peru, India, and Thailand between 2011 and 2013, compared with chloroquine plus primaquine. Tafenoquine alone at 600 mg prevented relapse in 91.9 % of cases versus 77.3 % with primaquine and 37.5 % with chloroquine alone at 6 months. Coadministration of tafenoquine and chloroquine had no clinically significant adverse effects and was well tolerated [400]. In 2000–2001, the protective efficacy of tafenoquine against falciparum and vivax malaria was 100 % in the Australian Defence Forces deployed to East Timor [401]. However, tafenoquine belongs to the 8-aminoquinoline class, which is associated with hemolytic anemia in individuals with inherited glucose-6-phosphate dehydrogenase (G6PD) deficiency. Therefore, research is ongoing to develop a point-of-care diagnostic to identify individuals with G6PD deficiency, to support well-tolerated and effective use of drugs for a radical cure of patients infected with *P. vivax*. Thus, the development of new antimalarial drugs that display G6PD-dependent hemolysis is crucial.

Endoperoxide OZ439

The most advanced of the new molecules is a second-generation endoperoxide, OZ439, which was designed to have superior pharmacokinetics to the artemisinins [402]. OZ439 is a member of the ozonide class of antimalarials [403]. Endoperoxide in an ozonide could deliver efficacy equal to that observed with the naturally produced artemisinins. A stabilized ozonide, OZ03, which has a simple structure, was sufficient to demonstrate excellent in vitro potency. The high lipophilicity and low solubility, however, had to be addressed, and this need led to an introduction of polarity and ionizable groups in a region of the molecule that was synthetically tractable yet did not compromise potency. This development initially resulted in OZ277 (arterolane), which was the first clinical candidate and which was licensed to Ranbaxy [404]. Indeed, the combination of OZ277 and piperaquine received approval in India in 2012 under the name Synriam™, and it has been widely used to treat malaria patients in India over the last 6 months. OZ277, however, has lower exposure in patients than expected, and this limitation was hypothesized as being due to instability in infected blood, due to an interaction with ferrous iron. The amide with a phenyl ring, which helped to stabilize the ozonide, was substituted by an ether-linked base. The resultant compound, OZ439, was shown to have improved infected blood stability, it was able to cure mice infected with *P. berghei* from a single 30 mg/kg dose, and it progressed as the potential single dose cure candidate [403]. OZ439 has demonstrated clinical efficacy as a single agent in phase II clinical development [405]. It is now being tested in combination safety studies, and it will start combination efficacy studies. Studies in both healthy volunteers and infected patients have shown significant plasma exposure for as long as 20 days, suggesting it might be possible to use as part of a single-dose therapy for uncomplicated malaria [402]. In patients, OZ439 drives the reduction of parasites at approximately the same rate as artesunate.

Spiroindolone KAE609 (NITD609)

The spiroindolone class was found by screening a library of natural products and "natural product-like" compounds at Novartis. The starting "hit" had an intriguing structure and good potency, and impressively for a starting point, it suppressed parasitemia in the *P. berghei* mouse model of malaria by >99 % with a single dose of 100 mg/kg. Excellent medicinal chemistry was applied to contract the seven-membered ring, to define the stereochemical structure/activity relationship and to replace the lipophilic bromine atom. This process resulted in a second compound that had increased potency yet reduced lipophilicity—the ideal outcome from the standpoint of medicinal chemistry. However, its metabolic stability was still non-optimal; this shortcoming was fixed by judicious positioning of halogens on the tetrahydro-beta-carboline ring. The resulting compound, the spiroindolone NITD609, had even greater potency and excellent pharmacokinetics [406]. NITD609 rapidly inhibited protein synthesis in *P. falciparum* and showed pharmacokinetic properties compatible with once-daily oral dosing, and it had single-dose

efficacy in a rodent malaria model [406]. In addition, NITD609 inhibited the early and late development of *Plasmodium falciparum* gametocytes in vitro in a dose-dependent fashion over a range of 5–500 nM [407]. Using the standard membrane feeding assay, NITD609 is also a very effective drug in reducing transmission to the *Anopheles stephensi* mosquito vector. PfATP4, a Na^+ efflux ATPase, is the target of NITD609 [408]. NITD609 at dose of 30 mg daily for 3 days cleared parasitemia rapidly in adults with uncomplicated *P. vivax* or *P. falciparum* malaria [409]. This first-in-humans randomized, double-blind, placebo-controlled, ascending single and multiple oral dose study was designed to evaluate the safety, tolerability, and pharmacokinetics in healthy volunteers of NITD609, and it showed that NITD609 was tolerated, with transient gastrointestinal and genitourinary adverse events of mild to moderate intensity [410].

Imidazolopiperazine KAF 156 (GNF136)

Metabolite identification and excellent medicinal chemistry, in which the metabolically susceptible position on the piperazine was blocked with two methyl groups, led to the isomer KAF156. KAF156 demonstrated a good overall profile with an ED_{99} in the *P. berghei* mouse of 1.1 mg/kg [411]. Consistent with the previously reported activity profile of this series, the clinical candidate KAF156 showed blood schizonticidal activity with 50 % inhibitory concentrations of 6–17.4 nM against *P. falciparum* drug-sensitive and drug-resistant strains, as well as potent therapeutic activity in mouse models of malaria with 50, 90, and 99 % effective doses of 0.6, 0.9, and 1.4 mg/kg, respectively [412]. When administered prophylactically in a sporozoite challenge mouse model, KAF156 was completely protective at a single oral dose of 10 mg/kg [412]. Finally, KAF156 displayed potent Plasmodium transmission blocking activities both in vitro and in vivo [412]. The first-in-humans, single- and multiple-ascending-dose study in 70 healthy male volunteers showed that KAF 156 was tolerated, with self-limited mild to moderate gastrointestinal and neurological adverse events [413].

Triazolopyrimidine-Based Inhibitor DSM 265

The *P. falciparum* enzyme dihydroorotate dehydrogenase (PfDHODH) is known to be essential for the survival of the parasite. The three-dimensional structure of the enzyme–inhibitor complex was resolved, and the subsequent lead optimization program resulted in the identification of the preclinical candidate. DSM1 was an interesting molecule, but it showed non-optimal pharmacokinetics on repeat dosing and insufficient potency. First, progress was achieved in the improvement of its pharmacokinetics by substituting electron-withdrawing groups in the aniline ring; due to the hydrophobic nature of the binding site, only lipophilic groups have had major success in this case, e.g., DSM191 [414]. A second breakthrough occurred using the X-ray crystal structure; it was clear that limited substitution of the triazolo carbon could be achieved, and combined with electron withdrawal, it could reduce desolvation of the heterocycle and improve potency. These changes advanced DSM265, which has a good potency and safety profile, from preclinical studies [415]. The compound is currently in preclinical development.

Dihydrofolate Reductase (DHFR) Inhibitor P218

Dihydrofolate reductase (DHFR) inhibitors, such as pyrimethamine, have been widely used for the treatment of malaria, although their clinical efficacy has been compromised by resistance. P218 is a next-generation inhibitor of DHFR. P218 has a good pharmacokinetic profile, and it is selective and highly efficacious; initial safety testing of P218 indicated a good safety margin between toxicity in animals and the predicted effective human dose [416]. It was found that mutant residues did not reduce the binding affinity of P218 to PfDHFR [417].

Methylene Blue

Methylene blue (MB) is an old antimalarial drug that is no longer in use. In 1891, Guttmann and Ehrlich were the first researchers to report on the antimalarial properties of a synthetic thiazine dye, methylene blue, when they described the clinical cure of two patients after oral administration of MB [418]. Cardamatis wrote in *Progrès Médical* that he found methylene blue to be very effective in the early stages of severe malaria cachexia, in cases that were resistant to quinine [419]. Currently, there is no methylene blue available globally that complies with European Pharmacopoeia. To date, the pharmaceutical use of methylene blue has been stymied by contamination with organic impurities and heavy metals with recognized toxicity. Provence Technologies and its subsidiary, Provepharm, conducted 4 years of research that resulted in the first European Pharmacopoeia-grade methylene blue: Proveblue®. This drug was obtained from an innovative synthetic and heavy metal-free pathway using pharmaceutical-grade reagents (patent application N°FR06/06330, which has been extended to the international PCT reference number PCT/FR/2007/001193). The total concentrations of metals, including Azure B (the most important impurity in methylene blue), and other impurities in Proveblue® are <20 ppm, <2 %, and <0.5 %, respectively. Proveblue® was previously demonstrated to possess in vitro antimalarial activity against 23 *P. falciparum* strains that were resistant to various antimalarial drugs [420]. Proveblue® exhibited noticeable synergistic effects in combination with mefloquine and quinine and highly synergistic effects associated with dihydroartemisinin [421]. Treatment with 1–10 mg/kg of weight of Proveblue® for 5 days significantly reduced or prevented cerebral malaria in mice [422–424]. The IC_{50} for Proveblue® ranged from 0.88 to 40.2 nM, with a mean of 5.3 nM, against *P. falciparum* from Dakar, Senegal [32]. These data showed that Proveblue® is active in vitro, in

agreement with previous studies of methylene blue with organic, as well as inorganic, impurities in parasites from Nigeria, Kenya, and Thailand [425–427]. Methylene blue is also active against *P. vivax* [427]. Another advantage of the use of Proveblue® is that methylene blue has gametocytocidal properties, and it can reduce the transmission of *P. falciparum* [428–430]. The combination of methylene blue with artemisinin-based combination therapy has been confirmed to be effective against the gametocytes of *P. falciparum*. The gametocyte prevalence of *Plasmodium falciparum* was significantly lower in the artesunate–amodiaquine–methylene blue group than in the artesunate–amodiaquine group on Day 7 of follow-up (36.7 % versus 63.3 %) [431].

Diagnosis and Treatment of Metronidazole-Resistant *Trichomonas vaginalis* Infection

76

Jeffrey D. Smith, Sarah L. Cudmore, and Gary E. Garber

1 Introduction

Trichomonas vaginalis is the causative agent of trichomoniasis. There is an estimated prevalence of 276.4 million *T. vaginalis* infections worldwide. Important complications due to *T. vaginalis* infections are increased transmission of HIV, and infant morbidity due to preterm birth, low birth weight, and vertical transmission. Metronidazole and tinidazole are 5-nitroimidazole drugs used for treatment of *T. vaginalis* infections. *T. vaginalis* infections not responding to 5-nitroimidazole drugs used for standard therapy is a concern for adult sexual health due to persistence of infection and its complications as well as the risk for increased spread of disease due to clinical symptom relief following treatment without microbiological cure. At least a low level of metronidazole resistance is likely in 2–6 % of infections globally. Tinidazole resistance is strongly correlated to metronidazole resistance ($r=0.8709$, $P<0.0001$). Despite significant improvements in diagnostics in the past decade, new treatments are lacking. Alternative treatments tested in vitro rarely progress to clinical trials. So far, no consistently effective, non-nitroimidazole treatments are available to combat metronidazole-resistant *T. vaginalis* infections.

2 Trichomonas vaginalis

Trichomonas vaginalis is one of the four protozoan species of the family Trichomonadidae known to parasitize humans. Members of this family are characterized by their variable morphology, being spheroid or ovoid in form in axenic culture, but assuming an ameboid shape on contact with other cells [1, 2]. Trichomonads reproduce by longitudinal binary fission and lack a cystic stage, although large, round "pseudocysts" have been known to form under unfavorable conditions. All Trichomonadidae possess five anterior flagella, four of which are free moving. The fifth recumbent flagellum is anchored along the organism as a part of the undulating membrane. This membrane extends along at least half the length of the organism, and is supported by a noncontractile costa. Motility, described as "bobbing" or "quivering," is characteristic of this family of organisms [3, 4].

T. vaginalis is the only trichomonad known to cause disease in humans. It is the causative agent of trichomoniasis. *T. tenax*, usually found in the mouth, has been implicated in respiratory infection but its pathogenicity has never been confirmed [5]. *Pentatrichomonas hominis* [6] and *Trichomitus fecalis* have generally been isolated from the lower gastrointestinal tract. However, to date only one case of *T. fecalis* has been confirmed, leaving its identity as a human parasite in question [7].

Nutritionally, *T. vaginalis* is a fastidious organism. Lacking pathways for de novo synthesis of purines [8], pyrimidines [9], fatty acids, and sterols [10], the protozoan relies on salvage pathways to provide the necessary components of lipid and nucleotide metabolism. Amino acid synthesis and conversion is also thought to be limited. Carbohydrates are the preferred source of energy for metabolism. However, metabolic pathways for using amino acids, especially arginine, threonine, and leucine, as energy sources also exist [11], and energy generation using arginine probably takes place even if carbohydrates are available [12].

Energy metabolism takes place in the cytoplasm (for amino acids and carbohydrate glycolysis) and in an organelle called the hydrogenosome (for adenosine triphosphate (ATP) production via substrate-level phosphorylation). The hydrogenosome is analogous in structure and function to the mitochondrion in higher eukaryotes, although it lacks cristae and cytochromes [13, 14]. In the hydrogenosome, pyruvate is decarboxylated by an enzyme called pyruvate:ferredoxin oxidoreductase (PFOR). Ferredoxin serves as a terminal

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_28

electron acceptor for PFOR, eventually leading to the production of acetate [15]. The fermentative metabolic processes of *T. vaginalis* also lead to the production of H_2, CO_2, lactate, and glycerol, the proportions of which vary depending on whether the organism grows in the presence or absence of oxygen [16].

A microaerophilic organism, *T. vaginalis* grows well under anaerobic conditions; however, some strains can tolerate oxygen well enough to be grown in ambient air. Optimum conditions are generally considered to be at 37 °C in moist air with 5 % CO_2 for growth in both axenic and tissue culture (this microaerophilic environment is similar to that found in the human vagina). Interestingly, *T. vaginalis* aerotolerance has often been found to reflect a particular strain's susceptibility to metronidazole, the drug most commonly used to treat trichomoniasis [17, 18].

3 Epidemiology

3.1 Prevalence and Transmission

With a prevalence of 276.4 million people infected worldwide, trichomoniasis is the most common nonviral sexually transmitted infection (STI) [19]. It is ubiquitous, being found in all races and cultures, but is especially prevalent among the underprivileged, injection drug users, individuals with multiple sex partners, and those who exchange sex for money [20]. It is estimated that at least one million new cases emerge in the United States yearly, many in African Americans [20, 21]. Globally, *T. vaginalis* infection is most prevalent in Africa and Asia, with infection rates reaching 40–60 % in some populations [19, 22].

Trichomoniasis has long been considered a disease of women, but the disease can also cause significant morbidity in men. Prevalence rates are highest in men with partners diagnosed with vaginal trichomoniasis [23]. Previous studies had shown that less than 5 % of the cases of nongonococcal urethritis are attributable to *T. vaginalis* [24]. However, a recent decline in the rates of chlamydial infection in the United States has been accompanied by an apparent increase in the frequency of *T. vaginalis* infection. Up to 17 % of male patients with nongonococcal, nonchlamydial urethritis are now confirmed to be suffering from trichomoniasis [25]. A similar rate of *T. vaginalis* infections was reported in men with urethritis attending a STI clinic in Malawi [26]. It is not yet clear, however, whether this trend represents a bona fide increase in the rate of trichomoniasis, or an improvement in diagnosis of the disease.

The prevalence of *T. vaginalis* infection in women has been found to vary significantly among different populations. Studies have shown that the rate of infection in women attending family planning clinics is about 5 % [27]. Reports from STI clinics indicate that anywhere from 1 to 40 % of female patients are identified with trichomoniasis [28]. The highest rates of infection are found in sex trade workers and women incarcerated in correctional facilities, where 50–75 % of these groups are infected with *T. vaginalis* [27].

The rate of transmission of *T. vaginalis* differs between sexes. Studies have shown that 15–70 % of men who have contact with an infected female partner will develop infection [29, 30]. Women exposed to the parasite via an infected male partner have a 65–100 % chance of developing trichomoniasis [30, 31]. *T. vaginalis* has been found to be able to survive for short periods of time outside of a host if sufficient moisture is maintained. Viable specimens have been obtained from body fluids (urine, semen, and vaginal exudates) 3–6 h after being emitted from the body [32, 33]. Live trichomonads have also been isolated from warm, damp washcloths 24 h after incubation [34], and from insufficiently chlorinated swimming pool water for up to 48 h [35, 36]. However, there have been no confirmed cases of trichomoniasis caused by exposure to contaminated objects.

Few nonsexual modes of transmission have been documented. Shared bathing water was implicated, though unconfirmed, as a source of infection in adolescent girls in Ndola, Zambia [37]; iatrogenic transmission is suspected in a female patient of a traditional healer who was diagnosed with *T. vaginalis* infection following the healer touching the female patient's genitals using his fingers [38]; lastly, perinatal transmission has been reported in a number of cases wherein clinical presentation is often respiratory disease [39–41].

3.2 Association with Human Immunodeficiency Virus and Other STIs

Patients with trichomoniasis are at an increased risk of contracting other STIs. This can be due to lifestyle risk factors (e.g., poverty or promiscuity), but may also be a reflection of the fact that *T. vaginalis* cytotoxicity towards urogenital tract epithelial cells (and the increase in vaginal pH commonly seen in infections of women) helps to create an advantageous niche for other sexually transmitted infectious organisms [42]. It is also possible that a preexisting STI could increase the likelihood of developing a trichomonal infection upon exposure to the parasite. One clinical study reported that 30 % of women diagnosed with *T. vaginalis* infection were accompanied by at least one other STI [43].

Similar to other STIs, *T. vaginalis* infection significantly increases the risk of contracting human immunodeficiency virus (HIV) (odds ratio 2.74, 95 % CI 1.25–6.00; relative risk 2.57, 95 % CI 1.05–4.02; hazards ratio 2.05, 95 % CI 1.43–4.65) [44]. Reasons for increased risk include damage to the mucosal surface, disruption of normal flora and pH facilitating viral penetration and survival, and an increased

number of immune cells at the genital mucosa enabling infection of these cells by HIV [44–46]. Another issue to consider is that *T. vaginalis* coinfection with HIV significantly increases HIV-1 RNA shedding in women (odds ratio 4.07, 95 % CI 1.78–9.37) [47]. Given that *T. vaginalis* and HIV are endemic in similar areas of the world, this means that prevention of trichomoniasis could be an important step in reducing global HIV/AIDS rates.

4 Clinical Aspects

4.1 Trichomoniasis in Men

Trichomoniasis in men is usually an asymptomatic carrier state [24, 48–51]. When symptomatic infection does occur, it presents as a mild urethritis. Clinical symptoms are similar to nongonococcal urethritis and include small amounts of clear or purulent discharge, and discomfort or a burning sensation during urination or after sexual intercourse. Rare cases of acute male trichomoniasis are characterized by more severe manifestations of urethral symptoms [52]. An extragenital *T. vaginalis* infection causing bilateral conjunctivitis has been reported in an adult male. Cause of the infection was linked to ocular exposure to genital secretions or fluids of a recent sex partner. No diagnosis of *T. vaginalis* in the sex partner was conducted [53].

The incubation period for *T. vaginalis* infection in men is usually less than 10 days, although longer incubation periods do occur [52]. Spontaneous resolution of both unapparent and symptomatic infection is common [49]. Studies using more sensitive diagnostic techniques are required to verify this data. One study showed that 70 % of untreated, symptomatic men had cleared the parasite within 2 weeks [29]. However, it has also been found that some cases of persistent nongonococcal urethritis, particularly those that have responded poorly to antibiotic therapy, may in fact be caused by resilient or resistant strains of *T. vaginalis*.

Prostatitis is the most common complication associated with trichomoniasis. Balanoposthitis, epididymitis, and other inflammations of the external genitalia are also frequently seen. Associations of trichomoniasis with prostate cancer remain undetermined [54, 55]. There is also evidence linking persistent *T. vaginalis* infection to urethral disease and infertility [56–58].

4.2 Trichomoniasis in Women

Unlike infection in men, trichomoniasis in women is usually persistent. Incubation periods range from 4 to 28 days [34]. Establishment of symptomatic infection usually involves a rise in the normal vaginal pH of 4.0–4.5 to a pH of 5.0 or higher (some of the virulence factors of *T. vaginalis* have been found to be inhibited at normal vaginal pH) [59]. This rise in pH is probably attributable to a concomitant decrease in acid-producing vaginal *Lactobacillus*, although the mechanism by which lactobacilli are inhibited or eliminated has not yet been elucidated but may be related to phagocytosis by trichomonads as demonstrated in vitro [60]. The symptoms of trichomoniasis are known to worsen during menses. This is likely a reflection of the fact that iron is an important mediator of many of the parasite's metabolic and pathogenic pathways (particularly cellular adherence) [61]. Nearly all cases of urogenital trichomoniasis are found in women of reproductive age, but it is not known if this is due to the unsuitability of the vaginal environment in premenarche and postmenopausal women, or is simply a reflection of the parasite's niche as an STI.

Asymptomatic infection rates are as high as 80 %, but about 30 % of women with an unapparent infection will develop symptomatic trichomoniasis within 6 months [23, 62]. Symptomatic infection is rated as mild, acute, or chronic. Chronic infection generally shows a similar clinical presentation to the mild form of the disease, but lasts for an extended period (i.e., years) and/or shows antibiotic resistance. Mild *T. vaginalis* infection is characterized by pruritus, dyspareunia, and sometimes dysuria. Small amounts of mucopurulent vaginal secretion are often present. Acute trichomoniasis usually presents with vulvar and vaginal erythema, and 2 % of cases show characteristic small hemorrhagic spots on the vagina and cervix, known as strawberry cervix [63, 64]. Use of a colposcope will increase the diagnosis of a strawberry cervix to about 90 % of patients with acute symptoms [64]. Copious discharge is often yellow or green in color, malodorous, and mixed with mucus [63, 64].

T. vaginalis infection has been implicated as a cause of cervical erosion and in the development of cervical cancer, although carcinogenicity likely can be related to high rates of coinfection with human papilloma virus [65]. Other complications associated with trichomoniasis arise when the parasite invades tissues outside the vagina. Skene's and Bartholin's glands are often infected, and ascending infection has been associated with endometritis and infertility [66]. *T. vaginalis* infection can be especially hazardous for pregnant women, predisposing them to premature rupture of the placental membrane, premature labor, and low birth weight babies [64, 67, 68].

4.3 Diagnosis

Diagnosis of trichomoniasis is difficult to make on the basis of clinical presentation alone. The high frequency of asymptomatic infection contributes greatly to underdiagnosis of the disease as well as the lack of resources for diagnosis particu-

larly in areas with the highest prevalence of trichomoniasis. In addition, the symptoms of *T. vaginalis* infection are often similar to those found in bacterial urogenital infection. As previously mentioned, symptomatic trichomoniasis in men presents as nongonococcal urethritis. Many symptoms associated with trichomonal infection in women are also common to bacterial vaginosis. For example, in STIs with bacterial etiology, vaginal pH is elevated in 90 % of cases [69, 70] and a positive "whiff" test, the presence of a fishy odor when vaginal exudate is mixed with 10 % potassium hydroxide, may be present (as in 50 % of trichomoniasis cases) [69, 71]. As coinfection with other STIs is not uncommon, it is important that specific tests for trichomoniasis be undertaken to prevent misdiagnosis and inappropriate treatment.

Microscopic diagnosis of *T. vaginalis* in women is usually performed after sampling vaginal exudates from the posterior fornix with a sterile cotton-tipped applicator. For men, urethral swabs are the most sensitive sample for culture, although a fresh semen sample or urine is also frequently used [48]. If a sufficient number of trichomonal cells are present (at least 10^4 trichomonads/mL), immediate diagnosis may be possible by microscopic examination of a wet mount, but is not used for diagnosis of *T. vaginalis* in men because wet mount lacks sensitivity [72]. *T. vaginalis* cells are similar in size to leukocytes, but can be identified by their characteristic motility [73, 74]. Unfortunately, the reliability of this test is highly variable, and its sensitivity has been quoted in the literature as anywhere from 40 to 90 % [75]. Additionally, if the test is not performed immediately, specimens are usually kept moist in physiological saline or transport medium. Although this does not (in the short term) affect the viability of trichomonads, it does have a profound negative effect on their motility [76] and thus the ability to recognize the organism on wet mount evaluation.

The diagnosis of trichomoniasis most often used due to affordability and acceptable sensitivity (44–75 %) is cultivation of the organisms in axenic medium [72]. Diamond's TYM (trypticase-yeast extract-maltose) supplemented with serum and antibiotics to prevent growth of bacteria and yeast has been found to yield reasonable results. Alternatively, a commercial InPouch TV (Biomed Diagnostics, California, USA) culture medium is available for detection of *T. vaginalis*. The InPouch TV system has benefits over the aforementioned Diamond's TYM preparation. The InPouch TV system can be stored at room temperature, is contained within a clear plastic pouch that can be examined by microscopy without needing to sample the culture, does not require immediate incubation after adding a sample, and does not require warming before use (Biomed product insert). Vaginal specimens can be inoculated into medium immediately or after storage in saline, and growth of motile trichomonads confirms a positive diagnosis. Diagnosis of *T. vaginalis* via cultivation also has the advantage that cultivated trichomonads can be maintained for further testing (i.e., antibiotic susceptibility). The disadvantage of this technique is that trichomonads do not grow quickly, and a minimum of 3 days for samples from women and 5 days for samples from men should be allowed before rendering a negative diagnosis [72, 77].

A number of fixed staining techniques have also been employed in the diagnosis of trichomoniasis. These include Giemsa [78], acridine orange [79], and the Papanicolaou (Pap) smear [80], among others. Unfortunately *T. vaginalis* cells often lose their characteristic shape on fixation. Studies on the diagnostic utility of the conventional or liquid Pap smear have shown its sensitivity to range from 44 to 96 % [72, 81]. A note of caution with these fixed staining techniques, there is a high frequency of false positive results (probably due to the similarity in size and shape of *T. vaginalis* and leukocytes). Between 20 and 30 % of uninfected women will be falsely diagnosed as having trichomoniasis [82].

Nucleic acid amplifications tests (NAATs) are the most sensitive tests available for the diagnosis of *T. vaginalis* in both men and women [48]. NAATs may not be used in resource-limited settings due to the required cost, infrastructure, and training. The APTIMA *T. vaginalis* assay (Hologic Gen-Probe Inc, California, USA) is the first United States Food and Drug Administration (FDA) approved NAAT that has reported sensitivity ranging from 88 to 100 %, with specificity of 98–100 % [72]. Other validated in-house polymerase chain reaction tests have been reported to have similar sensitivity and specificity [72].

NAATs have important advantages and disadvantages over culture. The need for viable organisms is not required for NAATs. Specimen storage and processing requirements are not as stringent. However, NAATs can detect nonviable organisms and may result in a false report of persistent infection following treatment. The follow-up time from treatment to reduce the number of false positive reports of infection using NAATs was investigated by Williams and colleagues [83]. Three weeks following treatment, 85 % of female vaginal samples were negative for *T. vaginalis* [83]. Resolution of clinical symptoms following treatment and a positive NAAT should not be immediately ruled as a false positive. Subclinical infections due to treatment failure have been suggested to be a source of a persistent infection rather than due to reinfection [84]. No FDA approved point-of-care NAAT tests are available at this time.

Three non-amplified point-of-care molecular tests are available. The OSOM TV Trichomonas Rapid Test (Sekisui Diagnostics, California, USA) and Kalon TV agglutination test (Kalon Biological, Surrey, UK) are two commercially available *T. vaginalis* antigen detection tests. Sensitivities range from 77–98 % and 55–99 %, respectively, with speci-

ficities >90 % [72]. A nucleic acid probe hybridization test, Affirm VPIII Microbial Identification Test (Becton Dickinson, Maryland, USA), provides detection of *T. vaginalis*, *Gardnerella vaginalis*, and *Candida albicans. T. vaginalis* sensitivity of the AFFIRM VPIII test has been reported to be 64 % with specificity of 100 % [72]. OSOM and Affirm VPIII have been approved for use as a diagnostic tool in the United States by the FDA. A major disadvantage of the non-amplified molecular tests is a lack of validation for use in asymptomatic women or for use in men [72]. On the other hand, these tests require little training or added infrastructure.

A new point-of-care molecular diagnostic tool is currently under development and testing on clinical vaginal swabs has been reported. The detection limit was evaluated to be five *T. vaginalis* cells. The sensitivity and specificity were 95.5 % and 95.7 %, respectively [85, 86]. The test targets a genetic biomarker that is present in multicopy within and unique to the *T. vaginalis* genome. Three stages of the test lead to identification of *T. vaginalis*. DNA from the test sample is extracted, and if target *T. vaginalis* DNA is present, then the target biomarker is amplified. The amplified products are identified using an electrochemical endpoint detection method. Results can be realized within 30 min.

Finally, it should be noted that isolation of trichomonads to confirm infection in males is often unsuccessful. It is hypothesized that this is because certain aspects of the male genitalia (e.g., an oxidative environment [87], zinc in prostatic fluid [88]) create an inhibitory milieu in which parasite numbers are greatly limited. In the absence of sensitive tests, it is important to assume that any male partner of an infected woman likely harbors the parasite himself. Concurrent treatment of the sexual partner(s) to prevent reinfection is essential.

4.4 Treatment

Metronidazole has been the drug of choice for the treatment of *T. vaginalis* infection since its development in 1959. Derived from the *Streptomyces* spp. antibiotic azomycin, metronidazole (1-(β-hydroxyethyl)-2-methyl-5-nitroimidazole) is a member of the nitroimidazole family of prodrugs whose metabolic products have been found to effectively eliminate infection by a number of protozoa and Gram-negative bacteria [89]. Other members of this family, including nimorazole, ornidazole, secnidazole, and tinidazole, are used throughout the world for the treatment of trichomoniasis. A nitroimidazole designated EU11100 was synthesized. This drug was shown to be both less toxic than metronidazole and effective at a lower concentration, but to date no clinical trials have been published [90].

Infants who contract *T. vaginalis* during vaginal delivery from an infected mother usually do not require treatment because infection generally resolves within a few weeks as the infant's (maternal) estrogen levels wane. However, if infection becomes symptomatic or progresses past the 6th week of life, metronidazole is generally administered. Treatment is often a single 50 mg/kg dose, or a 10–30 mg/kg dose daily for 5–8 days [91]. Canadian guidelines recommend a dose of 15–20 mg/kg, divided into three doses daily for 7 days, or a single dose of 40 mg/kg (to a maximum of 2 g) for the treatment of trichomoniasis in children.

Oral metronidazole is the treatment of choice for trichomoniasis in adults. The recommended regimens are a single 2 g dose oral metronidazole, a single 2 g dose oral tinidazole, or 500 mg oral metronidazole twice a day for 7 days [92, 93]. The single-dose treatment is preferred, as adherence is better than with multiple doses, and the overall amount of drug taken is reduced. However, the incidence and severity of side effects does increase slightly with the larger single dosage. Metronidazole can also be administered intravenously. This method is often utilized when patients show some intolerance to the drug, as side effects tend to be less severe than with oral treatment. Intravenous metronidazole is administered in a dosage of 500 mg to 2 g over 20 min [91].

A number of topical intravaginal preparations have been used to alleviate the symptoms of trichomoniasis in women. These medications include clotrimazole, nonoxynol-9, and povidone-iodine creams and gels, arsenical pessaries, furazolidone, paromomycin preparations, and both cream and insert metronidazole preparations. There are no topical treatments for trichomoniasis in men [20, 94].

The usefulness of non-nitroimidazole vaginal creams and inserts as a cure is doubtful, and no studies have shown definitive proof of efficacy [95]. However, these treatments are effective for relief of symptoms. The exception is hamycin, a drug related to amphotericin B. Currently in use in India as a topical treatment for trichomoniasis, hamycin has been found to effectively eliminate infection with both metronidazole-sensitive and -resistant strains of *T. vaginalis*. However, both clinical trials and in vitro testing on tissue culture have shown that the level of toxicity displayed by the drug toward eukaryotic cells makes it a poor choice of treatment [96].

Vaginal administration of metronidazole has been shown to be relatively ineffective as a cure, eliminating infection in up to 50 % of cases [97–99]. This is probably due to the fact that trichomonads are not always confined to the vagina, frequently invading Skene's, Bartholin's, and other glands, as well as the urethra [66]. Bioavailability of metronidazole as a vaginal suppository compared to IV infusion range from 20 to 56 % (oral metronidazole bioavailability is >90 % compared to IV infusion) [100]. As such, a topical vaginal medication is inadequate in completely eliminating infection. However, in cases of recalcitrant *T. vaginalis* infection, vaginal preparations are often added to the treatment regimen to

increase the chances of effecting a cure by increasing local drug concentration, and because of their comparatively lower risk of side effects (compared to oral administration) [97, 101]. A recent randomized controlled trial compared oral single-dose 2 g metronidazole versus a high-dose metronidazole and miconazole vaginal suppository (750 mg metronidazole/200 mg miconazole nitrate) twice a day for 7 days to treat *T. vaginalis*. The vaginal suppository resulted in similar efficacy of clinical and microbiological cure versus oral single-dose metronidazole (80 % versus 90 %, respectively) [102]. The sample size was small, but is evidence for a potentially useful combinatorial drug therapy for treatment of *T. vaginalis* infections in women that results in less systemic adverse effects compared to oral metronidazole.

Metronidazole regimens are generally well tolerated, and side effects are rarely of a severity that would necessitate discontinuation of metronidazole therapy. Common side effects include nausea and vomiting, headache, insomnia, dizziness, drowsiness, and rash. Patients taking oral metronidazole have also complained of dry mouth and metallic taste during the course of treatment. More serious side effects such as peripheral neuropathy, palpitation, confusion, eosinophilia, and leukopenia are rare, and seem to be associated with the nitroimidazole family. Cessation of therapy leads to mitigation of side effects, and no long-term adverse events have been identified in humans [28].

Cure rates for oral and intravenous metronidazole therapy of trichomoniasis range from 85 to 95 % on the first course of treatment. This rate increases if sexual partner(s) are treated simultaneously to prevent reinfection [91]. Partner treatment is highly recommended given the frequency of asymptomatic *T. vaginalis* infection.

Single-dose metronidazole treatment of *T. vaginalis* with concomitant bacterial vaginosis or HIV and nevirapine-based antiretroviral therapy have been associated with higher rates of treatment failure [103–106]. Multi-dose treatment with metronidazole, in these cases, should be considered while taking into account patient-specific risk of nonadherence.

5 Metronidazole Resistance

5.1 Mechanisms

Two proposed mechanisms for metronidazole resistance will be discussed. In both mechanisms metronidazole resistance is classified as aerobic or anaerobic. The first mechanism proposed involves metronidazole activation via hydrogenosomes [107–113]. The second mechanism is flavin reductase-based [17, 114–116]. Metronidazole enters *T. vaginalis* by passive diffusion wherein the drug is reduced by single and double electron transfers that result in production of toxic metabolites [107, 117]. Potential toxic radicals could be nitro radicals, nitrosoimidazole, or hydroxylamineimidazole [118]. However, the pathway for reduction of metronidazole to its active metabolites is still under debate. The target of the toxic metabolites is not clear. One target could be DNA, where transient binding of the active drug leads to disruption and breakage of chromosomal strands, and rapid cell death (within 5 h) [119]. The DNA of *T. vaginalis* contains about 71 % adenine and thymine residues, and these AT-rich regions are proposed to be both the site of metronidazole activity and the reason for the drug's specificity [120]. It is also possible that metronidazole metabolites target and disrupt proteins and protein trafficking [17, 109].

The first mechanism of metronidazole resistance in the hydrogenosome involves activity of enzymes proposed to be responsible for metronidazole activation. Within this organelle, the drug competes with hydrogenase (the terminal enzyme of pyruvate decarboxylation) for ferredoxin-bound electrons. Metronidazole is reduced and toxic metabolites via the formation of nitro radicals are produced [107, 117].

Aerobic resistance could be a result of impaired oxygen-scavenging mechanisms that lead to a decrease in the metabolism of metronidazole due to oxygen competition for ferredoxin-bound electrons. Increased oxygen concentration and reduction via ferredoxin leads to a decrease in the amount of metronidazole being reduced (i.e., less production of active metabolites), and the oxidation of metronidazole metabolites back into prodrug by oxygen and oxygen radicals (termed "futile cycling") [112, 121]. Decreased ferredoxin activity has also been implicated in aerobic resistance [113, 122], although oxygen-scavenging deficiency alone may be responsible [123]. Since metronidazole enters *T. vaginalis* through passive diffusion, reduced metabolism of the drug into its active form will result in less overall trafficking into the cell, and lower efficacy. Aerobic resistance is responsible for nearly all cases of clinically resistant trichomoniasis.

Anaerobic resistance develops when hydrogenosomal proteins involved in the reduction of metronidazole are downregulated or absent. Studies using laboratory-produced resistant strains of *T. vaginalis* and the related cattle infectious trichomonad, *Tritrichomonas foetus*, have shown that the transcription of ferredoxin, PFOR, and hydrogenase is drastically reduced or completely eliminated in highly resistant strains [110, 111]. Anaerobically resistant *T. foetus* strains often have modified hydrogenosomes that are significantly smaller than those found in metronidazole-sensitive trichomonads, presumably reflecting their decreased activity [111]. Reduced hydrogenosome size has only been demonstrated in laboratory-induced metronidazole-resistant strains of *T. vaginalis* and not in clinically resistant or susceptible strains [124]. Unlike aerobically resistant trichomonads, which use oxygen to detoxify metronidazole, anaerobically resistant *T. vaginalis* is extremely sensitive to oxygen and may survive only in an anaerobic environment. It is

hypothesized that this is because PFOR and hydrogenase have roles in protecting the trichomonad from reactive oxygen radicals. In addition, *T. vaginalis* possesses hydrogenosomal oxidase- and peroxidase-reducing enzymes that help protect the parasite from cell damage due to toxic oxygen species [108]. Reduction of hydrogenosomal function may lead to a downregulation in the activity of enzymes that protect *T. vaginalis* from oxygen stress. The extreme sensitivity of anaerobically resistant *T. vaginalis* to oxygen likely explains why such strains are rarely involved in disease, as the urogenital environments of men and women are aerobic and microaerophilic, respectively.

A second mechanism of resistance has been proposed because PFOR-mediated activation of metronidazole which requires ferredoxin was unaffected by knock-out of ferredoxin genes and the modified strain remained sensitive to metronidazole [17]. In the second mechanism of metronidazole resistance, Leitsch and colleagues have reported on cytosolic flavin reductase (FR), previously named NADPH oxidase, which is a key enzyme for flavin-mediated redox reactions in *T. vaginalis* [17, 114–116].

Diminished or absence of FR activity has been documented in clinical metronidazole-resistant *T. vaginalis* isolates [115]. Mutations of FR induced in vitro have led to metronidazole resistance in sensitive isolates [17]. Additionally, the authors propose that changes in ferredoxin, PFOR, and hydrogenase activity could be a result of reduced activity of flavin-mediated redox reactions. Therefore, changes observed in the first mechanism described do not induce metronidazole resistance, but are a result of resistance [17, 114].

In a study to determine the role of flavin-mediated redox reactions, resistance to metronidazole was attained following the use of diphenyleneiodonium (DPI) flavin inhibitor on *T. vaginalis* isolates grown under anaerobic conditions. The trichomonads were not viable when treated with DPI under microaerobic or aerobic conditions [114] and so these findings could not be applied to aerobic resistance. Whether thioredoxin reductase that was completely inhibited by DPI or FR that was nearly completely inhibited by DPI was responsible for induced metronidazole resistance was unclear. In another study, assays of clinically resistant isolates have demonstrated reduction of FR activity, rather than thioredoxin reductase of which the activity remained unaffected compared to metronidazole-sensitive isolates [115]. Yet, the clinically resistant isolates were aerobically resistant rather than anaerobically resistant and levels of FR were not consistently directly associated with levels of aerobic resistance [115].

Leitsch and colleagues [116] identified seven full length genes of FR, denoted *FR1-FR7*. FR1 activity was significantly impaired in metronidazole-resistant strains. In a laboratory-induced anaerobically resistant strain, C1res, and a clinical anaerobically and aerobically resistant strain, B7268, FR1 activity was absent. Interestingly, sensitivity to metronidazole under aerobic conditions was mostly restored in B7268 when a plasmid carrying a functional *FR1* gene was transfected. This finding is evidence of a role of FR in aerobic resistance, which was not elucidated by the DPI inhibitor study.

Impairment of oxygen-scavenging mechanisms described above remains an explanation for aerobic metronidazole resistance. The mechanism that leads to impairment of oxygen scavenging is unclear. Flavin reductase and NADH oxidase are the only two known oxygen-scavenging mechanisms of *T. vaginalis*. Metronidazole impairs NADH oxidase function [116]. Thus isolates with impaired FR function and treated with metronidazole under aerobic conditions accumulate intracellular oxygen that causes futile cycling of metronidazole [116, 125]. Futile cycling results in restoration of the parent drug, metronidazole, eliminating toxic metabolites. Still, further studies are required to elucidate the role of flavin-mediated redox pathways and ascertain a direct mechanism of resistance.

Other mechanisms of resistance that have been proposed include malate-dependent electron transport within the hydrogenosome, single nucleotide polymorphisms in nitroreductase genes, and inactivation by hydrogenosomal iron-sulphur flavoproteins [126–128]. Lastly, there is a lack of data to explain differences in cross-resistance of metronidazole and tinidazole.

5.2 Diagnosis of Resistance

Infection with metronidazole-resistant *T. vaginalis* is generally suspected when two standard courses of treatment fail to cure, and noncompliance and reinfection can be ruled out. Current estimates are that 2–6 % of cases of trichomoniasis will be caused by parasites with some degree of resistance to metronidazole [59, 129–133]. Rates in specific regions can be significantly higher; a study of prevalence of in vitro metronidazole resistance in Papua New Guinea reported detection of metronidazole resistance in 17.4 % of 23 cases examined [134]. Low or moderately resistant trichomonads are the cause of most recalcitrant infections, although highly resistant organisms have also been isolated from clinical samples.

Metronidazole susceptibility tests for *T. vaginalis* are similar to drug susceptibility assays for other microorganisms. Susceptibility testing usually follows the procedure reported by Meingassner and Thurner [130]. A number of samples of axenic medium containing a range of metronidazole concentrations (0.2–400 μg/mL) are prepared. The trichomonal isolate is then inoculated into each drug-medium sample and incubated, for at least 48 h. Metronidazole susceptibility can then be assessed by calculating the minimum inhibitory concentration (MIC) and/or minimum lethal

concentration (MLC) of drug for the organism. Inhibitory and lethal concentrations are obtained by observing the parasites for motility after the incubation period. The samples containing immobile trichomonads are then inoculated into fresh drug-free medium, incubated (again for at least 48 h), and reexamined for live cells. The MIC is the lowest metronidazole concentration at which nonmotile parasites survived (i.e., proliferated after the second inoculation). The MLC is the lowest concentration at which all trichomonads were killed (i.e., no growth on secondary inoculation).

In vitro metronidazole susceptibility testing is usually performed under aerobic conditions. This is partly because aerobic testing better reflects the environment in which *T. vaginalis* infection is found, and partly because anaerobic testing does not always accurately reflect clinical presentation [135]. In addition, MIC and MLC values can be over five times higher in aerobic testing compared to anaerobic [22], thereby allowing better discrimination of the resistance results.

Currently, there is no standard in vitro assay for the determination of *T. vaginalis* susceptibility to metronidazole. Different researchers favor various techniques, under different conditions (aerobic vs. anaerobic), to calculate different results (MIC vs. MLC). A survey of the literature on aerobic susceptibility testing shows that a strain of *T. vaginalis* having an MIC lower than 10 μg/mL, or an MLC lower than 50 μg/mL is generally considered metronidazole susceptible. A trichomonad with an MLC of >400 μg/mL (MIC of >50 μg/mL) would represent a highly drug-resistant strain of the parasite. Unfortunately, there is no direct correlation between the results of in vitro susceptibility assays and recommended dosages for clinical metronidazole treatment [136]. In vitro testing does not necessarily reflect the level of in vivo metronidazole susceptibility of a clinical isolate or predict outcome of treatment [132, 137, 138]. Thus there can be difficulty in determining a continuing course of therapy if primary treatment fails [139]. However, in one study the majority of patients treated according to metronidazole susceptibility results were cured following the use of susceptibility testing results [137]. Susceptibility testing is not routinely available in most diagnostic laboratories.

5.3 Standard Treatment After Initial Treatment Failure

Infection caused by metronidazole-resistant *T. vaginalis* can often be cured with increased doses of the drug and an extended course of therapy. Standard dosages following treatment failure include 500 mg oral metronidazole twice a day for 7 days, or 2 g oral metronidazole or tinidazole once a day for 5 days. Not surprisingly, there is a greater rate of adverse events associated with an increased (often double) treatment dose. In an attempt to limit side effects, treatment of refractory infection often combines oral and vaginal metronidazole therapy, or involves intravenous administration of the drug [140]. Some success has also been reported in a combination of standard metronidazole treatment and arsenical or clotrimazole pessaries, or zinc sulfate or betadine (povidone-iodine) douches [139, 141, 142]. Although evidence as to the efficacy of these therapies as cures is somewhat anecdotal, it is known that the treatments do ameliorate the symptoms of acute trichomoniasis.

Cases of highly drug-resistant *T. vaginalis* infection are difficult to resolve, as very high doses of metronidazole are toxic to the patient. With no alternatives to nitroimidazole drugs available, patients suffering from recalcitrant trichomoniasis are sometimes resigned to recurrent infection, relying on palliative measures to control symptoms. Fortunately such cases are infrequent. Overall, the cure rate for refractory trichomoniasis is 80 % for the first course of extended/combined therapy, assuming patient compliance and no reexposure [143]. The Centers for Disease Control and Prevention recommends consultation with a specialist and susceptibility testing for recalcitrant *T. vaginalis* infections [93].

5.4 Alternative Treatments for Metronidazole-Resistant Infections

There are very few therapeutic alternatives for the treatment of *T. vaginalis* infection. The 5-nitroimidazole family of drugs represents the only therapies currently proven to safely and effectively treat trichomoniasis. Of the nitroimidazoles, metronidazole and tinidazole have superior trichomonicidal activity, with most studies showing tinidazole to have a cure rate equal to that of metronidazole, but being effective at a slightly lower dosage (1.5 g single dose) [143–146]. Reports of high dose oral tinidazole in combination with intravaginal treatments such as tinidazole, clotrimazole, paromomycin, or ampicillin have demonstrated cure of recalcitrant infections [147–150].

A comparison of in vitro susceptibility of resistant isolates to metronidazole and tinidazole showed a strong correlation between metronidazole resistance and tinidazole resistance ($r=0.8709$, $P<0.0001$) [151]. Therefore, there is a definite need for non-nitroimidazole-based treatments.

An intravaginal preparation, paromomycin, has reported cure of 15 of 29 patients with recalcitrant trichomoniasis [147, 150, 152–158]. Two patients with metronidazole-resistant *T. vaginalis* infections responded to combination therapy of high-dose oral tinidazole combined with paromomycin cream intravaginally for 2 weeks. Unfortunately, as was the case with hamycin (mentioned previously), side effects have been noted that include pain and ulceration of the genital mucosa, making it unlikely that paromomycin is an ideal treatment alternative [156, 159].

Povidone-iodine has failed to cure recalcitrant *T. vaginalis* in three patients [148, 160, 161]. Cure was reported for two patients [162, 163]. Combination of povidone-iodine pessaries with intravaginal metronidazole cured two patients [162]. Povidone-iodine failed as alternative treatment to overcome nitroimidazole allergy in one case [164]. Eight and 30 % of patients that failed "orthodox" treatment also failed povidone-iodine treatment in a study that compared two durations of povidone-iodine treatment [165].

Arsenic had been used as a treatment for trichomoniasis before metronidazole was available. Acetarsol (arsenical pessaries) cleared metronidazole-resistant *T. vaginalis* infection in 4/6 patients reported from four case reports [141, 142, 147, 157].

Acidification of the vagina using acetic acid or boric acid has been reported in a handful of case reports. Based on five patient cases, acetic acid has not been reported to provide relief of infection [152, 158, 160, 166]. Multiple rounds of boric acid were required for microbiological cure in two patients [152]. One successful treatment with boric acid was reported as an alternative treatment due to metronidazole allergy [164].

Evidence for the use of nonoxynol-9 for recalcitrant *T. vaginalis* infections is limited. Two curative and two failed treatments have been reported [147, 157, 160, 162]. There are three reported failures and one success of combination of furazolidone and nonoxynol-9 as an alternative treatment for allergy to metronidazole and metronidazole-resistant *T. vaginalis* [148, 149, 153, 164]. The best evidence that suggest lack of efficacy comes from a randomized trial that reported 17.6 % cure of metronidazole-sensitive *T. vaginalis* infections using nonoxynol-9 versus 100 % cure rate using metronidazole [167].

Nifuratel and furazolidone are nitrofuran-class drugs. Nifuratel has not been licensed for use in the United States, but is used as a gynecological treatment of trichomoniasis in other regions. The efficacy of nifuratel has been reported in studies from the 1960s and 1970s with variable efficacy (38–80 %) [168, 169]. Recent studies have reported effectiveness in vitro and in vivo [170, 171]. Goodhew and Secor [170] noted contact dermatitis as an adverse reaction. Also, Evans, and Catterall [172] reported three adverse events of facial rash and generalized urticaria. However, a randomized trial by Mendling et al. [171] reported non-inferiority of nifuratel and a comparable safety profile. Furazolidone, despite in vitro activity, is unlikely to provide microbiological cure of *T. vaginalis* infections [20, 137, 143, 148, 149, 153, 164, 173, 174]. Furazolidone is contraindicated for use during pregnancy and is also not approved for use in the United States due to genotoxic and carcinogenic effects [175, 176]. Despite numerous reports of treatment failures with furazolidone, this drug has been used as a last resort in cases of recalcitrant *T. vaginalis* infections that have failed other alternative treatments.

A number of compounds containing nitro groups similar to nitroimidazoles have been investigated for activity against *T. vaginalis*. Nitazoxanide is a 5-nitrothiazolyl proven to be active against a broad spectrum of parasites in vitro. The drug was shown to exhibit trichomonicidal activity against both metronidazole-sensitive and -resistant strains. In addition, the drug has been shown to have low toxicity (at least in vitro) [124, 177, 178]. Nitazoxanide treatment of *T. vaginalis* has no reported successes [148, 173]. Analysis of the nitrothiazole derivative, niridazole, has shown it to possess multiple modes of action that contribute to broad-spectrum antimicrobial activity. Although specific mechanisms of action have not yet been elucidated, both metronidazole-sensitive and -resistant strains of *T. vaginalis* were found to be inhibited by the drug [179]. However, toxicity is a major concern and no reports of niridazole treatment of *T. vaginalis* were found. Sulfimidazole possesses two functional groups: a sulfonamide and a 5-nitroimidazole. In vitro testing has shown the drug to be effective against both aerobic and anaerobic bacteria, and metronidazole-sensitive and -resistant *T. vaginalis*. It should be noted however that MLCs for resistant trichomonads were approximately five times higher than for sensitive strains, potentially reflecting *T. vaginalis* resistance to the activity of the 5-nitroimidazole group [180]. Drugs with sulfonamide groups have had very limited treatment success [160, 181].

Disulfiram, a drug used to treat alcoholism, and its metabolite ditiocarb have shown in vitro trichomonicidal activity against both metronidazole-sensitive and -resistant strains of *T. vaginalis*. This is interesting since metronidazole can induce reactions similar to those of disulfiram, specifically nausea and vomiting, if taken with alcohol [170, 182].

This review does not provide treatment guidelines for patients infected with metronidazole-resistant *T. vaginalis* infections nor has an extensive list of all anecdotal treatments reported in literature. Some of the cases reported above and the dosages of the successful treatment have been summarized by Seña et al. [95]. However the successful case reports may be influenced by the previously failed regimens, combinations of therapy use and patient not returning for a late follow-up who had initial symptomatic improvement.

A vast number of studies, beyond the scope of this chapter and the highlights provided above, have been published that report in vitro susceptibility of *T. vaginalis*. For example, a screening of 1040 drugs from the US Drug Collection Library was conducted by Goodhew and Secor [170]. Two non-nitroimidazole drugs, disulfiram and nithiamide, were identified that had the best efficacy to inhibit growth of *T. vaginalis* in vitro, but were not as effective as metronidazole. Other drugs, plant-derived and microorganism-derived products tested in vitro have been summarized by Seña et al. [95]. Although preliminary in vitro research has been conducted on the trichomonicidal activity of a large number of

drugs, testing rarely proceeds to clinical trials. With rates of metronidazole-resistant *T. vaginalis* infection on the rise and current alternative treatments being unreliable, it is imperative that effective alternative therapies become available.

5.5 Infection Prevention

Infection control of sexually transmitted trichomoniasis is the same as for other STIs. Condoms are effective in preventing the spread of disease, and reduced transmission has been shown in women using either oral (hormonal) or prophylactic vaginal (i.e., nonoxynol-9) contraception [183]. Circumcision has not been proven to be an effective method to prevent *T. vaginalis* infections in males, but male circumcision may indirectly reduce prevalence in females (prevalence risk ratio 0.52, 95 % CI 0.05–0.98) [44, 184].

As *T. vaginalis* parasites can be passed from mother to newborn during vaginal birth, treatment of pregnant women to prevent perinatal infection is an option. Previously there have been concerns about metronidazole teratogenicity, based on studies showing mutagenicity in bacteria and carcinogenicity in mice [185, 186]. This led to the reluctance to treat pregnant women, or to limiting treatment to the second or third trimester. Several meta-analyses have shown, however, that children born to mothers treated with metronidazole showed no increase in birth defects compared to controls [187–190]. Additionally, it would seem beneficial to treat infections because there is a proven association between trichomoniasis and pregnancy complications such as preterm labor and low birth weight infants. Paradoxically, treatment may carry a risk of increased preterm labor. Four studies have been conducted that report on pregnancy outcomes following metronidazole treatment [191–194]. Generalizability of the findings is impeded by each study using a cohort with distinct population characteristics. Nonetheless, a recommendation to treat pregnant women infected with *T. vaginalis* is complicated by one of the four studies reporting a significant increase in risk of preterm labor. The other three studies report no significant change in risk of preterm labor. All four studies report no significant change in risk of low birth weight deliveries [195, 196].

Currently, there is no vaccine available against *T. vaginalis* infection and sufficient criteria for the infection to be reportable have not been met [197, 198]. However, the existence of a successful vaccination model in mice [46, 199], as well as a vaccine already commercially available for prevention of related *T. foetus* infection in cattle [200, 201], gives hope that eventually the disease will be preventable. Given the relationship between trichomoniasis and other STIs, especially HIV, the development of a vaccine would be an excellent step in preventing morbidity and mortality due to this and other sexually transmitted infections.

Drug Resistance in Leishmaniasis

77

Shyam Sundar and Jaya Chakravarty

1 Introduction

Leishmaniasis, a vector-borne disease, is caused by an obligate intracellular protozoan of the genus *Leishmania*, order Kinetoplastida, family Trypanosomatidae and is transmitted by the bite of female sand fly vectors. Clinical manifestations range from self-healing cutaneous ulcers to systemic multiorgan disease. It broadly manifests as visceral leishmaniasis (VL; also known as kala-azar), cutaneous leishmaniasis (CL), and mucocutaneous leishmaniasis (MCL). VL is caused by the *Leishmania donovani* complex: *L. donovani*, the causative organism of VL in the Indian subcontinent and Africa; *L. infantum* (*L. chagasi*) which causes VL in the Mediterranean basin, Central and South America. CL is caused by various *Leishmania* species. Based on its geographical distribution, CL can be divided into Old World (OWCL) which includes southern Europe, the Middle East, parts of southwest Asia, Central Asia, and Africa. OWCL is caused by *L. aethiopica*, *L. donovani*, *L. infantum*, *L. major*, and *L. tropica*. New World cutaneous leishmaniasis (NWCL) occurs in Mexico and Latin America and is caused by multiple species of both the *Leishmania* subgenera: *L. amazonensis*, *L. infantum*, *L. mexicana*, *L. venezuelensis* and the *Viannia* subgenera: *L. braziliensis*, *L. guyanensis*, *L. panamensis*, *L. peruviana*. MCL is caused by New World *Leishmania* species *L. braziliensis* and *L. panamensis*. Diffuse CL, a severe form of CL, is caused by *L. aethiopica* in the Old World and *L. mexicana* and *L. amazonensis* in the New World [1, 2].

2 Epidemiology

Leishmaniasis is endemic in 98 countries with more than 350 million people at risk. Approximately 0.2–0.4 million VL cases and 0.7–1.2 million CL cases occur each year. More than 90 % of global VL occurs in just six countries: India, Bangladesh, Sudan, South Sudan, Brazil, and Ethiopia. CL is more widely distributed, with about one-third of cases occurring in each of three regions, the Americas, the Mediterranean basin and western Asia from the Middle East to Central Asia. The ten countries with the highest estimated case counts, Afghanistan, Algeria, Brazil, Colombia, Costa Rica, Ethiopia, Iran, Sudan, Syria, and Peru, together account for 70–75 % of globally estimated incidence of CL [3]. HIV-VL coinfection has been reported from more than 35 countries. Initially, most of these cases were from south-western Europe, but the number of cases is increasing in sub-Saharan Africa, especially Ethiopia, Brazil, and South Asia [4–6].

The only proven vectors of human disease are sand fly of species *Phlebotomus* in the Old World (Asia, Africa, and Europe) and *Lutzomyia* in the New World (the Americas) [1]. Transmission is of two types: anthroponotic where the vector transmits the disease from infected to healthy humans and zoonotic where the vector transmits the disease from an animal reservoir to humans. In South Asia and the Horn of Africa, the predominant mode of transmission of VL is anthroponotic, and humans with kala-azar or post-kala-azar dermal leishmaniasis (PKDL) provide the major reservoir for transmission [2, 7, 8]. In the Mediterranean, the Middle East, and Brazil, VL is zoonotic, with the domestic dog as the most important reservoir host sustaining transmission [8]. Most CL have zoonotic transmission except those caused by *L. tropica*, which is predominantly anthroponotic. Reports from Europe have shown that transmission of the infection can occur via needle-sharing in HIV/VL coinfected patients in southern Europe, and threaten to convert an apparently zoonotic disease into the anthroponotic form [9, 10].

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_29

Sand flies inoculate the promastigote form of the parasite into the skin of the host. In the human host, these are taken up by macrophages or the dendritic cells, where they transform into aflagellar amastigotes. The future course of infection and the type of disease produced depend upon the species of *Leishmania* and the immune response mounted by the host.

Visceral leishmaniasis, also known as "Kala-azar," is the systemic and most severe form, characterized by prolonged and irregular fever often associated with rigor and chills, splenomegaly, lymphadenopathy, hepatomegaly, pancytopenia, progressive anemia, and weight loss. If untreated, VL is uniformly fatal. These, coupled with poor sensitivity of immunological tests in these patients, pose considerable diagnostic difficulty. Patients with VL may develop a chronic form of dermal leishmaniasis characterized by indurated nodules or depigmented macules, and is called PKDL [11]. PKDL is quite common (occurring in >50 % patients with VL) in Sudan, and may occur concurrently with VL [11, 12]. In the Indian subcontinent it occurs only in a small proportion of patients, 6 months to several years after an episode of VL [13]. Spontaneous healing occurs in most patients in Sudan; however, in India treatment is considered necessary. Treatment of PKDL is difficult and requires prolonged courses of antileishmanial drugs irrespective of the geographical location. Patients with PKDL serve as an important reservoir of infection, and VL outbreaks have been linked to PKDL [14]. Leishmaniasis is also emerging as an important opportunistic infection in HIV-infected patients. In Ethiopia 10.4–40 % of VL patients were coinfected with HIV in different centers [15, 16]. HIV and *Leishmania* infection reinforce each other. HIV patients are more likely to develop visceral leishmaniasis (due to reactivation of a dormant infection or clinical manifestation after primary infection). Patients characteristically have high disseminated parasite loads. Visceral leishmaniasis negatively affects the response to antiretroviral treatment and is difficult to cure in coinfected patients, especially those with CD4+ counts <200 cells/μL, who typically relapse [1], thus making them another potential source for the emergence of drug resistance. The clinical features are usually similar to a classic VL patient; however at times there may be involvement of unusual sites, e.g., infiltration of skin, oral mucosa, gastrointestinal tract, lungs, and other organs, especially in patients with low CD4+ counts.

Cutaneous leishmaniasis is a major health problem in some countries [17–22]. In the Old World, it is caused by *Leishmania major*, and manifests as a papule, which enlarges and ulcerates producing painless ulcer with raised and indurated margin. Most patients have 1–2 lesions, which heal spontaneously, but occasionally lesions may be multiple and disabling with disfiguring scars, which create lifelong aesthetic as well as social stigma. *L. tropica* may cause persistent, spreading scarring lesions associated with exaggerated cellular hypersensitivity (leishmaniasis recidivans or lupoid leishmaniasis), and is a difficult problem to treat [23, 24].

New World CL is mainly zoonotic and is most often caused by *L. mexicana*, *L.* (*V.*) *panamensis*, *L.* (*V.*) *braziliensis*, and *L. amazonensis*. A wide range of forest animals act as reservoirs, and human infections with these species are predominantly rural. Diffuse cutaneous leishmaniasis (DCL), a rare syndrome produced by *L. aetheopica* and *L. amazonensis*, develops because of defective antigen-specific cell-mediated response [25, 26]. The lesions are chronic, disseminated, and nonulcerative. They never heal spontaneously, and relapses following treatments are quite frequent. MCL (espundia) produces extensive destructive lesion of nasopharyngeal mucosa. The disfiguring lesions lead to mutilation of the face. It is commonly caused by *Leishmania* species of the New World, such as *L. braziliensis*, *L. panamensis*, and *L. guyanensis*, but mucosal lesions have also been reported in the Old World due to *L. donovani*, *L. major*, and *L. infantum* in immunosuppressed patients [27, 28].

Usually, each species is true to type; but occasionally a dermatotropic species (e.g., *L. tropica*) may cause visceral disease, or the viscerotropic *L. infantum* may cause self-healing skin lesions [29]. Viscerotropic and dermatotropic strains of *L. infantum* can be distinguished by isoenzyme analysis. But this distinction breaks down in the face of HIV coinfection, in which many hitherto unknown zymodemes have been identified *L. braziliensis*, almost uniquely, has the capacity to produce secondary mucosal lesions of the nose and mouth [17].

3 Antileishmanial Agents and Drug Resistance

The armamentarium of antileishmanial is small and includes pentavalent antimonials, amphotericin B deoxycholate and its lipid formulation, paromomycin, miltefosine, azoles, and pentamidine. For several decades, pentavalent antimonials (Sb^v) have been the standard first-line drug for the treatment of leishmaniasis. In the recent years, drugs like oral miltefosine, and paramomycin and newer therapies like single-dose liposomal amphotericin B (L-AmB) and combination therapies have been added in the treatment of VL. At the same time, as these new therapies are becoming available, drugs like Sb^v and miltefosine are being threatened by the development of resistance [30].

3.1 History of Geographical Spread of Resistance

For more than 80 years, pentavalent antimonials (Sb^v) have been the sheet anchor for the treatment of leishmaniasis in every endemic region of the world. In most parts of the

world, about 98–99 % previously untreated patients with VL respond well to Sb^v. However, the endemic region for VL in North Bihar, India, has the unique distinction of being the only region in the world from where widespread failure to Sb^v has been reported [31, 32]. Sb^v had been the drug of choice for the treatment of VL in this region for several decades. Till the late 1970s, a small daily dose (10 mg/kg; 600 mg maximum) for short duration (6–10 days) was considered adequate, when unconfirmed reports suggested 30 % treatment failure with this regimen from four most severely affected districts: Muzaffarpur, Samastipur, Vaishali, and Sitamarhi [33]. An expert committee revised the recommendations to use Sb^v in two 10-day courses with an interval of 10 days [34], and improvements in cure rates (99 %) were noted [35]. However, only a few years later, another study noted 86 % cure rates with this regimen [36]. In 1984, a WHO expert committee recommended that pentavalent antimony be used in doses of 20 mg/kg/day up to a maximum of 850 mg for 20 days, and the repetition of a similar regimen for 20 days in cases of treatment failures [37]. Four years later, Thakur et al. evaluated the WHO recommendations and reported that 20 days' treatment with 20 mg/kg/day (maximum 850 mg) cured only 81 % of patients; however, on extending the treatment for 40 days, 97 % of patients could be cured [38]. Three years later, the same group noted a further decline in cure rate to 71 % after 20 days' treatment, and recommended an extended duration of treatment in nonresponders [39]. Jha et al. [40] found that extending the therapy for 30 days could cure only 64 % patients in a hyperendemic district of Bihar. From these findings it became clear that antimony refractoriness was on ascendancy, but the reports were sketchy and not under strictly controlled conditions. In two studies carried out under strictly supervised treatment schedules, we observed that only about one-third of the patients could be cured with the currently prevailing regimen [31, 41]. The incidence of primary unresponsiveness was 52 %, whereas 8 % of the patients relapsed. Incidentally, only 2 % of the patients from the neighboring state of (Eastern) Uttar Pradesh (UP) failed in the treatment [31]. There were reports of antimony resistance spreading to the Terai regions of Nepal, especially from the district adjoining the hyperendemic areas of Bihar, where up to 30 % of the patients seems to be unresponsive, though in Eastern Nepal a 90 % cure rate had been reported [41]. Thus, it was reconfirmed that a high level of Sb^v unresponsiveness existed in Bihar and its adjoining region while, the drug continued to be effective in other areas. In a study to determine whether acquired drug resistance was present in Bihar, *L. donovani* isolates were taken from responders and nonresponders. In vitro amastigote-macrophage assay showed that isolates from patients who did respond to sodium stibogluconate treatment were threefold more sensitive, with 50 % effective doses (ED 50) around 2.5 μg Sb/mL compared to isolates from patients who did not respond (ED 50 around 7.5 μg Sb/mL) [42]. The significant differences in amastigote sensitivity supported the concept of acquired resistance in Bihar.

HIV/VL coinfected patients respond poorly to Sb^v, as the drug needs an intact immune system to be effective, and the response is not as good as in immunocompetent patients. Initial parasitological cure with Sb^v could be as low as 37 % [43], and eventually most of the initially cured patients tend to relapse. A recent study from Ethiopia revealed only 43.9 % of HIV-VL coinfected patients were cured with SSG [44]. These relapsing patients may provide a human reservoir for resistant *Leishmania* with consequent emergence of primary resistance.

There is considerable variation in sensitivity to Sb^v among primary isolates from untreated patients with cutaneous leishmaniasis, which correlates with patients' response to treatment [45]. Primary resistance is quite uncommon, but resistance develops in patients with VL, CL, and MCL who have relapsed. Chances of response to further courses of antimonials diminish once there is a relapse after the initial Sb^v treatment [46].

Pentamidine isethionate was used as a second-line drug after widespread Sb^v failure in Bihar, with nearly 100 % cure rate for more than a decade despite being toxic [47]. Its most dreaded toxic effect was insulin-dependent diabetes mellitus in a significant proportion of patients [48]. In later studies, a decline in the efficacy from 100 to ~70 % was noticed. In the face of increasing unresponsiveness, and the associated serious toxicity, pentamidine fell into disrepute and its use was abandoned for the treatment of VL in the Indian subcontinent [49, 50]. While it is no longer used for VL, it is being used for NWCL due to *L. guyanensis* and *L. panamensis* with excellent results [51–53].

Amphotericin B (AmB), a polyene antibiotic, was used as a first-line therapy in areas with Sb^v resistance in Bihar, India. It has excellent cure rates (~100 %) at doses of 0.75–1.00 mg/kg for 15 infusions on daily or alternate days. It has been used extensively in Bihar with uniformly good results [54, 55]. To minimize the adverse events of amphotericin B, various lipid formulations have been introduced where deoxycholate is replaced with other lipids leading to less exposure of the free drug to the organs. Tolerance is greatly improved and adverse effects, including nephrotoxicity, are minimized which enables delivery of large doses of the drug over short periods of time. The dose requirement of liposomal amphotericin B (L-AmB) varies from region to region; while in the Indian subcontinent a small dose induces high cure rates, a higher dose is needed for Eastern Africa, the Mediterranean region, and Brazil [56–58].

Unresponsiveness and relapses after AmB occurs rarely, except among HIV-infected patients who tend to relapse frequently [59, 60]. In a HIV-VL coinfected patient with multiple

relapses treated with AmB, no resistance to AmB was seen in clinical isolates analyzed in vitro [59]. A rare case of Amphotericin B unresponsive *L.donovani* infection was reported from India. In vivo studies showed more than three times greater inhibition of AmB sensitive parasites compared to parasites with AmB relapse at a normal AmB dose in mice of 1.5 mg/kg body weight. Four single nucleotide polymorphisms (SNPs) were detected in this patient in the cysteine proteinase B gene affecting alignments in deduced amino acids [61]. The use of amphotericin B and its lipid formulations have dramatically increased, especially in the Indian subcontinent. Single dose of 10 mg/kg of liposomal Amphotericin B has recently been recommended as the preferred treatment for VL in the Indian subcontinent [1, 62]. With the increasing use of AmB in lipid formulations that have longer half-lives, the possibility of resistance cannot be ignored.

Miltefosine is an alkyl phospholipid (hexadecylphosphocholine) and the first oral antileishmanial agent registered for use in India from March 2002 following a Phase III trial in which 50–100 mg/day dose for 28 days resulted in a long-term cure rate of 94 % [63]. The efficacy of the drug varied with region; a study from Ethiopia showed that the final cure among non-HIV-infected patients 6 months after treatment in the miltefosine group was only 75.6 % [64]. The drug was chosen for the elimination program in India, Nepal, and Bangladesh for its ease of use and applicability in the control program [65]. The main concern with this drug was its long half-life of nearly a week which makes it vulnerable to develop resistance. Added to that frequent gastrointestinal adverse events, quick recovery (within 10 days most patients feel better) and absence of a directly observed treatment program are likely to drive the patients to prematurely discontinue the treatment and suboptimal compliance will ultimately lead to the development of parasite resistance [66]. Recent studies from the Indian subcontinent have shown that its efficacy has declined to 90.3 % and the relapse rate had doubled [67]. In a study from Nepal, 10.8 % and 20.0 % patients relapsed within 6 and 12 months after miltefosine treatment, respectively [68]. In another phase IV study from Bangladesh, enrolling 977 patients a final cure rate of 85 % could only be achieved [69]. Studies of miltefosine for OWCL are scarce; however, it has been used for NWCL, especially of *L. guyanensis* and *L. panamensis*, with good results [2].

Paromomycin (PM) is a broad-spectrum aminoglycosidic aminocyclitol belonging to the neomycin family. A Phase III trial in which a dose of 15 mg/kg PM sulfate (11 mg base) for 21 days gave a cure rate of 95 %, and was approved by the Indian government in August 2006 for the treatment of patients with VL [70]. Encouraged by this, a large Phase III study was done in Sudan, Ethiopia, and Kenya comparing the efficacy of PM alone at the dose shown to be efficacious in India against sodium stibogluconate (SSG) alone (20 mg/kg/day for 30 days) and a combination treatment of SSG and PM for 17 days. The overall efficacy of PM alone was significantly lower than SSG and it had to be discontinued [71]. Topical preparations of paromomycin, a soft paraffin-based ointment containing 15 % of paromomycin and 12 % methylbenzethonium chloride (MBCL), are effective against both Old World and New World CL [72]. A meta-analysis of 14 randomized controlled trials showed that in Sb^v-controlled trials, the efficacy of topical PM was not significantly different from that of intralesional Sb^v in the Old World CL (relative risk [RR] = 0.70; 95 % CI: 0.26–1.89), whereas topical PM was inferior to parenteral Sb^v in treating the New World CL (RR = 0.67; CI: 0.54–0.82) [73]. Clinical resistance to PM has not been reported most probably due to its limited use; however, being an aminoglycoside PM is at an increased risk of developing resistance, thus it is imperative to monitor treatment and avoid its use as monotherapy.

Azoles block ergosterol synthesis of *Leishmania* parasites. Ketoconazole, itraconazole, and fluconazole have all been used for CL in several studies. For NWCL due to *L. braziliensis* fluconazole, at the dose of 8 mg/kg per day, cured 100 % patients [74]. Ketoconazole at 600 mg/day for 28 days was 76 and 89 % effective in *L.* (*V.*) *panamensis* and *L. mexicana* CL in Panama and Guatemala but not effective for *L. braziliensis* [75, 76]. For OWCL Ketoconazole at a dose of 600 mg/day for adults and 10 mg/kg/day for children for 4–6 weeks obtained 89 and 80 % efficacy in Iran and Kuwait while it was ineffective in Turkey [77–79], while fluconazole showed 81 % cure rate for *L. Major* [80]. Clinical resistance to azoles in leishmaniasis has not been reported.

3.2 Clinical Significance of and Epidemiological Reasons for Drug Resistance

The reason for the emergence of antimony resistance was the widespread misuse of the drug which included free availability of drugs, use of drug by unqualified medical practitioners and inappropriate and inadequate dose. It was a common practice to start with a small dose and gradually build up the dose over a week. Drug-free intervals are given on the belief that it will prevent renal toxicity. Many a times, the daily dose of drug was split into two injections, given twice daily. These practices resulted in build-up of subtherapeutic blood levels of the drug, leading to progressive tolerance of the parasite to Sb^v. It was observed that only a minority (26 %) was treated according to the prescribed guidelines, and irregular use and incomplete treatments were common occurrences [81]. Almost half of the patients, receiving pentamidine as a second-line drug, had not received adequate antimony treatment before being labelled as refractory to Sb^v. These facts indicated large-scale misuse of antileishmanial drugs in Bihar, contributing to develop-

ment of drug resistance. There were several manufacturers of Sb^v in India, and quality of products was inconsistent, resulting in occasional batches being substandard and toxic, this added to the problems associated with Sb^v therapy causing serious toxicity and deaths related to the drug [82, 83].

Leishmania do not develop resistance to Sb^v spontaneously, unless they are subjected to drug pressure. In an experimental model, the parasite that was maintained in vitro passage in NNN media and posterior passage in hamster did not lose sensitivity to Sb^v [84]. However, resistance can be induced in the promastigote by repeated in vitro passage of the parasite with step-wise increase in concentration of Sb^v in the culture media [85]. The in vitro sensitivity also decreases progressively in relapsing patients [86]. There are clear indications that Sb^v resistance is a consequence of the exposure to a subtherapeutic dose of Sb^v. Though the in vitro data suggest that increasing the dose of Sb^v could overcome the unresponsiveness to a great extent, unfortunately further increase in the quantity of the drug would seriously jeopardize the safety of the patients [87]. Primary resistance emerges where man is the reservoir of infection, transmission is anthroponotic and intense, and there is a large biomass of parasite. In human-to-human (anthroponotic) transmission such as in the Indian and African subcontinents, once resistance gets established, it spreads exponentially and organisms sensitive to the drug get eliminated quickly, whereas the drug-resistant parasites continue to circulate in the community. There are no reports of either primary resistance or decline in the efficacy of Sb^v from other endemic foci of VL with canine reservoirs such as in Brazil and Southern Europe.

As for miltefosine, although the relapse rate of patients has increased in the Indian subcontinent, decrease in the susceptibility of parasites to miltefosine in vivo, a precursor of the emergence of drug resistance, has not yet been observed [68, 88, 89]. The plasma concentrations in cured and relapsed Nepalese patients were similar, indicating a similar exposure to miltefosine [68]. Another recent study from Nepal revealed that increased infectivity of the parasite is associated with miltefosine relapse [90]. Young age and male gender were associated with increased risk of VL relapse after miltefosine, suggesting that the mechanism of relapse is mainly host-related, i.e., immunological factors and/or drug exposure [91]. Achieving a sufficient exposure to miltefosine was found to be a significant and critical factor for VL treatment success, suggesting an urgent need to evaluate the recently proposed optimal allometric miltefosine dosing regimen [92]. Dorlo et al. demonstrated that children are significantly less exposed to miltefosine than adults when receiving a similar 2.5 mg/kg/day dosage of miltefosine [93] and proposed a new dosing algorithm to solve this apparent difference in drug exposure between age and body-size groups.

Unresponsiveness and relapses after AmB occurs rarely, except among HIV-infected patients who tend to relapse frequently [59, 60]. Rare cases of Amphotericin B unresponsive *L.donovani* infection has been reported from India [61, 94]. Single dose of 10 mg/kg of liposomal Amphotericin B has recently been recommended as the preferred treatment for VL in the Indian subcontinent [1, 62]. With the increasing use of AmB in lipid formulations that have longer half-lives, the possibility of resistance cannot be ignored.

Clinical resistance to PM has not been reported most probably due to its limited use, but being an aminoglycoside PM is at an increased risk of developing resistance.

3.3 Mechanism of Drug Resistance

Understanding the mechanism of drug resistance is crucial for preventing, monitoring, and reverting it. Unfortunately, little is known about the mechanism underlying the drug resistance as seen in human VL. However, there has been some insight into the possible mechanisms of resistance and characterization of probes for its detection using resistant mutants developed in the laboratories largely applying drug pressure.

Antimonial resistance is multifactorial. Reduced uptake of the drug, increased intracellular thiol levels, sequestration and rapid drug efflux are some of the mechanism known for antimony resistance. In *Leishmania*, aquaglyceroporin1 (AQP1), member of the aquaporin superfamily has been shown to facilitate uptake of Sb^{III} [95, 96]. Overexpression of AQP1 in *L. major* (LmAQP1) produces increased susceptibility to Sb^{III}, whereas gene deletion renders the parasite resistant [95, 97]. Studies on clinical isolates from India and Nepal indicated downregulation of AQP1 [98–100]. While, AQP1 RNA levels remained unaltered in resistant isolates of *L. braziliensis* and *L. guyanensis* [101, 102] and did not show consistent downregulation in another study from India [103].

Arsenite- or antimony-resistant laboratory mutants of all *Leishmania* species exhibit significantly increased levels of intracellular thiols, namely cysteine, GSH, and trypanothione (TSH), suggesting a role for thiols in resistance [99, 104]. The synthesis of two precursors GSH and spermidine determines the level of TSH. The γ-GCS gene encoding γ-glutamylcysteine synthetase, which catalyzes the rate-limiting step in GSH biosynthesis, has been found to be amplified in arsenite-resistant *L. tarentolae* [105], while the gene ODC which encodes ornithine decarboxylase, an enzyme involved in the regulation of spermidine biosynthesis, was also overexpressed [106, 107]. However, in clinical isolates results were variable. γ-GCS was neither amplified nor upregulated in *L. donovani* isolated from Sb^V-resistant patients from India [108, 109], but downregulation of γ-GCS

was observed in Nepalese isolates [99, 100]. In *L. guyanensis*, γ-GCS was overexpressed in therapeutic failure isolates [110]. Similarly, the precursor protein of spermidine biosynthesis, ODC was amplified at the genetic and protein levels in Indian *L. donovani*-resistant isolates [98, 109] and in *L. braziliensis* [101], but the gene was downregulated in isolates from Nepal [99]. Studies have shown that antimony-resistant isolates downregulate the expression of γ-GCS of macrophages, probably by downregulating host NFkB, which is known to regulate γ-GCS expression [110]. This would result in the reduction of intramacrophage GSH levels and promote an intracellular oxidative environment, thereby minimizing the intramacrophage reduction of Sb^{v} to its toxic form Sb^{III} [111]. This indicates that SAG resistance in *L. donovani* is associated with manipulation of both host and parasite thiol levels.

Another pivotal enzyme of the thiol metabolism responsible for maintaining the intracellular reducing environment through trypanothione is Trypanothione reductase (TR). Studies have shown increased RNA levels as well as enzyme activity of TR in Sb^{v}-resistant isolates of *L. donovani* [98] and Sb^{v}-resistant clinical isolates of *L. braziliensis* [101].

The ATP-binding cassette (ABC) superfamily of proteins has been widely reported to export xenobiotics [112, 113] outside the cell. These include the P-glycoprotein (P-gp) and multidrug resistance related protein (MRP). The first ABC transporter identified and characterized in *leishmania* was MRPA which was shown to confer antimony resistance by sequestering thiol-metal conjugates in an intracellular vesicle [114] rather than increased efflux. Upregulation of MRPA gene was observed in *L. donovani* isolates only from India [98, 108, 109] but neither from Nepal nor in *L. braziliensis* and *L. guyanensis* [101, 102].

However, *L. infantum* isolates from a HIV/VL coinfected patient on miltefosine maintenance showed a gradual decrease of the miltefosine susceptibility with the IC_{50} values of miltefosine increasing over time, from 5.00 to 50.10 μmol/L. and on sequencing the entire LdMt gene a new SNP, L832F, was found in the miltefosine-resistant strain which reverted back to the wild-type allele 3 years after withdrawal from miltefosine [115].

Miltefosine resistance can be easily induced in vitro. The transport of miltefosine over the parasite cell membrane is thought to be facilitated by a putative *L. donovani* miltefosine transporter (LdMT) and the protein LdRos3. It was shown that decreased miltefosine accumulation and defective inward translocation was the major determinant of decreased susceptibility [116], which was demonstrated to be mediated through inactivation of LdMT and LdRos3 [117–119]. It was shown that decreased miltefosine accumulation and defective inward translocation was the major determinant of decreased susceptibility [116], which was demonstrated to be mediated through inactivation of LdMT and LdRos3 [117–119]. In clinical isolates, low expression of the LdMT-LdRos3 complex was correlated to the natural nonsusceptibility to miltefosine of *L. braziliensis* strains. Increased efflux of miltefosine has also been implicated in miltefosine resistance, mediated through the overexpression of an ABC transporter: the *Leishmania* P-glycoprotein-like transporter (*Leishmania* ABCB1 or LtrMDR1) [120, 121] and *Leishmania*-specific ABC subfamily G-like transporters (LiABCG6 and LiABCG4 half-transporters) [122, 123]. Miltefosine elicit its effects by mitochondrial dependent-programmed cell death associated with generation of reactive oxygen species (ROS). It has been reported that *Leishmania donovani* mitochondrial iron superoxide dismutase-A (LdFeSODA) overexpression protects parasites from miltefosine by protecting the mitochondria of *Leishmania* from oxidative stress, thereby inhibiting programmed cell death [124]. Gene expression levels for LdFeSODA was 5.3-fold higher in MIL-resistant phenotypes upon drug treatment than the sensitive strains [125].

An amphotericin B-resistant clinical isolate which demonstrated eightfold-higher 50 % lethal doses (LD50) than an amphotericin B-sensitive strain altered membrane composition where ergosterol was replaced by cholesta-5,7,24-trien-3β-ol in the membrane of the resistant parasite, ATP-binding cassette transporters, and upregulated thiol metabolic pathway [94, 126]. Similar findings were observed in a laboratory-derived AmB-resistant *Leishmania* promastigote, where ergosterol was replaced by a precursor, cholesta-5,7,24-trien-3-ol [127].

In a line selected for resistance to paromomycin showed reduced accumulation of the drug associated with a significant reduction in the initial binding to the cell surface. The drug induced reduction in membrane potential and inhibition of protein synthesis were less pronounced in the resistant strain in comparison to the wild type [128]. In another study comparative proteomic analysis of the wild type and the paromomycin-resistant *L. donovani* strains showed upregulation of the ribosomal proteins in the PM-resistant strain (PRr) which could be one of the mechanisms utilized by the resistant parasites as a defense against PM. Upregulation of proteins that may have a role in intracellular survival and vesicular trafficking in the PRr strain was observed. Ultrastructural analysis by electron microscopy demonstrated increased number of vesicular vacuoles in PRr strain when compared to the wild-type strain. Vesicular sequestration of PM into the vacuoles by these resistant parasites might be involved in conferring the resistance phenotype [129].

Pentamidine-resistant promastigote clones of *L. donovani* and *L.amazonensis* were shown to have 18- and 75-fold reduced uptakes, respectively, and increased efflux [130].

3.4 Treatment Alternatives

With the growing treatment resistance in the Indian subcontinent there was a look out for alternative treatment which were effective, less toxic, simple to administer even in the periphery, and cost effective. In March 2007, a preferential pricing agreement with WHO (agreement between Gilead and WHO) reduced the price of L-AmB for endemic regions of developing countries to $18 per 50 mg vial [131]. Encouraged by this preferential pricing and the low dose of L-AmB required to cure VL in India a single dose of 10 mg/kg of body weight L-AmB was compared to the conventional amphotericin B deoxycholate administered in 15 infusions of 1 mg/kg, given every other day during a 29-day hospitalization. Cure rates at 6 months were similar in the two groups: 95.7 % (95 % confidence interval [CI]: 93.4–97.9) in the liposomal therapy group and 96.3 % (95 % CI: 92.6–99.9) in the conventional therapy group [62]. The preferential pricing, along with a single day of hospitalization, makes a single infusion of the liposomal preparation an excellent option for this region. This regimen was further tested in primary health centers in Bangladesh where the cure rate at 6 months was 97 % [132]. There was high acceptability of this regimen in Bangladesh; however, strengthening of infrastructure was required for its implementation in the sub-district level as the drug requires a cold chain [133]. Encouraged by the success of the single-dose L-AmB therapy in the Indian subcontinent a randomized controlled trial was done to compare the efficacy and safety of single dose of L-AmB 7.5–10 mg/kg body weight, or multiple doses, seven times 3 mg/kg on days 1–5, 14, and 21 in East Africa. However, the trial was terminated after the third interim analysis because of low efficacy of all the regimens. Definitive cure was 85 %, 40 %, and 58 % in patients treated with multiple doses, single doses of 7·5 or 10 mg/kg, respectively [134].

The growing resistance of the parasite to monotherapy and the use of multidrug therapy in diseases like tuberculosis, HIV, etc. suggested that multidrug therapy should be tested for the treatment of VL. The rationale behind use of multidrug therapy were increased activity through use of compounds with synergistic or additive activity acting at different sites, shorter duration of therapy, and lower dose requirement, thereby reducing chances of toxic side effects and cost, and preventing the emergence of drug resistance. In an experimental study, Seifert and Croft demonstrated activity enhancement index (AEI) of different drugs in vivo, where the highest potentiation of miltefosine activity was achieved with amphotericin B (AEI of up to 11.3). No significant interaction was observed when miltefosine was combined with SSG (AEI of up to 2.38). The potentiation of miltefosine in vivo was also achieved with the combination of miltefosine and PM (AEI of up to 7.22) [135].

The combination of Sb^v and PM has been extensively used in Southern Sudan by Médecins Sans Frontières (MSF), initially in patients who relapsed after conventional Sb^v and since 2002 as first-line therapy for VL.A large retrospective field evaluation by MSF showed that the initial cure rates and survival of patients on 17 days combination therapy with PM plus Sb^v was 97 % compared with 92.4 % among patients with 30-day Sb^v monotherapy [136]. In a recent large multicenter trial, this combination for 17 days had comparable efficacy to SSG treatment [137]. This combination is now the preferred regimen in this region.

Multidrug therapy has been studied in India. In a randomized, non-comparative, group-sequential, triangular design study, 181 subjects were assigned to treatment with 5 mg/kg of L-AmB alone, 5 mg/kg of L-AmB followed by miltefosine for 10 days or 14 days or 3.75 mg/kg of L-AmB followed by miltefosine for 14 days. When it became apparent that all regimens were effective, 45 additional, nonrandomized patients were assigned to receive 5 mg/kg of L-AmB followed by miltefosine for 7 days. Final cure rates were high (>95 %) and similar in all the groups. These results suggest that single infusion of L-AmB (in most instances, administered in an outpatient setting) followed by a brief self-administered course of miltefosine could be an excellent option against Indian kala-azar [138].

In a subsequent large Phase III study in the Indian subcontinent, three drug combinations (single injection of 5 mg/kg L-AmB and 7-day 50 mg oral miltefosine or 10-day 11 mg/kg intramuscular PM; or 10 days each of miltefosine and PM) were tested for the treatment of VL. All the combinations showed an excellent cure rate (>97 %) [139].

These trials established that the combination therapies are safe and effective options in the Indian subcontinent. They also require shorter duration of hospitalization which will lead to decongestion of the overcrowded treatment centers. Encouraged by this new treatment approach, an exploratory study with miltefosine alone and combinations of single dose of L-AmB (10 mg/kg) with SSG (20 mg/kg) for 10 days and L-AmB (10 mg/kg) with miltefosine for 10 days is being done in East Africa [140].

3.5 Treatment Guidelines

As the efficacy and required dosage of the antileishmanial agents vary in different areas, in 2010 WHO published the treatment recommendation based on these regional differences. For VL single dose of L-AmB and combination therapy are the preferred treatment options in the Indian subcontinent. The combination of Sodium stibogluconate with Paromomycin for 17 days is treatment of choice in East Africa and Yemen, whereas L-AmB up to a total dose of

18–21 mg/kg remains the choice in Mediterranean Basin, Middle East, and Central Asia. In India, Amphotericin B 60–80 doses over 4 months or miltefosine for 12 weeks are the recommended regimens for PKDL. In East Africa, PKDL is not routinely treated, as the majority of cases (85 %) heal spontaneously within 1 year. Only patients with severe or disfiguring disease, those with lesions that have remained for >6 months, those with concomitant anterior uveitis and young children with oral lesions that interfere with feeding are treated, with either SSG (20 mg/kg/day per day) for up to 2 months or a 20-day course of L-AmB at 2.5 mg/kg/day. For HIV-Leishmaniasis coinfection, lipid formulations of amphotericin **B** infused at a dose of 3–5 mg/kg/day or intermittently for 10 doses (days 1–5, 10, 17, 24, 31, and 38) up to a total dose of 40 mg/kg are recommended. Antiretroviral therapy should be initiated and secondary prophylaxis should be given till the CD4 counts are >200/μL. For HIV-CL coinfection, it is imperative to look for visceral involvement as immunosuppression due to HIV facilitates dissemination and may lead to disseminated CL and to VL. In the OWCL, local wound care with careful follow-up are indicated for patients with confirmed or strongly suspected infection with *L. major*; fewer than four lesions requiring immediate treatment; lesions <5 cm in diameter; no potentially disfiguring or disabling lesion (face, joints, toes, and fingers); no immunosuppression and possibility for follow-up. If at least one criterion is absent, local therapy should be given. Systemic antimonials are given for severe, complex lesions and in those with HIV infection. Fluconazole or a combination of antimonial and pentoxiphylline can be given for CL due to *L. major*. The recent PAHO guidelines recommends local treatment for NWCL in patients with single lesions up to 3 cm except in head or periarticular region in patients without immunosuppression but with possibility of follow-up. Systemic therapy is indicated for severe lesions and mucosal disease. Systemic antimonials are the drug of choice for NWCL and MCL. For CL caused by *L. panamensis* and *L. guyanensis*, miltefosine and pentamidine is also recommended [141].

3.6 Infection Control Measures

The epidemiology of different forms of leishmaniasis is quite diverse, with different ecological characteristics, different species of sand fly, and different reservoir hosts. Consequently, control strategies need to be tailored to the epidemiological characteristics of the disease. It is impossible to device a single control strategy. However, for any form of leishmaniasis, whether anthroponotic or zoonotic, early case detection and effective treatment will limit the disease-related morbidity and mortality. In anthroponotic foci, it also provides an effective control measure by reducing the reservoirs of infection. Access to antileishmanial drugs is an important issue, and availability of antileishmanial drugs in the endemic areas needs to be ensured, which along with tools for early diagnosis can effectively reduce the disease burden and thus transmission, more so in anthroponotic foci. It could also prove to be an important strategy to prevent emergence of drug resistance. Intense surveillance including active case detection and health education to raise the level of awareness among exposed population and promote community control measures are important for both vector and human reservoir control.

Vector control measures with residual insecticide spray can effectively control the disease in anthroponotic foci of VL. A classic example of the efficacy of this strategy is the near disappearance of VL cases in India in the 1960s when insecticides were used extensively as a part of the National Malaria Eradication Programme. Indoor residual spraying is one of the main means for controlling endophilic sandfly vectors and should be targeted to localities with active transmission. When exophilic or peridomestic sandfly species are involved, outer surfaces of domestic animal shelters and structures close to such dwellings (potential sandfly resting sites) must be sprayed. Personal protection against sand fly bite like insecticide-treated bed nets have been used with mixed results to prevent both VL and CL [142–144] but it is still an effective relatively cheap, sustainable method for sandfly control.

Control of reservoir hosts has been recommended as a component of control strategies for zoonotic visceral and cutaneous leishmaniasis. For zoonotic leishmaniasis, vector control through residual insecticide spraying of houses and animal shelters is restricted to the domestic and peridomestic areas such as Central and South America (*Lutzomyia longipalpis*). Regarding reservoir control, dogs being the main domestic reservoir, humane destruction of infected dogs, identified after annual screening of blood samples by serology, may be a way to control the disease. Nevertheless, the strategy of elimination is not satisfactory, as it provides only a transient effect, and there is always a concern over delay between sampling, diagnosis, and culling of dogs. More effective diagnostic tools may allow culling without delay. In the absence of a reliable tool for detecting infected dogs, dogs may be treated with topical insecticide, which will protect them from infection as well as prevent sand flies from biting the dogs. Another ingenious method tried has been applying deltamethrin-treated collar to dogs [145, 146]. It gives long-term protection against sand fly bite. However, these modalities of disease control, notwithstanding their limitation, are rarely used comprehensively in underdeveloped or developing countries where the disease is endemic.

Vaccination against different forms of leishmaniasis is a viable alternative for the control of the disease. Autoclaved whole parasites with BCG with or without alum have been

tested in randomized clinical trials in Iran and Sudan against CL and VL, respectively; however, they failed to provide adequate protection [147, 148]. Now second-generation vaccine consisting of recombinant proteins and genetic vaccines are being tested for both CL and VL. However, successful vaccination against leishmaniasis still remains a distant reality.

Occurrence, Measurement and Clinical Perspectives of Drug Resistance in Important Parasitic Helminths of Livestock

78

R.G. Woodgate, A.J. Cornell, and N.C. Sangster

1 Introduction

Helminthiases are amongst the most important diseases worldwide that affect sheep, cattle, and horses [1–10]. With anthelmintic treatment being a cornerstone of modern livestock helminth control, anthelmintic resistance is one of the key limitations of continued productivity and sustainability of livestock production. The impact of the resulting clinical or subclinical parasitism has been recognised with regard to sheep production for many decades [3, 11–15] and resistance to multiple anthelmintics is now common in sheep gastrointestinal nematodes [4, 11, 14]. In Australia alone, sheep nematodes are estimated to cost the national grazing industry in excess of $300 million annually [10]. The impact of anthelmintic resistance is now also becoming increasingly recognised with respect to cattle [4, 16–18] and horses [4, 19–22], and helminth parasites of livestock cause more than 55 % of all farm animal diseases in Europe [2].

An understanding of the general principles, specific mechanisms and measurement of anthelmintic resistance in both the laboratory and the paddock is critical in allowing continued profitable livestock production. This review concentrates on the occurrence, detection and clinical significance of resistance in the major nematode and trematode parasites of sheep, cattle and horses. The general principles regarding the development of anthelmintic resistance are discussed in light of an understanding to assist the slowing of worsening spread and to support effective and sustainable helminth control. There is also discussion of methods to detect, measure and monitor anthelmintic resistance.

2 Parasite Biology

The major gastrointestinal nematode parasites (GIN) of ruminants worldwide are summarised in Tables 78.1 and 78.2. These GIN have a similar direct, non-migratory life cycle, with parasitic immature and adult stages within the definitive host and free-living egg and larval stages. The third-stage larva is infective to the definitive host. Prepatent period is generally between 14 and 21 days in sheep and 21 and 28 days in cattle. The major GIN of horses are summarised in Table 78.3. More detailed information about each parasite's life cycle, biology and epidemiology can be found in a variety of excellent parasitology texts (e.g. 58, 59, 76).

Fasciola hepatica is a trematode parasite of the liver of sheep, cattle and horses, amongst other hosts. It is also zoonotic and is of particular importance as a parasite in human Asian populations. The life cycle is indirect and migratory, with aquatic snails of the *Lymnaea* genus as an intermediate host. *F. hepatica* prefers a warm, wet climate. Optimum temperature for development of stages outside the definitive host is above 15 °C.

Adult fluke, 25–40 mm long, reside in the bile ducts. Eggs are passed to the environment via host faeces and a miracidium emerges that is infective to *Lymnaea*. Following development in the snail, many cercaria emerge and eventually encyst on vegetation as metacercaria that are infective to the definitive host. Immature fluke migrate inside the host from the small intestine to the liver through the peritoneum. The prepatent period for *F. hepatica* is 70–84 days.

F. hepatica can be severely pathogenic. Acute disease and deaths can result from large numbers of migrating immature flukes damaging liver parenchyma, and can also be accompanied by infection with *Clostridium novyi*. Adult fluke can

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_30

Table 78.1 Major nematode parasites of sheep

Parasite	Key epidemiological features
Haemonchus contortus	– Adults, 20–30 mm in length, found in the abomasum
	– Highly pathogenic with fourth-stage larvae and adult worms sucking blood. Clinical signs in definitive host include anaemia, exercise intolerance, submandibular oedema and ascites
	– Highly fecund with mature female worms capable of producing up to 10,000 eggs per day
	– Prefer warmer, wet climates. Typically a summer rainfall parasite. Optimum ambient temperature for larval development between 25 and 30 °C
	– Hypobiosis in abomasal wall as third-stage larvae possible
Teladorsagia (previously *Ostertagia*) *circumcincta*	– Adults, 6–10 mm in length, found in the abomasum
	– Moderately pathogenic. Parasitise gastric glands. Clinical signs in definitive host are most commonly weight loss and intermittent diarrhoea
	– Mature female worm produces 50–100 eggs per day
	– Prefer temperate and moist or subtropical climates. Optimum larval development between 16 and 23 °C
	– Hypobiosis in abomasal wall as third-stage larvae possible
Trichostrongylus spp.	– Adult *T. colubriformis* and *T. vitrinus*, 4–7.5 mm in length, found in the small intestine. Adult *T. axei*, 3–8 mm in length, found in the abomasum
	– Mild to moderately pathogenic. *T. colubriformis* and *T. vitrinus* damage small intestinal mucosa, causing villous atrophy and inflammation. *T. axei* damages gastric mucosa causing inflammation and occasionally ulceration. Clinical signs in definitive host are most commonly weight loss and diarrhoea
	– Mature female *T. colubriformis* and *T. vitrinus* produce 100–200 eggs per day. Mature *T. axei* produces 50–100 eggs per day
	– *T. colubriformis* prefers warm moist climate, with optimum larval development between 25 and 28 °C. *T. vitrinus* prefers a cool moist climate, with optimum temperature larval development between 8 and 18 °C. *T. axei* prefers a temperate moist climate, with optimum larval development between 12 and 22 °C
Nematodirus spp.	– Adults, 10–25 mm in length, found in the small intestine
	– Generally very low pathogenicity except for *N. battus*, which in large numbers disrupts and erodes the small intestinal mucosa. Clinical signs for *N. battus* include diarrhoea, anorexia and polydipsia
	– Relatively low fecundity with mature female producing 25–30 eggs per day
	– Prefer cool, moist climates. Optimum larval development between 11 and 13 °C. *N. battus* is found mostly in the British Isles but may also occur in Norway, Sweden, the Netherlands and Canada

Table 78.2 Major nematode parasites of cattle

Parasite	Key epidemiological features
Ostertagia ostertagi	– Adults, 6–10 mm long, found in the abomasum
	– Hypobiosis in abomasal wall as fourth-stage larvae common
	– Moderately to very pathogenic, with two clinical forms both involving destruction of gastric glands. Type I disease occurs when fourth-stage larvae do not undergo hypobiosis but mature and replicate. Type II disease occurs with large-scale emergence of hypobiotic fourth-stage larvae from gastric glands. Main clinical signs include profuse watery diarrhoea and tissue oedema
	– Mature females produce about 200 eggs per day
	– Prefer cool, moist climates and subtropical regions with winter rainfall. Optimum larval development between 13 and 21 °C
Cooperia spp.	– Adults, 4–8 mm long, found in the small intestine
	– Mildly pathogenic, causing damage to the small intestinal mucosa. Clinical signs in definitive host include anorexia, depressed growth, diarrhoea and possibly submandibular oedema. Failure to control *Cooperia* can result in significantly reduced live weight gains in beef calves. *C. pectinata* and *C. punctata* have a greater impact on productivity than *C. oncophora*
	– Mature females produce 100–200 eggs per day
	– Prefer temperate to subtropical climates. Optimum larval development between 16 and 21 °C
	– Hypobiosis in intestinal wall as fourth-stage larvae possible
Haemonchus placei	– Similar life cycle and biology to *Haemonchus contortus*
	– Pathogenicity moderate to very high

Table 78.3 Major nematode parasites of horses

Parasite	Key epidemiological features
Cyathostomins	– Direct, non-migratory life cycle with free-living egg and larval stages
	– Third-stage larvae infective to definitive host
	– Prepatent period about 40 days. Larvae develop in wall of large intestine. Hypobiosis as fourth- and fifth-stage larvae occurs and can persist for years. Encysted larvae can comprise up to 90 % of burden in temperate areas of the northern hemisphere
	– Adults, 7–25 mm long, found in the caecum and colon
	– Adults cause mild disease but larval development from the mucosal pool causes inflammation and gland hypertrophy. Clinical signs are nonspecific and include ill thrift, anaemia and possibly diarrhoea. High burdens can seriously compromise the health of the affected horse
	– Prefer temperate climates
Strongylus spp.	– Direct, migratory life cycle with free-living egg and larval stages
	– Third-stage larvae infective to definitive host
	– Prepatent period is 200–332 days. There is larval migration within the vessel walls of the host's gastrointestinal blood supply
	– Adults, 14–24 mm long, found in the large intestine and caecum
	– Moderately pathogenic, except for *S. vulgaris* which is very pathogenic. Clinical signs include diarrhoea, pyrexia, anorexia, depression and weight loss. Larval migration can cause arteritis and thrombosis of intestinal blood vessels and may lead to bowel infarction and necrosis
	– Prefer temperate to warm and moist conditions
Parascaris spp.	– Direct, migratory life cycle with free-living egg and larval stages
	– Egg containing second-stage larvae infective to definitive host
	– Prepatent period is 70–84 days. Larval migration is hepato-pulmonary
	– Adults, 150–200 mm long, found in the small intestine
	– Mild to moderately pathogenic. Infection more common in horses under 2 years. Migrating larvae damage liver and lungs, and heavy infections of adult worms may cause impaction and perforation of small intestine. Clinical signs can include diarrhoea, colic and coughing, though most infections are subclinical
	– Mature female is highly fecund, producing up to 200,000 eggs per day
	– Eggs are extremely resistant in the environment and develop in all climates
Oxyuris equi	– Direct, non-migratory life cycle with free-living egg and larval stages
	– Egg containing third-stage larvae infective to definitive host
	– Prepatent period about 150 days
	– Adults, 9–150 mm long, found in the colon and rectum
	– Mildly pathogenic. Mature female lays eggs around the anus, causing intense perineal pruritis. Clinical signs include dull hair coat, hair loss, inflammation and scaling of the skin over the rump and tail head and weight loss due to restlessness and impaired feeding
	– Mature female is highly fecund, producing up to 50,000 eggs per day
	– Perineal environment provides ideal warm, moist microclimate for larval development. Spread to other horses favoured in a stable environment

cause chronic damage to bile ducts. Clinical signs include anaemia, exercise intolerance, jaundice, weight loss, reduced appetite and submandibular oedema.

3 Anthelmintic Classes, Modes of Action and Mechanisms of Resistance

Anthelmintics are designed for the purpose of treating infections with parasitic helminths. The major anthelmintic groups used in livestock worldwide include benzimidazoles, triclabendazole, imidazothiazoles/tetrahydropyrimidines, macrocyclic lactones, amino-acetonitrile derivatives, organophosphates, salicylanilides/substituted phenols and spiroindoles.

Each class of anthelmintic has a distinct mode of action and acts at a specific biochemical target site or sites. This specificity is the reason for their selective toxicity (killing helminths of particular phyla but not killing hosts) because even sites with equivalent function differ sufficiently between species. Importantly, resistance develops in a parasite to one chemical class at a time and the change renders them resistant to all members of that class. Resistance is inherited. In the simplest case, where an individual parasite is resistant due to a single genetic feature, a population of parasites will contain a certain proportion of resistant individuals. As that proportion increases then resistance is said to increase and this may be reflected in survival following treatment, survival in a test for resistance or an increase in the frequency of

a gene linked to resistance. Selection processes for each anthelmintic class are independent, but multiple resistance (resistance to more than one anthelmintic class) can occur in individual parasites.

Knowledge of resistance mechanisms can assist in developing tests for resistance. For example, if the molecular basis of resistance is known and it is the only or most common mechanism in a species, then molecular tests can potentially be developed to detect or describe the particular resistance. Even if they are not a confirmed mechanism of resistance, molecular changes may still provide useful markers. In another example, if a drug acts by causing paralysis, tests using egg hatching or larval migration may be useful if the resistance is expressed in eggs and larvae. The most common resistance mechanisms are changes in drug target molecules at the site of action and such changes may reduce the affinity of the drug for target sites in resistant compared with susceptible parasites. However, other mechanisms are possible such as changes in the structure or expression of proteins that function to lower drug levels in parasites through enhanced drug efflux or metabolism. Differences in genes associated with resistance may be referred to single-nucleotide polymorphisms (SNP). A difference in a single codon may confer a single amino acid difference in a protein sequence and lead to changes in the effect of the drug. A recent summary of the status of research into mechanisms is provided in Kotze et al. [23]. Only a summary of points pertinent to testing is provided here.

A large number of investigations have been conducted into resistance mechanisms; however very few observations have been found to provide conclusive explanations. One challenge that requires consideration is that resistance induced in the laboratory does not always arise through the same mechanisms as field resistance (where parasites are exposed under normal selection and survival conditions). As a result, the proposed mechanisms may be incorrect when applied to field resistance. Other challenges are that genetic variability in natural parasite populations confounds analysis and that worms respond to treatment by up- or down-regulating genes in ways that are protective rather than reflecting resistance mechanisms. Approaches to elucidating molecular mechanisms have relied largely on candidate gene approaches where researchers explore theories based on phenotypic observations. Whole-genome approaches are now available where lines of parasites can be compared using high-throughput sequencing and bioinformatic analysis. Nevertheless, proving the relevance of a mechanism is a difficult task.

The following is a brief summary of the current understanding of the modes of action (MOA) and mechanisms of resistance for the key anthelmintics currently used for the control of GIN and trematode parasites of livestock. The link between phenotype and genotype is emphasized here because of possible use of this knowledge in tests for resistance.

3.1 Benzimidazoles

Benzimidazole (BZ) carbamates have been used for parasite control in a number of species for several decades. The individual benzimidazoles show varying spectra and levels of activity. Albendazole is used in cattle and sheep for abomasal and intestinal nematodes, and is active against adult liver fluke at higher doses [24]. Ricobendazole has a spectrum of activity equivalent to albendazole [25]. Fenbendazole is used in sheep and cattle for susceptible abomasal and intestinal nematodes, and in horses for control of cyathostomins, *Strongylus*, *Oxyuris* and *Parascaris* at higher doses. Fenbendazole is the sulphide parent compound of oxfendazole, which is used for control of the same parasites [25]. Oxibendazole is used for control of susceptible GIN in cattle, sheep and horses [25].

These compounds bind to parasite β-tubulin causing microtubule depolymerisation and inhibiting a range of vital cellular processes. The discovery that tubulin from resistant parasites has lower binding affinity for BZs [26] led to exploration of the tubulin genes. Resistant isolates of many nematode species show a variable number and location of SNPs which confer amino acid changes in β-tubulin isotype 1. The following have been reported: (the notation for these SNPs in susceptible amino acid is followed by the position, and then the resistant amino acid) position 167 (F167Y), position 198 (E198A) and position 200 (F200Y). Generally, only one of these 'resistance' polymorphisms occurs in an individual worm and homozygous genotypes confer the resistance phenotype. In highly resistant parasite populations these polymorphisms appear in between 50 and 100 % of parasites which suggests that there are also other sites that modify resistance.

3.2 Triclabendazole

Though chemically a member of the BZ class of anthelmintics [63], triclabendazole has some unique structural differences and is only effective as a narrow spectrum treatment against the immature and adult stages of susceptible *Fasciola* in livestock [64]. Triclabendazole is the most widely used flukicide in sheep and cattle and is also effective in horses [36] though not often officially registered for this host species.

The exact mode of action of triclabendazole is uncertain [65], though it does not appear to interfere with tubulin like other benzimidazole compounds. Triclabendazole also has a stronger affinity for albumin than other benzimidazoles [66]. Suggested effects include interference with calcium transport in fluke, damage to fluke tegument, uncoupling of oxidative phosphorylation and interference with fluke protein synthesis or reproduction [65, 67, 68]. Recent research suggested influence on Pgp efflux of triclabendazole from resistant fluke [68].

3.3 Imidazothiazoles/Tetrahydropyrimidines

Levamisole has a broad spectrum of activity against susceptible mature stages of many major GIN of sheep and cattle, but shows less activity against immature forms and is ineffective against hypobiotic larval stages [25]. Levamisole has a relatively narrow safety margin, and is not approved for use in horses. Pyrantel and morantel are active against luminal parasites and are used widely against GIN of horses.

Tetrahydropyrimidines and imidazothiazoles have a common mode of action as cholinergic agonists at neuromuscular junctions causing spastic paralysis. The phenotype of resistant parasites involves reduced contractile response to these drugs as well as to acetylcholine [27]. These pharmacological differences suggest a change in the acetylcholine target site which is a pentameric membrane cation channel composed of ligand-binding and structural subunits. Following on from earlier studies, recent work has shown that a number of resistant isolates from several countries have a truncated transcript of *Hco-acr-8* likely due to an insert (indel) of 63 base pairs that is absent from susceptible worms [28]. A PCR-based test which selectively amplifies a product which includes the indel is proposed as a means of identifying resistant parasites. There is still work to do to validate the test and to elucidate the mechanism which probably relates to the likely role of *acr-8b* as an acetylcholine receptor subunit.

3.4 Macrocyclic Lactones

Macrocyclic lactones (MLs) are extremely potent and relatively safe parasiticides, active against immature and adult stages of ruminant GIN, including hypobiotic larval stages as well as tissue-dwelling parasites [29]. Several are also ectoparasiticides [29]. The ML class includes two subclasses: avermectins (AVM) (e.g. abamectin (ABA), ivermectin (IVM), doramectin (DOR), eprinomectin (EPR) and selamectin (SEL)) and the milbemycins (MIL) (e.g. moxidectin (MOX) and milbemycin (MILB)). MOX has been found to persist in adipose tissue, and this is thought to explain why MOX has been found to persist in plasma for significantly longer than ivermectin in cattle, sheep and horses [30, 31]. IVM, ABA and MOX are the only MLs used in horses and control susceptible *Parascaris*, *Oxyuris*, large strongyles and adult cyathostomins. In addition, MOX is effective against encysted stages of the cyathostomins, although efficacy is not complete [29, 32–35].

Macrocyclic lactones are agonists of glutamate-gated chloride channels (GGCC) in pharyngeal and body musculature of nematodes where they cause hyperpolarisation and relaxation. The subclasses may differ in some chemical characteristics, but are broadly thought to act in the same way and do share side resistance in cases of field resistance across several species. Further, some isolates of AVM-resistant parasites differ phenotypically, suggesting that there may be more than one mechanism responsible for resistance. The large number of putative mechanisms of resistance has led to suggestions that ML resistance is multigenic. In contrast, it is known that resistance developed extremely quickly against ivermectin, in less than eight generations, and so a single major gene seems a more likely explanation. Another confusing issue is that IVM appears to act at several sites.

When susceptible and resistant adult parasites from several species were studied in vitro the inhibitory effects (relaxation of body muscle) of the MLs were weaker in resistant isolates [36] and this effect occurred over a period of less than 1 min. Potential GGCC target sites have been cloned and expressed and ML binding to these proteins occurs, but changes in affinity or consistent molecular changes have not been found and so receptor site changes are unlikely to be involved in resistance mechanisms. Effects on drug transport as a mechanism of resistance have also been explored. The p-glycoproteins (Pgp) are transmembrane drug efflux proteins known to pump IVM out of mammalian cells. The hypothesis is that enhanced drug efflux can confer resistance. Whilst studies on transcription of various Pgp genes have been performed and several efflux inhibition studies attempted, unequivocal evidence of enhanced Pgp efflux as a mechanism of resistance to MLs in nematode parasites is lacking. Early descriptions of IVM-resistant *H. contortus* showed abnormal amphidial neuron morphology [37] and this suggested changes in chemoreceptor function. Some IVM-R *C. elegans* [38] have a defective dye-filling phenotype associated with the *dyf-7* gene. The *H. contortus* homologue, *Hco_dyf-7*, from a number of resistant isolates contains several SNPs that differ from susceptible worms, although none of the SNPs code for amino acid differences [39]. Whilst a mechanism is not clear it may involve drug exclusion or drug removal in resistant worms. These findings give hope for a molecular test for future application.

3.5 Amino-acetonitrile Derivatives

The amino-acetonitrile derivative (AAD) monepantel is one of the newest anthelmintics available for GIN control in sheep [40, 41], with broad spectrum activity against adult and larval GIN [42, 43] and high relative safety for sheep [44, 45]. Monepantel is a cholinergic agonist known to cause hyper contraction and paralysis by acting at a unique site on nematode body muscle membrane receptors [40, 46]. Resistance has been explored in experimentally selected isolates of *H. contortus* and SNPs in the *mptl-1* cholinergic receptor subunit are linked to the resistance phenotype [47–49].

Field isolates of monepantel-resistant nematodes have now been reported [50, 51] and it is anticipated that molecular data from these field cases could shed light on mechanisms of resistance.

3.6 Organophosphates

Organophosphates inhibit acetylcholinesterase, leading to accumulation of acetylcholine at nerve endings and therefore disrupted neurotransmission through hyperstimulation of nicotinic and muscarinic receptors. This results in neuromuscular spastic paralysis and death of parasites [52], but can also pose safety risks for hosts. Current sheep treatments contain naphthalophos, which is effective against both adult and inhibited *Haemonchus* and is moderately effective against other GIN [53, 54], or pyraclofos in combination with albendazole [40]. A single case of naphthalophos resistance has been published [55], however little further investigation or records of other field cases have occurred.

3.7 Salicylanilides/Substituted Phenols

Salicylanilides and substituted phenols (SA) include closantel (CLS), nitroxynil (NIT), niclosamide (NIC) and oxyclozanide (OXY) [56]. These chemicals are strongly bound to plasma albumin, which may account for their high efficacy against blood-feeding parasites [57], especially *Haemonchus* and *Fasciola*, and prolonged anthelmintic effect in some instances [58].

Salicylanilides and substituted phenols uncouple oxidative phosphorylation causing energy depletion in parasites [59–61]. Toxicity can be a risk following large doses [62]. Whilst resistance has occurred, there have been no studies to further elucidate mechanisms.

3.8 Spiroindoles

Derquantel (2-desoxoparaherquamide) is a semi-synthetic derivative of paraherquamide used for GIN control in sheep [69]. Spiroindoles are toxic to horses [70]. Derquantel is newly available commercially only in combination with abamectin and this product has shown excellent efficacy against most adult and immature trichostrongyloids of sheep [69, 71, 72]. It has variable efficacy against *Teladorsagia* and immature *Haemonchus* [69, 71, 73].

Derquantel acts as a competitive, but selective, cholinergic antagonist, blocking cation channels in nematode muscle cell membranes [69, 74, 75] leading to relaxation and rapidly induced flaccid paralysis of parasite musculature [59, 69, 70]. There are no published cases of field resistance yet.

4 Development of Anthelmintic Resistance

From a practical viewpoint, anthelmintic resistance is generally thought of as being present when there is an ‘increased frequency of individuals within a population able to tolerate doses of a compound compared to the frequency in a normal population of the same species’ [76]. Anthelmintic resistance is also heritable, passed from one parasite generation to the next, with the inheritance pattern of the gene(s) responsible being a key factor influencing both the speed of development and spread through a helminth population [77].

As anthelmintic treatments are likely to remain a cornerstone of effective livestock parasite control for the future, it is important to understand the general principles and mechanisms of resistance, in order to help sustain remaining anthelmintic efficacy for longer. There also appears little hope of long-term reversion of resistant helminth populations back to susceptibility after a period of no further exposure to the selective anthelmintic [78].

Sutherst and Comins [79] describe three components to the genesis of resistance. The first is establishment. This is largely a random event influenced by the population size and diversity and the mutation rate for the gene(s) in question. The second step is development. In this process, the use of the selective agent (the anthelmintic) allows resistance to develop but the prevalence of resistant alleles is too low for resistance to be clinically apparent. In the third step, dispersal, there is further selection and spread of the resistance genes through the wider population of the organisms. During this phase, clinical resistance (also termed field resistance) first appears. The processes of development and dispersal are influenced by biology, management and chance events, such as linkage disequilibrium and gene dispersal via an intermediate host. These processes are driven by the drug selection, reflected in survival and subsequent reproduction of parasites following drug treatment.

Factors influencing the development and dispersal of anthelmintic resistance with regard to livestock parasites have been well reviewed [10, 14, 77, 80–86].

Inappropriate dosing is one of the simplest ways to accelerate the development and dispersal of anthelmintic resistance. Under-dosing individual hosts can be a problem [87] and was considered common in some major production systems due to underestimation of animal liveweights when calculating dosage [88]. There has been considerable effort in making sheep producers aware of this risk, but the practice change of weighing at least a sample of animals from each group and dosing appropriately for the liveweight of the heaviest individual is still far from widespread [89, 90]. There could also remain a risk with cattle and horse producers [85, 91].

Excessive treatment frequency also exposes parasite populations to further selection for anthelmintic resistance, without accompanying benefits of improved productivity, health and/or welfare [16, 76, 92–96]. This has long been rec-

ognised as a potentially significant issue for sheep enterprises, and, more recently, equine nematode control [91, 97, 98].

Delivery method can also influence the risk of the development and dispersal of anthelmintic resistance. Oral formulations are most common for small ruminants, despite the potential risk of influence from activation of the oesophageal groove reflex [99–102]. Many studies have demonstrated oral treatments as more effective than topical and injectable formulations of the same active [103–106], despite at times lower anthelmintic concentrations in the plasma of treated hosts. Lanusse et al. [84] discussed the implications of the specific targeted parasite with regard to choice of delivery route, and this could explain the apparent increased effectiveness of oral treatments in some circumstances. There are also particular concerns with topical treatments in cattle [16, 107, 108], with influences on bioavailability from host coat characteristics, prevailing climate and licking behavior of the cattle in some cases [101, 108–112]. Persistent exposure of helminth populations to anthelmintics through slow-release and long-acting formulations is another potential risk [16, 76, 113–117].

Fasting sheep before anthelmintic treatment, to slow digesta flow and improve gut residence time, can have beneficial effects on the efficacy of less soluble anthelmintics [101, 118, 119], though this is not a sensible strategy for products with lower margins of safety, such as levamisole and naphthalophos [115].

Administration of a combination of effective anthelmintics, each with a different mode of action, has been suggested as another means to help prolong anthelmintic efficacy [12, 76, 84, 115, 117, 120–131]. Combination products are commercially available in some countries [69] and administering more than one effective anthelmintic is a way to deliver a higher combined efficacy [22, 132–136] and/or delay the development of anthelmintic resistance [126–128]. Modeling studies showed that the speed of selection for anthelmintic resistance is reduced by combining highly effective anthelmintic actives [12, 127, 128]. Combinations exert a greater efficacy against resistant genotypes, especially those carrying genes for resistance to only one of the actives in combination. This results in fewer resistant survivors to treatment, and subsequently a greater dilution of survivors by the remaining susceptible population in *refugia* [12].

Another strategy whereby administration of more than one anthelmintic with different modes of action is important is quarantine drenching [16, 76, 85, 115, 117, 137]. Whilst apparently not completed effectively in many livestock enterprises [90, 116, 138], treatment of new animals coming into a population or those returning from environments where infestation with parasites was possible, with a combination of highly effective anthelmintic groups, is a vital part of an overall worm control strategy. This should reduce the risk of introduction of new resistance alleles in incoming stock. Enhanced benefits are also possible by placing such stock into a high-worm *refugia* environment following treatment [115, 117].

The concept of *refugia* is more complicated for livestock producers, but is recognised as one of the currently most critical influences on anthelmintic resistance development and dispersal [12, 76, 83, 85, 116, 117, 139–150]. Livestock producers require a major mind-shift [83, 151] when comparing *refugia*-based worm control advice to previous recommendations of moving treated stock to low-contaminated environments to prolong treatment benefits [139, 152]. However, helminth control programmes can result in high selection pressure for the development and dispersal of anthelmintic resistance if eggs from parasites surviving treatments are able to develop in an environment where there is little non-selected helminth egg contamination to dilute them [140, 152].

Increasing *refugia* within a helminth control programme can be achieved in two ways. Targeting treatments, by selecting only those hosts who are clinically or subclinically affected by helminths, can prevent treatment of every individual within a group. This allows the parasites from untreated hosts to continue to contribute genetics, which are less selected for anthelmintic resistance, to subsequent helminth generations.

The FAMACHA® system of basing sheep treatments for *Haemonchus contortus* on the clinical anaemia of individual sheep is one such strategy [153, 154]. Targeted or selective treatment strategies have also been discussed for non-haemophagic sheep parasites [146, 147, 155, 156] and cattle [157] and horse GIN control [19, 21, 83, 91, 158, 159]. However, the actual choice of which animals within each group to leave untreated, without an obvious indicator such as clinical anaemia, can be far from simple [19, 21, 83, 85, 147, 155, 160–162]. Some authors have suggested leaving whole groups of animals untreated within an enterprise, and using this whole group as a moveable source of *refugia* [163].

Another way to reduce selection pressure for increased anthelmintic development and dispersal is by avoiding treatments at key epidemiologically selective times of low *refugia* due to prevailing environmental conditions. For example, the so-called summer drenching of sheep in environments with an extremely winter rainfall-dominant climate, such as Western Australia, can result in heavy selection for anthelmintic resistance [10, 76, 82, 161].

With all worm control strategies that promote increased *refugia*, care is needed to monitor helminth burdens and ensure that grazing environments do not become excessively contaminated with parasites [146] and/or animals that are left untreated succumb to the effects of the remaining parasites [161].

5 Measurement of Anthelmintic Resistance

The ability to measure and monitor anthelmintic resistance is a key component of sustainable livestock helminth control. The measurement of resistance is often scored as survival of parasites following a treatment and so parasite numbers (or values that reflect parasite numbers) are commonly recorded. These values are then analysed statistically (e.g. using *t*-tests or *F*-tests) and comparative efficacies generated. Resistance may also be recognised as a reduction in the period of protection that a persistent treatment provides. This provides different types of data and may be amenable to survival analysis.

The ultimate aim is a simple, rapid, inexpensive assay that can be applied by the animal's side to simultaneously assess the efficacy of all relevant anthelmintics against all of the nematode species of interest.

In practice, this has, thus far, proved very difficult to achieve. Currently there are a range of methodologies, which are applied in various circumstances, many of which have significant limitations. The pressure is on to further develop in vitro and genetic tests, however there still remains a lack of knowledge of the basic genetics of resistance mechanisms in many instances. Test sample isolation from livestock faeces, the preferred method to promote practical collection by livestock producers, also continues to pose challenges.

It is also important to remember that while reduced apparent efficacy may suggest anthelmintic resistance, this is just one potential cause of treatment failure. Other causes include misdiagnosis of another mimicking aetiological agent, inappropriate drug choice for the causal parasite, rapid reinfection after treatment, recrudescence of the same infection and product quality or administration issues [164, 165]. Another example is where faster metabolism in goats results in poorer efficacy of antiparasitic compounds compared with sheep [166]. There are also suggestions of differences between donkeys and horses with regard to moxidectin treatment [167].

5.1 In Vivo Bioassays

5.1.1 Treat and Slaughter Studies

The preferred definitive test for anthelmintic resistance assessment in all livestock species is a controlled sacrifice, or treat and slaughter, study [164, 168–176]. This test involves artificial infection of worm-free definitive hosts, individual treatment of confirmed infested animals at the recommended dose for the respective anthelmintic(s) and counting of the total number of surviving helminths after the slaughter of the hosts and completion of total worm counts.

This allows controlled assessment of true efficacy against immature and adult stages of the test parasites. Inclusion of positive as well as negative control groups can also allow generation of dose–response curves and then also effective dose 50 (ED_{50}) and resistance factor (RF) calculations.

The main disadvantages of this method include the cost of animal purchase and disposal, the ethics of euthanasing animals and the creation of worm-free test animals. Accordingly, it is now preferred to perform slaughter trials only when a novel isolation is made, because in many cases the relationship and correlations between in vivo and in vitro assays for anthelmintic resistance in parasites have been established [177].

A similar principle has also been applied to assess anthelmintic efficacy against *T. colubriformis* and *H. contortus* using guinea pigs [178] and jirds [179], respectively. Although these techniques are not likely to be used for field detection, they are useful experimental models because several dose rates of drug can be tested more quickly and cheaply than in sheep.

5.1.2 Faecal Egg Count Reduction Test

The most commonly used practical assessment of anthelmintic resistance in the field is the faecal egg count reduction test (FECRT). This test can be used to determine the prevailing anthelmintic resistance status of the common, significant nematodes, and hence help guide the choice of effective treatments. It has also been used to survey the prevalence of anthelmintic resistance [168].

There has been much detailed discussion of the best methodology for this approach [77, 168, 175, 180–190]. In summary for small ruminants:

- The test involves the identification of a suitably infested group of host species. Younger animals (3–6 months old) are preferred to avoid complications due to host immune status, and tested animals should not have been treated with test products during at least the previous 6 weeks.
- Groups of 10–15 identified animals are randomly allocated to each treatment. Another group is also identified as untreated negative control animals.
- Typically a subsample of the heaviest animals is then weighed and each animal individually dosed at the manufacturer's recommendation for the heaviest animal in their respective treatment group. Animals in the negative control group remain untreated.
- Animals are re-sampled between 10 and 14 days after treatment, with individual faecal samples identified according to treatment group. It is important to collect these samples before infestations after treatment could complete patency.
- Standard McMaster faecal worm egg counts are completed, using a floatation methodology, on each faecal sample.

Arithmetic group means of individual worm eggs counts are then compared between each treatment group and the

negative control group, to calculate the percentage reduction in worm egg count as a result of each treatment. This equates to the 'efficacy' of the applied treatment. Individual worm egg counts are preferred over composite testing [191, 192]. Arithmetic means are also preferred, as they have been found to provide a better, less biased estimate of efficacy, compared to geometric means, especially when a portion of the pre- or post-treatment counts are zero [193].

Logarithmic error calculations can be used to calculate confidence limits of the reduction percentages. An alternative method to calculate confidence limits when efficacy and/or nematode aggregation is high has also been suggested by Dobson et al. [194]. The generally accepted definition of 'resistance' has been when arithmetic mean reduction is less than 95 % and the lower 95 % confidence interval is below 90 % [189]. The use of these two criteria has been thought to result in a 95 % confidence of detecting clinical resistance [189], though there have been some concerns about the validity of results when only slight loss of efficacy is beginning to occur. It has even been suggested that if only one of the accepted criteria is met then a finding be made of 'suspected resistance' [195].

With development and testing of new anthelmintics in mind, Dobson et al. have also proposed to reframe the FECR as a binomial proportion if efficacy is estimated to be 100 % [194]. Where n and x are the total number of eggs counted (rather than eggs per gram) for all pre- and post-treatment animals, respectively, p (the proportion of resistant eggs) $= x/n$ and per cent efficacy is $100 \times (1 - p)$ (assuming equal treatment group sizes and detection levels, pre- and post-treatment).

Reduction results can be further enhanced by including culture of the remaining faeces collected post-treatment [168, 175, 196]. This allows attribution of the post-treatment egg count within each group to each of the parasite genera identified via identification of the cultured third-stage larvae, and this can be particularly important when treated sheep contain at least some highly fecund *Haemonchus contortus* [168, 197]. Replacement of the McMaster method by other floatation and/or centrifugation methods could also enhance sensitivity in some circumstances, for example, when test animals are only excreting low egg numbers [183, 198].

Software tools have been developed to further assist calculations and minimise errors in the FECRT. RESO5 is an anthelmintic efficacy calculator which uses calculations based on those published in a report of the Working Party for the Animal Health Committee of the Standing Committee of Agriculture [199]. It provides upper and lower confidence limits along with the mean FEC reduction, and indicates whether resistance is present. The original RESO program, as developed by Leo Wursthorn and Paul Martin of CSIRO, has undergone various additions and modifications which have been integrated into the most modern addition at this time [11]. The 'eggCounts' package, designed by Torgerson et al. within the software package R, is based on hierarchical Bayesian framework and incorporates both sampling error and overdispersion between animals to rigorously analyse the results of faecal egg counts [200].

To a large extent the interpretation of FECRT relies on a correlation between egg counts and nematode numbers. This relationship is not always strong [168]. Also, some anthelmintics can suppress egg production, rather than kill resistant worms [168], and this can result in an overestimation of treatment efficacy. Zero egg counts post-treatment that suggest that the worms are drug susceptible may mask cases where worms resume egg production more than 14 days after treatment. Sensitivity can be improved by using reduced dose rates of drugs, but this approach requires a good knowledge of resistance phenomena.

Another major generally accepted potential limitation of the FECRT is that it can only detect clinical resistance, often not until the frequencies of resistance alleles reach 25 % or more in the nematode population [140]. Thus genetic changes within nematode populations are not detected until significant. This is often suggested to reduce the likelihood of the possibility of long-lasting nematode population reversion to anthelmintic susceptibility following periods without exposure to anthelmintics previously considered unusable due to resistance levels [201–204].

Finally, another barrier to wider field adoption of this test is low producer enthusiasm for multiple yardings of sheep and treatment and faecal sampling of individual animals. In an attempt to counter some of this reluctance, a simplified test, DrenchCheck-Day10, has been promoted to sheep producers in Australia (www.wormboss.com.au; accessed on 15 May 2015).

Application of FECRT specifically for cattle has been discussed by several authors, and it is generally agreed that accurate determination of anthelmintic resistance is more difficult for bovines [4, 16, 205–211]. Nuances in nematode egg output [80, 205, 212–214] and influences of anthelmintic formulation and delivery route can all influence resistance test results for bovine nematodes [181]. It is recommended that tested anthelmintics are delivered orally to cattle [181] and strongyle egg detection is made as sensitive as possible [207, 211]. Larger treatment group sizes, individual pre-treatment worm egg counts, multiple post-treatment faecal sampling times, differentiation of worm egg counts to nematode genera and further evaluation of appropriate calculation methodology could help improve confidence in results [17, 209, 210, 215].

The specific application of FECRT for horses has also been discussed in detail [4, 20, 91, 159, 216–221]. Similar issues, with regard to relatively lower individual worm egg counts and overdispersion and greater aggregation of worm egg counts, occur in horses as for cattle [159], and this, again,

emphasises the importance of maximising the sensitivity of egg detection methods. Interpretation can also be more complicated for equine nematodes, and must consider original, lower than typical for sheep and cattle, efficacy levels for some anthelmintics against sensitive populations when originally registered [221]. This all suggests the need to consider modification of traditional efficacy guidelines for defining anthelmintic resistance in equine nematodes [19, 220, 221], and/or investigating more appropriate calculations to validly assess worm egg count reduction under some circumstances [159, 216, 222–224].

Another detail to consider in the evaluation of equine nematode anthelmintic resistance is the egg reappearance period [221, 225–227]. Reappearance of nematode eggs in horse faeces, at an interval after treatment, has been suggested as a useful guide to the early detection of the development of anthelmintic resistance [228–230].

There are also complications to be considered in the application of FECRT for evaluation of anthelmintic resistance in *Fasciola hepatica* [164]. The FECRT technique was originally developed and endorsed for nematodes [169, 181] but has been used for flukes, despite the validity being questioned at times. The lower sensitivity of faecal egg detection for *Fasciola*, intermittent egg shedding by adult flukes and possibility of ongoing release of eggs from the gall bladder after effective treatment of adult flukes can all complicate accurate interpretation of the results [231–238]. Triclabendazole resistance also can become evident in the immature stages of the fluke, that are not producing eggs, and hence these can avoid detection when using an FECRT. Consideration of these factors can still allow worthwhile application of the FECRT for *Fasciola hepatica* [239], including the testing of composite faecal samples [240], however the coproantigen reduction test, as is discussed later, is gaining popularity [235, 237, 241]. Application of PCR testing to better assess treatment effects on *Fasciola* has also been evaluated [242].

5.2 In Vitro Assays

In vitro methods of detection of anthelmintic resistance have received considerable attention, as potentially less expensive and time-consuming and more reliable, though usually more technically demanding, techniques to assess anthelmintic resistance.

By measuring the effect against a representative sample of parasites at each range of drug concentrations, a plot of response to treatment against dose can be generated. From this, the effective concentration 50 (EC_{50}) can be calculated. Modern computer analysis (e.g. GraphPad PRISM) has enabled more accurate curve fitting, as well as automated calculations of EC_{50} and standard errors. The EC_{50} is the effective concentration or dose of drug that affects 50 % of the parasite population. Similar expressions include the ID_{50} (inhibitory dose), LD_{50} (lethal dose), LC_{50} (lethal concentration) and CD_{50} (curative dose). The ratio of EC_{50} values between resistant and known susceptible populations of the same species is known as the resistance factor (RF).

5.2.1 Egg Hatch Assay

The egg hatch assay (EHA) was initially developed for the detection of thiabendazole resistance in sheep nematodes [243] and has been evaluated many times since for the assessment of benzimidazole resistance in sheep nematodes [244–252]. It has also been investigated for cattle [208, 253] and horse nematodes [152, 218, 254–258] and the detection of albendazole and triclabendazole resistance in *Fasciola hepatica* [242, 259–261].

The technique is described in detail by Taylor et al. [171] and Coles et al. [181]. In principle, fresh, clean, undeveloped helminth eggs are collected and incubated in the presence of a range of concentrations of the anthelmintic of interest. Following incubation, the proportion of unhatched eggs compared to larvae is calculated, after correction for egg mortality without the presence of anthelmintic, and a dose–response curve can be generated [258]. If possible, the known discriminating dose of the anthelmintic, which would result in 99 % or more of hatch inhibition in susceptible nematode isolates, is included to help increase test sensitivity [140, 181, 246]. There are concerns that EHA will not detect resistance until at least 25 % of the nematode population is resistant [140].

5.2.2 Larval Based Assays

The best characterised in vitro assay is the larval development assay (LDA) [177]. This test relies on the development of eggs, in a liquid or agar culture media, to first-, then second-, and then third-stage larvae in the presence of a range of concentrations of anthelmintics of interest. The proportion of eggs, L1 and L2 of the total eggs and larvae is calculated after correction for the number of undeveloped stages in the negative control replicates.

Advantages of the LDA include the following: a single, relatively simple composite faecal sample collection, no need to test susceptible isolates, simultaneous assessment of several anthelmintics is possible, dose–response data can be generated and sensitivity can be greater than 95 %. General disadvantages include that the validity of the assay as a measure of resistance must be confirmed under a range of conditions, trained laboratory staff are required and species identification of larvae is needed.

A commercial product, with anthelmintics pre-applied to a 96-well plate, was available as the Drenchrite® Test (Microbial Screening Technologies, Smithfield, Australia). This and other LDA methods have been utilised successfully to

assess a range of GIN from sheep and goats for benzimidazole resistance and levamisole resistance, and also macrocyclic lactone resistance in *Haemonchus contortus* [244, 245, 251, 262–271]. The test however lacks adequate sensitivity for useful assessment of ivermectin resistance in *Teladorsagia* [272]. LDA have also been investigated for assessment of anthelmintic resistance in cattle nematodes [273] and in horse nematodes, with some good and some less convincing results [216, 254, 256, 258, 274, 275].

The larval mortality assay (LMA) assesses the ability of fresh, exsheathed third-stage nematode larvae to survive a range of serial dilutions of anthelmintics of interest, and has been shown to be able to assess benzimidazole resistance in sheep nematodes [276, 277].

The larval migration inhibition assay (LMIA) assesses the ability of freshly cultured, exsheathed third-stage nematode larvae, in the presence of serial dilutions of anthelmintics, to migrate through sieves that will only allow the passage of viable larvae [171, 276]. The proportion of non-migrated larvae compared to total larvae can be used to calculate the effective anthelmintic concentration to inhibit migration of 50 % of the larvae (EC50), which can then be compared to known standards. Agar barriers have also been added to the test to improve sensitivity in some cases [283]. The Micromotility Meter™ [36, 278, 279] and the Worminator system [280] have also been suggested as possible ways to automate motility measurements. These have shown promise with third-stage larvae of *Haemonchus contortus* and adult *Cooperia oncophora* [36].

The LMIA was originally developed for sheep nematodes and found to be able to determine resistance to thiabendazole, levamisole, closantel and ivermectin [276, 281–283]. It has also been shown to have application for moxidectin resistance in sheep nematodes [269] and benzimidazole, ivermectin and moxidectin resistance in cattle nematodes [36, 190, 207, 273, 284]. Preliminary considerations have also occurred for horse nematodes [258].

The larval feeding inhibition assay (LFIA) assesses the effect of exposure of fresh first-stage larvae to serial dilutions of anthelmintic concentrations on the feeding activity of the larvae [78, 285, 286]. This approach has shown promise for detection of ivermectin and levamisole resistance in sheep nematodes [247, 285] and has also been used for adult worms [287]. There appears little success with horse nematodes [258].

5.3 Molecular Based Assays

5.3.1 DNA-Based Assays

DNA-based tests offer the potential for very sensitive detection of resistance. They could also offer the opportunity to search for potential resistance before anthelmintic treatment [288]. However, in order to design and use gene probes, the genetic basis of resistance must be known, and this is far from certain in most of the significant anthelmintic resistance examples for livestock.

Benzimidazole resistance is the only current example where genetic markers have been characterised and utilised to develop a useful assay for resistance. Resistance was first shown to be linked to the expression of tyrosine, rather than phenylalanine, at codon 200 of the isotype1 beta-tubulin gene [289, 290]. Other work has since identified additional candidate mutations at codon 167 [291] and codon 198 [292–294]; however these do not seem as consistent as resistance markers [291, 295, 296].

The marker at position 200 has been used to develop PCR-based resistance identification techniques in *Haemonchus contortus*, *Trichostrongylus colubriformis* and *Teladorsagia circumcincta* [181, 297–300], and *Haemonchus* spp. and *Ostertagia ostertagi* in cattle [295, 296, 301]. Investigations in horses have shown variable results [21, 219, 257, 302–305]. The latest work has investigated real-time PCR or pyrosequencing approaches to favour more practical field application of this molecular approach [248, 285, 306–309].

Recently a truncated transcript of *Hco-acr-8* was consistently identified in levamisole-resistant *Haemonchus contortus* [28]. This was absent from susceptible *Haemonchus* investigated in the same work, and thus was suggested as a potential marker genetic marker for levamisole resistance. Recent investigations into the *Hco_dyf-7* gene have also suggested this as a potential future marker for macrocyclic lactone resistance in *Haemonchus contortus* [39].

5.3.2 Immunological Based Assays

Given the concerns about the reliable application of FECRT for the detection of triclabendazole resistance in *Fasciola hepatica*, there has been some attention regarding the potential of ELISA tests to assist resistance detection. The development of a commercial coproantigen ELISA test (Bio-X Diagnostics, Jemelle, Belgium), based on the MM3 monoclonal antibody, offered more sensitive diagnosis that was also more responsive to successful fluke treatment than serological ELISA testing [310]. This test has shown promising results in a coproantigen reduction test, with post-treatment sampling 14 days after triclabendazole administration, in both sheep [235, 311, 312] and cattle [241].

6 Occurrence of Anthelmintic Resistance

6.1 Resistance in Sheep Helminths

Parasitic nematodes of sheep generally show greater levels and spectra of resistance to anthelmintics than those of cattle and horses (Table 78.4).

Table 78.4 Geographical distribution of reported anthelmintic resistance in important helminth parasites of sheep

	Benzimidazoles	Levamisole/ Morantel	Macrocyclic lactones	Aminoaceto-nitrile derivatives	Organophosphates	Triclabendazole	Salicylanilides

6.2 Resistance in Cattle Helminths

Despite widespread interest in anthelmintic resistance development in sheep and goats for decades, the investigation of anthelmintic resistance in cattle nematodes has only begun comparatively recently (Table 78.5). The prevalence of resistance in cattle GIN has proven to be surprisingly high in some regions.

6.3 Resistance in Horse Nematodes

The investigation of anthelmintic resistance in equine GIN has also only begun comparatively recently (Table 78.6).

In 1999, Coles et al. [344] reported suspicions of pyrantel resistance in *Strongylus vulgaris*; however no cases have been reported since.

7 Conclusion

Anthelmintic resistance is redefining best practice livestock helminth control. The traditional approach of regular prophylactic treatment without resistance monitoring has proved to be an unsustainable method of control.

The development and sustainable utilisation of novel anthelmintics are important for controlling parasite populations into the future, but a carefully planned approach combining chemical and non-chemical based control strategies is also required to slow the development of resistance and maintain the utility of remaining effective drugs now. Better understanding of resistance mechanisms and better practical and cost-effective tests to allow earlier detection of anthelmintic resistance changes in a parasite population will also be very valuable.

Part XII

Measurements of Drug Resistance

In Vitro Performance and Analysis of Combination Anti-infective Evaluations

79

Robert W. Buckheit Jr. and R. Dwayne Lunsford

1 Introduction

Antiviral or antimicrobial drug resistance and drug toxicities have provided great impetus to develop combination drug therapies that will suppress the emergence of resistant organisms and allow lower, less toxic doses of drugs to be administered. The evaluation of the activity of combinations of two or more anti-infective compounds has gained significant prominence in light of the innate ability of many infectious organisms to rapidly acquire drug resistance. Pathogens react to the administration of anti-infective agents by the outgrowth of preexisting infectious clones with resistance-engendering mutations and by accumulation of new mutations to allow escape from the suppressive effects of therapeutic drug regimens [1]. Resistance emerges through the error-prone mechanisms of the replicative machinery and through the transmission of resistance elements [2, 3], rendering monotherapeutic drug strategies problematic. Combination chemotherapy significantly decreases the risk that resistance will arise. In addition, combination chemotherapy may ameliorate toxicity by permitting lower and less toxic or nontoxic concentrations of synergistic drugs to be utilized.

In convergent combination therapy [4, 5], the drugs used in the combination target the same functional protein or enzyme, and there is the possibility that lower doses of the individual drugs might be used. A specific therapeutic regimen of several drugs that target multiple essential steps in the replication of the organism is sometimes referred to as divergent drug therapy [5]. This strategy benefits from the possibility that organisms resistant to one of the drugs in the combination therapy will remain completely sensitive to the others, whereas cross-resistance may also emerge, in the case that the drugs inhibit the same replication target. In some cases, targeting the same enzyme or protein may still be considered a divergent therapy since the target may include multiple sites for anti-infective action.

Combination therapies have taken great strides forward with the advent of highly active antiretroviral therapies (HAARTs) for patients with human immunodeficiency virus (HIV) infection, yielding therapeutic regimens routinely involving three to four drugs and creating additional challenges of compliance and drug–drug interactions. An example would be the use of nucleoside and non-nucleoside reverse transcriptase inhibitors which target distinct functional and structural components of the viral reverse transcriptase in treatment of infection by the human immunodeficiency virus (HIV) [6].

Another advantage of combination therapy strategies is that multiple infectious organisms can be targeted [7]. The prevalence of coinfections involving HIV is increasing [8], and it is critical to understand the effects of the HIV therapeutic agents when used in patients that are also administered as direct-acting antiviral agents targeting hepatitis C virus (HCV) or other opportunistic bacterial and fungal infections, including tuberculosis. Similarly, respiratory infections often include both viral and bacterial components [9], and thus it is important to understand the effects of drug interactions on the efficacy and toxicity of the agents targeting the individual agents.

Also of interest is the lack of approved combination therapy for infectious agents such as HBV, herpes viruses, and influenza viruses; the issue is attributed to either the small number of approved antiviral agents being within the same mechanistic class of inhibitor, the overall treatment expense, or the lack of standardization in analysis of the combination results. It is hoped that the in vitro evaluation of combination drug interactions will provide a quantitative and prioritized rationale for the development of specific combination therapies that will enhance the efficacy of therapy, reduce the incidence of drug resistance, and allow for less toxic and demanding therapeutic regimens.

Finally, though most in vitro combination assays involve the evaluation of efficacy, the evaluation and understanding of combined toxicity and possible antagonistic antiviral interactions are also of paramount importance as the therapy moves into the clinic [10]. For both efficacy and toxicity, the dose–response curve that is evaluated in vitro must define the drug interactions over a broad checkerboard pattern of drug concentrations. This thorough analysis allows the investigator to define the interactions at multiple drug ratios and identify the dose–response areas where different and distinct efficacy and toxicity interaction regions exist. For example, the combination nucleoside strategy of AZT and ribavirin employed in HIV therapy results in two completely different regions of interaction between the drugs, with a region of extreme synergistic antiviral activity giving way to a region of significant antagonistic antiviral activity [11]. Since the combination drug concentrations employed in the in vitro assays can only be truly evaluated at those concentrations that yield less than or equal to the maximal 100 % protection as evaluated from replication or growth of the infectious organism, the combination assays often are performed at concentrations which are much lower than those that would be utilized in the clinic and thus are inadequate for truly evaluating toxicity or efficacy effects at high concentrations. Separate assays at appropriate drug concentrations should always be performed to evaluate toxicity effects in parallel with efficacy evaluations.

In the discussion below, the methodology routinely used to define combination anti-infective evaluations is described. Evolving from the early use of isobolograms and the evaluation of combination chemotherapy strategies for use in cancer patients [12, 13], the combination interaction evaluations used in the past two decades for anti-infective research have primarily involved one of two methods: the three-dimensional surface models as described by Prichard and Shipman [14] and the median dose–effect equation developed by Chou and Talalay [15]. A detailed discussion of the primary methodology considerations and analysis alternatives for the performance of combination anti-infective assays will be provided, followed by a discussion of assay modifications that should be employed to fully define the effects of a drug combination regimen. The novel variations of standard combination assays described provide a greater understanding of the effects of combination therapy in the cellular and tissue environments where the interactions will occur.

From the perspective of effective and efficient drug development, it is critical to understand both the benefits and limitations of the assay methodologies used to evaluate drug combination interactions and the meaning of the results that are obtained. The goal is to choose the appropriate biological assay for use in the evaluations as well as the correct statistically relevant analysis option to define the interaction of the compounds. For combination assays, the in vitro analyses are reasonably straightforward, though adequate assay repetition must be used in order to truly and quantitatively determine the interaction of multiple chemotherapeutic agents. Translating in vitro data to in vivo utility is difficult in light of the natural pharmacokinetic variation in drug concentrations that occur in patients, but several pharmacokinetic models have been described that allow a greater understanding of the relevance and predictability of the in vitro results [16–18]. It is also important to appreciate how these combination data will be viewed by regulatory agencies prior to clinical testing. From a regulatory viewpoint, it is fair to say that the absence of synergistic toxicity and/or antiviral antagonism should be carefully evaluated and confirmed as synergistic, or additive results will be dependent on the dose and regimen used in the clinic and may not be predictable from in vitro assays [19].

The methodology and analysis tools described below are useful for both in vitro and in vivo evaluations and are applicable across the complete spectrum of anti-infective organisms for which combination therapy strategies must be developed.

2 Methods

2.1 Definition of the Dose–Response Curve and Selectivity Index for the Drugs Evaluated

Determination of the efficacy and toxicity of drug interactions requires the appropriate cell-based or biochemical/enzymatic assay and accurate statistical evaluation. The assays utilized for combination drug evaluations should be chosen carefully based on the proposed use of the drugs in the clinical setting. In some cases, both cell-based and biochemical assays [20, 21] are required to fully understand the combined effects of the drugs. Evaluation in multiple cell types, including fresh and established human cells, may be necessary depending on the target-cell specificity of the infectious organism.

The starting point for all in vitro evaluations of combination drug interactions is the precise determination of the dose–response curve for each of the individual agents that will make up the combination therapy in the appropriate assay model. The assay or assays will yield efficacy values at the 25 %, 50 %, 90 %, 95 %, and 99 % level (EC_{25}, EC_{50}, EC_{90}, EC_{95}, and EC_{99}, respectively). It is these efficacy concentrations that will be used in the combination assay methodology to set the correct dose–response surface to be evaluated in a checkerboard pattern of drug concentrations. Additionally, it is important to understand the concentrations of the test compound that cause direct cytotoxicity or cytostasis, yielding 25 %, 50 %, 90 %, 95 %, and 99 % inhibition of cell growth

(IC_{25}, IC_{50}, IC_{90}, IC_{95}, and IC_{99} concentration values, respectively). Upon definition of the efficacy and toxicity values for a drug across its dose–response curve, the selectivity (or therapeutic) index of the drugs can be calculated (SI_{25}, SI_{50}, SI_{90}, SI_{95}, or SI_{99}); the SI is obtained by calculating the ratio of the IC concentration to the EC concentration at a defined level of protection (IC*x*/EC*x*) where *X* is defined as the percent level of protection achieved [20].

The evaluation of the interaction of two drugs requires the selection of a dose–response curve for each of the test agents that begins at doses below a concentration yielding any biological effect, increasing in concentration until complete inhibition of the replication of the infectious organism is achieved. Once the dose–response curves for each individual component of the combination therapy have been defined, the combination of the two drugs in a checkerboard pattern will yield a broad dose–response surface in three dimensions with the drug concentrations forming the *x* and *y* axes and the biologic effect on the *z* axis. The individual dose–response curves form one part of the complete dose–response surface that can be evaluated.

In performing combination assays, it is important to recognize that in most in vitro assay systems, the end point boundaries range between 0 and 100 % inhibition, and thus combination drug effects cannot be quantified where the additive or synergistic interaction of the two compounds would be expected to exceed 100 % inhibition. The concentrations of the agents to be tested must be carefully chosen so that the activity of the two drugs is not evaluated at a large number of points where additive inhibition exceeds 100 %. Similarly, the combination interaction cannot be quantified when an antagonistic interaction results in the level of efficacy falling below 0 % protection, or where combination toxicity effects result in percent toxicity exceeding 100 %. In addition, the interaction of the two drugs may be different at different drug ratios, with the possibility of defining distinct regions of synergy, additivity, and antagonism across the entire dose–response surface. In general each of the test compounds will be evaluated over a range of concentrations that yield a progression of activity from 0 through 100 % with constant incremental increases in drug concentration. The most sensitive measure of compound interactions over the complete dose–response surface occurs when the incremental increases in drug concentrations are small (two- to threefold) from tested dose to the next higher tested dose.

Finally, the design of the combination assay is dependent on how the data will be analyzed at the conclusion of the experiments. For some analyses, such as the original Chou and Talalay methodology (see below), the assay configuration will involve selection of a ratio of the two drugs to be evaluated and the testing of the effects of the drug combination in fixed multiples of that ratio. Recently, it has been recognized that drug interactions must be observed over a very complete dose–response surface [22], and so most analyses are performed with a checkerboard of drug concentrations where every possible combination of concentrations of the two drugs is tested together, yielding a complete three-dimensional combination dose–response surface. Over the years the methodology employed to define the effects of two compounds used together has dramatically improved. The discussion below provides an overview of methodology that has been employed when investigators evaluate combination drug efficacy and toxicity.

It should be noted and emphasized here that the greatest problem with the performance of combination assays is overall assay reproducibility. The size of the combination assays can be extremely large (over 450 data points per assay for three-dimensional models such as MacSynergy II), and data are accumulated across multiple microtiter plates, yielding some level of data variability from assay to assay (inter-assay variability) and plate to plate (intra-assay variability). For combination drug analysis, it is thus important to develop and optimize assays with minimal inter- and intra-assay variation [23]. Our experience indicates that the overall interpretation (synergy, antagonism, additivity) is highly reproducible. Variability is usually observed in the peak level of synergy or antagonism and in the concentration of each drug that results in the peak of synergy or antagonism. In general, combination assays must be replicated in order to precisely and quantitatively define the interaction of two drugs; in our experience that has meant repetition of a given drug combination assay, a minimum of three to five times before the relative level of synergy and the concentrations employed to achieve maximal synergy can be discussed with confidence. Despite the use of microtiter plate formats, these assays require a substantial amount of test compound compared to routine anti-infective evaluations. For high-throughput screening prior to precise definition of the most potent combinations, single-plate combination assay formats may be used, especially under conditions in which test compound or target cells are limiting.

2.2 Analysis of the Interaction of the Drugs Used in Combination

The benefits of combination chemotherapy have long been recognized, and experience with the treatment of HIV infection has driven the utility of combination strategies to new levels of development with three to four drugs forming the core of current highly active antiretroviral therapies (HAART) regimens [24, 25]. The methodology used to analyze the results of combination testing also has evolved [11, 14, 22, 26–31]. A variety of statistical methods have been developed, all with inherent advantages and disadvantages. Over the entire course of preclinical development of an anti-infective

agent, each of these evaluation techniques may be best used depending on the type of assay employed. Some algorithms (such as the three-dimensional MacSynergy II programs) are best suited for extremely large sets of data, with many concentrations in replicate over a wide dose–response surface, whereas others are well suited for situations in which the number of data points available for analysis may be limited, such as in animal model testing (Chou and Talalay median dose–effect equations). The primary problems encountered in developing the models for the evaluation of combination interactions result from the fact that the combination dose–responses represent a three-dimensional issue analyzed in two dimensions and from the fact that no agreement on the definition of additive or synergistic interactions has been obtained [22]. Fortunately, the increasing use of automation and highly complex analysis performed by personal computers has allowed three-dimensional dose–response curves to be easily visualized and evaluated [14, 32].

In simplest terms, a three-dimensional combination drug assay has two independent variables (the concentrations of the two drugs being evaluated) and one dependent variable (the anti-infective activity of the drug combination). The activity of the drug combination can be visualized as a three-dimensional surface with the drug concentrations on the *x* and *y* axes and the biological effect of the combination on the *z* axis. At the zero concentration points for each individual drug, the two-dimensional dose–response curve for a single drug can be observed in the three-dimensional dose–response surface. Evaluation of this three-dimensional surface and defining in statistical terms how the compounds interact have been accomplished by a variety of methodologies discussed in more detail below.

The basic dose–response surface can be evaluated by connecting the 50 % inhibitory levels across the dose–response surface to create an isobol at the 50 % inhibitory value, with the line that is produced representing all combinations of the two drugs that achieve 50 % inhibition of the replication of the infectious organism. The isobol, or line of equal elevation, was originally derived from cartography and is simply the contour line representing various levels of inhibition of the organism [33–41]. The isobologram is the two-dimensional contour plot that results [35, 36, 40]. The shape of the contour lines forming the isobologram represents the three-dimensional dose–response surface and thus provides the definition of the interaction of the two compounds as synergistic, additive, or antagonistic [14, 31, 33, 42–46]. Typically, isobolograms are plotted at the 50 % inhibitory concentration; however any fixed inhibition value can be utilized, and in most cases, multiple isobolograms should be evaluated to understand the interaction of two drugs across the entire surface, since the complete dose–response surface may include regions of synergy, additivity, and antagonism.

In the development of the various analysis models, certain statistical principles were utilized as the basic assumptions underlying the evaluation of the data. For example, several of the programs, notably those defined by Chou and Talalay, based their approach on the median-effect principle [15, 47, 48]. The Loewe additivity model is the basis of the null reference model [39]. Loewe additivity assumes that two drugs should be indistinguishable from each other with respect to antiviral effects in a combination assay. Thus, in this analysis one assumes that if a given concentration of two drugs inhibits replication by a defined amount, any fractional concentration of one drug (Drug A) combined with the complementary fractional concentration of the second drug (Drug B) should inhibit replication by the same amount. Loewe additivity can be expressed as

$$1 = \mathrm{D_A} / \left(\mathrm{IC}_p\right)_\mathrm{A} + \mathrm{D_B} / \left(\mathrm{IC}_p\right)_\mathrm{B}$$

where D_A and D_B are equal to the concentrations of Drug A and Drug B in the mixture that elicits *p* percent effect and $(IC_p)_A$ and $(IC_p)_B$ are equal to the concentrations of Drug A and Drug B in the combination that elicits the same *p* percent effect on the replication of an organism.

Prichard and Shipman based their MacSynergy II analysis program [14] on the Bliss independence null reference model [49]. This model is based on statistical probability and assumes that two drugs should act independently to affect virus replication. Thus if Drug A affects the replication of a population of organisms to a defined level, then the addition of Drug B should affect the remaining population of organisms to the level it would have affected in the absence of Drug A. Bliss independence can be expressed as

$$Z = X + Y\left(1 - X\right)$$

where *X* is equal to the fractional inhibition produced by the dose of Drug A alone and *Y* is equal to the fractional inhibition achieved by Drug B alone and *Z* is equal to the predicted fractional inhibition.

Each of these models offers robust mathematical data interpretation. In the sections below, the various methods that may be employed to evaluate in vitro combination testing results will be described in greater experimental detail. Generally, the models that have been developed to evaluate drug combinations include the fractional product method, the multiple dose–response curve method, isobolograms, the combination index method, the differential surface analysis method, and parametric surface fitting methods [14, 15, 26, 32, 38, 43, 45, 46, 50–69].

2.2.1 Multiple Dose–Response Curves

The simplest method of interpretation of the effect of a second drug (Drug B) on the activity of a single agent (Drug A)

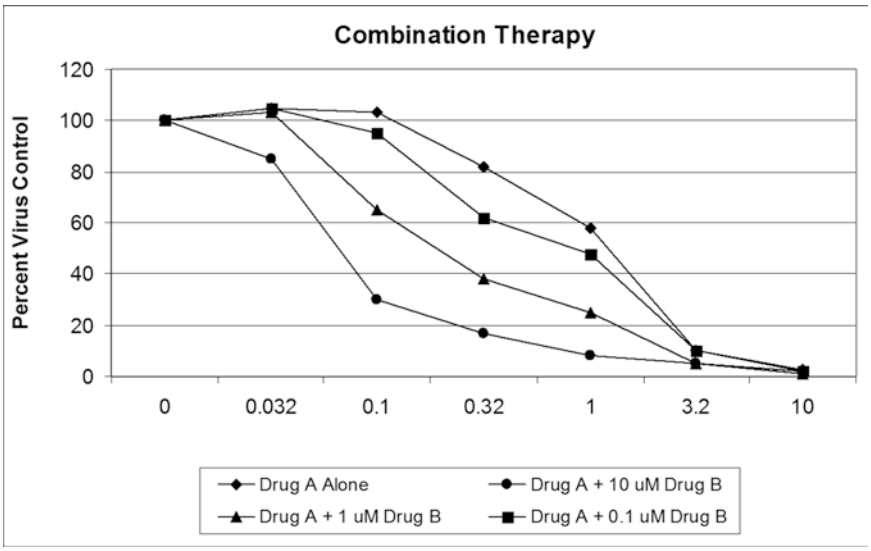

Fig. 79.1 Evaluation of combination interactions by multiple dose–response curve method. A representative example of the antiviral dose–response curve obtained with a single drug (Drug A) alone and with the addition of a single concentration of a second drug (Drug B). The various dose–response curves with increasing concentrations of Drug B may be compared to each other and that obtained with Drug A alone to evaluate the combination drug effect

is to evaluate the effect of a single concentration of Drug B on the dose–response curve of Drug A (Fig. 79.1). This evaluation superimposes the dose–response curves of Drug A obtained in the presence of Drug B, and increases or decreases in biological activity are observed as shifts in the dose–response curves due to the presence of the second agent. A wide variety of research papers have been published using this simple evaluation of the combination effects of two drugs [54, 59, 60, 65], and although the methods do not employ any statistical evaluation of the data that allow confirmation of the precise interaction as additive, synergistic, or antagonistic, the data evaluation does permit simple interpretation of positive or negative effects of the two drugs. Using this methodology, it is impossible to discriminate between slightly synergistic, slightly antagonistic, or additive interactions, although highly synergistic or highly antagonistic definitions are possible. Multiple dose–response curve evaluations are quite simple to perform, especially with a highly sensitive and reproducible assay system, but they obviously suffer from a lack of rigorous and statistics-based data evaluation and the ever-present issue of investigator bias in the interpretation of results.

2.2.2 Isobolograms

The classic method for detecting and characterizing departures from additivity between combinations is the isobologram methodology (Fig. 79.2) [39, 45, 56, 58, 63]. This method was originally introduced by Fraser [35, 36]. The use of the isobologram technique for analyzing drug combinations was extended by the work of Loewe and Muischnek [39], Loewe [38], and Berenbaum [33] (also see reviews by Gessner [37], Wessinger [41], and Berenbaum [34]). The isobologram is essentially a contour plot of a constant dose–response over the dose–response surface compared to a plot of the same contour under the assumption of additivity. Thus,

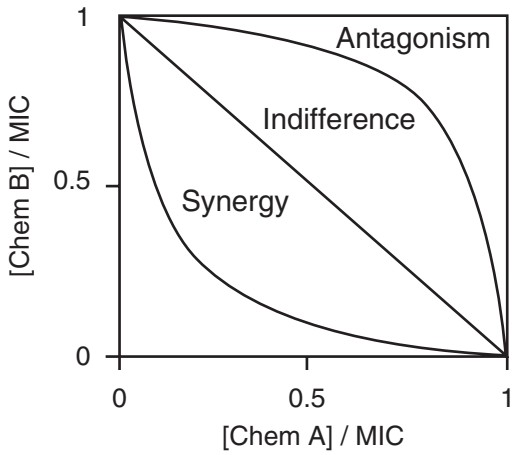

Fig. 79.2 Evaluation of combination interactions by isobologram method. A representation of the classical isobologram method for the evaluation of compound interactions

for a two-drug combination assay, the isobologram analysis compares the concentrations required to achieve a certain dose–response (such as 50 % inhibition of replication) to the line of additivity, formed by joining the 50 % inhibition concentrations of the two drugs when used alone as calculated experimentally. If the observed isobol falls below the line of additivity, the two drugs interact in a synergistic manner; if they fall above the line of additivity, the drugs are antagonistic. The predominant problem associated with the use of isobolograms to predict drug interaction is data variability. Isobolograms can be used to calculate the predicted interactions of two- or three-drug combinations.

2.2.3 Combination Index Method

Another widely used and accepted method for the analysis of anti-HIV data is the combination index method of Chou and

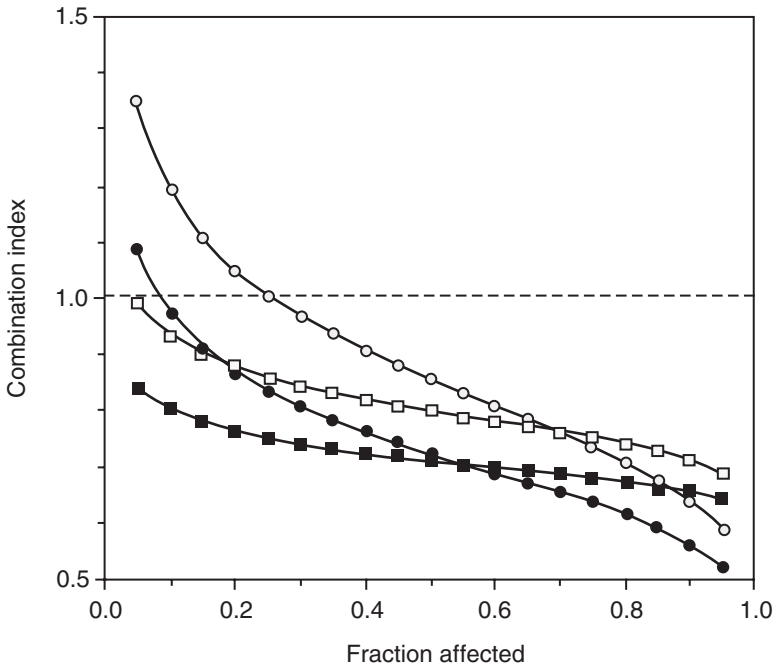

Fig. 79.3 Evaluation of combination interactions by median dose–effect equation method. Representative compound interactions as evaluated by the Chou and Talalay median dose–effect equation

Talalay (Fig. 79.3) [15, 26, 32, 51, 61]. As originally proposed, the experimental design of the Chou–Talalay method required that the total concentration of two drugs be altered, while fixed concentration ratios for the two drugs were maintained. The popularity of this method lies in the fact that relatively few samples are required for computer-based analysis and prediction of the nature of the drug interactions. However, since fixed drug ratios examine only the drug interactions along diagonal lines across the dose–response surface, it is possible the drug ratios chosen by the investigator do not reveal localized areas of synergism and/or antagonism on the drug dose–response surface plot. This means that several fixed-ratio drug combination experiments must be conducted to examine all diagonal lines across the dose–response surface. Recent adaptations of the combination index model now allow for the analysis of checkerboard patterns of drug concentrations as opposed to fixed ratios. The statistical model of Chou and Talalay is reported to be most useful when data points are limited, such as in animal studies. The limitation of the Chou and Talalay method remains the lack of confidence intervals in the statistical analysis of the data.

Through utilization of Monte Carlo mathematical modeling techniques, a probabilistic model, called ComboStat, simulating processes influenced by random factors (e.g., experimental variability associated with repetition of drug combination studies) was developed [51]. Upon application of this mathematical model, statistically relevant confidence intervals have now been assigned to the combination index values produced by the Chou–Talalay method. Using this methodology, it is possible to accurately interpret the Chou–Talalay drug combination index and statistically discriminate between mild synergism/antagonism and additivity. Unfortunately, the use of ComboStat, like the original Chou and Talalay program, requires drug combination studies with fixed drug concentration ratios. As mentioned above, this approach only examines drug interactions at diagonal lines across the dose–response surface, and local domains of synergism and antagonism can be missed unless all diagonals on the dose–response surface are examined.

2.2.4 Three-Dimensional Surface Analysis

The Prichard and Shipman MacSynergy II model evaluates combination data with assumptions based on same-site or different-site modes of action [14, 53, 62, 66, 67]. The more rigorous evaluation assumes the compounds being evaluated act at the same site to inhibit the replication of the infectious organism. The MacSynery II algorithm utilizes the data obtained with each drug alone to calculate the expected level of inhibition of the drug combination at each drug concentration in a checkerboard pattern, generating a three-dimensional surface of expected activity (Fig. 79.4). The actual data points determined experimentally are derived from the antiinfective assay and are plotted as the Antiviral Surface Plot. The expected activities are subtracted from the experimentally determined values at each data point, resulting in the generation of a three-dimensional synergy plot. If the expected and realized activities at each point are identical, a flat plane results indicating the interaction of the two drugs is additive. If the realized activity is greater than the expected level of activity, positive values are obtained, resulting in regions extending above the plane. These points represent the drug concentrations at which the activities of the drugs

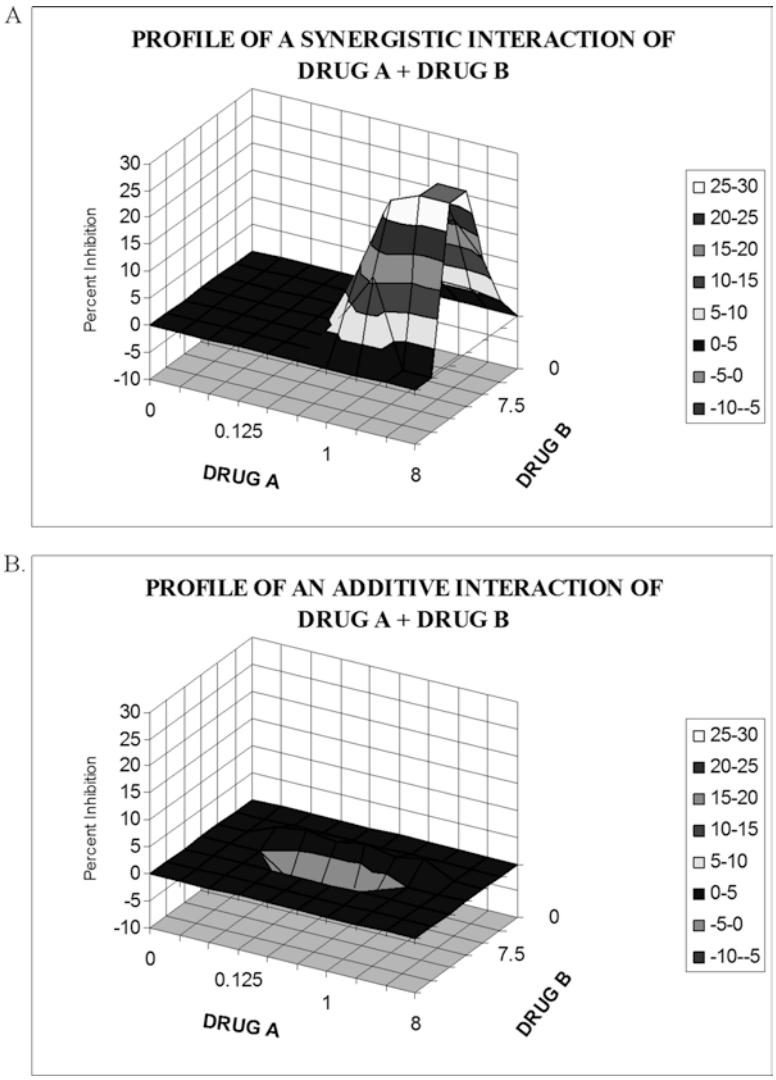

Fig. 79.4 Evaluation of combination interactions by three-dimensional surface method (MacSynergy II). Representative examples of MacSynergy II-based three-dimensional synergy plots illustrating synergistic (**a**), additive (**b**), antagonistic (**c**), or both synergistic and antagonistic (**d**) drug interactions when evaluated in cell-based combination assays

together are greater than that expected or are synergistic. An antagonistic interaction occurs when the realized level of protection is less than that expected; negative values are plotted three dimensionally as regions extending below the plane. The concentrations of the two compounds yielding maximal synergistic activity can be visualized easily with the Antiviral Contour Plot. MacSynergy II also calculates the volume of the synergy peaks or antagonism depressions, and these are used to quantify the amount of synergy or antagonism. The synergy volumes are calculated at the 95, 99, and 99.9 % levels of confidence.

2.2.5 Parametric Surface Fitting

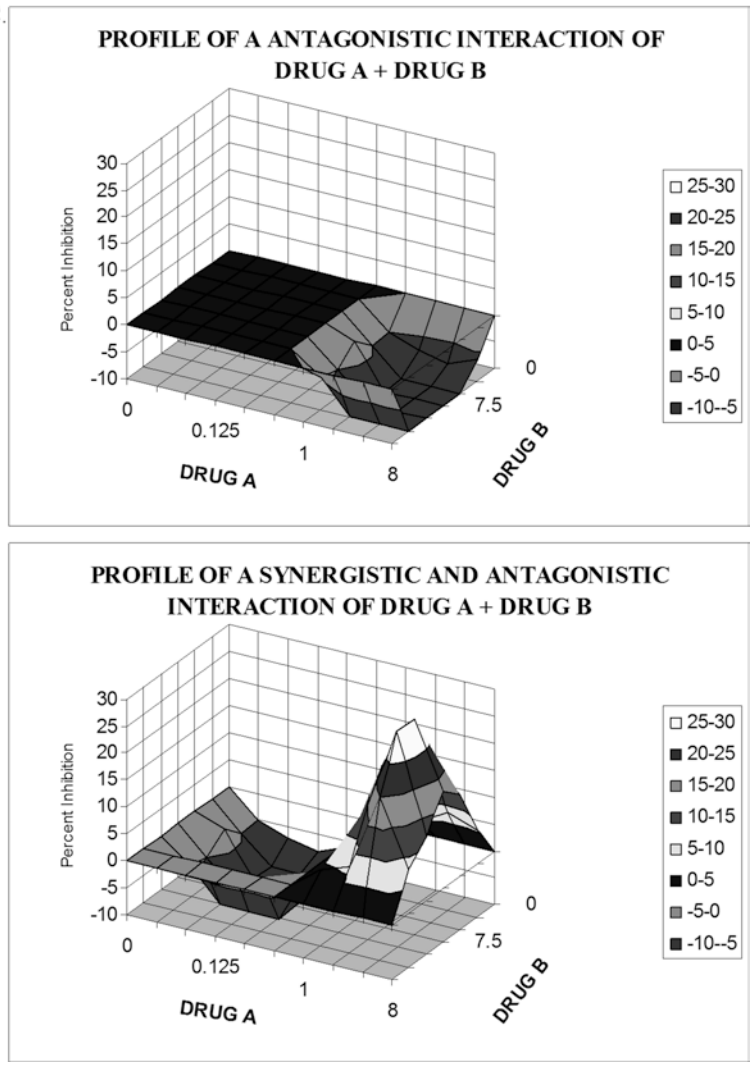
Parametric surface fitting is another three-dimensional modeling technique that uses response surface methodology to fit equations to the experimental data (an example is the COMBO software package) [43, 52, 57, 64, 70]. Mathematical parameters are used to define the surface as additive, synergistic, or antagonistic. The parametric surface fitting uses the Loewe additivity equation. Two models have been developed. Unfortunately, both are difficult to utilize and have the inherent problem that the equations were designed to fit a smooth three-dimensional surface, yielding results that are too simplistic for an irregular and complex three-dimensional surface like that obtained from antiviral combination assays.

2.3 Additional Considerations in Design of Combination Drug Evaluations

In addition to choosing the correct assay and an appropriate means of analysis, there are other considerations in developing a combination therapy regimen for clinical testing and use. These considerations are based on the proposed use of the combination therapy, the potential presence of other infections or drugs, the target of the therapy, and the poten-

Fig. 79.4 (continued)

C.



tial for greater than two drugs being utilized. These considerations and their importance will be discussed below.

2.3.1 Combination Efficacy and Combination Toxicity

Evaluation of the combination interactions of two or more compounds should include the evaluation of effects on both anti-infective efficacy and cellular toxicity. In most cases, the drug concentration ranges chosen for the combination evaluation extend from a low dose with no biologic effect through a high dose that yields at or near 100 % replication inhibition efficacy. These concentration ranges rarely touch on concentrations that are toxic to the host cells, and thus combination toxicity cannot be appropriately evaluated. Thus, in these assays, the toxicity portion of the dose–response curve is not observed, although in some cases synergistic toxicity may be observed when significant combination toxicity is present or when the selectivity index for the individual compounds is extremely narrow. Combination toxicity should be evaluated over a dose–response curve for the individual compounds that extends from a low concentration with no observed toxic effect on the host cells to a high concentration that results in significant toxic effects. These assays are possible after the complete dose–response curves for the individual compounds have been defined. All of the analysis methodologies described above for the evaluation of the combination assays may be used to predict combination toxicity effects. It is possible for anti-infective synergy to be observed that can be explained by a reduction in the toxicity of the two test compounds when used together. For example, we have shown that the efficacy of ribavirin and interferon-α is synergistically enhanced by the addition of a third compound being developed as an anti-HCV clinical therapeutic; the increased antiviral efficacy of the combination is explained by the action of the third compound in reducing the toxicity of ribavirin, thus enhancing its antiviral interaction and synergistic activity with interferon. Similarly, combinations of anti-HIV NCp7 zinc finger inhibitors with many approved anti-HIV

drugs have yielded synergistic anti-HIV activity with the antiviral efficacy derived from the reduced toxicity of the combination of test compounds. In vivo, triple-drug therapy of pegylated interferon with ribavirin and a second-generation HCV protease inhibitor has led to shortened therapy with high efficacy associated with more favorable tolerance and safety profiles, particularly in patients with cirrhosis [71]. Combination therapy of two direct-acting HCV inhibitors was recently FDA approved in order to eliminate the use of interferon and ribavirin [72]. Evaluation of these HCV drugs in combination with HIV HAART is still in clinical trials for use in HIV/HCV coinfections [73].

2.3.2 Mutually Exclusive and Mutually Nonexclusive Evaluations

Analysis of combination interactions using some of the available programs, such as MacSynergy II, requires the user to determine if the analysis should assume that the drugs inhibit the same or different anti-infective targets. These combination parameters have been defined as mutually exclusive and mutually nonexclusive combinations. As a combination therapy strategy, these two therapeutic regimens have also been described in the literature as convergent (same site) or divergent (different site) anti-infective therapies. In our evaluations we have determined that the choice of analysis options may be even more complex than the simple definition of the target enzyme, protein, or replication pathway. For example, the combination of AZT and ritonavir is a mutually nonexclusive therapy, targeting two different steps in the virus replication cycle and two distinct HIV proteins. However, the combination of the nucleoside RT inhibitor AZT with the non-nucleoside RT inhibitor Sustiva could be evaluated using either the mutually exclusive or mutually nonexclusive equations, since they target the same enzyme (RT) but at completely different sites on the enzyme. In many cases, compounds are evaluated in combination assays before the mechanism of action is known or compounds may have a primary and a secondary mechanism of action. We have found that the use of the mutually exclusive evaluation equations provides a more robust evaluation of the interaction of the test compounds.

2.3.3 Performance and Evaluation of Three-Drug Combination Assays

With the increasing incidence of transmission of drug-resistant organisms, more than two drugs are often given to patients simultaneously. The numbers of drugs that can and should be used in combination in the clinical setting requires methodology for evaluating combinations of greater than two test drugs. Prichard and Shipman first described the use of MacSynergy II for evaluating the interaction of three drugs in combination [74]. In these assays, the combination dose–response surface was evaluated for the two-drug combination of acyclovir and 2-acetylpyridine thiosemicarbazone, generating a dose–response surface including 45 data points, each defined in triplicate to allow calculation of the 95 % confidence interval for each data point. This dose–response surface was replicated five times, and each replicate included a single dose of 5-fluorodeoxyuridine. For each of the five replicate dose–response surfaces, the activity defined for the two-drug combination was subtracted, yielding the change in activity that resulted from the addition of the third drug. As with the two-drug interaction analysis using MacSynergy II, the synergy volume can be calculated, and the concentrations of the drugs that yield synergistic interactions can be directly defined. Using the checkerboard pattern of evaluation, regions of different interactions can also be observed and quantified.

2.3.4 Combination Testing with Resistant Organisms

One of the primary driving forces for the use of combination therapy strategies in the clinic is to suppress the selection and replication of drug-resistant organisms. The component drugs of the combination therapy should each have the capacity to inhibit the replication of viruses that are resistant to the other drugs used in the regimen. In some cases, the drugs used must be able to suppress the replication of resistant viruses that were selected to drugs within the same class of inhibitor. The in vitro evaluation of the interaction of two or more drugs should be extended to include evaluation of the ability of the combination of drugs to inhibit drug-resistant viruses, especially the variety of multidrug-resistant (MDR) [75] viruses that have begun to circulate in the patient population. With an estimated 10 % of new infections involving the transmission of resistant organisms [76, 77], this has become increasingly important for anti-HIV therapy. Therapeutic combinations must be evaluated for inhibition of drug-resistant organisms when searching for drugs for pathogens including 3TC-resistant hepatitis B virus strains, amantadine-resistant and oseltamivir-resistant influenza virus strains, protease inhibitor-resistant HCV, antibiotic-resistant bacteria, and drug-resistant tuberculosis. A number of research reports have demonstrated the ability of a combination of drugs to inhibit a drug-resistant virus to one of the components of the drug regimen. In most cases synergistic or additive antiviral interactions are observed with drug-resistant strains when the test concentration of the drug to which the virus has become resistant is increased relative to the level effective against wild type. These results would suggest that clinical resistance can be overcome by increasing the dose or by defining and using the highest possible concentration of a drug to essentially sterilize the patient of replicating virus.

Table 79.1 Combination drug-resistant virus selection using dose escalation method

	Amino acid change (no. of passages in cell culture) with the following Compound 1			
Compound 2	None	Calanolide A	Costatolide	Dihydrocostatolide
None	–	T139I	T139I/L100I	L100I

2.3.5 Combination Resistance Selection Evaluations

A variety of resistance selection strategies are available to select for drug- or antibiotic-resistant organisms. These same strategies can be used to select for viruses or bacteria that are resistant to a combination of drugs either sequentially or in a true combination fashion (Table 79.1). We have observed that the pattern of resistance-engendering mutations changes dramatically when a combination of agents are used in the selection strategy. Resistance selection strategies usually employ a high fixed concentration of the drug used for selection (or combination of drugs) or use the technique of serial passage of the microbe in the presence of increasing concentrations of the test compound. Since these techniques are routinely employed to select for resistant organisms, the methods do not always provide additional data on the relative anti-infective impact of the combination strategy. Techniques have been developed for the passage of the organism in the presence of drug that are highly standardized with regard to selection pressure (i.e., the EC_{50} or EC_{90} concentration from passage to passage). We have employed a virus transmission sterilization assay with single and multiple drugs to rapidly select for drug-resistant virus strains in the presence of a variety of fixed high concentrations of the test drugs.

2.3.6 Combination Assays to Evaluate Treatment for Multiple Infectious Organisms

Another important consideration in the design of a combination therapy strategy is the effect of the individual drugs on those drugs being used to treat other infectious disease organisms. This is especially important when considering therapies for transplant patients undergoing immunosuppression (neutropenia), for immune-compromised AIDS patients, and in situations involving viral and bacterial coinfection. The combination assay strategies discussed in this chapter can be utilized for evaluating the effects of the agents on other indications. For example, an antiviral agent designed to treat HIV infection can be evaluated in antibacterial or antifungal assays to determine if the addition of the antiviral agent has any positive or negative effect on the efficacy and toxicity of antimicrobial agents. Conversely, antimicrobial agents should be evaluated for their effects on the HIV therapy. Since the drugs may not be active against the target organisms used in the assay (e.g., the antimicrobial agent versus HIV), it is important to utilize therapeutically relevant concentrations of the agent as opposed to trying to define a concentration that is actually active against the nonspecific organism. The use of checkerboard drug concentration format for these assays allows the broadest possible dose–response surface to be evaluated.

2.3.7 A Special Case: Potentiation and Suppression

In some cases, the two test agents may include one that does not have any detectable activity against the organism being tested or may not be active in the particular assay being employed. In this case, discussions of synergistic and antagonistic interactions of the agents are not completely correct. Combination assays and analysis programs can be performed on these combinations of agents exactly as described above, but the results of the assays should be expressed in terms of potentiation (or enhancement) and suppression (or inhibition) of activity, depending on whether the result was synergistic or antagonistic as defined by the analytical end point of the assay. The terms potentiation and suppression are generally correct when discussing combinations of agents active against different organisms. Compounds that have activity in chronic infection models but not in acute infection models against the same organism might be evaluated in potentiation assays with compounds that only exhibit efficacy in the acute infection models. As discussed previously, it is important to carefully choose the drug concentrations to

be evaluated so that concentrations are therapeutically relevant, even if a particular drug is inactive, and that a broad dose–response surface is evaluated.

2.3.8 Biological Relevance of the Test System to the Therapeutic Strategy

When considering the effectiveness of a combination therapy, it is critical to select the appropriate system and assay for use in the evaluations. Since most combination therapies will be utilized for the therapeutic treatment of systemic infections, the assays to be utilized should have relevance to the biology of the infection. Thus, appropriate cell lines and virus strains should be used, and the assay may be modified to more closely mimic the therapeutic environment through the addition of serum proteins and other additives. Combination products may also find utility as vaginal or rectal microbicides (prevention or preexposure prophylaxis regimens) or for the treatment of wounds or other topical and mucosal infections. In these systems, the cells used for the assays, the isolates chosen for evaluation, and the additives used to mimic the infectious environment will be modified to reflect the therapeutic use of the compound. Determining the appropriate end point measurement of antiviral effectiveness is also important, as in HSV-1 labialis infections where lesion development and progression in recurrent disease is dependent primarily on the proinflammatory host response rather than virus replication as in the initial infection. Combination therapy of a topical antiviral with an anti-inflammatory agent is under investigation for recurrent HSV infection, where antiviral agents have only shown moderate effect on lesion healing time unless you treat early in the prodromal stage [78]. For some regimens, it is also important to consider the method of formulation of the final product and to perform the combination evaluations under those conditions. For example, the final form of a topical vaginal microbicide often includes excipients that may have therapeutic or toxic effects and that may potentiate or suppress activity of the drug of interest [79]. We have also clearly shown that appropriate formulation of drug products may substantially enhance the absorption/permeation of a drug into target cells or tissues, yielding enhanced antiviral effectiveness (and possibly enhanced toxicity).

2.3.9 In Vitro Pharmacologic Models and Evaluations

Combination methods have recently been developed to take into account pharmacodynamics of drug exposure [18]. In these model systems, the concentrations of the drugs in contact with the cells are continuously modified to approximate the plasma concentrations of the drugs in a human being. Thus rather than culturing cells and virus in the presence of fixed concentrations of the two drugs, in the pharmacodynamic model each drug concentration is fluctuated as it would be in the patient, allowing the investigator to model antiviral and toxic effects more realistically than in tissue culture systems. Though this model is an advancement that can aid in prioritizing combination therapies for clinical use, these methods are very expensive and time consuming and are not practical for routine and high-throughput evaluation of combinations of compounds. In addition, these are still in vitro assays: metabolism of the compounds, generation of metabolites, and interaction with tissues do not occur, and thus they do not completely reflect in vivo use.

3 Virologic Evaluations

3.1 Virus Replication and Functional Cell-Based Assays

The most relevant cell-based assays include clinical strains of virus and fresh human cells. For HIV, assays using fresh human PBMCs, monocyte/macrophages, and dendritic cells, as well as assays with tissues such as cervical explants for microbicide testing, have been developed [6, 20, 80]. For a number of other viral agents, a variety of in vitro screening assays involving measurement of cytopathic effects, virus replication, or plaque-formation assays can be performed [81–93]. In these cases, the end points of the assays are quantitative readouts of virus production and typically involve measurement of a viral enzyme, measurement of a viral capsid protein, or measurement of infectious virus. These values can be entered into the analysis programs defined above as actual raw data values or the values expressed as a percentage of the virus or cell control. Although many of these assays are suitable for high-volume screening, in general the variability in fresh human cell populations requires that many replicates of these assays be performed unless a highly standardized and reproducible infection of the primary cells can be achieved. In addition, the cost of both the assay and the availability of adequate cell numbers or tissues can affect the number of replicates that can be performed.

3.2 Assays Measuring Cytopathic Effects

For anti-infective testing for most organisms, a simple, reproducible, and cost-effective solution to high-throughput combination antiviral evaluations is to utilize assays that quantify virus-induced cytopathic effects (CPE) and the ability of test agents to suppress these cytopathic effects [81–93]. A number of tetrazolium dyes and other colorimetric reporters can be used to quantify viability in the cell cultures, and the differential between virus and cell controls can be used as the measure of percent protection. These percent protection (or percent cell viability) values can be easily imported

directly into the analysis programs and the combination interaction quickly evaluated. One drawback of these assays is that the virus replication is not measured directly, but rather an effect of decreased viral replication is measured (which should, in most cases, be proportional to the level of virus produced). The compound not only has to suppress virus production but also has to suppress the CPE, which may not be a natural feature of viral infection in the patient. In addition, virus-induced CPE assays routinely use laboratory-derived strains of virus and established human cells that may not accurately mimic infection in patients. Despite these caveats, CPE assays are the assay of choice for high-throughput combination evaluations in light of their extreme reproducibility (low intra- and inter-assay variability) and low cost. CPE assays are available for nearly all infectious organisms routinely screened in anti-infective development programs. Viral plaque reduction assays are a similar but more labor-intensive approach since the plaques produced by infection must be microscopically counted, introducing greater cost, variability, and level of assay difficulty than assays using reporter dyes.

3.3 Enzymatic and Biochemical Assays

Biochemical assays that directly quantify the ability of a test compound to inhibit the target enzyme or block binding to a target protein are (in most cases) the simplest and least expensive of the various combination assay formats [20]. Biochemical or enzymatic assays effectively reproduce antiviral mechanism of action assays. The readouts of these assays usually have radioactive, colorimetric, fluorescent, or chemiluminescent end points, and the values obtained can be compared to a positive and negative control allowing percent inhibition values to be calculated. These values can be directly imported into the programs for analysis of the combination interaction. Although these assays are usually rapid, inexpensive, easy to perform, and extremely reproducible and quantitative, they have several disadvantages. First, they do not take place in the intact cell. These assays do not require the test agents to actually penetrate the cell membrane and accumulate at the site of action. A second issue of biochemical importance is metabolism by the intact cell, such as the phosphorylation required for nucleoside analogs. Antagonistic effects on metabolism would be missed in a biochemical assay. Third, biochemical assays do not provide information on combination toxicity obtained through cell-based assays. Finally, quite often the enzyme that is targeted by one component of the combination therapy is not targeted by the other, and therefore the combination biochemical assay merely informs the investigator whether or not the inactive drug potentiates or interferes with the activity of the active drug in the limited context of the biochemical assay.

3.4 Chronic and Acute Infection Assays

A special case of cell-based assays involves testing of agents in cells that are chronically infected with an infectious organism and that constitutively or latently produce virus. Though most approved antiviral agents target steps that occur early in the infection cycle, assays with chronically or latently infected cells quantify the effects of test agents on late stages of virus production such as transcription, translation, virus assembly, maturation, and release from the infected cell. The strengths and weaknesses of these cell-based models are identical to those presented above for virus replication-based assays. Though the throughput and reproducibility are much higher than that observed for primary human cell assays, the chronic systems typically require more expensive systems for end point detection. In any event, for compounds that target late stages of infection, it is important to test the combination efficacy and toxicity in both acute and chronic infection models in combination with agents that are more than likely active only in the acute infection models. These assays will essentially confirm that the chronic infection inhibitor will not interfere with the acute infection inhibitor and vice versa.

3.5 Cell-Free and Cell-Associated Virus Transmission Assays

The bulk of antiviral assays performed measures the amount of virus that is produced from infected cells which serves as the inoculum for successive rounds of viral infection. The activity of antiviral agents alone and in combination is measured by reduction of the amounts of virus produced from these infected cells via measurement of viral proteins, enzymes, and infectious progeny. It has been shown that infectious virus may be transmitted from an infected to an uninfected cell directly, without an extracellular phase (or perhaps an extremely short duration of time between release and reinfection). Antiviral assay methodology to measure cell-to-cell transmission has been developed which includes the cocultivation of infected and uninfected cells with measurement of virus-induced syncytium formation and rapid progeny virus production from the co-cultured cells [94]. Data from these assays may involve semiquantitative or quantitative measurement of syncytium formation (or virus-induced cytopathic effect) and measurement of virus burst from the co-cultured cells.

4 Microbiologic Evaluations

The concept of using antimicrobial drugs in combination dates back to the early days of chemotherapy. Combination therapies historically were used either as a means to extend

the therapeutic spectrum against diverse genera and organisms of unknown sensitivity or as a means to stem the tide of selection for drug-resistant strains during extended treatment regimens. Representative examples are the well-known combination of trimethoprim and sulfamethoxazole used for multiple bacterial indications [95], multidrug therapy for tuberculosis [96], and eradication of *Helicobacter pylori* in peptic ulcer disease [97]. Other examples that fall into the combination category range from the streptogramin drug Synercid® (a mixture of quinupristin and dalfopristin 30:70 w/w for parenteral administration, Monarch Pharmaceuticals) indicated for vancomycin-resistant *Enterococcus faecium* to Augmentin® (multiple formulations of amoxicillin and the beta-lactamase inhibitor clavulanate, GlaxoSmithKline Pharmaceuticals) used primarily for community-acquired pneumonia (CAP), bronchitis, and otitis media. Amoxicillin/clavulanate is unique in that it combines an antibiotic with an inhibitor of a common resistance mechanism (secreted beta-lactamase).

4.1 Methods to Study Antibiotic Interactions

Several in vitro methods have been devised to measure the interaction between two or more antibiotics in bacterial culture systems. The primary goal of these studies was to determine whether the drugs acted in synergy to increase killing efficiency above that seen with either agent alone or whether they were antagonistic to each other and thus could have the potential to decrease efficacy and adversely affect clinical outcome. All methods provide either a direct numerical readout such as the fractional inhibitory concentration index (FICI) of a checkerboard test or measurable changes in growth dynamics and viable cell count as seen in time-kill assays from broth cultures.

4.1.1 Checkerboard Testing

This system is an extension of standard broth microdilution methodologies used for the determination of minimum inhibitory concentration (MIC) [98, 99]. Presently, no officially recognized checkerboard testing standard exists. However, starting inoculum densities and scoring of bacterial growth at the end of the assays generally follow the MIC microdilution protocols of the Clinical and Laboratory Standards Institute (CLSI; formerly the NCCLS). Checkerboards are simple arrays of serial dilutions of each drug in two dimensions across microtiter plates. Individual MIC values for each drug are determined against the test organism prior to the assay. Starting drug concentrations are selected such that they bracket the respective MICs by three or four dilutions. After dilution, the plates are incubated and each well is read as for a standard MIC assay. Once wells are scored for growth inhibition, fractional inhibitory concentrations (FICs) are calculated by dividing the MIC of the first drug in combination with the MIC of that drug when used alone. The same process is carried out for the second drug. Both FIC values then are added together to create the fractional inhibitory concentration index (FICI) for the combination. FICI values ≤ 0.5 indicate synergy, whereas values >4.0 indicate antagonism. Values between these two end points represent no significant interaction. Since previous literature sources have made claims as to the significance of intermediate FICI values falling between 0.5 and 4.0, the editorial board of the Journal of Antimicrobial Chemotherapy in 2003 instituted the requirement that these values be used for manuscript submission and required that intermediate values should be labeled as no interaction [100]. These recommendations appear to have broad acceptance in the field. Despite this acceptance the checkerboard MIC test suffers due to lack of reproducibility and the fact that the assay only measures bacteriostatic effects. Variability in the MIC evaluation as well as testing a bacteriostatic agent in combination with mostly bactericidal agents may be the cause for the overestimation of synergy experienced with the checkerboard test. Confirmation of these combination MIC assays should be obtained with a quantitative time-kill assay [101].

4.1.2 Time-Kill Testing

Although not as simple to configure as checkerboard arrays, time-kill assays provide both a kinetic readout of bacterial kill rates over the course of the experiment as well as an indication of synergy, antagonism, or indifference after 24 h of antibiotic exposure and are often used to confirm the results determined in the checkerboard assay. These tests are based on the macroscale broth method used for the determination of bactericidal activity as specified by the CLSI [102]. Broth cultures are configured with test organism, and drugs are added either alone or in combination at fractions or multiples of the MIC (generally ranging from 0.25 to 2 times the MIC) [103]. Cultures can be monitored over the course of exposure to examine bacterial growth/kill kinetics and at the end of the assay period for determining synergy, indifference, or antagonism. In this system, as determined by Eliopoulos and Moellering, an interpretation of "synergy" required a ≥ 2 $\log_{10}$ decrease in cfu/mL by the drug combination when compared with its most active constituent after 24 h and a ≥ 2 $\log_{10}$ decrease in the cfu/mL below the starting inoculum. Likewise, the drug combination was considered to be "antagonistic" if there was a ≥ 2 $\log_{10}$ increase in cfu/mL, and "no interaction" was the interpretation of a <2 $\log_{10}$ change in cfu/mL. White et al. defined synergy as a combination that produced ≥ 2 $\log_{10}$ reduction in colony forming units (CFU) compared to the most active of the two drugs when

used alone [103]. Likewise, ≥ 100-fold increase in CFU indicated antagonism, whereas <10-fold change indicated indifference.

4.1.3 E-Test Strip

The Epsilometer or E-test strip (AB Biodisk, Solna, Sweden) has been utilized for synergy testing [103]. In this configuration, an E-test strip for each drug is placed onto an agar plate inoculated with the test organism. The strips are laid onto the agar surface in a crossed pattern such that the perpendicular intersection of the two strips contact at the precise point on the scale of the individual MIC for each drug. Following incubation, a zone of inhibition radiates out from that point of intersection. The MIC of each drug in combination is read off each scale by noting where the zone of inhibition contacts each strip distal to the point of intersection. FICI values are calculated by the same process as that used for the checkerboard test. Frequent agreement between the E-test, checkerboard, and time-kill assays was found in this study [103], but there was sufficient variability and discordance between the tests to suggest that neither one could be used alone when evaluating new drug combinations. Therefore, when testing new antibacterial agents or combinations of currently approved drugs for new indications, multiple assays should be performed and compared.

4.2 Combination Testing and Prediction of Clinical Outcome

Despite the availability of testing methods for possible interactions between antibiotics used in combination, the final determination, as with any therapy, is whether or not there is a favorable therapeutic outcome. Few examples of synergistic combination therapy exist in the literature, and generally these tend to describe special situations such as therapies for Gram-negative sepsis in neutropenic patients or enterococcal endocarditis [104–106]. Even recent guidelines for combination therapy in normal adult community-acquired pneumonia (CAP), where a macrolide-class drug is recommended together with a beta-lactam, are directed toward increasing spectrum in order to cover atypical organisms rather than for any synergistic pharmacodynamic consideration [107]. Investigators must consider the pharmacokinetic properties of the individual agents. Will combining two drugs with vastly different serum half-lives (such as a macrolide and a beta-lactam) have relevance at the actual site of infection? What about differences in tissue distribution at those sites [108]? One can also argue that static testing methods such as the checkerboard assay have little relevance to the dynamic environment encountered in vivo and that alternative models may be more relevant for predicting clinical outcome [109]. At best, assays such as the checkerboard and time-kill can help predict whether any overt antagonism may exist between two antimicrobial drugs and whether the possibility remains for synergism in vivo.

4.3 Combination Antibiotic Products for the Treatment of Biofilms

Combinations of antibiotics have been found to be effective in the treatment of chronic bacterial infections such as staphylococcal infections which are associated with biofilm formation. The formation of biofilms has been shown to significantly decrease the susceptibility of pathogenic bacteria to antibiotic treatment relative to the individual planktonic organism [110–113]. Biofilm formation has thus been suggested to be a mechanism of antibiotic resistance and combination approaches to attack both the infectious microorganisms, and the structure of the biofilm may be necessary.

As mentioned above the activity of combinations of antibiotics is most commonly evaluated in vitro using standard susceptibility tests based on broth microdilution and diffusion. These methods, however, do not take into consideration the specific requirements for the evaluation of the activity of products against the complex structure and often heterogeneous makeup of the biofilm. Although valuable information for combination biofilm inhibition studies can be obtained using the checkerboard MIC testing and time-kill analysis as described above, additional tests are needed which will take into account the different population of bacterial cells that constitute the biofilm [114]. Biofilm susceptibility assays can be performed using a variety of methods [115–117]. In addition to defining problems in the feasibility of multiple comparative biofilm inhibition studies, for a variety of reasons, the different methodologies used for evaluating combination antibiotic products targeting biofilm formation are not amenable to comparing results obtained from different studies [114]. These significant differences in methodology include varying times of exposure [113], different antibiotic concentrations [118], varying growth states of the bacteria (i.e., adherent [119] vs. suspension [112, 120]), degree of adherence of different bacteria, the support surface used to grow the biofilm, age of the biofilm, and the medium and specific growth conditions (rich medium versus minimal essential medium) in which the organism was grown.

It is critical in the development of new and novel therapies involving combinations of antibiotics that the individual and composite population of cells responsible for biofilm formation are also being targeted and that the assay variables described above are taken into consideration when deciding on the appropriate methodology to use.

Acknowledgments The authors gratefully acknowledge the assistance of Ms. Karen W. Buckheit, M.S., and Ms. Tracy Hartman, M.S., in the preparation and editing of this manuscript.

Antimicrobial Susceptibility Testing Methods for Bacterial Pathogens

80

Fred C. Tenover

1 Introduction

Gone are the days when the antimicrobial susceptibility pattern of a bacterial isolate could be predicted simply on the basis of its species identification. Although *Streptococcus pyogenes* isolates remain susceptible to penicillin, one has to continually ask—for how long? With the discovery of strains of *Staphylococcus aureus* that are highly resistant to vancomycin [1], the emergence of carbapenem-resistant *Enterobacteriaceae*, and strains of *Acinetobacter* species that are pan resistant [2, 3], the role of antimicrobial susceptibility testing in guiding therapy for infectious diseases is becoming increasingly important [4]; it is a key function of clinical microbiology laboratories. Results guide physicians in their selection of appropriate antimicrobial therapy for patients with infections. Yet, ironically, many of these novel resistance phenotypes are not easily detected using the automated susceptibility testing methods so prevalent in today's clinical laboratories [5, 6]. The ability of the clinical laboratory to detect emerging resistance profiles is often directly related to the extra efforts expanded to catch novel resistance mechanisms. Although resistant bacteria were common previously only in intensive care units of hospitals, multidrug resistance has become an issue among strains of community-acquired pathogens such as *Salmonella*, *Shigella*, and even *Neisseria gonorrhoeae* [7–9]. To complicate matters even further, resistant organisms that arise in the community are now also spreading into healthcare settings [10, 11]. Thus, it is imperative that changes in resistance patterns of a wide range of bacterial pathogens be monitored continually to insure optimal treatment both of the individual patients and for maintaining the efficacy of empiric therapy regimens. Antimicrobial susceptibility test methods include disk diffusion and minimal inhibitory concentration (MIC) methods, such as broth microdilution, agar dilution, and agar gradient diffusion. MIC tests often utilize semi- or fully automated platforms to decrease time to results and improve workflow. Microbiology laboratories often employ supplemental tests to maximize detection of unusual or borderline-resistant phenotypes or emerging resistance mechanisms that may be missed by standard methods. Qualitative results (susceptible, intermediate, or resistant) for antimicrobial agents may be accompanied by quantitative values for MIC test to help guide dosing regimens. Molecular-based tests, such as polymerase chain reaction assays and film arrays, are used with increasing frequency to provide rapid results, often within 1 h, for resistance genes or mutations associated with antimicrobial resistance to improve antimicrobial therapy. Such assays have gained widespread acceptance for methicillin-resistant *Staphylococcus aureus* (MRSA) in positive blood cultures, vancomycin resistance genes in enterococci, and multidrug-resistant strains of tuberculosis from patients with respiratory disease. This chapter will explore in detail the methods used for antimicrobial susceptibility testing of bacterial pathogens.

2 Antimicrobial Susceptibility Testing Methods

The two major phenotypic methods of determining the susceptibility of a bacterial isolate to an antimicrobial agent are disk diffusion and minimal inhibitory concentration (MIC) testing. In the United States, based on informal surveys, approximately 85% of susceptibility test results are produced using automated methods, while the remainder is mostly the result of disk diffusion testing. However, clinical laboratories also utilize a series of screening and confirmation tests to detect subtle resistance mechanisms and insure the accuracy of antimicrobial susceptibility test reports (Table 80.1). More recently, molecular methods to detect antimicrobial resistance genes and mutations associated with resistance phenotypes have been introduced into clinical

Table 80.1 Phenotypic screening and confirmation tests

Test name	Resistance phenotype detected	Organism groups
Aminoglycoside resistance, high level	Synergistic activity with ampicillin, penicillin, or vancomycin	Enterococci
Cefoxitin disk test	*mecA*- and *mecC* -mediated oxacillin resistance	Staphylococci
D-Zone test	Inducible clindamycin resistance	Staphylococci, streptococci
Extended-spectrum beta-lactamase screening and confirmation tests	Extended-spectrum cephalosporin resistance	*Escherichia coli*, *Klebsiella* species, *Proteus mirabilis*
Carba NP test	Carbapenem resistance	*Enterobacteriaceae* and *Pseudomonas* species
Modified Hodge test	Carbapenem resistance	*Enterobacteriaceae*

microbiology laboratories. While the most commonly used test is likely the direct detection of MRSA in nasal, wound, or positive blood culture bottles using real-time polymerase chain reaction (PCR) assays [12], a variety of other testing platforms, including microarrays, film arrays [13], and peptide-nucleic acid fluorescent in situ hybridization assays (PNA-FISH) [14] are also used in clinical microbiology laboratories to detect antimicrobial-resistant organisms.

2.1 Disk Diffusion

The disk diffusion method has one of the more colorful histories among clinical microbiology tests that includes luminaries in anti-infective research such as Alexander Fleming, John Sherris, and William Kirby, international collaborative studies headed by the highly influential microbiologist Hans Ericsson, and even a US Supreme Court decision [15–17]. The method as we now know it consists of placing paper disks saturated with inhibitors of bacterial growth (i.e., antimicrobial agents) on a lawn of bacteria seeded on the surface of an agar medium, incubating the plate overnight, and measuring the presence or absence of a zone of inhibition around the disks. In the early 1950s, there was little standardization of disk content, inoculum size, or incubation conditions among laboratories performing the tests. Oftentimes multiple disks, each with a different concentration of the same antimicrobial agent, were used to assess susceptibility. Ericsson and colleagues developed a standardized single disk method that was widely used in Scandinavia [18]. This served as the basis for an international collaborative study that eventually produced a standardized method. Studies conducted at the University of Washington in the mid-1960s resulted in the technique often referred to as the "Kirby-Bauer method," which was published by Bauer and colleagues in 1966 [19]. This method standardized the variables of disk size, inoculum size, temperature, and time of incubation. Results were reported qualitatively as susceptible, intermediate, or resistant. Around this same time, several companies manufactured disks for testing in the United States, but the amount of drug present in the disks varied significantly from lot to lot. The US Food and Drug Administration accepted the responsibility for monitoring the content and potency of each lot of disks manufactured in the United States. A challenge to that authority by a disk manufacturer made its way to the US Supreme Court in 1962. In their decision, the Supreme Court not only reaffirmed the responsibility of the FDA to monitor each batch of disks for potency but noted that manufacturers of antibiotic disks had a legal obligation to describe how the disks were to be used [20]. The US Supreme Court recommended the single disk method of Bauer et al. as the standardized testing method of choice. The rejection rate of antimicrobial disk lots by the FDA dropped from 66 % in 1958 to only 5 % in 1962. The disk diffusion method described by Bauer et al. has been continually expanded and improved by the Clinical and Laboratory Standards Institute (CLSI, formerly known as the National Committee for Clinical Laboratory Standards) in the United States. Several other international societies (e.g., the British Society for Antimicrobial Chemotherapy and the European Union Committee for Antimicrobial Susceptibility Testing (EUCAST)) have similar techniques. Alternative disk-based methods including the Roscoe NeoSensitabs and the Australian Calibrated Dichotomous Sensitivity (CDS) method are also used in some countries. Instruments that measure the zones of inhibition using cameras can speed the process of reading disk diffusion plates. These instruments can also transform the zone diameter readings into approximate MIC values.

2.2 Minimal Inhibitory Concentration (MIC) Testing

The goal of MIC testing is to provide a quantitative result (in μg/mL) along with a categorical interpretation (susceptible, intermediate, or resistant) that can guide antimicrobial therapy more precisely, particularly for infections in body sites where antimicrobial agents achieve lower concentrations than in serum (e.g., cerebrospinal fluid and bone). MIC testing can be performed by one of several methods including agar dilution, broth microdilution, and agar gradient dilution or by one of several automated methods. Quantitative MIC results are also useful when long-term therapy is required, as for bacterial endocarditis and osteomyelitis.

2.2.1 Agar Dilution

The agar dilution method involves preparing a series of agar plates containing the antimicrobial agent to be tested in increasing concentrations, usually in doubling dilutions (i.e., 1, 2, 4, 8, 16, 32 μg/mL, etc.). A suspension of the organism to be tested is prepared to equal the turbidity of a 0.5 McFarland standard [approximately 1×10^8 colony-forming units (CFU) per mL], and 1–5 μL of this suspension is placed on each of the series of plates with increasing concentrations of the antimicrobial agent using a Steers replication (delivering approximately 5×10^4 CFU per spot). Thirty different bacterial isolates (plus quality control organisms) can be tested simultaneously on each agar plate. Non-fastidious organisms are incubated at 35 °C for 16–18 h usually in ambient air, while fastidious organisms, such as *Streptococcus pneumoniae*, are incubated from 18 to 24 h, typically in a CO_2-enriched atmosphere. The agar dilution method, while laborious due to the time required to prepare each set of agar plates for each antimicrobial agent to be tested, is often cost-effective for laboratories that test large numbers of bacterial isolates against a limited set of antimicrobial agents. The testing medium is usually Mueller-Hinton agar for non-fastidious organisms and Mueller-Hinton agar containing 5 % sheep blood for fastidious organisms. The exceptions are *Haemophilus influenzae* isolates, which requires HTM or MF-H media, and *Neisseria gonorrhoeae*, which requires GC medium.

2.2.2 Broth Microdilution

Broth microdilution is the standard method used in most reference laboratories in the United States and abroad. The method typically tests twofold dilutions of multiple antimicrobial agents in 96-well disposable plastic trays. The test medium is typically cation-adjusted Mueller-Hinton broth or for fastidious organisms, cation-adjusted Mueller-Hinton broth containing 5 % lysed horse blood. A suspension of the organism to be tested is prepared in saline or Mueller-Hinton broth to the turbidity of a 0.5 McFarland standard [approximately 1×10^8 CFU/mL]. The suspension is diluted 1:20 in saline and 1–5 μL of this suspension is transferred to the 96-well tray containing doubling dilutions of the antimicrobial agents to be tested (usually between 8 and 12 antimicrobial agents per tray) using a disposable plastic inoculator (the inoculum size varies with the size of the pins in the inoculator). The final inoculum size is 5×10^5 CFU/mL or 5×10^4 CFU/well.

2.2.3 Automated Susceptibility Testing Methods

A series of commercially available automated and semiautomated methods are available to assist laboratories in testing and reporting the results of antimicrobial susceptibility tests. Most of the methods combine bacterial identification and susceptibility testing reagents in a single panel or card to enhance the speed with which antimicrobial susceptibility testing results can be reported. Many systems also incorporate software programs to interpret the results and prepare reports that can be linked readily to laboratory information systems, which in turn deliver the results to the patients' electronic medical record. The goal of the automated methods is to reduce the time necessary to produce accurate identification and susceptibility test results and facilitate the testing of multiple antimicrobial agents. Indeed, results may be available for some bacterial species in as little as 6 h, versus the 16–18 h often required for disk diffusion testing or standard MIC tests. For staphylococci, the results of oxacillin and vancomycin tests often require prolonged incubation times (often 24 h) to achieve accurate results. Some software programs employ "expert systems" to enhance reporting by recognizing and flagging unusual results, such as ampicillin-susceptible *Klebsiella pneumoniae*, where the bacterial identification and susceptibility pattern are conflicting with typical results for wild-type *K. pneumoniae* populations, or rare results, such as carbapenem-resistant *Enterobacteriaceae* or vancomycin-resistant *Staphylococcus aureus*.

Overall, automated systems work well, although they have traditionally shown problems with certain resistance phenotypes including oxacillin-resistant *S. aureus* strains [21] and *Pseudomonas aeruginosa* strains that are resistant to beta-lactam agents, such as piperacillin [22].

2.2.4 Agar Gradient Dilution

Agar gradient dilution incorporates MIC testing into a format similar to the setup of a disk diffusion test. The antimicrobial agent is microencapsulated on the back of a plastic strip and, when placed on the surface of an agar plate, the antimicrobial agent diffuses off of the strip into the agar medium in a rapid and predictable fashion forming a gradient. The agar gradient strips evaluate the inhibitory potential of a single antimicrobial agent over a large range of concentrations. Several strips containing different antimicrobial agents can be arranged on a single agar plate. The agar gradient method is particularly useful for testing fastidious microorganisms such as *Campylobacters* [23], pneumococci [24], and anaerobic bacteria [25, 26] where only a limited number of antimicrobial agents need to be tested. Agar gradient strips are available from several commercial manufacturers.

3 Interpretive Guidelines

Once a disk diffusion zone of inhibition has been measured or an MIC for an antimicrobial agent has been determined, and the microbiologist has affirmed that the quality control results indicate that the testing system has performed appropriately, the results of the susceptibility test have to be interpreted. For most antimicrobial agents, the results transmitted to the patient's chart will be either "susceptible," "intermediate,"

or "resistant." If an MIC method was used, the results transmitted may include the quantitative MIC result as well. However, for some antimicrobial agents, such as daptomycin when testing staphylococci, the results transmitted will be either "susceptible" or "non-susceptible." This is because at the time of the drug was approved for use by the US Food and Drug Administration and when interpretive criteria (i.e., breakpoints) were established by the CLSI, there were inadequate numbers of resistant strains available on which to establish intermediate and resistant breakpoints [27]. The lack of interpretive intermediate and resistant breakpoints often poses a challenge for the automated methods which, depending on the system, will either leave the interpretation field blank for a non-susceptible result or place an "N" or "NS" (for non-susceptible), or an "NI" (for non-interpretable), in the interpretation field—a result that may be confusing to the physician reading the laboratory report. Some microbiology laboratories will override these "non-S, I, or R results" and simply report them as resistant to avoid confusing physicians.

Recently, a new interpretive category called "susceptible dose dependent" (SDD) was introduced for reporting results for cefepime for bacterial infections. Although this category has been used for reporting results for antifungal susceptibility testing for several years, its application for cefepime results for bacterial infections is novel. It is meant to bring clarity to the intermediate category by indicating to the physician that the organism causing the infection may still respond to cefepime if high doses of the drug are used.

The categorical interpretations used for disk diffusion and MIC test results are drawn from one of several standard-setting organizations. In the United States, breakpoints for antimicrobial agents are set initially by the Food and Drug Administration. After the FDA establishes their interpretive criteria, data are gathered and reviewed by CLSI, which independently established breakpoints. Usually, the breakpoints coincide, although for some agents, they may differ. The description of the reference disk diffusion method and the interpretive criteria for antimicrobial agents approved in the United States, and several antimicrobial agents available only outside of the United States, are available in the CLSI M2 document (Performance Standards for Antimicrobial Disk Susceptibility Tests). The M2 series is revised every 3 years. The agar and broth dilution reference (MIC) methods are described in CLSI document M7 (Methods for Dilution Antimicrobial Susceptibility Tests for Bacteria that Grow Aerobically), which also is revised every 3 years. A separate document containing the interpretive criteria for both disk diffusion and MIC testing, quality control ranges, and methods for preparing and diluting antimicrobial agents is published each year in January (the M100 series). Similar documents are published online by the European Union Committee for Antimicrobial Susceptibility Testing (EUCAST) (see http://www.srga.org/Eucastwt/bpsetting.htm), the British Society for Antimicrobial Chemotherapy (see http://www.bsac.org.uk/), and other organizations. A document outlining interpretive criteria for susceptibility tests conducted with infrequently isolated or fastidious bacteria (M45) is also published by CLSI [28].

4 Resistance Phenotypes That Require Specialized Testing

4.1 β-Lactam Agents

Resistance to penicillins, cephalosporins, and carbapenems among gram-negative organisms is usually mediated by β-lactamases, either intrinsic or acquired, that hydrolyze the β-lactam ring of the antimicrobial agent, which detoxifies the drug. Although other mechanisms of resistance, including efflux and porin changes limiting access of beta-lactam agents may occur, there is no specialized testing to detect these mechanisms. Among gram-positive organisms, in addition to β-lactamases, β-lactam resistance can be mediated by changes in the affinity of the penicillin-binding proteins (PBPs) for the antimicrobial agent. Among staphylococci this is usually mediated by acquisition of a novel PBP (i.e., PBP 2a), while in pneumococci and viridans streptococci, reduced affinity is usually the result of remodeling of the PBP genes by incorporating foreign DNA to form mosaic genes. Beta-lactam resistance in both gram-positive and gram-negative organisms poses unique challenges for antimicrobial susceptibility testing methods.

Detection of oxacillin (or methicillin) resistance in staphylococci is difficult primarily because oxacillin-resistant strains tend to grow more slowly and often show heteroresistance, i.e., only a fraction of the bacterial population actually manifests the resistance phenotype [29]. Methicillin resistance can be mediated by either the *mecA* or *mecC* gene, the latter (originally designated as mec_{LGA251}) having been described recently from both humans and animals [30]. Various strategies have been used over the years to increase the likelihood of detecting the resistant subpopulation including growing the strains at 35 °C instead of 37 °C, adding 2 % NaCl to the testing medium, and incubating the test for a full 24 h [21]. More recently, based on studies by Felten et al. [31], Skov et al. [32], Swenson and Tenover [33], and others, CLSI has described a cefoxitin-based disk diffusion test that accurately predicts the presence of the *mecA* and *mecC* genes among both *S. aureus* and coagulase-negative staphylococci (CoNS). The test can be read in 16–18 h and replaces the use of the oxacillin disk for disk diffusion testing for both *S. aureus* and CoNS and now is also the preferred drug for MIC testing according to CLSI and EUCAST.

Among the *Enterobacteriaceae*, the major susceptibility testing challenges are to detect the presence of extended-

spectrum beta-lactamases (ESBLs) and carbapenemases. Before 2012, CLSI and EUCAST used detection of these enzymes to modify the interpretation of MIC and disk diffusion results from S to R in an attempt to insure accuracy. However, during the last several years, both organizations have instituted lower MIC breakpoints and larger disk diffusion zone diameters in lieu of testing for enzymes to try and improve accuracy of reporting by increasing the sensitivity of detecting resistant strains directly without having to use supplemental tests. Detection of the enzymes (i.e., the mechanism of beta-lactam resistance), which was seen as confusing to physicians and often was ineffectively implemented in laboratories, is now used primarily for infection control activities and epidemiology. Some critics have objected to this approach noting that the lowered breakpoints have not solved the problems of detecting resistant isolates [34].

ESBLs are primarily derivatives of bla_{TEM}, bla_{SHV}, and $bla_{CTX\text{-}M}$ genes (although there are multiple other less common ESBLs) that mediate resistance to aztreonam and third-generation cephalosporins (such as cefotaxime, ceftriaxone, and ceftazidime) [35–37] and, in some cases, fourth-generation cephalosporins (such as cefepime and cefpirome) [38]. (An up-to-date list of β-lactamases can be found at http://www.lahey.org/Studies/.) Since the ESBLs do not hydrolyze all of the extended-spectrum cephalosporins at similar rates, some organisms may show resistance to some cephalosporins but susceptibility to others, even though the latter cephalosporins will not be clinically effective [39, 40]. To identify strains of *Escherichia coli*, *K. pneumoniae*, and *Proteus mirabilis* that contained ESBLs, organisms were tested with cefotaxime and ceftazidime, by either disk diffusion or broth microdilution, in the presence and absence of clavulanic acid, i.e., a β-lactamase inhibitor. If the zones of inhibition increased by 5 mm or more in the presence of clavulanic acid, or the MICs decreased by 3 or more doubling dilutions in the presence of clavulanic acid when compared to the results in the absence of clavulanic acid, the strain were said to contain an ESBL [41]. Thus, the results for all penicillins, cephalosporins, and aztreonam (but not cephamycins, such as cefoxitin or cefotetan) were reported as resistant if ESBLs were detected. β-lactam-β-lactamase inhibitor combinations, such as piperacillin-tazobactam, were reported as they tested (either susceptible, intermediate, or resistant), since they may still have been effective clinically against some ESBL-producing strains of *K. pneumoniae* or *E. coli* [42]. However, interpretive changes are no longer made if the lower breakpoints have been instituted by the laboratory. Similar strategies to identify plasmid-mediated AmpC β-lactamases using boronic acid have been described [43, 44]; however, these tests were never been promulgated by CLSI and thus did not impact the reporting of penicillin or cephalosporin results.

Carbapenemases have emerged within the Ambler class A beta-lactamases including KPC, GES, SME, and IMI; the class B metalloenzymes, including NDM, VIM, and SPM; and among the class D beta-lactamases including OXA48, OXA181, and OXA232. The Modified Hodge Test (MHT) was introduced to detect these enzymes but proved to be ineffective for some carbapenemases, such as NDM. Using MHT was part of CLSI guidelines for several years before lower breakpoints were established. Now, it is primarily used for epidemiologic purposes unless a laboratory has been unable to implement the new lower breakpoints for carbapenems, in which case the MHT is still useful. Other phenotypic tests that can be performed on isolate colonies to detect carbapenemase activity include the carbaNP assay, which is a colorimetric test for carbapenem hydrolysis that is simple and provides results often in less than 2 h [45].

4.2 Macrolides, Azalides, Lincosamides, and Streptogramins

The macrolides, which include agents such as erythromycin and clarithromycin, and the azalides, such as azithromycin, are commonly administered oral (and parenteral) drugs used for the treatment of many bacterial clinical infectious syndromes. Resistance is due either to inactivation of drug (mediated by erythromycin esterases or phoshorylases), efflux of the drug out of the cell, or by modification of the site of action [46]. The latter mechanism, in which the 23S RNA of the 50S ribosome unit is methylated at a specific adenine residue, which prevents binding of the antimicrobial agent to the ribosome, leads to high-level resistance to macrolides but also affects lincosamides (such as clindamycin) and streptogramins (such as pristinamycin), since all three classes of drugs act by binding to the same site on the bacterial ribosome. The so-called MLS_B resistance phenotype (for macrolide–lincosamide–streptogramin$_B$) is typically observed in staphylococci and streptococci. Strains of staphylococci and streptococci that test as erythromycin resistant but clindamycin susceptible may contain an inducible *erm* gene encoding MLS_B resistance or an efflux gene such as *msrA* (in staphylococci) or *mefA* (in streptococci). Since mutations in the *erm* genes can lead to inducible clindamycin resistance, and thus clindamycin treatment failure, it is important to differentiate these two resistance mechanisms in the clinical laboratory to enhance the accuracy of reporting (efflux-mediated resistance cannot mutate to clindamycin resistance). The D-zone test, which is a disk diffusion-based assay, uses an erythromycin disk that is placed 15–25 mm away from a clindamycin disk on an agar plate seeded with a lawn of the test organism [47]. Blunting of the zone of inhibition between the erythromycin and clindamycin disks (which forms a "D" shape) indicates the presence of an

inducible *erm* gene. A circular zone of inhibition (normal zone) indicates a negative test. If the D-zone test is positive, the results for clindamycin are reported as resistant [48].

4.3 Aminoglycosides

Aminoglycosides are commonly used in conjunction with β-lactam agents (or vancomycin in gram-positive-associated infections) to treat serious bacterial infections, such as endocarditis, because the two groups of drugs frequently act synergistically, especially against enterococci [49]. Resistance to aminoglycosides is typically mediated by enzymes that modify the drug so that uptake into the bacterial cell is impaired [50]. These include acetylases, adenylylases, and phosphorylases. In addition, there are 16 s rRNA methylases, multiple efflux pumps, and cell wall permeability barriers that also mediate aminoglycoside resistance.

The number of genes encoding variants of the aminoglycoside-modifying enzymes is remarkably large and diverse. To determine whether there is likely to be synergy between an aminoglycoside (i.e., gentamicin or streptomycin) and a cell wall-active agent (either ampicillin or vancomycin) specifically for treating enterococcal infections, special disk diffusion and MIC tests to detect high-level aminoglycoside resistance have been established by CLSI [41]. The presence of high-level resistance to either aminoglycoside will negate the likelihood of synergistic activity with a cell wall-active agent.

4.4 Sulfa Drugs and Trimethoprim

The sulfa drugs and trimethoprim both inhibit the enzymatic pathway that synthesizes dihydrofolate. The two drugs are usually tested together in a 19:1 ratio of sulfamethoxazole to trimethoprim [41]. Because MIC tests using this combination of drugs often result in trailing endpoints (i.e., a gradual reduction of growth instead of a clear break between the wells of an MIC plate showing growth and those with no growth), the well showing ≥80 % inhibition of growth is usually chosen as the MIC.

4.5 Glycopeptides

Glycopeptide resistance can be mediated by a series of genes that effectively remodel the cell wall of an organism by altering the D-alanine-D-alanine binding site of vancomycin to D-alanine-D-lactate or D-alanine-D-serine through introduction of an altered ligase enzyme (e.g., *vanA*). The family of acquired vancomycin resistance genes now includes *vanA*, *vanB*, *vanD*, *vanE*, *vanG*, and *vanM* [51–53]. The *vanA* resistance determinant has been recognized among enterococci [54] and *S. aureus* isolates [55], the latter due to acquisition of Tn*1545* and its variants [56]. A second mechanism of resistance noted among glycopeptide-intermediate *S. aureus* (GISA) strains (also called vancomycin intermediate strains or VISAs) is the thickening of the cell wall in conjunction with metabolic changes that make *S. aureus* isolates no longer susceptible to glycopeptides [57–59]. While detection of *vanA*-mediated resistance in *S. aureus* has been a challenge for automated MIC methods [60] and in some cases for GISA isolates, GISA isolates have not been detected in the clinical laboratory using disk diffusion [61]. Clinical laboratories typically augment their testing for glycopeptide resistance in staphylococci (whether the use an automated susceptibility method or disk diffusion) by inoculating a Brain Heart Infusion agar plate containing 6 μg/mL of vancomycin with approximately 10^6 CFU of the staphylococcal strain to be tested [61]. This is a very sensitive method for detecting GISA strains as well as VRSA. A modified Etest method may be used to detect GISA isolates [62].

Recently the *vanG* resistance determinant was detected in *Streptococcus agalactiae* [63].

4.6 Fluoroquinolones

Fluoroquinolones are used widely to treat a variety of infections around the world. Resistance to fluoroquinolones typically arises by alterations in the target enzymes (DNA gyrase and topoisomerase IV) and through changes in drug entry and efflux [64]. The discovery of plasmid-mediated horizontally transferable genes encoding quinolone resistance (e.g., *qnrA*, *qnrB*, and *qnrS*) perhaps explains some of the rapid emergence of resistance to these drugs [65, 66]. Likewise, AAC(6′)-Ib-cr, a variant aminoglycoside acetyltransferase capable of modifying ciprofloxacin and reducing its activity, also seems to provide low-level quinolone resistance [67]. It appears that low-level resistance to fluoroquinolones (by whatever mechanism) may be responsible for clinical failures when treating *Salmonella typhi* [68] and non-typhoidal *Salmonella* infections [69]. Strains isolated from patients who failed therapy typically show ciprofloxacin MICs that are elevated (0.25–1 μg/mL compared with typical MICs of 0.003–0.06 μg/mL) but still in the susceptible range; however, the nalidixic acid MICs are usually resistant (MIC > 16 μg/mL). Although, a nalidixic acid screen test was recommended by CLSI for several years to detect strains with low-level ciprofloxacin resistance, lower ciprofloxacin MIC breakpoints have been implemented to provide more reliable data for detecting low-level fluoroquinolone resistance.

4.7 Oxazolidinones

Oxazolidines, such as linezolid, have broad activity against many gram-positive organisms [70]. Resistance to the oxazolidinones among staphylococci and enterococci may be due to modification of ribosomal RNA often through a G to T substitution at position 2765, or one of several other mutations [71, 72], or by acquisition of the *cfr* gene. The *cfr* determinant can mediate resistance to the drugs in the $PhLOPS_A$ classes (i.e., phenicols, lincosamides, oxazolidinones, pleuromutilins, and streptogramin A antibiotics) [73]. Detection of resistance to linezolid, particularly among staphylococci, can be difficult by agar-based methods such as disk diffusion and agar gradient dilution, which tend to lack sensitivity to detect some resistant isolates. Studies at CDC have indicated that broth-based MIC methods typically have better sensitivity for detecting resistance [74].

4.8 Lipopeptides

Daptomycin is an example of a lipopeptide that is rapidly bactericidal for most gram-positive bacteria [75–78]. Testing daptomycin typically requires the presence of 50 mM Ca++ in the broth or agar medium to achieve accurate results. Disk diffusion testing lacked adequate sensitivity to detect reduced susceptibility to daptomycin in clinical studies. Thus, the disk diffusion test was removed from the CLSI documents. However, the agar gradient method was shown to work well [79].

5 Molecular Tests to Detect Resistant Bacteria

5.1 General Considerations

Molecular assays, such as real-time PCR, microarrays, line probes, and film arrays, offer both rapid turnaround times and high sensitivity for identifying antimicrobial resistance genes or mutations associated with resistance in bacterial isolates, even in bacteria directly in clinical samples. Such results may be used in conjunction with other rapid technologies for bacterial identification to guide therapy or to decide whether to implement on a patient contact isolation precautions [80, 81]. Several commercial methods for identifying gram-positive cocci in blood culture bottles test for the presence of *mecA* or *mecC* in addition to identifying *S. aureus* to indicate the presence of MRSA [12, 82]. Additional molecular assays for use on positive blood culture vials include the presence of the vancomycin resistance genes, *vanA* and *vanB*, for detection of resistance genes in enterococci, while other assays test for the presence of the bla_{KPC} carbapenem resistance gene, which may be present in gram-negative organisms [13].

5.2 Detection of Resistance in *Mycobacterium Tuberculosis*

Commercial PCR assays that use molecular beacon technology can detect mutations in the ribosomal RNA polymerase gene *rpoB* that are associated with rifampin resistance in *M. tuberculosis*. Rifampin resistance is frequently a marker of multidrug resistance in *M. tuberculosis*. The PCR assays can be directly on expectorated sputum samples or concentrated pellets prepared for mycobacterial culture and produce results in <2 h [83]. Line probes that utilize reverse hybridization also can be used to assess both mutations associated with rifampin and isoniazid resistance, as well as resistance to second-line drugs, such as fluoroquinolones. These can also be used directly on specimens and report results in approximately 5 h [84].

5.3 Molecular Assays for Detecting Colonization with MRSA, Vancomycin-Resistant Enterococci, and Carbapenem-Resistant Organisms (CRO)

Screening patients being admitted to hospitals or other healthcare institutions for nasal colonization with MRSA has become relatively common in the United States, Europe, and elsewhere around the world as part of enhanced infection control programs to limit its spread. Screening for MRSA can be accomplished by plating material from nasal swabs directly on selective agar media that inhibit the growth of most organisms, while allowing MRSA to produce clearly identifiable colonies. However, this often requires 18–72 h depending on the medium used, whether an overnight broth enrichment step is included, and the number of confirmatory tests undertaken by the laboratory to prove that the organism growing on the agar is MRSA [85]. A more rapid approach uses molecular amplification tests, such as PCR, that simultaneously target the *mecA* (or *mecC*) gene and a chromosomal DNA sequence that is unique to *S. aureus*, thereby linking the resistance gene specifically to the *S. aureus* strain that carries it [86, 87]. PCR-based assays for MRSA detection often can be completed in <2 h from the time the nasal swab specimen arrives in the laboratory, versus the 18–72 h often required to complete an agar-based identification test. Amplification-based assays are more expensive to perform, but the rapid turnaround time can be important when trying to control the spread of MRSA in a hospital setting [88].

Molecular assays for VRE and CROs to identify colonized patients to aid in infection control efforts have been instituted in a variety of healthcare settings. These assays, which target both *vanA* and *vanB* vancomycin resistance

genes [89], or multiple carbapenem resistance genes (e.g., bla_{KPC}, bla_{VIM}, bla_{NDM}, bla_{OXA48}, and bla_{IMP}), are often more sensitive than conventional agar screening media for detecting resistant organisms, with results available often in <1 h. For CROs, no single agar media is effective [90]. For enterococci, while there is a high correlation between the results of molecular assays for detection of *vanA* in rectal swab samples and positive cultures for VRE isolates containing *vanA*, the correlation of PCR assay results and cultures for *vanB*-positive samples is lower, i.e., *vanB*-positive enterococci containing the *vanB* gene have not been recovered for several PCR-positive samples. This probably reflects the fact that organisms in bowel flora other than enterococci, such as *Clostridium* species, can harbor the *vanB* resistance determinant [91]. Correlation of results for detection of CROs by culture and molecular methods, however, is very high [92].

6 Summary

The goal of antimicrobial susceptibility testing is to provide practitioners with data that will assist them in choosing the optimal antimicrobial agent to treat an infection in a patient and to implement appropriate infection control measures to curb the dissemination of certain epidemiologically significant multidrug-resistant organisms. Susceptibility testing in most clinical microbiology laboratories represents a combination of phenotypic assays that provide at least qualitative results (susceptible, intermediate, or resistant) for a series of antimicrobial agents and often quantitative results (MICs) that can guide dosing regimens. Molecular-based tests, such as real-time PCR, may provide rapid information on the presence of resistant bacteria in wound specimens or positive blood culture bottles. Rapid identification of patients colonized with MRSA, CRO, ESBL, or VRE can assist in infection control decisions. Finally, rapid detection of *M. tuberculosis* and rifampin resistance-associated mutations directly in clinical samples can optimize therapy especially for multidrug-resistant TB strains.

Drug Resistance Assays for *Mycobacterium tuberculosis*

81

Sebastian G. Kurz and Max Salfinger

1 Introduction

Timely detection of patients harboring drug-resistant *Mycobacterium tuberculosis* strains is of paramount importance for effective treatment and also for preventing epidemics of drug-resistant tuberculosis. Bacteriologic methods currently in use for detection of drug resistance are the agar proportion method and the use of automated liquid medium systems. In addition, genotypic methods are increasingly employed as screening tests and complement conventional antimicrobial susceptibility testing. Accurate detection of clinically meaningful minimal inhibitory concentrations is the prerequisite for pharmacokinetic and pharmacodynamic correlations.

2 Drug-Resistant Tuberculosis as a Public Health Problem

Drug resistance has been recognized from the beginning of antituberculous chemotherapy [1]. Over the last decades, an alarming increase in drug-resistant tuberculosis (TB) cases has been observed, including multidrug-resistant (MDR) strains being resistant to the two most effective first-line drugs isoniazid (INH) and rifampin (RIF). The Global Project on Anti-Tuberculosis Drug Resistance Surveillance, launched by the World Health Organization (WHO) and the International Union Against Tuberculosis and Lung Disease in 1994, has been continuously expanded and now has data available for 144 countries that harbor 95 % of the world's TB cases. Whereas the overall portion of MDR-TB cases worldwide remains relatively steady at 3.3 % for new cases and 20 % for previously treated cases, percentages in Eastern European and Central Asian countries that share the major burden of MDR-TB disease reach 35 % for new cases and 75 % for previously treated cases, respectively [2]. Treatment for MDR-TB disease is more complex and of longer duration and requires accurate determination of resistance profiles to reach successful outcomes [3]. Therefore, timely and reliable laboratory diagnosis of drug resistance is essential to meet this challenge.

3 Definitions and Terminology in the Field of Tuberculosis

3.1 Drug-Resistant Strain

A drug-resistant strain is defined as a strain with the capacity to grow in the presence of higher concentrations of a drug that is usually effective against *M. tuberculosis*, compared to a "wild-type" strain obtained from a patient never treated with anti-tuberculosis drugs [4, 5].

3.2 Critical Concentrations

The critical concentration for each drug has been defined as the single concentration that allows distinction between a resistant and susceptible strain. Initially this was defined for egg-based Löwenstein-Jensen medium [5] and subsequently for agar media [6, 7]. The critical concentration is defined as the concentration which prevents growth from the vast majority of susceptible colonies but still allows growth of resistant strains. The critical concentration may not reflect precisely the concentrations that are actually interacting with the bacterial inoculum, because drugs are partially inactivated

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_33

during the media preparation process. Therefore, critical concentrations do not reflect the concentrations attainable *in vivo* and no such correlation should be attempted. Directly related to the concept of critical concentration is that of critical proportion, which takes into account a Gaussian distribution of antimicrobial susceptibility in a given culture. This explains that even in cultures from antimicrobial susceptible isolates, a proportion of bacilli are expected to grow in the presence of a drug at the critical concentration. If the proportion of colonies are beyond the expected critical concentration (1 % for most of the first-line drugs), the strain is found to be resistant.

3.3 Direct and Indirect Antimicrobial Susceptibility Tests

For direct testing, the drug-containing medium is inoculated with a processed clinical specimen such as sputum (usually containing a sufficient number of bacteria as determined by microscopy). Indirect testing is performed on a pure culture grown from the clinical specimen.

3.4 Primary (Initial) Drug Resistance

Resistance to any drug detected in a strain obtained from a newly diagnosed patient without prior history of antimicrobial therapy is called primary drug resistance. It indicates that the patient has been infected with a drug-resistant strain.

3.5 Secondary (Acquired) Drug Resistance

Drug resistance detected in a strain obtained from a patient who has been treated before or is still undergoing treatment with the corresponding anti-tuberculosis agent(s) is suggestive of resistance acquired during treatment.

3.6 Multidrug Resistance

Resistance to **both** RIF and INH, with or without resistance to other drugs, is called MDR.

3.7 Extensively Drug Resistance

Resistance that extends beyond the MDR phenotype that includes both resistance to fluoroquinolones and at least one injectable second-line agent is called extensively drug resistance (XDR).

3.8 Poly-resistance

Resistance to any two or more drugs that does not fulfill criteria for MDR may include resistance to RIF or INH, if the isolate is not resistant to both RIF and INH and thus is not MDR.

3.9 First-Line Drugs

The initial treatment regimen for patients newly diagnosed with tuberculosis is composed from the first-line drugs: INH, RIF, pyrazinamide (PZA), and ethambutol (EMB).

3.10 Second-Line Drugs

All other available anti-tuberculosis drugs represent a backup for selection in cases of drug resistance or intolerance to the first-line drugs: capreomycin, amikacin, kanamycin, moxifloxacin, levofloxacin, ethionamide, para-aminosalicylic acid (PAS), clofazimine, and cycloserine. Recent additions with less well-established efficacy and/or limited clinical data are bedaquiline, delamanid, linezolid, amoxicillin/clavulanate, imipenem/cilastatin, meropenem, and clarithromycin.

4 Indications for Antimicrobial Susceptibility Testing (ASD)

In resource-rich countries, antimicrobial susceptibility testing for clinical *M. tuberculosis* isolates is standard of care in order to ensure optimal drug therapy. However, in many areas of the world which share the major burden of TB, this standard cannot be met. Therefore, the WHO has outlined a programmatic approach that allows for targeted testing directed at individuals at particularly high risk for drug-resistant TB. The following risk factors have been identified: failure of new TB regimens with persistent sputum acid-fast bacilli (AFB) smear positivity at months five or later, delayed sputum conversion, exposure to a known drug-resistant TB case, relapse and return after lost follow-up, exposure to institutions with high drug-resistant TB prevalence, comorbid conditions associated with malabsorption, and HIV in some settings [8].

5 Agar Proportion Method

The major advantage of performing antimicrobial susceptibility tests in agar plates is related to the transparency of the medium, which makes it possible to observe the growing colonies at the beginning of their formation. Therefore, final

results can be reported within 2–3 weeks for most isolates, instead of 4–6 weeks or more when using egg-based media. There are two types of agar medium that can be used for either **direct** or **indirect** test: Middlebrook 7H10 and Middlebrook 7H11. Middlebrook 7H11 agar provides better growth of drug-resistant TB strains compared to Middlebrook 7H10 [9]. Detailed description of their preparation and use can be found in the appropriate publications [6, 7, 10]. These media are made from commercially available 7H10 or 7H11 agar base.

Some strains may have genetically predetermined low-level resistance to INH [11]. Therefore, two concentrations of INH shown in Table 81.1 are needed to distinguish between low and high levels of resistance to this drug. A higher concentration of streptomycin in addition to the critical concentration of this drug (as shown in Table 81.1) is usually employed in agar media.

For a direct test, after the digestion-decontamination procedure, the concentrated sputum sediment is inoculated into plates, 0.1 mL per quadrant. For an indirect test, two sets of plates are used: one inoculated with 10^{-3}-fold and the other with 10^{-5}-fold dilutions of the bacterial suspension adjusted to the optical density of the McFarland #1 standard.

Table 81.1 Critical concentrations (μg/mL) for testing *M. tuberculosis* in solid and liquid media

Drug	L-J	7H10 Agar	7H11 Agar	MGIT960	VersaTREK
References	[8]	[8]	[8]	[8]	[47]

Linezolid	–	–	–	1.0	–

L-J: Löwenstein-Jensen medium
7H10 Agar: Middlebrook 7H10 agar
7H11 Agar: Middlebrook 7H11 agar
[a]Isoniazid: Some laboratories may test an additional higher INH concentration in order to differentiate between low- and high-level INH resistance
[b]Moxifloxacin: Two concentrations are proposed. In programs using both ofloxacin/levofloxacin and moxifloxacin, possible testing is for moxifloxacin only at both concentrations, or test ofloxacin/levofloxacin at higher concentration. In programs using ofloxacin/levofloxacin, only test these drugs. In programs using only moxifloxacin, test at higher concentration of moxifloxacin

The plates are incubated at 35–37 °C for 3 weeks, protected from light, in an atmosphere of 5–10 % CO_2 for 7H10 and 7H11 agar plates; however, CO_2 is not essential when performing the indirect method. The colonies are counted, and the results are reported as the percentage (proportion) on the basis of comparison of the number of colony-forming units (CFU) on drug-containing and drug-free quadrants. The isolate is considered "resistant" if this proportion is 1 % or greater for all drugs except PZA. The criterion for PZA is 10 %; however, PZA is no longer tested on agar media. If growth is not sufficient at the 3-week reading, then the plates are reexamined at the 6-week reading, but in such a case only "susceptible" results are considered valid. This is because growth at 6 weeks in drug-containing quadrants may be related to drug degradation during the prolonged incubation period, rather than to the occurrence of true drug resistance.

6 Antimicrobial Susceptibility Testing (Indirect) in Liquid Medium

The need for expedited detection of drug resistance was first addressed in the 1980s by developing the antimicrobial susceptibility testing procedure [12–14] for the semiautomated BACTEC460 system introduced by Becton Dickinson (Sparks, MD). Non-radiometric, walkaway systems, all fully automated and computerized, are now commercially available: BACTEC960 MGIT (Becton Dickinson Microbiology Systems, Sparks, MD) and VersaTREK, formerly ESP-II Culture System, by Difco (Thermo Fisher Scientific, Cleveland, Ohio).

In the BACTEC960 MGIT system, the bacterial growth detection is based on consumption of oxygen, which causes the indicator embedded in the bottom of tubes to fluoresce, and the instrument continuously monitors the increase of fluorescence. Comparison of these patterns in drug-containing and drug-free tubes is analyzed by the instrument and automatically reported as "susceptible" or "resistant."

In the VersaTREK system, growth monitoring is based on reduction of pressure in the vials due to the consumption of oxygen by the growing bacteria. The conclusion is based on comparison between drug-free controls and drug-containing vials after positive readings have occurred for 3 consecutive days in the drug-free vial. "Susceptible" is reported if no growth is detected in drug-containing vials, and "resistant" is reported if growth is detected in a drug-containing vial at this time point.

For all of these systems, critical concentrations have been developed (Table 81.1). Two concentrations of INH are performed to distinguish between low and high levels of resistance to this drug [10, 11]. Critical concentrations of various second-line and newer compounds were suggested for the BACTEC960 MGIT systems [15] (Table 81.1).

A report simply stating "resistant" may not be enough for the clinician to provide adequate care for a patient with MDR-TB or even XDR-TB. There is a growing body of evidence that additional information is needed such as the specific genetic mutation and/or the determination of the minimal inhibitory concentration (MIC) for patients with drug-resistant TB [16]. Furthermore, strains with elevated MIC for RIF may be reported by systems using liquid media as susceptible, missing a potential red flag [17]. There are mainly two approaches to determine the MIC of a particular compound: macro-dilution and micro-dilution assays. In 2009, Springer et al. described a new method for quantitative AST by the use of BACTEC960 MGIT and EpiCenter instrumentation [18], and in 2012, Hall et al. published an evaluation of the Sensititre MycoTB Plate for AST of *M. tuberculosis* complex [19]. The Sensititre *Mycobacterium tuberculosis* MIC Plate (Thermo Fisher Scientific, Cleveland, Ohio) is CE/IVD marked and for research use only in the USA.

7 Molecular Phenotypic and Genotypic Methods

Traditional approaches based on solid and liquid media assays are hampered by long turnaround times due to the slow growth of *M. tuberculosis*. Molecular methods hold promise to speed up the process and to offer clinicians timely and accurate information that can be taken into account at the very beginning of therapy. With the advent of microfluidic "lab-on-a-chip" technologies, it may become possible to detect drug-resistant genotypes in point-of-care settings outside of the laboratory [20].

Genotypic methods detect the bacterial DNA or RNA sequences associated with drug resistance. A persistent challenge to the application of genotypic approaches is the complexity of the underlying genetics of drug resistance. High-level resistance to most tuberculosis drugs, including INH, can result from diverse mutations in multiple genetic loci [21, 22]. Adding to the complexity, some mutations in known drug resistance loci can confer low-level resistance, which may not be clinically significant. Although most drug resistance mechanisms are genetically complex, there is an exception to this rule with *M. tuberculosis:* More than 95 % of RIF-resistant isolates of *M. tuberculosis* carry point mutations or small deletions/insertions in an 81-base region of the *rpoB* gene coding for the β subunit of DNA-dependent RNA polymerase or in a smaller region near the 5′ end of the gene. This was established in numerous studies conducted throughout the world [22–25]. RIF is a first-line anti-tuberculosis drug, and it is considered to be a surrogate marker for MDR-TB [26, 27]. Accordingly, the development of genotypic antimicrobial susceptibility testing methods has mainly focused on this locus.

Most approaches use in vitro DNA amplification such as PCR in combination with diverse methods for detecting specific mutations known to result in drug resistance, most commonly line probe assays and molecular beacons.

Line probe assays allow identification of single base mutations that confer drug resistance. After DNA extraction from the clinical specimen, gene regions of interest are amplified via PCR and the single-strand amplicons bind to highly specific immobilized DNA probes. The bound DNA fragment becomes visible as a band by an enzymatic color reaction (e.g., biotin). Two currently commercially available line probe assays have received recommendation status by the WHO and related organizations, INNO-LiPA-Rif.TB (Fujirebio Europe, Ghent, Belgium) and GenoType MDR*plus* (Hain Lifescience, Nehren, Germany) which has been further developed to capture resistance markers of several drug classes.

The INNO-LiPA-Rif.TB was the first commercially available line probe assay. It uses a set of primers that allow PCR amplification of a region of interest in the *rpoB* gene where rifampin resistance mutations are located, and several oligonucleotide probes that span the resistance mutation region, as well as an upstream sequence that is specific for *M. tuberculosis* complex [28]. The assay proved very accurate when applied on culture specimens with sensitivities greater than 95 % and specificity of 100 %, with some loss in sensitivity (80–100 %) when directly applied to clinical specimens [29, 30].

The GenoType MTBDR assay and its successor, the GenoType MTBDR*plus*, are based on multiplex PCR and offer probes for both rifampin mutations (*rpoB*) and the most common INH resistance mutations (*katG* and, in the GenoType MTBDR*plus*, *inhA*) and thus allow detection of MDR-TB strains. In a 2008 meta-analysis on isolates, it was highly accurate for detection of RIF resistance with pooled sensitivity and specificity of 98 % and sensitivity for INH of 84 %, which improved to about 90 % when *inhA* testing was included (MTBDR*plus* assay) [29]. A further development is the GenoType MTBDR*sl* assay which allows detection for mutations that confer resistance to fluoroquinolones and the injectable drugs amikacin and capreomycin. Its performance against culture-based antimicrobial susceptibility testing was the subject of a recent Cochrane meta-analysis [31]. It was found to be highly specific with greater than 98 % for all classes. For quinolones, a pooled sensitivity of 83 % was found when applied on isolates, with similar results when applied to AFB smear-positive specimens. Pooled sensitivities for second-line injectable drugs amikacin, kanamycin, and capreomycin were 76.9 % for cultures and 94.4 % for AFB smear-positive specimens, respectively. The authors conclude that due to its modest sensitivity and excellent specificity, the test can be used as a rapid rule-in test on AFB smear-positive specimens (direct testing) for MDR-TB and

XDR-TB. However, it still would miss one in four cases of XDR-TB, which makes culture-based antimicrobial susceptibility testing necessary for specimens which were not identified as resistant.

In 2011, the Hain GenoType MTBDR*plus* V2 was introduced with improved sensitivity which may allow testing of AFB smear-negative sputum specimens [32, 33]).

Around the same time, the NTM+MDR-TB Detection Kit 2 (Nipro Corporation, Osaka, Japan) was developed which offers rifampin and INH resistance detection based on *rpoB*, *katG*, and *inhA* with excellent performance, as well as identification of various nontuberculous mycobacteria [34]. Both the Hain GenoType MTBDR*plus* V2 and the NTM+MDR-TB assay were compared to the GenoType MTBDR*plus* in an extensive non-inferiority analysis by FIND and, based on their excellent performance characteristics, received recommendation status for endorsement by the WHO for rapid detection of MDR-TB in AFB smear-positive specimens [35].

The Xpert MTB/RIF (Cepheid, Sunnyvale, CA, USA) diagnostic system is a PCR-based platform which allows detection of *M. tuberculosis*-specific sequences as well as rifampin resistance mutations using **molecular beacons** [36]. Gene areas of interest are amplified via PCR. Molecular beacons are oligonucleotides that form hairpin-like loops. They carry the sequence of interest in the middle and short repetitive sequences at each end which close the loop by hybridization. A fluorophore is attached to the 5′ end and a quencher molecule to the 3′ end, respectively, which suppresses the fluorescent signal while to loop is closed. When the probe binds to its complementary DNA strand, the loop opens and fluorescence is restored which can be detected [37]. Specimens are simple to prepare and the single-use cartridge technology allows for safe and reliable handling with minimal training. Since its introduction, a large body of literature has accumulated. Its performance has been systematically reviewed by the Cochrane collaboration [38]: Pooled sensitivities from 27 studies were 89 % (95 %; CI 85–92 %) and pooled specificities 99 % (98–99 %). Performed on AFB smear-negative specimens, pooled sensitivities were still 67 % (60–74 %). For rifampin resistance, pooled sensitivity was 95 % with a specificity of 98 %. Based on these characteristics, Xpert MTB/RIF is now approved by the US Food and Drug Administration (FDA) for both AFB smear-positive and smear-negative sputum specimens.

It is increasingly recognized that the capabilities of currently available molecular platforms need to be expanded from being a screening tool alone toward the delivery of an individualized and detailed resistance profile, as recently outlined by *Somoskovi* and *Salfinger* [16]. The following are examples of potential limitations of currently used molecular testing platforms: Recent reports of rifampin mono-resistance rates as high as 11.6 % [39] highlight the problem of potential overdiagnosing MDR-TB when relying on detection of RIF resistance as a surrogate for MDR-TB. Similarly, INH mono-resistance has been described, which can remain undetected if RIF testing is not followed by conventional antimicrobial susceptibility testing and may lead to MDR-TB if inadequately treated with the standard regimen. INH is a prodrug that needs to be activated by a peroxidase encoded by *katG*. The most common *katG* mutation at codon 315 can be readily identified and is associated with high-level INH resistance. However, other less common *katG* mutations exist that lead to variable degree of resistance and would need to be identified by conventional INH testing, so that culture-based testing should not be foregone by a negative *katG* screen. In contrast, mutations in the promoter region of the target gene *inhA* also lead to low-level INH resistance, which can be overcome by increasing INH doses. On the other hand, these mutations have been associated with cross resistance to ethionamide.

The complex genetic background of most drug resistance mechanisms is currently being matched with the continuous technological progress to improve speed and quality of sequencing. Whole genomic scale analysis of individual isolates is currently being evaluated as a tool to predict the drug resistance phenotype [40].

For the foreseeable future however, molecular testing needs to be correlated with phenotypical antimicrobial susceptibility testing in order to capture novel resistance mechanism that are likely to arise. Similarly, as molecular tests are being expanded to different drug targets, there is a need for adaptation to prevailing resistance mutations at the local level [16, 41].

8 Pharmacokinetic and Pharmacodynamic Considerations

A growing body of evidence raises concerns that currently used standard dosing regimens for first-line agents do not reach adequate serum concentrations in a significant proportion of patients. This has been linked to treatment failure and development of drug resistance despite supervised directly observed therapy [42]. The concept of pharmacokinetic and pharmacodynamic (PK/PD) correlation aims at optimization of dosing regimens to attain drug exposure with maximal microbial killing effect (see [43] for review). The principal paradigm is that there is a quantifiable relation between drug concentration observed over time and microbiological killing, which can be evaluated in preclinical models (hollow fiber model, animal models) and translated into humans. The elements of this approach include: First is the determination of minimal inhibitory concentration (MIC) value that is associated with treatment success. Second is the determination of PK/PD parameter which

correlates best with bactericidal effect (Cmax/MIC, AUC/MIC, or T%/MIC). This is determined empirically and may be different for each drug. For example, in most of the first-line drugs, this is the ratio of total amount of drug in a given time interval over MIC (AUC/MIC), and efficacy is not affected by splitting doses. For aminoglycosides, in contrast, it is the maximal attained concentration over MIC (Cmax / MIC). This indicates that the aminoglycosides should be administered in large single doses to be most effective. It is noteworthy that this relation remains constant for different MIC, and an increase in drug exposure may be able to compensate for an elevated MIC. Third is the ability to reliably predict the serum concentration profile over time. On a population level, this is usually done by Monte Carlo simulations, which assume differences in drug absorption and clearance to be present in a certain distribution within the population. On an individual level, it is impractical to measure drug levels at multiple time points. Instead, therapeutic drug monitoring commonly relies on a single time point, usually drawn at 2 h post-drug administration to capture the serum peak. Limited sampling strategies aim to find a single time point specimen that correlates best with expected AUC [44].

It is clear that the ability to accurately determine the MIC is at the heart of this approach. Once the PK/PD parameter for optimal effect is determined, drug dosing can be optimized based on the MIC of the individual strain. Conversely, it has been argued that the currently employed MIC breakpoints are too optimistic and that using standard dosing regimens, treatment of drug-susceptible disease harbors the risk of treatment failure [45]. A further development of this approach is to determine PK/PD targets to prevent development of resistance. It has been shown that drug exposure that leads to effective killing may still be insufficient to prevent development of resistance [46].

Acknowledgments We thank the authors of the previous version of this chapter, the late Leonid Heifets and Gerard Cangelosi.

Fungal Drug Resistance Assays

82

Sevtap Arikan-Akdagli and John H. Rex

1 Introduction

The increase in opportunistic mycosis as well as the emergence of antifungal resistance and the development of novel antifungal drugs necessitated the development of standard phenotypic drug resistance assays for fungi. Microdilution methods for testing yeasts (CLSI M27-A3 and EUCAST E.Def 7.2 assay) and filamentous fungi (CLSI M38-A2 and EUCAST E.Def 9.2 assay) are available. Disk diffusion assays for testing *Candida* (CLSI M44-A2) and nondermatophytic molds (CLSI M51-A) have also been standardized. Despite their availability and increasing knowledge of epidemiological cutoff values, these assays still have limitations. Most notably, clinical MIC breakpoints are as yet undetermined for some important drug–genus combinations. In an effort to standardize methodologies that might solve these problems as well as approaches that would support assay automation, techniques based on gradient strip method, colorimetric microdilution, agar dilution, flow cytometry, sterol quantitation, and isothermal microcalorimetry are also being studied. MALDI-TOF MS and genotypic assays are other approaches currently explored for detection of antifungal resistance.

2 The Need for Fungal Drug Resistance Assays

Fungal infections have drawn attention in the last three decades for several reasons. First, there has been a remarkable increase in the number of patients whose immune system is compromised due to various reasons. As invasive mycoses have emerged as significant causes of morbidity and mortality for this particular patient population, the term "fungal infection" no longer only means a "superficial infection." Second, the number and variety of antifungal agents increased. This is the outcome of the demand for more efficacious and less toxic antifungal drugs to treat serious infections and the developments in pharmaceutical industry. As a result, several possible therapies exist for some situations [1–5]. Third, fungal infections refractory to antifungal therapy because of primary or secondary resistance of the infecting strains to the antifungal agents used for treating these infections are observed [6–17].

In the era where we have more patients with serious fungal infections, more alternatives to treat these infections, and patients who become or remain resistant to therapy, the best way to optimize the antifungal therapeutic strategies and to predict clinical outcome is to determine the susceptibility profiles of the infecting fungal strains to the antifungal drugs. This great demand thus resulted in the standardization of fungal drug resistance assays and sustained efforts to define their utility.

2.1 Studies to Assess Correlation of In Vitro Susceptibility with Clinical Outcome

The ultimate goal of routine fungal resistance assays is to predict clinical outcome and permit monitoring and selection of antifungal therapy. The inquiry of to what extent this goal was achieved has been the key question. A meta-analysis of in vitro–in vivo correlation studies that included patients

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_34

infected with *Candida*, *Cryptococcus*, or *Histoplasma* and treated with various azoles (fluconazole, itraconazole, or ketoconazole) found a clinical success rate of 91 % for infections due to isolates susceptible to the antifungal agent used for treatment and a 48 % response rate for those infections treated with agents predicted to be resistant [18]. Interestingly, these percentages approximated the clinical success rates reported for treatment of various bacterial infections due to susceptible/resistant strains. Based on these data, the concept referred to as "90–60 rule" has been proposed and states in summary that susceptible isolates respond about 90 % of the time and resistant isolates respond about 60 % of the time. This conceptual model reminds us that susceptibility assays are helpful in predicting clinical response but represent only one of many factors that influence response. Factors such as pharmacokinetic properties of the drug, immune status of the host, severity of the infection, presence (and removal) of prosthetic devices, and surgical management of the site of infection are all relevant, and each, in turn, may be the most powerful factor in a given situation.

Following this meta-analysis, available in vitro–in vivo correlation data expanded further to include those for various antifungal drugs against different fungal genera. Of specific note, some in vitro–in vivo correlation studies, particularly those for amphotericin B, have found limited correlations between in vitro susceptibility and clinical outcome. For amphotericin B and *Candida*, various in vitro susceptibility testing settings, including Clinical and Laboratory Standards Institute (CLSI) microdilution and Etest methods, antibiotic medium 3, and RPMI 1640 media, have failed to generate MICs that correlated with clinical outcome [19]. Similarly, in vitro susceptibility tests could not predict early clinical outcome in patients with cryptococcosis treated with amphotericin B-flucytosine or fluconazole [20]. As also discussed in Sect. 3.4.1, these observations of lack of correlation particularly for amphotericin B might be related to the technical difficulties in demonstration of amphotericin B resistance in vitro [21].

Correlation data for patients with candidiasis who are treated with echinocandins have recently expanded, particularly after the demonstration of isolates with secondary resistance to echinocandins, suggesting that clinical failure with echinocandin therapy correlates with FKS mutations and elevated echinocandin MIC values in patients with candidiasis due to FKS mutant *Candida glabrata* strains [22–27]. These data further strengthened the clinical significance of in vitro antifungal susceptibility testing and the correlation of in vitro susceptibility data with clinical outcome. Echinocandin resistance also appears to exist within *Aspergillus* spp. but is less well understood in part because susceptibility testing is not often performed and in part because susceptibility methods are suboptimal. Laboratory-engineered mutations in the target enzyme are associated with in vivo resistance and even hypervirulence in some cases [28]. Isolates from breakthrough clinical infections have not been exhaustively studied.

Finally, in vitro–in vivo correlation data for cases with *Aspergillus* infections and mucormycoses have also been reported but remain limited. For *Aspergillus*, the emergence of strains with well-defined point mutations in lanosterol 14-alpha demethylase produces increased azole MICs and is associated with clinical failure [14, 25, 29–33]. The demonstration of the presence of secondary azole resistance in *Aspergillus fumigatus* strains also further strengthened the use of antifungal susceptibility testing in routine practice. As previously discussed for yeast genera, correlations of MICs with outcome are less certain for amphotericin B against molds as well. Some of these data suggest no correlation of in vitro amphotericin B susceptibility profile with clinical response to aspergillosis [34], whereas other data appear to support an association between high amphotericin B MIC values and poor clinical outcome in cases of aspergillosis [35, 36] or those infected with Mucorales (*Apophysomyces elegans*, specifically) [37].

Overall and based on the available in vitro–in vivo correlation data, routine antifungal susceptibility testing is currently accepted as a useful adjunct for prediction of clinical outcome and guidance of antifungal therapy particularly in *Candida* and *Aspergillus* infections. However, it is not surprising that the prediction power of the in vitro antifungal susceptibility test results is incomplete given the influence of multiple factors on clinical response, including the immune system of the host in particular.

3 Reference Antifungal Susceptibility Testing Methods Interpretive Guidelines

3.1 CLSI Reference Antifungal Susceptibility Testing Methods

3.1 CLSI Reference Broth Dilution Methods (M27-A3 and M38-A2)

Based on multicenter studies that started at the beginning of the 1990s, the CLSI (Clinical and Laboratory Standards Institute, formerly National Committee for Clinical Laboratory Standards (NCCLS)) subcommittee on antifungal susceptibility testing standardized reference broth dilution methods for both yeasts (*Candida* spp. and *Cryptococcus neoformans*) and molds (*Aspergillus* spp., *Fusarium* spp., *Pseudallescheria boydii*, *Rhizopus* spp., mycelial form of *Sporothrix schenckii*, dermatophytes, and dematiaceous molds). The revised and currently available CLSI microdilution documents for testing yeasts and molds are CLSI M27-A3 [21] and M38-A2 [38], respectively. Of specific note, the standardization and inclusion of test parameters for dermato-

Table 82.1 Principal test parameters of CLSI M27-A3, EUCAST E.Def 7.2, CLSI M38-A2, and EUCAST E.Def 9.2 methods [21, 38, 80, 89]

Test parameters	Microdilution methods standardized for testing yeasts		Microdilution methods standardized for testing filamentous fungi	
	CLSI M27-A3	EUCAST E.Def 7.2	CLSI M38-A2	EUCAST E.Def 9.2
Test medium	RPMI 1640 medium (with L-glutamine and without bicarbonate), with phenol red as a pH indicator and buffered with MOPS [(3-*N*-morpholino) propanesulfonic acid] (pH = 7 at 25 °C), glucose, 0.2 %	RPMI 1640 medium (with L-glutamine and without bicarbonate), with phenol red as a pH indicator and buffered with MOPS [(3-*N*-morpholino) propanesulfonic acid] (pH = 7 at 25 °C), glucose, 2 %	RPMI 1640 medium (with L-glutamine and without bicarbonate), with phenol red as a pH indicator and buffered with MOPS [(3-*N*-morpholino) propanesulfonic acid] (pH = 7 at 25 °C), glucose, 0.2 %	RPMI 1640 medium (with L-glutamine and without bicarbonate), with phenol red as a pH indicator and buffered with MOPS [(3-*N*-morpholino) propanesulfonic acid] (pH = 7 at 25 °C), glucose, 2 %
Inoculum density	$0.5–2.5 \times 10^3$ cfu/mL adjusted by spectrophotometric measurement	$0.5–2.5 \times 10^5$ cfu/mL adjusted by spectrophotometric measurement	Molds other than dermatophytes: $0.4–5 \times 10^4$ cfu/mL adjusted by spectrophotometric measurement Dermatophytes: $1–3 \times 10^3$ cfu/mL adjusted by hemocytometric measurement	$1–2.5 \times 10^5$ cfu/mL adjusted by hemocytometric or spectrophotometric measurement
Microdilution plates	96 U-shaped wells	96 flat-bottom wells	96 U-shaped wells	96 flat-bottom wells
Incubation temperature	35 °C	35 °C	35 °C[a]	35 °C
Time of reading	24–72 h[b] (varies depending on the fungal genus, antifungal drug, and sufficiency of growth)	24–48 h[c] (varies depending on the fungal genus and sufficiency of growth)	24–72 h[d] (varies depending on the fungal genus and sufficiency of growth)	24–72 h[e] (varies depending on the fungal genus and sufficiency of growth)
MIC reading method	Visual	Spectrophotometric (530 nm)	Visual	Visual

[a]Incubation at 30 °C may be preferable for some strains of *Alternaria* spp. that do not grow well at 35 °C

[b]In case of adequate fungal growth, acceptable time of reading is 24 h for the echinocandins; 24 or 48 h for amphotericin B and fluconazole; 48 h for flucytosine, itraconazole, voriconazole, ravuconazole, and posaconazole; and 72 h for all referenced drugs against most *Cryptococcus neoformans* isolates

[c]MICs are read at 24 h for isolates that exhibit adequate growth. Further reincubation for 12–24 h is required for strains that grow poorly at 24 h. Of specific note, in case of poor growth of a *Cryptococcus* strain at 48 h, the next step should be repeat MIC testing by incubation at 30 °C

[d]MICs are read at 21–26 h for *Rhizopus* spp.; 46–50 h for *Aspergillus* spp., *Fusarium* spp., and *Sporothrix schenckii*; and 70–74 h for *Scedosporium* spp. The recommended echinocandin MEC reading time is 21–26 h for *Aspergillus* spp. and *Paecilomyces variotii*, 46–72 h for *Scedosporium* spp., or the first day when sufficient growth is observed in the growth control well. MIC readings for the dermatophyte isolates are performed after 4 days of incubation

[e]Specified recommendations for MIC reading time are 24 h for strains belonging to order Mucorales (in presence of sufficient growth) and 48 h for most of the remaining molds. A further extension of the incubation to 72 h (but not more) is acceptable (e.g., for *Scedosporium* strains) to achieve sufficient growth in the growth control well

phytes have been an addendum to CLSI M38-A2 methodology. These parameters for testing dermatophytes were standardized following multicenter analyses initiated in 2003 [39, 40] and summarized in Table 82.1.

The initial CLSI broth dilution method was a broth macrodilution performed in sterile tubes. Since the data obtained later provided a good correlation between macro- and microdilution assays [41, 42], broth microdilution method performed in sterile, disposable, microdilution plates with 96 U-shaped wells is now applied, based on its more practical and more cost-effective nature. The major test parameters proposed in CLSI M27-A3 and M38-A2 documents (as compared to those recommended in corresponding EUCAST documents) and the relevant MIC reading endpoints are summarized in Tables 82.1 and 82.2, respectively. In addition to the methodologic documents, CLSI also publishes informational supplements to provide updated information for quality control limits, interpretive guidelines, and test parameters. Among these is the CLSI M27-S4 document [43] which is the informational supplement for CLSI M27-A3 method. Interested readers are encouraged to review the cited CLSI documents for further details of these reference assays.

3.1.2 CLSI Reference Disk Diffusion Methods (M44-A2 and M51-A)

Following the successful development of standardized broth dilution methods for antifungal susceptibility testing of fungi, the next step was to simplify this approach and make it more attractive for small-volume testing. Disk diffusion has long been a popular and simple technique for susceptibility testing, and this methodology has been adapted by the CLSI

Table 82.2 CLSI and EUCAST recommendations for MIC reading endpoints for various fungal genera–antifungal drug combinations [38, 43, 80, 89]

Antifungal drug	Fungal genus or group	Recommended MIC reading endpoint	
		CLSI	EUCAST
Amphotericin B	All fungal genera relevant for testing amphotericin B	MIC-0	Yeasts: ≥90 % reduction in growth as compared to the growth control well in spectrophotometric[c] measurement Molds: The lowest concentration that yields complete inhibition of growth visually
Azoles relevant for testing against the specified fungal genus or group	Yeasts (*Candida* and *Cryptococcus*, specifically)	MIC-2	≥50 % reduction in growth as compared to the growth control well in spectrophotometric[c] measurement
	Aspergillus and most of the other opportunistic molds[a]	MIC-0	The lowest concentration that yields complete inhibition of growth visually
	Dermatophytes[b]	MIC-1	
Echinocandins	Candida	MIC-2	≥50 % reduction in growth as compared to the growth control well in spectrophotometric[c] measurement
	Aspergillus (and other opportunistic molds)[a]	MEC	The lowest concentration that yields the change from filamentous to granular growth pattern (as assessed macroscopically or in microscopic examination if macroscopic evaluation is not demonstrative). The microscopic reflection of this change is that from long, hyphal appearance (as observed in the growth control well) to short, stubby, branched hyphal clusters
Flucytosine	Yeasts (*Candida* and *Cryptococcus*, specifically)	MIC-2	≥50 % reduction in growth as compared to the growth control well in spectrophotometric[c] measurement
Ciclopirox	Dermatophytes[b]	MIC-1	–
Griseofulvin	Dermatophytes[b]	MIC-1	–
Terbinafine	Dermatophytes[b]	MIC-1	–

MIC-0: The lowest concentration that yields complete inhibition of growth visually
MIC-1: The lowest concentration that yields ~80 % reduction in growth as compared to the growth control well visually
MIC-2: The lowest concentration that yields prominent (~50 %) reduction in growth as compared to the growth control well visually
MEC: The lowest concentration that produces small, rounded growth pattern as compared to the filamentous growth observed in the growth control well macroscopically
[a]Referred to as "conidia-forming molds" in general in EUCAST EDef 9.2 document
[b]Includes species of *Microsporum*, *Epidermophyton*, and *Trichophyton*
[c]Recommended wavelength for measurement of the absorbance of the microplate is 530 nm. Alternatively, 405 or 450 nm may also be used

to antifungal agents. Based on studies of *Candida* vs. fluconazole and voriconazole [44–47], a standardized method (M44-A2) for antifungal disk diffusion susceptibility of yeasts, particularly for *Candida* vs. fluconazole, voriconazole, and caspofungin, is available and used for antifungal surveillance studies [9, 48, 49]. This method employs the basic rules of Kirby–Bauer disk diffusion method. Mueller–Hinton agar supplemented to 2 % glucose and 0.5 μg/mL methylene blue dye (pH = 7.2–7.4 at room temperature after gelling) is used as the test medium. While the supplementation with glucose provides favorable growth, addition of methylene blue enhances zone edge definition [50]. The inoculum density to be used in the test is adjusted in sterile saline to that of 0.5 McFarland standard either visually or spectrophotometrically at 530 nm, yielding a final concentration of $1–5 \times 10^6$ cells/mL. The results are read after incubation of the plates for 18–24 h at 35 °C at the inhibition zone diameter where a prominent reduction in growth is observed. Pinpoint colonies that are observed at the edge of the inhibition zone and large colonies within the zone should be ignored. The incubation period may be extended to 48 h only for isolates which grow insufficiently at 24 h. Disk diffusion interpretive criteria are available for fluconazole, voriconazole, caspofungin, and micafungin vs. *Candida* [51–54].

The disk diffusion method has also been investigated for other antifungal drugs and/or yeast genera, such as posaconazole vs. *Candida* [55–57]; micafungin vs. *Candida* [52]; amphotericin B, flucytosine, and azoles vs. *Saprochaete capitata* (formerly *Blastoschizomyces capitatus* and *Geotrichum capitatum*) [58]; and fluconazole and voriconazole vs. *Trichosporon* spp. [59].

Antifungal susceptibility testing by using disk diffusion method has been explored also for filamentous fungi causing invasive infections, particularly for testing of caspofungin and micafungin vs. *Aspergillus* and *Fusarium* [60, 61]; posaconazole vs. *Aspergillus*, *Rhizopus*, *Mucor*, *Scedosporium*, and *Fusarium* [62, 63]; and posaconazole, voriconazole, itraconazole, amphotericin B, and caspofungin vs. *Absidia*, *Aspergillus*, *Alternaria*, *Bipolaris*, *Fusarium*,

Mucor, *Paecilomyces*, *Rhizopus*, and *Scedosporium* [64]. The results of these studies in general suggested an acceptable degree of correlation between disk diffusion and CLSI reference dilution assays and were followed by documentation of a standardized disk diffusion assay by CLSI (M51-A) for testing filamentous fungi causing invasive infections [65]. The method is standardized for *Alternaria*, *Aspergillus*, *Bipolaris*, *Fusarium*, order Mucorales, *Paecilomyces*, *Pseudallescheria boydii*, and *Scedosporium prolificans*, in particular. Nonsupplemented Mueller–Hinton agar (without addition of calcium, magnesium, glucose, or methylene blue dye) (pH = 7.2–7.4 at room temperature) is the recommended test medium to be used in CLSI M51-A disk diffusion assay. Test inoculum containing conidia or sporangiospores is prepared spectrophotometrically and in accordance with the procedure outlined in CLSI M38-A2 document to yield an inoculum density of $0.4–5 \times 10^6$ cfu/mL. The inoculated agar media are incubated at 35 ± 2 °C for 16–24 h for order Mucorales; 24 h for *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger*; 48 h for other *Aspergillus* spp.; and 48–72 h for *Alternaria*, *Bipolaris*, *Fusarium*, *Paecilomyces*, *P. boydii*, and *S. prolificans*. For mold-active triazoles, inhibition zone diameters are measured at the endpoint of prominent reduction in growth by ignoring the slight trailing around the zone edge as well as the filamentous growth extending into the inhibition zone. The recommended endpoint for reading the inhibition zone diameters for echinocandins is also similar to that of triazoles as specified for caspofungin in CLSI M51-A document. The inhibition zone diameters are measured by ignoring the trailing growth within a well-defined inhibition zone around an echinocandin disk. In contrary, trailing growth should be taken into consideration when interpreting the results for amphotericin B. Performance standards including the expected ranges for quality control isolates and the established epidemiological cutoff values (ECV) for CLSI M51-A methodology are documented in informational supplement CLSI M51-S1 [66]. Importantly, the ECVs documented in CLSI M51-S1 document remain yet tentative and have not been approved to be used for clinical testing.

CLSI M51-A method is standardized only for filamentous fungi causing invasive infections. While the results suggest an acceptable degree of correlation with CLSI reference dilution assay in general, disk diffusion susceptibility testing for dermatophytes remains yet investigational. It has been used for testing fluconazole, itraconazole, terbinafine, ravuconazole, and voriconazole against *Microsporum* and *Trichophyton* [67, 68] and ciclopirox olamine, fluconazole, griseofulvin, ketoconazole, itraconazole, miconazole, naftifine, posaconazole, ravuconazole, terbinafine, and voriconazole against *Microsporum*, *Epidermophyton*, and *Trichophyton* spp. [69–71].

Tablet diffusion assay is another agar-based susceptibility testing method which has also been studied in comparison with the CLSI reference disk diffusion assay. This method employs commercially available antifungal tablets (Neo-Sensitabs, Rosco Diagnostica, Denmark) instead of disks and has yielded acceptable percent agreement rates in general with reference disk diffusion and microdilution methods when testing amphotericin B, fluconazole, voriconazole, itraconazole, and caspofungin against *Candida* or *C. neoformans* [72–74]. Tablet diffusion assay has also been compared to CLSI microdilution and/or disk diffusion assays for testing filamentous fungi, including strains of *Absidia*, *Alternaria*, *Bipolaris*, *Aspergillus*, *Fusarium*, *Rhizopus*, *Paecilomyces*, and *Scedosporium* spp. The categorical agreements of tablet and disk diffusion assays with microdilution assay were found to be similar for amphotericin B, caspofungin, itraconazole, and voriconazole but lower for posaconazole for tablet diffusion assay (84 % for tablet vs. 96 % for disk diffusion assay) [75].

Using the previous MIC breakpoints and interpretive zone diameters, reference disk diffusion assays occasionally yielding results that differ from those obtained by broth-based testing were reported [44, 50, 76–79]. Some isolates that were susceptible to fluconazole were categorized as fluconazole-resistant by disk diffusion assay. Disk diffusion assay also failed to differentiate some of the fluconazole-resistant isolates from the dose-dependent susceptible ones. Even more importantly, some fluconazole-resistant isolates were categorized as fluconazole-susceptible by disk diffusion assay using the previous breakpoints. Recent comparison of the fluconazole [51] and voriconazole [53] susceptibility categories obtained by broth-based testing to those generated by disk diffusion assay and by using the revised species-specific interpretive criteria yielded high agreement rates and very major error rates of 0—<1 %. For caspofungin and micafungin, on the other hand, disk diffusion breakpoints alternative to the revised ones have been proposed to improve the separation between wild-type and mutant isolates of *Candida* [52].

3.2 EUCAST Reference Broth Dilution Methods

A broth dilution assay for susceptibility testing of yeasts standardized by the European Committee on Antifungal Susceptibility Testing (EUCAST) Subcommittee on Antifungal Susceptibility Testing (AFST) is also available and has been revised as EUCAST definitive document EDef 7.2 [80]. The assay is similar to the CLSI broth dilution method, except that RPMI 1640 supplemented to 2 % glucose (CLSI uses 0.2 % glucose), an inoculum density of $1–5 \times 10^5$ cells/mL, and microdilution plates with 96 flat-bottom wells are used. The detailed comparison of the major test parameters proposed in EUCAST EDef. 7.2 and CLSI M27-A3 docu-

Table 82.3 Recommendations for application of *routine* fungal drug resistance assays for clinical yeast isolates [18, 92]

Indication	Antifungal drug(s) to be tested/recommendation(s)
Invasive infection due to *Candida* spp.[a]	Azoles, particularly fluconazole, and an echinocandin[c]
Invasive *Candida* infection (unexpectedly) refractory to initial therapy	Susceptibility testing for amphotericin B, flucytosine, fluconazole, voriconazole, and an echinocandin as an adjunct consultation with an experienced microbiologist
Refractory mucosal infection due to a *Candida* sp. that fails to respond to standard therapy at the standard dose	Azoles, particularly fluconazole
Refractory *C. neoformans* infection that fails to respond to standard therapy at the standard dose[b]	Fluconazole

[a]Susceptibility testing is particularly recommended for *C. glabrata*. Although susceptibility profiles may be predictable in general for other *Candida* spp., susceptibility testing appears still beneficial due to the possibility of strain-based secondary resistance to one or more antifungals
[b]Due to the lack of relevant MIC breakpoints for fluconazole vs. *C. neoformans*, susceptibility test results can provide general guidance only by comparison of the MIC results to those of the other strains of the same genus. If the MIC of that particular drug is relatively high for that strain when compared to those of the other strains of that genus, this may indicate microbiological resistance
[c]Due to the unresolved problems of interlaboratory variability observed when testing against *Candida* spp. by CLSI and EUCAST methods, in vitro susceptibility testing of caspofungin is currently not recommended. Anidulafungin or micafungin may be used as surrogate marker of echinocandin susceptibility until the problem is resolved [87]

ments and the recommended MIC reading endpoints are summarized in Tables 82.1 and 82.2, respectively.

Multicenter evaluation of the EUCAST assay showed that the method yields reproducible results [81], and comparative studies suggest a good correlation (92 % agreement rate) between CLSI and EUCAST antifungal susceptibility methods when testing amphotericin B, flucytosine, fluconazole, and itraconazole against *Candida* spp. [82].

Further studies that compared the fluconazole MICs generated by EUCAST and CLSI methods for *Candida* validated the very good correlation between the two methods. However and notably, the EUCAST MICs were found to be slightly lower than the CLSI MICs [83], especially for isolates with MICs above 2 μg/mL. Using the 24-h MICs and the ECVs, essential and categorical agreement rates suggested excellent correlation between EUCAST and CLSI methods when testing fluconazole, posaconazole, and voriconazole against various *Candida* spp. (categorical agreement rates varying from 91 to 99 %, 94 to 99 %, 94 to 99 % for fluconazole, posaconazole, voriconazole, respectively) [84]. Similarly, high categorical agreement rates of >90 % were observed for the EUCAST and CLSI methods in general when testing caspofungin, anidulafungin, and micafungin against *Candida* spp. except for lower agreement rates found for caspofungin against *C. glabrata* (85.3 %) and *C. krusei* (54.5 %). Importantly, both EUCAST and CLSI methods were able to distinguish FKS mutant strains of *Candida* spp. from the wild-type isolates at a high level [85]. A more recent study on susceptibility testing of ten systemically active antifungal agents against a collection of *Candida* strains including wild-type and non-wild-type collections for both azoles and echinocandins confirmed the high agreement rates for EUCAST and CLSI methods in general (overall categorical agreement rate 95.0 % with 2.5 % very major and major discrepancies) [86].

Importantly, lower (85 %) agreement rates were detected when testing caspofungin (10 % of the results categorized as non-wild-type by EUCAST and wild-type by the CLSI method). This study also revealed other specific problem points of lower agreement rates (amphotericin B, anidulafungin, and isavuconazole against strains of *C. glabrata*, itraconazole and posaconazole against most of the tested species, and caspofungin against *C. parapsilosis*, *C. tropicalis*, *and C. krusei*) that need to be addressed in future studies focused on further harmonization of the two methods [86]. Of specific note and as also discussed in Table 82.3, in vitro susceptibility testing for caspofungin using in the CLSI or EUCAST methodology is currently not recommended due to technical problems [87]. Anidulafungin or micafungin should instead be used for class-based testing. The currently accepted species-specific clinical MIC breakpoints to be used for EUCAST method and *Candida* are revised periodically and available on the EUCAST website [88].

Optimal parameters for antifungal susceptibility testing of conidia-forming molds have also been proposed and revised by EUCAST-AFST (EUCAST definitive document, EDef 9.2) [89]. These include the use of RPMI 1640 supplemented to 2 % glucose as the test medium and $1–2.5 \times 10^5$ conidia/mL (hemocytometric or spectrophotometric adjustment) as the inoculum density and are detailed in Table 82.1. An overall agreement rate of 92.5 % was achieved between the EUCAST standard and the CLSI method in previous studies when testing posaconazole and voriconazole against *Aspergillus*. Notably, the EUCAST method tended to generate higher MICs as compared to the CLSI method for *Aspergillus* isolates with discrepant results [90]. More recent studies also suggested very high essential agreement rates between the two methods within ±1 dilutions for posaconazole (87.7 %), voriconazole (96.3 %), and itraconazole (99.6 %) against *Aspergillus* [91]. Interpretive breakpoints have now been proposed by EUCAST for some *Aspergillus* spp. and antifungal drugs. These clinical breakpoints are available on the EUCAST website and periodically revised [88]. The detailed comparison of the major test parameters

proposed in EUCAST EDef. 9.2 and CLSI M38-A2 documents and the recommended MIC reading endpoints are summarized in Tables 82.1 and 82.2, respectively.

3.3 Clinical MIC Breakpoints and ECVs/ECOFFs for Interpretation of the Results Obtained by CLSI and EUCAST Microdilution Methods for *Candida* and *Aspergillus*

As also partly summarized in the previous subsection, species-specific clinical breakpoints for some antifungal agents and a number of *Candida* spp. determined by CLSI [43, 92] and EUCAST [25, 88] methods are available. ECVs have also been established for some species–antifungal drug combinations and may be useful particularly for cases where clinical breakpoints remain yet undetermined [92]. Current species-specific breakpoints are now commonly used in routine practice as well as in global surveillance studies to clarify temporal and geographic trends of resistance in *Candida* [93].

Clinical breakpoints for some *Aspergillus* spp. and antifungal drugs have also been established to be used for interpretation of results obtained by EUCAST methodology [25, 88, 94]. ECVs, on the other hand, are available for a number of *Aspergillus* spp. and antifungal drugs for CLSI [95–98] as well as EUCAST methodology [25, 99].

Due primarily to the difficulties of establishment of clinical breakpoints based solely on in vitro–in vivo correlation data, setting breakpoints based on pharmacokinetic and pharmacodynamic data and ECVs as well as clinical experience is now a common approach. To exemplify, EUCAST "rationale documents" [99] give an outline of the information on which the EUCAST clinical breakpoints are based [25]. The number of fungal genus–antifungal drug combinations where clinical breakpoints have been established is steadily expanding. Currently, the major goals of CLSI and EUCAST-AFST committees are determination of clinical breakpoints (and ECVs when determination of clinical breakpoints is yet not possible) for more and more fungal species and antifungal drugs and harmonization of CLSI and EUCAST broth microdilution methods [51].

3.4 Specific Points Under Discussion for Reference Antifungal Susceptibility Testing Methods

The development of standard assays for testing resistance to antifungal agents has been a remarkable progress. These assays are now widely used as a routine adjunct for prediction of clinical outcome and optimization of antifungal therapy. However, certain limitations of these methods have been under discussion.

3.4.1 Amphotericin B Susceptibility Tests

The distribution of amphotericin B MICs in a narrow range and the related difficulties in separation of resistant strains from the susceptible ones have long been a matter of discussion for both yeasts (*Candida*) and filamentous fungi. In efforts to overcome this drawback, various alternatives of the standard susceptibility testing method have been studied previously. Some investigators have found that the use of antibiotic medium 3 (AM3) instead of RPMI [100] and the application of Etest rather than broth dilution [101] enhanced the discrimination of amphotericin B-resistant *Candida*. However, the data obtained in other workers' hands did not support these findings [102] and the issue remained controversial. It was also observed that technical issues such as the lot of AM3 used for testing may also produce variation within the results [43, 103].

As an alternative approach, some studies using a combination of MIC and minimum fungicidal/lethal concentrations (MFC/MLC) suggested a meaningful correlation between in vitro and clinical resistance for some *Candida* [102] and *Aspergillus* [35] infections treated with amphotericin B. However, as with the MIC methods, further studies unfortunately failed to fully support these findings. An analysis of the amphotericin B MICs of strains isolated from candidemic patients showed that prediction of clinical amphotericin B resistance was not possible by any of the commonly used in vitro methods (CLSI microdilution, Etest) and test parameters (RPMI 1640 and AM3 as the test media, MIC and MLC as the interpretive criteria) [19]. On the other hand, the data published for the correlation of in vitro amphotericin B susceptibility with clinical outcome in mold infections (*Aspergillus* and Mucorales, in particular) also remained controversial. While some studies suggested the lack of potential of amphotericin B MIC testing in determination of resistance and prediction of clinical outcome [34], others supported its existence [35–37]. Overall, the technical problems in determination of in vitro amphotericin B resistance persist and await further approaches.

Amphotericin B remains as an important antifungal agent and patient care decisions must still be made with currently available data. EUCAST interpretive breakpoints have been established for amphotericin B vs. *Candida* and some *Aspergillus* spp. [88]. CLSI ECVs for amphotericin B vs. *Candida* [92] and some *Aspergillus* spp. [95] are also available.

3.4.2 Time Required to Finalize the Fungal Resistance Tests

The isolation of the infecting fungus, the growth of the fungus for the fungal resistance assay, and the interpretation of the assay take more than 48 h. This time is often even longer for molds. As a result of this drawback, fungal resistance

assays often give the clinician little early guidance in the choice of antifungal therapy for a particular infection. Fortunately, other clues can be applied during the early days of a given infection. Azole susceptibility profiles of *Candida* strains are generally predictable once the species of the isolate is known. For example, strains of *C. albicans* are mostly very susceptible to azoles, whereas those of *C. glabrata* may present with resistance at rates varying from one center to another [18, 93, 104–106]. Once antifungal therapy is initiated based on the knowledge on species-based primary resistance and the relevant epidemiological data for that specific center, the fungal resistance results of the particular infecting strain will then be available and can be used to guide therapy.

4 Other Methods for Antifungal Susceptibility Testing

4.1 Commercially Available Systems

4.1 Colorimetric Broth Dilution Methods

Determination of azole, flucytosine, and echinocandin MICs for yeasts demands grading of the amount of growth in comparison with that in growth control well. Making this assessment requires experience. In order to ease the challenge of grading the results, colorimetric indicators or fluorescent dyes may be used. Colorimetric methods have been employed by commercial assay systems, such as Sensititre YeastOne (Trek Diagnostic Systems Inc., Westlake, Ohio, which incorporates alamarBlue as the oxidation–reduction colorimetric indicator) and ASTY panels (Kyokuto Pharmaceutical Industrial Co., Ltd., Tokyo, Japan).

For situations that do not permit use of commercially prepared systems, alamarBlue or other colorimetric indicators may also be added in-house to RPMI broth, followed by the application of conventional reference microdilution method. The endpoint determination in these methods is mostly based on the visual observation of the color change. Using alamarBlue, blue indicates no growth, purple indicates partial inhibition of growth, and red indicates growth.

The commercially available Sensititre YeastOne (Trek Diagnostic Systems Inc., Westlake, Ohio) [58, 107–119] and ASTY panels [120, 121] were compared to the CLSI or EUCAST method for *Candida*, *Aspergillus*, or other clinically significant filamentous fungi by various investigators. In a study that compared the Sensititre YeastOne panel with CLSI microdilution method for *Candida*, agreement rates of 93 %, 68 %, 78 %, and 80 % were attained for amphotericin B, fluconazole, itraconazole, and flucytosine, respectively. These results suggested relatively low rates of correlation, particularly for fluconazole and itraconazole [108]. While the agreement rate was found to be low (57 %) for itraconazole vs. *Candida* in some other studies as well [109], the results obtained by other investigators did not fully support this finding [110]. Some studies, on the other hand, have reported relatively lower agreement rates between Sensititre YeastOne and CLSI method when testing azoles and using the previous breakpoints (fluconazole, itraconazole, and voriconazole) against *C. glabrata*, specifically (categorical agreement rates of 34 %, 68 %, and 87 % for fluconazole, itraconazole, and voriconazole, respectively). These results emphasized the need for cautious interpretation of the Sensititre YeastOne results, particularly when testing azoles against *C. glabrata* [113]. Comparison of the Sensititre YeastOne with EUCAST reference method, on the other hand, when testing amphotericin B, flucytosine, fluconazole, and voriconazole against yeast isolates (that consisted of *Candida* strains, in major), yielded essential agreement rates of 98 %, 96 %, 97 %, and 96 %, respectively [118]. Given the revision of the breakpoints for *Candida*, comparison of the Sensititre YeastOne panel with the reference methods by using these current species-specific breakpoints is now the relevant approach. For caspofungin, micafungin, and anidulafungin and by using the species-specific breakpoints (or the ECVs when breakpoint remains undetermined for that species), Sensititre YeastOne was found to be in complete agreement with CLSI method (categorical agreement rates ranging from 93.6 % (caspofungin) to 99.6 % (micafungin) and less than 1 % very major or major errors) [122]. Of specific note, tentative wild-type populations and ECVs have been determined for Sensititre YeastOne method to be used when testing echinocandins, amphotericin B, and flucytosine against *Candida* spp. [123].

The utility of Sensititre panel/alamarBlue has been investigated also for susceptibility testing of *Aspergillus*. In one of these studies, the use of alamarBlue and reading the results spectrophotometrically yielded comparable results with CLSI method in 94 % of the cases for itraconazole and voriconazole, 25 % of the cases for flucytosine, and 64 % of the cases for amphotericin B [124]. In contrast to other results, agreement rates were found to be <66 % and >77 % for itraconazole and amphotericin B, respectively, at 24 h when the Sensititre method (endpoint: slight growth–MIC–purple for itraconazole, complete inhibition of growth–MIC–blue for amphotericin B) was compared to the CLSI method (endpoint: MIC-0 for both drugs) for *Aspergillus* strains. In the same study, the Sensititre method tended to produce lower MICs compared to the CLSI method, and agreement rates varied depending on the MIC endpoint used and the incubation period, yielding more comparable results at 48 h and by using MIC–blue endpoint [125]. Other studies also suggested higher agreement rates at 48 h [126]. In other studies that compared Sensititre YeastOne with CLSI M38-A method, overall agreement rates of 93 %, 90 %, and 97–99 % were obtained for amphotericin B, itraconazole, and voriconazole, respectively, for *Aspergillus* spp. [111, 127].

The agreement between Sensititre YeastOne panel and CLSI microdilution method has been explored in a few studies for filamentous fungi other than *Aspergillus* [114, 127, 128]. In one of these studies, posaconazole was tested by Sensititre YeastOne and CLSI methods against various filamentous fungi, including *Aspergillus*, *Fusarium*, *Rhizopus*, *Absidia*, and *Mucor*. By using the MIC–blue endpoint at 24 h, overall agreement rate within ±1 dilution range was found to be 94 % [114]. The comparison of these two methods for voriconazole against *Fusarium* spp., *S. apiospermum*, and *Rhizomucor pusillus*, on the other hand, showed percent agreement rates of 97–99 % at 48 or 72 h depending on the species [127].

Published data for ASTY panel are more limited. For *Candida*, ASTY panel provided high overall agreement rates of 93 (24 h) and 96 % (48 h) for amphotericin B, 5-fluorocytosine (5FC), fluconazole, and itraconazole against *Candida*. Agreement rates were found to range from 90 % with itraconazole and flucytosine to 96 % with amphotericin B at 24 h and from 92 % with itraconazole to 99 % with amphotericin B and flucytosine at 48 h [120]. For *Trichosporon asahii*, overall agreement rate between colorimetric microdilution panel and CLSI method was reported as 97.7 % when testing amphotericin B, flucytosine, fluconazole, miconazole, itraconazole, and voriconazole [121].

Conclusively, using the colorimetric assays, isolates with discordant results as compared to the reference method may be observed, and these need to be evaluated with the reference assays particularly for routine purposes. Now that the breakpoints have been revised and species-specific breakpoints are currently accepted, categorical agreement rates between the reference methods and Sensititre YeastOne are now being reexplored. One study investigating the correlation between CLSI method and Sensititre YeastOne for caspofungin and micafungin vs. *Candida* revealed promising results (very major and major errors, <1 %) [122]. Establishment of tentative method-specific ECVs for Sensititre YeastOne panel for testing echinocandins, amphotericin B, and flucytosine against *Candida* spp. is also noteworthy [123]. Further studies are required to determine the accuracy of the colorimetric assays particularly for strains with borderline MICs.

4.1.2 Fully Automated Broth Dilution Method

A fully automated commercially available system (VITEK-2 yeast susceptibility test, bioMerieux, Inc.) has been developed for antifungal susceptibility testing. VITEK-2 test evaluates the MIC results spectrophotometrically. Using the previous breakpoints, the system was found to be in very good agreement in general with the reference CLSI method (categorical agreement rates of 97.2 % and 88.3 % at 24 h and 48 h, respectively) when testing fluconazole against *Candida*, and very major errors were very seldom observed (0 % and 0.2 % at 24 h and 48 h, respectively) [129]. The VITEK-2 susceptibility results obtained for caspofungin, micafungin, and posaconazole against *Candida* were also found to be in very good agreement with those obtained by CLSI method by using the previously proposed breakpoints (categorical agreement rates of 99.8 %, 98.2 %, and 98.1 % for caspofungin, micafungin, and posaconazole, respectively) [130]. Using the current species-specific breakpoints, VITEK-2 system remained comparable to CLSI method when testing fluconazole and voriconazole against *Candida* [131] and fluconazole against *Candida* and *Cryptococcus* [132]. These comparative data using the current species-specific breakpoints are as yet limited, and further analyses using the new breakpoints and adequate numbers of resistant and intermediate strains are required.

4.1.3 MIC Strip (Gradient Strip) Method

MIC strip method is an agar-based diffusion assay that provides MIC values and quantitative measure of fungal resistance. Previously referred to as Etest® (AB BioDisk, Solna, Sweden) method, it has now been renamed due to the recent availability of multiple commercial products. It is being studied for both yeasts and molds although the available data are more extensive for yeast genera. The method uses plastic strips impregnated with a stable concentration gradient of the antifungal agent to be tested. MIC strips carrying amphotericin B, ketoconazole, fluconazole, itraconazole, flucytosine, voriconazole, posaconazole, caspofungin, anidulafungin, and micafungin are available.

Except for testing amphotericin B for which antibiotic medium 3 agar may be used [101, 133], the most relevant and commonly used test medium for MIC strip method is RPMI 1640 supplemented to 2 % glucose [134]. Casitone agar (azoles) [135, 136] and yeast nitrogen base (*C. neoformans*) [137] have been used by some investigators. In addition, similar to that in disk diffusion methodology, Mueller–Hinton agar supplemented with 2 % glucose and 0.5 μg/mL methylene blue is also being used [57, 74, 138–141] and may produce sharper edges of inhibition ellipse and less intra-elliptic growth when used particularly for testing azoles against heavy trailer *Candida* strains.

The inoculum density to be used in the test is adjusted in sterile saline to that of 0.5 McFarland standard either visually or spectrophotometrically at 530 nm, yielding a final concentration of $1–5 \times 10^6$ cells/mL. In accordance with the basic rules of disk diffusion assays, the adjusted inoculum is swabbed onto the agar plate and the Etest strip is placed onto the inoculated medium. The results are read as MICs after incubation of the plates at 35 °C for 18–24 h and 48 and 72 h (when needed, particularly for *C. neoformans*). The MIC of that particular drug is the concentration designated on the strip at the point where the inhibition ellipse intersects the strip. For azoles and other drugs such as flucytosine that tend

to produce partial inhibition, the growth inside the ellipse and the tiny colonies produced near the edge of the ellipse are neglected when reading the MIC value. This provides a reading endpoint that approximates MIC-2 of broth dilution assay and eases the precise determination of MICs particularly of isolates that tend to trail heavily.

The utility of MIC strip method for antifungal susceptibility testing of yeasts (predominantly *Candida* and *C. neoformans*) and filamentous fungi (mostly *Aspergillus* and less extensively *Rhizopus*, *Fusarium*, *Scedosporium*, *Paecilomyces*, and *Acremonium*) has been explored by several investigators. For *Candida*, percent agreement rates of the method (specifically Etest®) with CLSI reference method were found to be 90–98 % for amphotericin B [142], 82–100 % for fluconazole [113, 134, 143, 144], 80–95 % for itraconazole [113, 143], 91–100 % for voriconazole [113, 144, 145], 83–95 % for posaconazole [56, 57, 146], and 77–100 % for caspofungin [142, 147]. Of note and importantly, when the previous breakpoints were used and the correlation of the susceptibility categories was considered, Etest® tended to be less correlated with CLSI method (percent categorical agreement rates of 55 %, 74 %, and 76 % for fluconazole, itraconazole, and voriconazole, respectively), particularly when testing azoles against *C. glabrata* [113]. Correlation of Etest with EUCAST reference microdilution method has also been explored for yeasts (*Candida* strains, in major), yielding essential agreement rates of 98 %, 96 %, 97 %, and 95 % for amphotericin B, flucytosine, fluconazole, and voriconazole, respectively [118].

For *C. neoformans*, percent agreement rates of Etest® with CLSI reference method were found to be 99 % for amphotericin B [148] and 81 % for fluconazole [149]. Overall, Etest appeared in good agreement with the CLSI method when testing amphotericin B and fluconazole against *C. neoformans* [74]. The percent agreement rates for the other antifungal drugs were 54 % for itraconazole [149], 89 % for flucytosine [149], and 94 % for voriconazole [148]. Of specific note and in some previous studies, Etest appeared to ease the discrimination of amphotericin B resistance for both *Candida* and *C. neoformans* regardless of the test medium used (RPMI 1640 supplemented to 2 % glucose or antibiotic medium 3) [101, 133, 150].

For *Aspergillus*, percent agreement rates of Etest® with CLSI reference method were found to be 89–98 % for amphotericin B [111, 151], 67–100 % for itraconazole [111, 151, 152], 93–100 % for voriconazole [151–153], and 69–80 % for caspofungin [154]. Less data are available for Etest and other filamentous fungi (*Rhizopus*, *Fusarium*, *Scedosporium*, *Paecilomyces*, and *Acremonium*) [136, 155, 156]. For these genera, percent agreement rates were overall high (80 and 96 % on Casitone and RPMI, 2 % glucose agar, respectively) but tended to vary extensively (0–100 %) from one genus to another [136].

In some instances, as for testing *Trichosporon asahii*, Etest® was found to yield consistently lower MICs with a wider MIC range for amphotericin B and higher MICs for azoles (fluconazole and itraconazole) when compared to reference microdilution method [157]. Similar findings were recorded when testing *C. neoformans* as well; Etest® voriconazole MICs were higher than reference microdilution MICs for isolates that yielded discordant results with the two methods [148]. However, such a consistent trend of Etest to increase the MICs for all azoles was not always observed [152].

The performance of the Etest® for direct antifungal susceptibility testing of yeasts in positive blood cultures has also been investigated. The results of this study showed that correlation of direct Etest® with reference macrodilution method was ≥80 % for amphotericin B, flucytosine, and ketoconazole, while it was 64–70 % for itraconazole [158].

In summary, MIC strip method is a practical method that provides quantitative measure of fungal resistance. The agreement of the Etest® method with the reference assay has been found to be high in general [78, 113, 134, 145, 152, 159]. However, genus-, species-, and incubation period-dependent variations in Etest–CLSI reference method percent agreement rates may be observed [42, 113, 125, 136, 153, 160]. Standardization of the test parameters and the interpretive reading criteria as well as its correlation with clinical outcome should be addressed further. Most importantly and in relation to the recent revisions of the CLSI and EUCAST breakpoints, categorical agreement rates of MIC strip method with the reference microdilution methods by using these revised species-specific breakpoints need to be revisited.

4.2 Other Investigational Methods for Antifungal Susceptibility Testing

4.1 Flow Cytometry

The utility of flow cytometric susceptibility tests for rapid determination of fungal resistance of *Candida* (amphotericin B, fluconazole, caspofungin, and flucytosine), *Aspergillus* (amphotericin B, itraconazole, voriconazole), and *C. neoformans* (amphotericin B, fluconazole) has also been investigated [161]. The method employs various membrane potential-sensitive or DNA-binding vital dyes (3,3′-dipentyloxacarbocyanine iodide, propidium iodide, acridine orange, or FUN1) and is based on determination of alterations in fungal cell viability. The decrease or increase in fluorescence intensity of the cells stained with the dye following exposure to the drug and the "minimum fluorescence-enhancing concentration" (MFEC) of the drug are determined. The results are available in 3–8 h. The method appears to be well correlated in general with the reference

method and Etest [162–167], as well as clinical outcome [168, 169]. In contrary to the high agreement rates in general, essential agreement rate of 40 % with CLSI reference method has been reported for flow cytometry when testing caspofungin against *C. krusei* [170]. Flow cytometry provides rapid detection of resistance and has also been proposed as a useful and accurate method for identification of *Candida* strains that are resistant to amphotericin B [171]. Despite these advantages, its availability remains limited only to some centers due to the need for a flow cytometer, and the method is not used in routine practice of antifungal susceptibility testing [172].

4.2.2 Ergosterol Quantitation

Sterol quantitation method that measures cellular ergosterol content rather than growth inhibition has also been investigated as a fungal resistance assay. The method appeared to be useful particularly for *Candida* isolates that exhibit heavy trailing as these tend to produce unclear visual MIC endpoints for fluconazole and itraconazole at 48 h [173]. The method provides accurate results in general but is not practical for use in routine susceptibility testing. Also and importantly, since the currently accepted MIC reading time point is mostly 24 h in general for the reference methods when testing *Candida*, the problem of unclear visual endpoints particularly at 48 h is not much experienced in daily practice of antifungal susceptibility testing.

4.2.3 Metabolic (XTT) Assay

Tetrazolium salts may be used to detect in vitro antifungal susceptibility by determination of metabolic activity [174]. The eventual color change that reflects metabolic activity may be evaluated spectrophotometrically by measuring the optical density. The yellow tetrazolium salt turns purple when it is cleaved to its formazan derivative.

An antifungal susceptibility assay that uses the tetrazolium salt 2,3-bis{2-methoxy-4-nitro-5-{(sulfenylamino) carbonyl}-2H-tetrazolium-hydroxide} (XTT) was reported to yield high levels of agreement of >97 % for MIC-0 of amphotericin B and 83 % for MIC-0 of itraconazole vs. *Aspergillus*, suggesting potential reliability of this method [175]. The XTT assay has been also used for rapid susceptibility testing of fungi belonging to order Mucorales (*Rhizopus*, *Cunninghamella*, *Mucor*, and *Absidia* spp.). Percent agreement rates were found to be 93 %, 76 %, and 67 % for amphotericin B, posaconazole, and voriconazole, respectively. Importantly, the results were achievable as early as 6–12 h after inoculation [176]. Of specific note, XTT assay is commonly used for determination of antifungal susceptibilities of *Candida* biofilms [177, 178]. The method needs to be standardized for its potential use in routine antifungal susceptibility testing.

4.2.4 Agar Dilution and Agar Screening Methods

In accordance with its basic principles, agar dilution method employs agar medium plates containing twofold dilutions of the antifungal agent and inoculated with the suspensions of the fungal strains to be tested. The agar dilution method has been explored for amphotericin B, fluconazole, itraconazole, ketoconazole, and flucytosine vs. *Candida* [179, 180]; caspofungin, micafungin, and anidulafungin vs. *Candida* [181]; fluconazole vs. *C. neoformans* [182]; flucytosine vs. *C. neoformans* [183]; amphotericin B, itraconazole, and voriconazole vs. *A. fumigatus* [184]; ketoconazole, itraconazole, and terbinafine against *Malassezia* [185]; caspofungin vs. *Aspergillus* [186]; and terbinafine, naftifine, and itraconazole vs. *Microsporum*, *Epidermophyton*, and *Trichophyton* spp. [69, 187]. Agar dilution was also used for testing the antifungal activity of other compounds, such as boric acid [188] and *Melaleuca alternifolia* (tea tree) oil [189] against *Candida*.

While the agar dilution method remains unstandardized and labor-intensive for antifungal MIC determinations, an agar screening method recently appeared to gain significance for initial screening and rapid presumptive determination of secondary triazole resistance in *Aspergillus* (particularly, *A. fumigatus*) strains. The proposed method is based on determination of growth on a four-well RPMI 2 % glucose agar plate supplemented with itraconazole (4 μg/mL), voriconazole (1 μg/mL), and posaconazole (0.5 μg/mL) in each of the three wells and no antifungal drug in the fourth well for growth control assessment [30, 190, 191]. The agar screening plates are also commercially available (Balis Laboratorium V.O.F., Boven-Leeuwen, the Netherlands). In case of existence of growth in any of the triazole-containing wells, the strain may further be tested by a reference method for determination of corresponding MICs and definitive azole susceptibility categories. Further recommendations are awaited for the utility of the agar screening method in routine practice of azole susceptibility testing of *Aspergillus*.

4.2.5 Isothermal Microcalorimetry

Isothermal microcalorimetry is a novel method investigated for determination of in vitro antifungal resistance as well. Specifically, the method uses the growth-related heat production and the endpoint of "minimal heat inhibitory concentration" (MHIC, μg/mL) for determination of antifungal resistance [192]. It has so far been investigated for rapid detection of voriconazole resistance in *A. fumigatus* strains, where detection of voriconazole resistance was possible in 8 h [193]. The method has also been explored for antifungal susceptibility testing of Mucorales, *Fusarium*, and *Scedosporium*, yielding correlation rates of 67 %, 92 %, 75 %, and 83 % with CLSI MIC data generated for amphotericin B, voriconazole, posaconazole, and caspofungin, respectively

[194]. The applicability of isothermal microcalorimetry for determination of antifungal susceptibility of *Candida albicans* in artificial urine sample and determination of MIC values for amphotericin B, flucytosine, fluconazole, and tioconazole were also studied and provided promising results [195]. Isothermal microcalorimetry yet remains investigational as a fungal drug resistance assay. The limitations of the method are the availability of limited data for a few number of fungal genera, the requirement of special instrumentation, and the current lack of validation studies.

4.2.6 MALDI-TOF MS (Matrix-Assisted Laser Desorption Ionization–Time-of-Flight Mass Spectrometry)

Besides its utility for fungal identification, MALDI-TOF MS is now being explored for its potential use as a fungal resistance assay as well. MALDI-TOF MS was so far tested for determination of in vitro susceptibility to caspofungin using wild-type and FKS mutant *Candida* and *Aspergillus* strains and proved to yield accurate results when compared to CLSI reference method (complete essential agreement for all isolates and categorical agreement rates of 94 % for *Candida*) [196]. A MALDI-TOF MS-based method that relies on the proteome changes detectable after incubation of *C. albicans* strains with caspofungin for 3 h at a concentration of MIC "breakpoint" value has also been developed and reported for rapid detection of caspofungin resistance [197].

The available data for antifungal susceptibility testing using MALDI-TOF MS-based technology remain yet preliminary and limited in terms of fungal genera as well as tested antifungal drugs. Further studies are required for clarification of any potential utility and relevance of MALDI-TOF MS as a fungal drug resistance assay in the future of antifungal susceptibility testing.

5 Determination of Fungicidal Activity

For specific settings, determination of fungicidal activity may provide useful hints of likely clinical outcome. This may be achieved either by determination of the MICs initially, followed by MFC on solid media (mostly defined as the least concentration yielding growth of <3 colonies, approximating 99–99.5 % killing activity) or by time–kill experiments [198–203]. Animal models are also being used for assessment of fungicidal activity. Experimental models of disseminated candidiasis and aspergillosis have proven to be very useful for determination of fungicidal effect. Specifically, the assessment of residual fungal burden in animal models has been shown to be well correlated with the MFC measurements and time–kill results [204].

There is yet no standard procedure for determination of MFCs. A multicenter study investigated the reproducibility of MFC testing for itraconazole, posaconazole, ravuconazole, voriconazole, and amphotericin B vs. *Aspergillus* spp. In this study, MFC was defined as the lowest drug concentration that yielded <3 colonies which approximated 99–99.5 % killing activity, and the reproducibility of using four different media (RPMI 1640, RPMI 1640 supplemented to 2 % glucose, antibiotic medium 3, and antibiotic medium 3 supplemented to 2 % glucose) was investigated. The highest reproducibility (96–100 %) was achieved with amphotericin B and the results were good across all four media. Reproducibility rates were still high but more medium-dependent for azoles (91–98 %) [205]. Similarly, optimal testing conditions for MFC determinations were investigated for filamentous fungi other than *Aspergillus* as well [206]. These studies remain significant as being the initial steps for standardization of MFC testing.

While investigations are being carried out for determination of fungicidal activities of various drug–fungal genus combinations, it seems likely that demonstrations of the utility of fungicidal measures will be limited. It may possibly be useful for specific clinical presentations, such as endocarditis, meningitis, septic arthritis, and osteomyelitis, or in existence of poor clinical response to standard, normally effective antifungal therapies in neutropenic patients [204].

For time–kill experiments, the test isolates are exposed to varying concentrations of the drug (e.g., ranging from 0.0625 to 16 times the MIC). Samples are then withdrawn at predetermined time points and plated. The viable colony counts on the plates are determined after incubation, and the results are plotted as time–kill curves. The method is labor-intensive but provides more detailed information about the pharmacodynamic properties of the drug and whether the killing activity of the antifungal agent for an individual strain is dependent on the concentration [198, 200, 207–213]. Similar to MFC testing, no reference method is available for time–kill experiments. Time–kill assay parameters that have been shown to yield reproducible results for *Candida* were proposed by some investigators. These parameters were specified as 10^5 cfu/mL as the inoculum size, RPMI 1640 medium as the test medium for antifungal drugs other than echinocandins (AM3 for echinocandins), 30 μL as the transfer volume, 35 °C with agitation as the incubation setting, and ≥99.9 % reduction in cfu/mL from the starting inoculum as the endpoint [214].

Overall and conclusively, determination of fungicidal activity by MFC measurements or time–kill assays is yet far from global standardization and awaits further investigations.

6 Indications for Use of Fungal Drug Resistance Assays

Fungal drug resistance assays, determination of MIC values in particular, are used (a) for routine purposes to predict the clinical outcome and optimize the antifungal therapy, (b) to provide epidemiological data for the susceptibility profiles and resis-

tance rates of the infecting strains to commonly used drugs at a particular center, and (c) to determine the in vitro antifungal activity of the novel compounds under investigation.

Unlike the application for bacteria and antibacterial agents, the use of routine fungal drug resistance assays is indicated only for some fungal strains isolated from clinical samples. These indications are currently more clearly defined for yeasts, particularly for *Candida*, and are listed in Table 82.3 [18, 92, 215]. Of specific note, susceptibility testing does not appear beneficial when intrinsic resistance or reduced susceptibility is known for an antifungal drug against all strains of a genus (e.g., fluconazole against *Candida krusei*). However and importantly, it may provide significant data for an infecting species with possibly high rates of acquired resistance for antifungal drugs (e.g., fluconazole against *Candida glabrata*; amphotericin B against *C. glabrata*, *Candida guilliermondii*, and *C. krusei*; amphotericin B, fluconazole, and echinocandins against *Candida rugosa*). In this latter case of possibility of high rates of acquired resistance, monitoring closely for signs of clinical failure and performing susceptibility tests are needed [92].

As the initial step in routine practice, identification of the infecting fungal strain to "species" level remains of uppermost significance not only for prediction of any possible existence of primary resistance to one or more antifungal agents but also for interpretation of the antifungal susceptibility test results which now are based on "species-specific" MIC breakpoints and ECVs [92].

For filamentous fungi, the relevance and benefit of routine application of these tests are less well-defined and require to be warranted by further in vitro–in vivo correlation studies. One important exception is *Aspergillus*. The existence and clinical significance of secondary triazole resistance in *A. fumigatus* strains, in particular, have recently been documented, and azole resistance in *Aspergillus* is now a concern in clinical practice. Based on this, testing mold-active triazoles against *Aspergillus* (particularly, against *A. fumigatus*) strains (by an initial agar screening test, followed by MIC determination where needed) now appears to be beneficial at least in a number of situations, including the existence of high prevalence of azole resistance in *A. fumigatus* in environmental or clinical isolates in that particular geographic area or center and/or the history of previous azole exposure for the particular case. Further recommendations are awaited for determination of definitive indications of routine azole susceptibility testing in clinical *Aspergillus* strains [7, 10, 28, 172, 190, 216, 217].

7 In Vitro Antifungal Combination Studies

Due to the low clinical response rates to monotherapy particularly in some opportunistic mycoses, such as aspergillosis, fusariosis, and zygomycosis, as well as availability of the new drugs, antifungal combination studies are now appealing. The best and most relevant method for testing in vitro interaction of antifungal agents is yet unknown. Most of the accumulated data on in vitro combination studies used checkerboard method (based on determination of fractional inhibitory concentration (FIC) indices) [218–226], and it still remains as the most commonly applied method for in vitro combination studies. However, there are significant problems about its performance, standardization, and interpretation [227]. Crossed Etest method [218, 228–231] and time–kill studies [218, 230–232] are the other methods used for testing in vitro antifungal interactions. Assessments of the antifungal interactions by a fully parametric response surface approach (Greco model) have also been undertaken [233–237] but appear equally difficult to interpret. Many questions yet remain to be resolved for rationale use of combination antifungal therapy, and standard in vitro methods and animal models followed by clinical trials appear to be the most relevant way of determination of the actual clinical efficacy of antifungal combinations [238–242].

8 Conclusions and Current Recommendations for Antifungal Susceptibility Testing

In the last two decades, there has been a great progress in standardization and application of fungal resistance assays. However, the issues that still remain to be resolved and clarified do exist though are getting less. Finally, while fungal resistance assays currently appear as a significant aid in prediction of clinical outcome and guiding therapy, the influence of the host factors is strong and limits the overall ability of susceptibility testing to completely predict response.

Viral Phenotypic Resistance Assays

83

Jacqueline D. Reeves and Neil T. Parkin

1 Introduction

The emergence of the human immunodeficiency virus (HIV) pandemic in the early 1980s led to a marked escalation in virology research. A rapidly expanding knowledge base percolated not only within the HIV field but also in that of other viral diseases. The identification of drug targets in these viruses led to the development and approval of antiviral agents. However, especially for HIV, it quickly became apparent that the use of these agents could select for drug-resistant viruses. The need for assays to identify resistant strains and to guide physicians in treatment decisions was urgent. Today, the availability of numerous antiretroviral agents for HIV therapy, combined with assays to guide their use, allows the selection of combination regimens that can effectively suppress HIV replication for many years. The vast amount of experience gained over many years of HIV drug development and clinical research notably hastened more recent hepatitis C virus (HCV) drug development efforts. Combination drug regimens for HCV that include one or more direct-acting antiviral agents to different targets have been evaluated rapidly and optimized to minimize the emergence of resistance-associated variants and to promote viral clearance.

Phenotypic susceptibility assays are used for some viruses in a clinical setting. For HIV, they can help with the selection of the most active drug regimen for an individual's viral population. They are also employed in research studies, drug discovery, and preclinical and clinical stages of drug development, for example, to characterize resistance and cross-resistance patterns for new drugs and to establish correlations between discrete genotypic changes and drug susceptibility.

Viral phenotypic susceptibility assays are designed to determine the observable susceptibility or resistance of a virus to an antiviral agent. Numerous types of assay have been described including classic plaque assays and more recent recombinant virus assays (RVAs). Susceptibility or resistance to an antiviral agent in cell culture is often reported as the concentration of antiviral agent that inhibits viral replication by 50 or 90% (IC_{50} or IC_{90}, respectively). The IC_{50} or IC_{90} is typically compared to that of a control or reference virus that is assumed to be drug sensitive, and the results are expressed as a ratio (often referred to as fold change or resistance index) of the experimental virus versus the control (e.g., IC_{50} experimental virus/IC_{50} control virus).

This chapter reviews the major phenotypic antiviral susceptibility assays, with a focus on HIV- and HCV-related assays. The use of intact virus assays, the development and clinical applications of recombinant virus assays for HIV drug resistance, replication capacity and coreceptor tropism determination, the use of HCV replicon assays for drug development, and the status of phenotypic assays for other viruses including HBV, CMV, HSV, and influenza virus are discussed.

2 Intact Virus Susceptibility Assays

2.1 Plaque Assays

Plaque assays were originally developed to study bacteriophages in the early twentieth century [1]. In the early 1950s, the assay was adapted for poliovirus by Dulbecco and Vogt [2–4] and catapulted animal virology forward. Plaque assays are based upon the principle that a single virus particle infecting a single cell in a monolayer culture will lead to a local area of cytopathology (a "plaque") after subsequent infection of adjacent cells when the culture is overlaid with a semisolid nutrient medium to prevent long-range secondary infection through diffusion. The amount of time required for plaque formation depends on the type of virus, cells, and growth conditions. Plaques are identified visually, often by staining the remaining viable cells. The plaques then appear

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_35

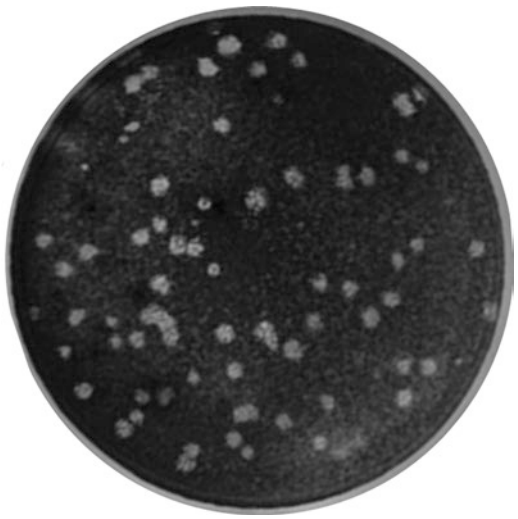

Fig. 83.1 Plaque assay. Crystal violet stained microtiter plate well showing HSV plaques in Vero cells (Image *source*: http://en.wikipedia.org/wiki/File:Plaque_assay_macro.jpg)

as clear circles in a stained monolayer of cells (Fig. 83.1). Alternatively, the monolayer can be stained with an antibody specific for viral antigens and the plaques (or foci) identified by colorimetric or fluorescence detection methods. The number of "plaque-forming units" (pfu) or "focus-forming units" (ffu) in a given volume is a measure of the infectious virus titer in a sample.

Plaque assays can be used to measure drug susceptibility. For example, serial dilutions of an antiviral agent can be added to the growth medium of both control and test virus infections. A dose-response curve (pfu/mL versus drug concentration) can then be generated, and the IC_{50} or IC_{90}, or change in IC_{50} or IC_{90} relative to control, can be determined. These types of "plaque reduction assays" have been utilized to measure drug susceptibility of many viruses, including influenza [5], herpes simplex (HSV) [6], cytomegalovirus (CMV) [7], varicella zoster virus (VZV) [8], and HIV-1 [9] (see below). One advantage of plaque assays over some other types of infectivity assays is that they can provide a visual assessment of viral fitness, as reflected by the size of the plaque. In addition, the presence of a low-level minority species of resistant virus can be detected by virtue of in vitro selection that can occur during a culture-based assay.

2.2 Virus Yield or Antigen Expression Assays

As an alternative to plaque reduction assays, virus released into the liquid medium of an infected cell culture in the absence and presence of antivirals can be measured by various techniques and used to quantitate antiviral susceptibility. The quantity of virus in the medium can be determined based on infectivity (e.g., by plaque assay or 50 % infectious dose ($TCID_{50}$) titration), viral antigen production (e.g., by ELISA), cytopathic effect (CPE), or viral nucleic acid production. Virus yield reduction assays have been used to measure drug susceptibility of several viruses including HIV [10], HSV [11–13], influenza virus [5, 14], and CMV [12, 15, 16], as detailed below.

2.3 Limitations of Intact Virus Assays

Plaque reduction and viral yield reduction assays are labor intensive, and some have limited precision, making them difficult to perform on a large scale for routine clinical use. The assays use replication-competent virus, which may undergo multiple rounds of infection during the assay. Thus for viruses that replicate with a high error rate, the virus tested in the assay could have acquired altered characteristics compared to those of the original virus sample. Additional limitations of intact virus assays include biosafety concerns that can make large-scale operations involving handling of infectious virus stocks a logistical obstacle. The ability to recover infectious virus from clinical specimens is not always reliable and is dependent on titer and fitness, which can vary considerably. Finally, some viruses do not form visible plaques, and others lack an in vitro cell culture system (or a system amenable to routine use) for clinical isolates and thus cannot be studied using plaque or other cell-based assays that rely on infection by intact viruses derived from clinical material.

3 Phenotypic Drug Susceptibility Assays for HIV-1

3.1 Plaque Reduction Assays

Initial measurements of HIV drug susceptibility, including the first description of zidovudine-resistant HIV-1 from infected individuals [9], were made using a plaque reduction assay in HeLa cells engineered to express the CD4 receptor [17]. Plaques, or foci, of infected cells could be identified and counted based on the propensity of the infected cells to fuse and form multinucleated syncytia; reduction in plaque/focus number in the presence of drug was used to derive IC_{50} values. Detection of infected cells was simplified by introduction of a β-galactosidase reporter gene under the control of the HIV-1 LTR [18]. Initially, these assays only generated plaques or foci with syncytium-inducing (SI) virus, since HeLa cells naturally express the CXCR4 coreceptor, but not CCR5 (see Sect. 3.5). Artificial expression of CCR5 in HeLa/CD4 cells, or other cell lines, overcame this obstacle [19–22].

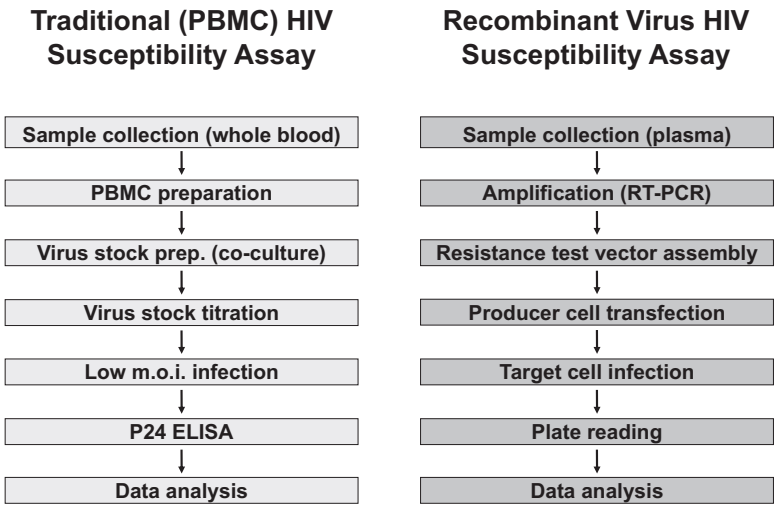

Fig. 83.2 Comparison of the process flow for intact virus (PBMC) and recombinant virus (PhenoSense HIV) assays

3.2 Peripheral Blood Mononuclear Cell-Based Assays

In the early 1990s, an alternative HIV phenotypic assay method was developed in which peripheral blood mononuclear cells (PBMCs) from an HIV-infected individual were co-cultured with phytohemagglutinin (PHA)-stimulated PBMCs from a seronegative donor [10] (Fig. 83.2). After approximately 7 days, the supernatant of the culture was collected as the viral stock and was subsequently titrated (based on p24 antigen production) on more PHA-stimulated donor PBMCs for an additional 7 days. An appropriate dilution of the viral stock was then added to PHA-stimulated donor PBMCs and grown for a further 7 days in the absence and presence of an antiretroviral agent. The supernatant was harvested and p24 antigen measured by an ELISA to quantitate virus production and generate susceptibility curves and IC_{50} or IC_{90} values. While this assay was standardized and provided useful phenotypic drug susceptibility/resistance data, it was cumbersome, imprecise, and slow. In addition, it is possible that the HIV stock derived from latent provirus in infected PBMCs does not reflect the strains circulating in the plasma.

3.3 Recombinant Virus Assays

The first recombinant virus assay for HIV generated viable virus by homologous recombination of a reverse transcriptase (RT)-deleted SI viral clone with a PCR-derived pool of RT sequences derived from proviral DNA samples [23]. Recombinant, replication-competent virus was amplified in a T-cell line and the virus harvested after 8–10 days, followed by virus titration and determination of drug susceptibility in a HeLa CD4+ cell foci reduction assay [23] or cell killing assay using a colorimetric readout [24, 25]. This assay represented a major step forward as it eliminated the need for donor PBMC cultures, thus standardizing viral stock production. Additionally it reduced the potential for the selection of virus stocks in culture that might differ from those represented in original sample due to the selective effects of different HIV gene products, particularly envelope. However, the use of proviral DNA may not fully reflect the circulating replication-competent virus, and the turnaround time for these assays (3–4 weeks) was still significant. This assay was later modified to measure HIV protease (PR) inhibitor susceptibility and to amplify sequences from plasma viral RNA instead of proviral DNA [26]. The assay was commercialized by Virco (Antivirogram®) in 1998 but discontinued for routine clinical use in 2010.

Significant advances that facilitated the use of phenotypic assays for routine clinical use occurred in the late 1990s. Both VIRalliance and ViroLogic (now Monogram Biosciences Inc.) developed and commercialized more rapid HIV phenotypic assays to measure resistance to antiviral drugs. The VIRalliance assay (Phenoscript™) [27] involves separate amplification of the gag-PR and the RT regions of HIV from RNA extracted from plasma samples. Each PCR product is then separately co-transfected into HeLa cells along with a proprietary plasmid vector. Infections are limited to a single cycle to ensure that the recombinant virus accurately reflects the amplified region from a clinical sample. Single-cycle infection is achieved by the deletion of the envelope region from the vector; recombinant virus is pseudotyped with the G-protein of the vesicular stomatitis virus (VSV-G). For testing of protease inhibitors, the transfected viral producer cells are incubated in the presence of serial dilutions of drug. The resulting recombinant virus is then used to infect indicator cells containing a *lacZ* gene under the control of the HIV-1 LTR. For testing of RT inhibitors, virus produced in the absence of drug is added to cells pretreated with serial dilutions of drug. β-Galactosidase in infected cells is quantitated using a CPRG-based colorimetric assay. This assay is no longer available for routine clinical use.

In the PhenoSense® phenotypic assay developed by Monogram Biosciences Inc., plasma-derived PR/RT sequences are amplified as one amplicon and inserted into a luciferase reporter resistance test vector (RTV) using restriction enzyme digestion and DNA ligation [28] (Fig. 83.2). Viral stocks are prepared by co-transfecting HEK293 cells with the test vector DNA and an expression vector that produces the amphotropic murine leukemia virus (aMLV) envelope protein. For the testing of protease inhibitor susceptibility, transfected producer cells are incubated in the presence of serial dilutions of drug. Pseudotyped viruses harvested from the transfected cells are then used to infect fresh HEK293 cells. For the assessment of RT inhibitors, virus produced in the absence of drug is added to cells pretreated with serial dilutions of drug. The production of luciferase is dependent on the completion of a single round of replication (infection, reverse transcription, and integration). Drugs that inhibit viral replication reduce luciferase activity in a dose-dependent manner, allowing the quantitative measurement of antiretroviral drug susceptibility (Fig. 83.3). The assay was subsequently adapted to allow the measurement of HIV integrase (IN) inhibitor susceptibility (PhenoSense® Integrase) [29, 30] and, more recently, the measurement of HIV PR/RT/IN inhibitor susceptibility, in conjunction with genotypic resistance analysis, from a single RTV (PhenoSense® GT plus Integrase) [31]. The assay was also adapted to allow assessment of maturation inhibitor susceptibility (Gag assay) for research and drug development purposes [32]. The distinguishing features of various HIV drug susceptibility assays are summarized in Table 83.1.

The recombinant virus assays described above share some drawbacks. Clinically relevant thresholds that define resistance are not known for all drugs (see below). The presence of a minority species of resistant virus(es) may be missed if their relative proportion and/or fitness is below that required for the IC_{50} to shift above the cutoff; the proportion required varies for each drug and mutation pattern. However, both of these limitations (interpretation and detection of minor species) also apply to standard population genotyping assays. Alternative approaches such as traditional clonal phenotypic or genotypic analysis are too expensive and cumbersome for routine clinical use. However, recent advances in "single genome sequencing" methodologies could allow the cost-effective genotypic analysis of minor species if deemed clinically relevant. Partly to minimize the potential for missing the presence of resistant virus, current recommendations emphasize the need to draw a blood sample while an individual is still taking a failing drug regimen to avoid the possibility of archived drug-sensitive virus from outgrowing the resistant variants [33].

Studies that have compared results from different HIV-1 phenotyping assays are limited. Qari et al. tested a panel of 38 samples, many of which were sensitive to all antiretrovirals, in the PhenoSense and Antivirogram assays [34]. Over 90 % of individual results were considered concordant, using a dichotomous scoring system based on susceptibility cutoffs in use at the time of the study. The majority of discordant results had a fold change in IC_{50} values close to the cutoff used. Miller et al. used a panel of 28 specimens, which included a greater proportion with drug resistance, and compared all three assays that were commercially available at that time [35]. Again, the results generally had a good concordance. The most comprehensive analysis comparing PhenoSense and Antivirogram was published by Zhang et al. and demonstrated an improved precision for PhenoSense with nucleoside RT inhibitors [36].

3.3.1 Phenotype Test Interpretation

The interpretation of phenotypic susceptibility assay results is enhanced by relevant thresholds, or "cutoffs", that are

intended to define the point above which the utility of a given drug begins to decline. "Clinical cutoffs" based on virologic response data from clinical trials provide the most clinically relevant threshold but are also the most difficult to define. To date, clinical cutoffs included in the PhenoSense, PhenoSense GT, PhenoSense Integrase, and PhenoSense GT Plus Integrase HIV assays have been defined for 14 drugs [31, 37–47]. The Phenoscript assay included clinical cutoffs for nine drugs [48, 49] and Antivirogram for four drugs [37, 40, 50–52] (Table 83.2). In the absence of clinical cutoffs, two alternative types of cutoffs have been used. The "assay" cutoff is defined by the intrinsic variability and technical limits of the assay during repeated testing of clinical samples. The "biological" cutoff is defined by an upper limit of the distribution of susceptibility exhibited by wild-type viruses, for example, the mean fold-change +2 standard deviations [53] or the 99th percentile [54]. The clinical relevance of biological cutoffs is limited, however, since the FC value that may be associated with declining virological responses can vary according to the drug. Importantly, the biological cutoff reflects both natural variation in viral susceptibility and inherent assay variability. Thus, such cutoffs may differ among assays that have different intrinsic variability.

3.3.2 Adaptation of Recombinant Virus Assays to Entry Inhibitors

HIV entry inhibitors include peptide inhibitors of virus-cell fusion and small molecules or antibodies that can target the viral envelope protein (Env) or cell-surface proteins (e.g., CD4, CCR5, or CXCR4) to prevent infection of cells [62, 63]. Enfuvirtide (ENF) is a synthetic peptide fusion inhibitor based upon the heptad repeat 2 (HR2) domain in the gp41 subunit of HIV-1 Env. ENF binds specifically to the HR1 domain in gp41 and resistance maps to this region [64–66]. To monitor the emergence of ENF resistance, two of the rapid phenotypic assays (Phenoscript and PhenoSense) that were originally developed for evaluating PR/RT resistance were modified [61, 67]. For Phenoscript, a fragment of the envelope gene (*env*) spanning gp120 and part of gp41 is amplified and co-transfected with an *env*-deleted proviral vector. Recombinant virus is used to infect cells containing an HIV LTR-β-gal reporter gene and expressing CD4 and one or both of the HIV coreceptors, CCR5 or CXCR4. In the PhenoSense Entry assay, the entire *env* gene (gp160) is transferred to an expression vector and co-transfected with a luciferase reporter viral vector. Resulting viral pseudotypes are used to infect cells expressing CD4 and CCR5 and/or

CXCR4. Both assays use inhibition of the reporter gene activity to generate IC_{50} or IC_{90} data. Studies using these assays, as well as others, revealed that natural variation in ENF susceptibility can be quite extensive [61, 67]. A clinical interpretation of these differences has been hindered by the lack of studies allowing for the derivation of a clinical cutoff for ENF; therefore, a biological cutoff is used to define a virus as having reduced susceptibility.

Recombinant virus entry assays can also be used to assess resistance to entry inhibitors that target Env interactions with CD4, CXCR4, or CCR5, including attachment inhibitors and chemokine receptor antagonists. For some inhibitors, including the CD4 antibody ibalizumab and the CCR5 antagonist maraviroc (MVC), resistance in a phenotypic assay can be observed as increases in IC_{50} and IC_{90} values and/or as a reduction in the maximum percent inhibition (MPI) obtained, visualized as a "plateau" at which infection can no longer be inhibited further with increasing drug concentrations [68–70].

3.4 Assays for HIV Fitness and Replication Capacity

Viral fitness is defined as the ability of a virus to reproduce within a defined environment. Mutations that confer drug resistance often reduce viral fitness in the absence of drug by interfering with one or more critical steps in the replication cycle. Replication capacity (RC) refers to the ability of a virus to replicate in the absence of drug as compared to that of a wild-type, drug-sensitive control virus. Several methodologies for determining viral fitness have been described, including replication-competent virus growth kinetic assays that

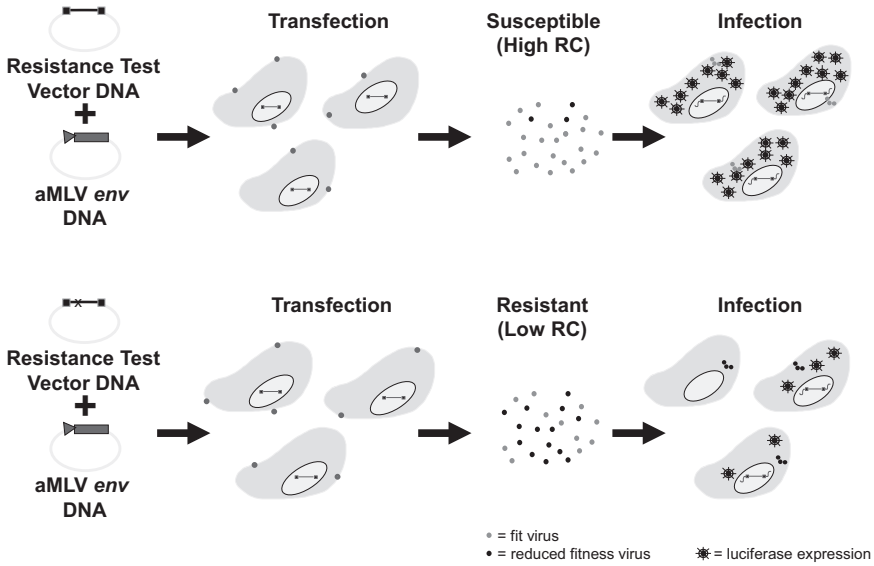

Fig. 83.4 Replication capacity assay (PhenoSense HIV). Drug-resistant viruses often exhibit reduced replication capacity (RC) compared to drug-susceptible viruses

compare the efficacy of viral replication of two or more variants in parallel or competitive cultures. Competitive culture assays measure the proportions of competing viruses over time using a variety of techniques including a recombinant marker virus assay [71] and a heteroduplex tracking assay [72]. A competition assay is regarded by many as the standard methodology to evaluate viral fitness because of its ability to measure the replicative abilities of two viral strains under identical conditions. However, the laborious nature and extended turnaround time of these assays make them impractical for routine clinical use. More rapid, single-cycle, phenotypic susceptibility assays have been adapted to measure RC (Fig. 83.4). In this case, the reported RC only relates to the portion of the amplified sequence transferred to the recombinant virus (i.e., PR and the partial gag and RT sequences included in the amplified fragment), and so the data must be interpreted carefully. Nonetheless there is evidence that if fitness differences are related to changes in PR/RT, the recombinant virus RC assay is a good surrogate of in vivo fitness [73].

Studies have shown that there is a wide distribution of RCs among wild-type HIV lacking phenotypic or genotypic resistance [54, 74, 75]. In general, drug-resistant HIV has been found to possess reduced RC and in vivo fitness, as demonstrated by the reappearance of less resistant virus in individuals whose antiretroviral therapy is interrupted, concomitant with an increase in viral load and decrease in CD4 cell count [73]. However, transmitted multidrug-resistant forms of HIV remain resistant for long periods of time even in the absence of drug pressure and with low viral fitness [75–77], presumably because the reversion rate is slower than that for outgrowth of archived drug-sensitive strains or due to unfavorable (unfit) intermediate forms on the pathway back to a drug-sensitive progenitor [78]. The availability of a convenient RC assay and accumulation of large amounts of data has enabled studies correlating the presence of specific resistance-associated mutations with low RC [79–86]. Such analyses may facilitate the formulation of treatment strategies designed to force the development of certain mutations which also reduce viral fitness [87, 88]. While the clinical utility of measurements of viral fitness or RC for a given individual is unclear, some reports have indicated a correlation between low RC and preservation of CD4 cell counts [74, 75, 89, 90].

3.5 Determining Coreceptor Tropism for HIV-1

HIV-1 infection requires interactions between the viral Env surface glycoprotein (gp120), the cellular receptor (CD4), and a coreceptor (e.g., CCR5 and/or CXCR4) [91]. CCR5 is expressed on primary T-cells and macrophages and is predominately used as a coreceptor by HIV transmitted between individuals and viruses present during early infection [92]. CXCR4 is expressed on many cell types, including primary T-cells, macrophages, thymocytes, and T-cell lines. CXCR4-using viruses are more commonly found in individuals with advanced disease [92]. However, it is not clear whether CXCR4 use precedes and causes more rapid disease progression or is merely the consequence of a change in target cell availability.

The discovery of HIV coreceptors enabled the development of HIV-1 entry inhibitors that target CCR5 in particular, including MVC (Pfizer, approved), vicriviroc (Schering-Plough, development halted), aplaviroc (GlaxoSmithKline, development halted), cenicriviroc (Takeda Pharmaceutical and Tobira Therapeutics, development for HIV on hold), and PRO 140 (CytoDyn Inc.) [62, 63]. The clinical development

of coreceptor inhibitors, and subsequent approval of MVC, necessitated the development of validated assays to determine coreceptor tropism [93, 94]. More recently, gene therapy-based approaches targeting CCR5 have further heightened interest in coreceptor usage and assays to measure it [95].

3.5.1 MT-2 Assays

CXCR4-using viruses can induce the formation of syncytia (syncytium-inducing (SI) virus) when cultured on the CXCR4-bearing MT-2 cell line. MT-2 cells lack CCR5 and are unable to be infected by CCR5-using HIV-1. Thus prior to the identification of coreceptors, CCR5-using HIV-1 isolates were classified as non-syncytium inducing (NSI). Two standardized MT-2 assay approaches have been described to evaluate coreceptor tropism. In one [96], there is a requirement to generate viral stocks from PBMC co-cultures, as described above. These stocks are titrated and can then be used to infect MT-2 cells. Since MT-2 cells express CXCR4 but not CCR5 [97], only SI (CXCR4-tropic) HIV-1 will be able to infect and induce the formation of syncytia. The assays are typically read 14 days or more after infection. Assessment requires microscopic inspection of individual cultures to determine the presence (SI) or absence (NSI) of syncytia. The second method utilizes direct cocultivation of MT-2 cells with an HIV-infected individual with PBMCs, followed by microscopic examination [98]. Prior to the identification of coreceptors, MT-2 assays were a common method of determining HIV phenotype in clinical research settings. Early studies utilizing an MT-2 assay established the SI phenotype as an important marker of disease progression [99]. Despite these findings, the MT-2 assay has not become a routine clinical monitoring test, owing to the time- and labor-dependent nature of the assay process, the lack of ability to directly alter this phenotype by previously available antiretrovirals, the potential drawback that the virus tested is derived from stimulated lymphocytes and not plasma virus and thus may not be representative of circulating virus, the nonquantitative nature of the assay readout (SI or NSI), the variable ability of CXCR4-tropic viruses to induce syncytia, and the potential for some non-CXCR4-tropic viruses to induce syncytia via an alternative coreceptor(s) [100].

3.5.2 Recombinant Viral Assays for Tropism

Entry susceptibility assays (see above) have been modified to enable the determination of HIV coreceptor tropism [93, 94, 101]. Recombinant viruses are used to infect mammalian cell lines expressing CD4 and either CXCR4 or CCR5. One such high-throughput assay (Trofile®, Monogram Biosciences Inc.) [93, 94] has been utilized in the clinical development of coreceptor inhibitors and is commercially available for selecting individuals suitable for MVC treatment. This single-cycle assay utilizes luciferase reporter pseudotype viruses and quantitates luciferase activity as relative light units (RLUs) to assess infection of U87 cells expressing CD4 and either CXCR4 or CCR5. As a confirmatory step, luciferase production must be inhibitable by an antagonist specific for the coreceptor being evaluated. This step is particularly relevant when infection levels are low and result in luciferase activity close to background levels. In June 2008, the original Trofile assay was superseded by an assay with enhanced sensitivity for the detection of minority variants [94]. This improved sensitivity allowed for the earlier detection of emergent CXCR4-using subpopulations in longitudinal samples and further optimized the selection of individuals for CCR5 antagonist therapy [94, 102–105]. The enhanced sensitivity Trofile assay is considered the current benchmark for coreceptor tropism evaluation. A version of this assay that utilizes cell-associated HIV-1 DNA as a template (Trofile® DNA), rather than plasma virus RNA, became available in 2010 to support treatment decisions in the context of virologic suppression [106].

The Tropism Recombinant Test (TRT; VIRalliance) is similar to the original Trofile assay except that a smaller region of the *env* gene (V1–V3) is amplified, and the readout is based on colorimetric assessment of β-galactosidase activity [101]. This assay was to be made available through Eurofins, but is not currently offered for routine clinical testing. The two recombinant tropism assays (TRT and the original Trofile assay) gave largely concordant tropism results (85 %) in a comparative study, with a few unresolved discordances and no evidence of differences in sensitivity [107]. While the V3 loop in the gp120 domain of Env is the major determinant of coreceptor use, regions outside of V3, and even outside of gp120, can also influence coreceptor tropism and thus may account for some discordant results between V3-based assays and those that utilize the entire Env [108].

A number of other recombinant virus-based tropism tests have been developed for research applications or exploratory clinical applications. These include:

(a) The Toulouse tropism test (TTT) which evaluates gp120 and the ectodomain of gp41 cloned from plasma virus or cell-associated DNA [109]. From a comparative analysis of tropism results for 24 samples, 92 % concordance to the enhanced sensitivity Trofile assay was obtained [109].
(b) A promoter-PCR (pPCR) assay in which overlapping PCR is used to assemble a CMV promoter to a population of full-length *env* genes which are then directly co-transfected with an Env-defective luciferase reporter HIV construct to generate pseudovirions, avoiding cloning/recombination steps [110]. Using this assay, results for 9/9 samples were concordant with the original Trofile assay [110].
(c) The VERITROP™ cell-to-cell fusion assay which utilizes a yeast-based homologous recombination approach to clone *env* genes into a HIV vector [111]. A comparative study to the original Trofile assay demonstrated 74 % (56/76) concordant results [111].

3.5.3 Comparison of MT-2 and Recombinant Virus Coreceptor Tropism Assays

There are important differences between MT-2 and recombinant virus assays. These assays typically evaluate HIV from distinct compartments: stimulated lymphocytes versus plasma. MT-2 assays utilize intact virus and recombinant assays evaluate the viral *env* gene. MT-2 assays permit multiple cycles of replication (and possible amplification of viral subpopulations and/or viral adaptation to culture conditions), while recombinant assays limit replication to a single cycle.

An SI result in an MT-2 assay is an established surrogate for HIV-1 CXCR4 utilization. This is supported by limited data examining the relationship between phenotypes determined by the MT-2 assay and the Trofile coreceptor tropism assay. In one study, 11 individuals with HIV determined to be SI in the MT-2 assay [112] had coreceptor typing performed retrospectively with the Trofile assay; virus from all 11 individuals was X4 or dual/mixed (DM (dual: CCR5 plus CXCR4. Mixed: populations of viruses with mixed tropisms that include CCR5- and CXCR4-using viruses)). Luciferase activity obtained on CXCR4-expressing cells infected with pseudovirions from these 11 samples was not uniform but rather varied over a very broad range of RLUs. Further studies will be required to determine whether this is clinically meaningful.

In a second study, the Trofile assay was utilized to determine the coreceptor tropism of virus from individuals prior to entry into a clinical trial of vicriviroc for the AIDS Clinical Trials Group 5211 study [113]. MT-2 assays were performed retrospectively among baseline isolates and revealed only limited discordance between the two assays [114]. Notably, the virus recovery rate among lymphocyte samples processed for the MT-2 assay was low (50 %) compared to the proportion of samples successfully phenotyped by the Trofile assay (>90 %). In a third study, the original and enhanced sensitivity Trofile assays were used to retrospectively evaluate sequential samples from individuals previously evaluated in an MT2 assay. Results were highly concordant and the evolution of coreceptor tropism from R5/NSI to DM/SI over time was noted in both assays [105].

4 Phenotypic Drug Susceptibility Assays for Hepatitis B Virus

Several specific antiviral drugs are now available for chronic HBV infection, including pyrimidine analogues (telbivudine, lamivudine) and purine analogues (tenofovir, entecavir, adefovir). As is the case for HIV, the use of these drugs can lead to the emergence of drug-resistant strains, associated with mutations within the polymerase gene [115] (see also chapter by Stephen Locarnini). With prolonged therapy and continued viral replication, mutations can accumulate and lead to significant cross-resistance between some polymerase inhibitors. Thus it may be important to detect and measure HBV drug resistance to manage the therapy of treatment-experienced HBV-infected individuals. To date, no detectable resistance has been observed following up to 7 years of treatment with tenofovir [116, 117]. However, preexisting adefovir resistance can decrease tenofovir activity [118].

While some HBV cell culture models have been described [119, 120], HBV presents unique challenges due to the fact that no routine robust cell culture system has been established to support the replication of HBV isolates (e.g., for viral spread assays). Therefore, phenotypic assays for the measurement of HBV antiviral drug susceptibility typically rely on several alternative methodologies and are limited to research/clinical research applications.

Phenotyping assays using full-length genomes from parental or mutant laboratory strains have been applied to study HBV resistance in transient assays [121, 122]. Cells able to support transient HBV replication (e.g., HepG2 or Huh7) are transfected with HBV plasmid vector constructs. Intracellular genome replication, dependent on the activity of the parental or altered HBV polymerase, is then compared in the presence and absence of the antiviral drug. Replication is traditionally monitored by Southern blotting; however this technique has limited clinical application due to the cumbersome nature of the readout. Additional concerns include questionable relevance of the behavior of individual mutations in a laboratory virus strain background.

Baculovirus vector-based HBV phenotyping assays to evaluate drug susceptibility have also been described [123, 124]. These approaches allow for efficient transduction of recombinant HBV baculoviruses into hepatoma cell lines. Most HBV drug-resistant variants have been found to replicate in such a system and to demonstrate the expected drug resistance phenotype. However, the procedure is still too cumbersome for routine use in the clinic.

A HBV phenotyping approach that employs PCR amplification of full-length HBV genomes from clinical samples may provide more relevant drug susceptibility information [125]. Clones or quasispecies populations of these genomes can be used instead of parental or mutant laboratory strains in transient transfection studies, using Southern blotting or real-time quantitative PCR approaches to monitor replication [126–129]. A modified version of one assay was commercialized by VIRalliance, but is no longer offered routinely [127]. A variant assay allows the phenotypic assessment of HBV polymerase/RT sequences from clinical specimens of genotypes A to H in the context of a recombinant genotype A HBV backbone [130, 131]. Polymerase/RT sequences are more easily amplified compared to full-length genomes; therefore, this approach facilitates the analysis of clinical samples with lower viral loads.

5 Phenotypic Drug Susceptibility Assays for Hepatitis C Virus

From 2001 through May 2011, HCV infection was treated with a combination of pegylated interferon alpha (peg-IFNα) and ribavirin (RBV) [132]. This entailed a long treatment course with significant side effects that was only approximately 50 % effective for individuals with genotype 1 HCV, the most common HCV genotype in North America [133–135]. Over the past few years, extensive antiviral drug discovery/development efforts have focused on direct-acting antiviral (DAA) agents that primarily target the NS3/4A protease, NS5B polymerase, or NS5A protein of HCV [132]. This has resulted in the approval of a number of different treatment regimens that variably incorporate protease inhibitors (boceprevir, telaprevir, simeprevir, asunaprevir, paritaprevir, grazoprevir), nucleoside (sofosbuvir) or non-nucleoside (dasabuvir) polymerase inhibitors, and NS5A inhibitors (daclatasvir, ledipasvir, ombitasvir, elbasvir, velpatasvir) [132]. Viral strains resistant to most of these compounds can rapidly emerge with suboptimal treatment regimens, given the error-prone nature of the HCV RNA-dependent RNA polymerase and high replication rate of HCV in vivo [136–142]. Thus, as for HIV, DAAs are utilized in combination/coformulated regimens, including with other DAAs with a different mechanism of action and with peg-IFN-α and/or RBV [132].

As for HBV, there is no cell culture system available for the routine culture of clinical isolates of HCV. To date, most in vitro HCV virology studies have been performed using genotype 1 or 2 subgenomic replicons [143–150] or a genotype 2a infectious cDNA clone [151–153]. Adaptive mutations can facilitate replication in cell culture. Replicons with resistance to virtually every compound tested so far can be selected in vitro. Such studies have been highly informative with respect to determination of the location of sites on the protease, polymerase, or NS5A protein that interact with the inhibitor and for the characterization of cross-resistance [139, 154–163]. For example, there appear to be four and possibly five distinct sites where allosteric inhibitors of the NS5B polymerase bind, as determined by the largely non-overlapping sets of mutations selected by the different classes of compound [164]. Variants associated with in vitro resistance to polymerase, NS3/4A protease, and NS5A inhibitors have also been detected in HCV from individuals treated with these inhibitors and largely overlap the in vitro findings [139, 165].

Recombinant replicon systems for assessing the drug susceptibility of plasma-derived HCV have been developed. These assays are currently utilized for research purposes and to support the phenotypic analysis of DAA susceptibility in preclinical and clinical drug development programs [166]. Plasma virus NS3 protease and NS5A or NS5B sequences can be transferred to a luciferase reporter-based replicon vector for susceptibility testing [161, 167–172], such as in the PhenoSense HCV NS3 protease and NS5A and NS5B assays (Monogram Biosciences Inc.; Fig. 83.5). Assay formats are similar to recombinant assays for HIV-1, in that target sequences are amplified from plasma by RT-PCR, transferred to a viral vector, introduced into cells, and cultured with serial dilutions of various inhibitors. Key differences include the requirement for in vitro RNA transcription (since the system relies on RNA, not DNA), typically an electroporation step, rather than transfection, and the use of limited number of cell types (derivatives of Huh-7 cells including those "cured" of HCV infection) which are able to support the high level of replication needed for the transient transfection assay format (Fig. 83.6).

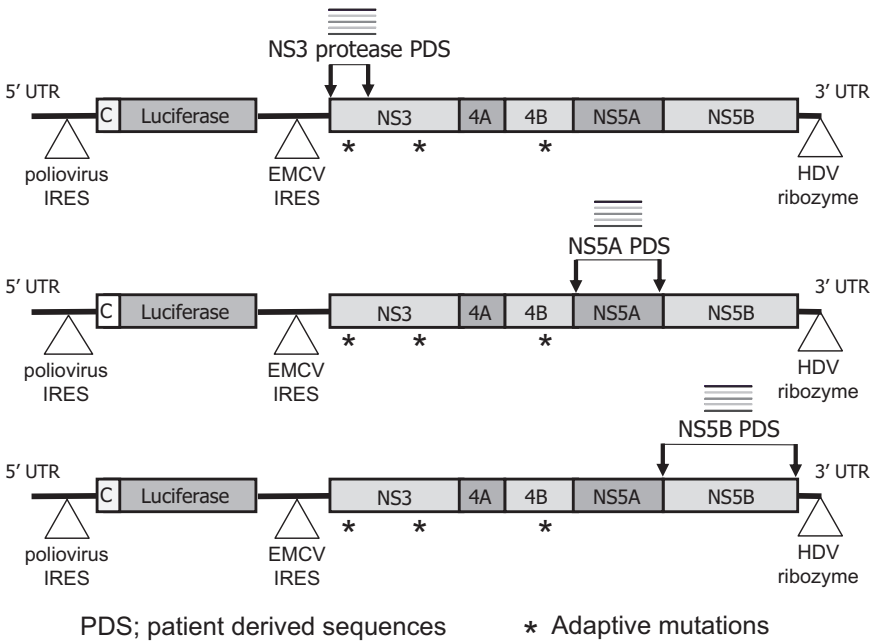

Fig. 83.5 Resistance test vectors for HCV replicon assays (PhenoSense HCV)

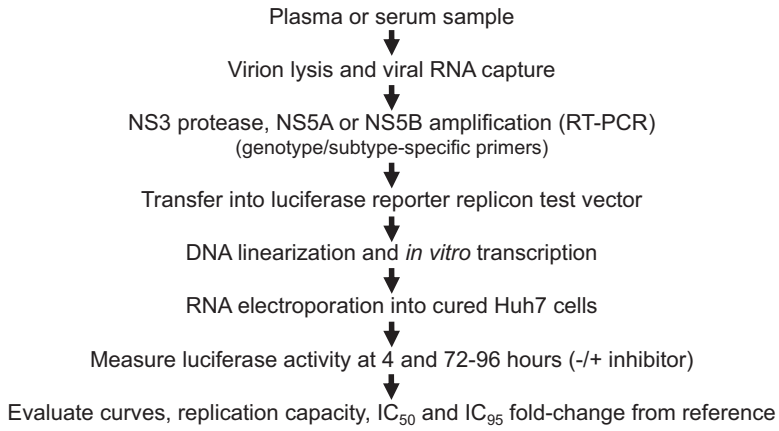

Fig. 83.6 Process flow for HCV replicon assays with clinical samples (PhenoSense HCV)

Challenges for phenotyping HCV clinical samples are related to the extensive diversity between HCV genotypes and subtypes and include (a) the design of primers and RT-PCR conditions that enable the amplification of a high percentage of samples at low viral loads; (b) the relatively low replication capacity of replicons containing some plasma-derived viral sequences, such as NS3 protease regions from protease inhibitor-resistant variants; (c) the lack of replication with some inter-genotypic recombinants, such as non-GT1 NS3 protease regions in a GT1 replicon backbone; and (d) the availability of a limited number of replicon backbones. HCV diversity has also proven challenging for drug development, with a number of inhibitors exhibiting variable potency within and between HCV genotypes. Natural variation in susceptibility to DAAs within a genotype can range from relatively narrow (e.g., within approximately 10-fold for some nucleoside inhibitors) to wide-ranging (e.g., over 1000-fold with some non-nucleoside polymerase inhibitors), in the absence or presence of known resistance-associated variants [167, 173]. However, as high sustained virologic response (SVR) rates can be obtained with combinations of potent antivirals, phenotypic viral resistance assays are not currently appropriate for routine clinical use as they are for HIV-1. Current guidelines do recommend the use of a genotypic viral resistance assay to select appropriate candidates for treatment with simeprevir in combination with peg-IFN-α/RBV or sofosbuvir [174,174b]. Clinical trials have shown that the efficacy of simeprevir/peg-IFN-α/RBV can be substantially reduced when the NS3 protease Q80K polymorphism is detected at baseline in HCV genotype 1a. Similar findings were observed following simeprevir/sofosbuvir treatment of individuals with cirrhosis. In phenotypic assays, Q80K confers an approximate 10-fold reduction in simeprevir susceptibility [175–177]. Guidelines also recommend genotypic viral resistance analysis of NS5A prior to the use of elbasvir/grazoprevir in HCV genotype 1a infected individuals [174b]. The presence of resistance-associated polymorphisms at amino acid positions 28, 30, 31 or 93, that confer at least a 5-fold reduction is elbasvir susceptibility in phenotypic assays, are associated with reduced efficacy in a 12 week treatment regimen. Treatment duration of 16 weeks with RBV intensification is recommended if variants at positions 28, 30, 31 or 93 are identified [174b].

6 Phenotypic Drug Susceptibility Assays for Herpesviruses (HSV, CMV, VZV)

While virus isolation and growth for the clinically important alpha herpesviruses, such as herpes simplex virus (HSV), cytomegalovirus (CMV), and varicella zoster virus (VZV), are technically possible, as with HIV it is wrought with practical obstacles including low reproducibility, long turnaround time, labor intensity, and biosafety concerns. Therefore, traditional plaque reduction assays for HSV [6], CMV [7] and VZV [8, 178] have been adapted for higher throughput [179] or are being replaced by recombinant virus systems [180–182], including some which rely on reporter gene readout such as secreted alkaline phosphatase (SEAP) [183]. Uncertainty about the clinically meaningful level of resistance is a major issue with the use of some of these assays [184, 185], as it is for HIV-1. Plaque reduction assays for the clinical evaluation of HSV-1/2 drug resistance are available from a limited number of reference or specialized laboratories.

7 Phenotypic Drug Susceptibility Assays for Influenza Virus

Phenotypic drug susceptibility assays for intact influenza virus have mainly been limited to plaque assays, often in Madrin-Darby canine or bovine kidney (MDCK or MDBK) cells. These assays have been successfully used to test the amantadine, rimantadine (adamantane derivative M2 ion channel inhibitors), and ribavirin (not approved for influenza

treatment) susceptibility of multiple strains of influenza [186]. Adamantanes are ineffective for the treatment of influenza B viruses, which lack the M2 protein, and widespread adamantine resistance among influenza A viruses has limited their utility this past decade [187].

In the mid-1990s, the advent of potent neuraminidase (NA) inhibitors such as zanamivir and oseltamivir provided new antiviral options for influenza treatment and created renewed interest in assays to assess influenza antiviral susceptibility. Phenotypic assays to measure NA activity were developed and are based on an enzymatic assay of virus particle-associated NA, using fluorescent or chemiluminescent NA substrates [188–191]. Commercial kits (Applied Biosystems), as well as in-house assays, are currently utilized routinely. In these assays, viral stocks are first titrated to select an assay input that is on the linear portion of the enzyme activity curve. An appropriate dilution of virus and drug are then mixed and incubated together, after which the fluorescent or chemiluminescent substrate is added. After incubation, the reaction is terminated and the amount of NA-released product is measured [192]. Fluorescent assays are more cost-effective, while chemiluminescent assays can have shortened incubation times and wider dynamic ranges, but both enzymatic assays are faster and more reliable than plaque assays. Alternative assays using virions pseudotyped with hemagglutinin and/or neuraminidase have also been described and can allow the biosafe evaluation of susceptibility to neuraminidase inhibitors [193–195]. However, for pseudotype as well as the traditional fluorescent or chemiluminescent assays, since some aspects of NA inhibitor resistance are associated with the hemagglutinin protein [196–199], NA enzyme or pseudovirion release assays may not completely reflect the inhibitor susceptibility of the intact native virus. An assay in which HA-expressing cell lines provide HA in trans to pseudotype HA-deleted, green fluorescent protein-expressing influenza viruses may facilitate analysis of influenza antivirals as well as neutralizing antibodies in a reconstituted virus system [199b].

Both fluorescent and chemiluminescent assays are rapid and reproducible and are used clinically as well as for surveillance [200, 201]. Phenotypic testing for neuraminidase inhibitor susceptibility is particularly useful when new viruses arise or new inhibitors become available, such as peramivir. Given the concern about spread of NA inhibitor-resistant influenza viruses, the Neuraminidase Inhibitor Susceptibility Network (NISN) was originally established to monitor resistance around the world using the chemiluminescent assay outlined above. In 2006, the NISN reported that at 3 years post the introduction of NA inhibitors, the detection of resistant viruses was limited (8 out of 2287 samples tested), but required continued surveillance as inhibitor use became more widespread [202]. Indeed, subsequent surveillance efforts by the NISN, the World Health Organization, as well as other groups, using fluorescent or chemiluminescent phenotypic assays, as well as sequence-based assays, identified widespread resistance to oseltamivir in circulating seasonal influenza from late 2007 to early 2008 and in the 2008–2009 season [187]. Viruses that arose late in the 2008–2009 season and that circulated/arose in following seasons through 2013–2014 had a low incidence of resistance on whole (2 % or less globally); however, clusters of resistant viruses identified in a number of communities in different countries warrant ongoing surveillance [187, 203, 204].

Drug Resistance Assays for Parasitic Diseases

84

Danielle Légaré and Marc Ouellette

1 Introduction

Protozoa and helminths have, by far, the greatest impact in terms of morbidity worldwide. The status of protozoa and helminths control, both in human and veterinary medicine, is challenged as the current medications against these parasites are losing their efficacy due to increasing and even further spreading drug resistance. Despite this alarming statement and the high burden imposed by parasites, research progress in parasitic diseases lags behind many other infectious diseases. Recent innovative technologies may significantly impact parasite diagnostics and their control in the near future, catalyzed by a better knowledge in drug resistance mechanisms. The present chapter review drug resistance assays in major protozoan and helminthic diseases, point-of-care tests and multiplexing assays for drug resistance testing, and opportunities for innovations in the field.

2 Drug Resistance

Parasitic diseases cause millions of human deaths every year with a major impact in terms of disability-adjusted life year (DALYs) [1]. Drug resistance is the ability of parasites to sustain growth and persist despite the presence of a drug. As long as drugs are used to treat parasitic infections, the chance of resistance developing to those drugs is present. All parasites covered in this chapter (Table 84.1) have developed resistance to nearly all available drugs used against them or will eventually develop resistance if drugs are not used appropriately. One useful strategy for reducing the appearance of resistance is drug combinations. This has been most useful against malaria [2] and is now advocated for other parasites, although the limited number of drugs often limits the possibility for effective combination. Apart from drug combination, the monitoring of drug resistance in parasitic pathogen collected from patients is not only helpful to guide initial treatment decisions (e.g., to avoid the use of nonoptimal medicine in case of drug resistance) but also helps in preserving the efficacy of existing molecules. Testing for resistance in parasites is labor intensive, however not well standardized, and hence not routinely available in clinical laboratories, especially in low-income countries.

2.1 Generalities: *Protozoa*

Drug resistance in protozoa can be inferred from clinical studies or from animal models, more frequently using in vitro tests and, with our increased understanding of the molecular mechanisms of resistance, using molecular DNA-based methods. Briefly, during clinical studies, a cohort of patients with clinical symptoms are treated and monitored over time for either failure to clear parasites or for relapse. Although relevant in terms of clinical context, one may not have the possibility of following closely the patients, and treatment failure or relapse may be due to several factors, including noncompliance, host immunity, variations of drug absorption and metabolism, reinfection, etc. A second form of in vivo tests deals with animal models and could be used (when available) when parasite isolates cannot be easily adapted to in vitro conditions. These animal model tests are expensive however and require special settings and qualified personnel and consequently, are not used frequently. In vitro tests are thus by far the most frequently used way to monitor drug resistance in protozoan parasites, but they require that the pathogenic organisms are grown in culture, in the presence of increasing concentrations of drugs and in either the presence or absence of in vitro cultured host cells. In most in vitro assays, the drug concentration that inhibits parasite growth (or its maturation or development) is used as an endpoint. Some in vitro methods call for adaptation of parasites to

Table 84.1 Major protozoan and helminthic diseases in humans

Disease	Pathogen	Burden
Trypanomatid parasites		
Chagas disease	*Trypanosoma cruzi*	An estimated 25 million people are at risk in 21 countries in Central and South America (and more recently in the USA) with ~10 million people infected. There are 1 million new cases of chronic disease and more than 10,000 deaths annually. DALYs[a] burden is estimated at 0.55 million
Human African trypanosomiasis (sleeping sickness)	*Trypanosoma brucei rhodesiense* or *Trypanosoma brucei gambiense*	Of the 36 countries considered endemic for HAT, the Democratic Republic of the Congo alone accounts for 2/3 of reported cases. Other highly affected countries include Angola, Southern Sudan, and Uganda. The estimated number of actual cases is 20,000–50,000 with an estimated population at risk of 70 million people and a DALYs burden of 0.56 million. HAT has been targeted by WHO for elimination by 2020
Animal African trypanosomiasis (Nagana)	*T. vivax*, *T. congolense*, *T. brucei brucei*, *T. evansi, T. theileri*, and *T. equiperdum*	Economically, *Trypanosoma congolense* is the most important species and represents a major constraint to livestock productivity, particularly in the developing countries of Africa
Leishmaniasis	*Leishmania* spp.	The various forms of leishmaniasis affect populations in more than 95 countries with 350 million people living at risk, 12 million people infected, about 2 million of new cases per year, and an annual death rate of ~60,000 people. DALYs burden is estimated at 3.32 million
Apicomplexan parasites		
Malaria	*Plasmodium* spp.	Malaria occurs in over a hundred countries. Malaria encounters for 300–500 million annual cases with nearly a million deaths. DALYs burden is estimated at ~40 million
Toxoplasmosis	*Toxoplasma gondii*	Toxoplasmosis is present in every country. The global annual incidence of congenital toxoplasmosis alone has been estimated at 1.5 per 1000 live births, causing 1.2 million DALYs. High burdens were seen in South America and in some Middle Eastern and low-income countries
Cryptosporidiasis	*Cryptosporidium* spp.	*Cryptosporidium* spp. are recognized as major waterborne coccidian parasites worldwide. The disease may account for up to 25 % of childhood diarrhea cases in developing countries. Coccidian parasites are considered AIDS-defining opportunistic pathogens, but their screening is not done even in known HIV patients in most routine laboratories at the primary care level due to the lack of knowledge, expertise, and technique. DALYs burden for cryptosporidiosis is unknown
Coccidiosis	*Eimeria* spp. and *Isospora* spp.	*Eimeria* spp. is causing avian coccidiosis. Infections in human are rare. *Isospora belli* only infects human and some primates. DALYs burden for *Eimeria* and *Isospora* spp. in human is unknown
Anaerobe parasites		
Trichomoniasis	*Trichomonas vaginalis*	Trichomoniasis is the most common curable nonviral sexually transmitted infection worldwide, accounting for about 276 million cases annually. Among women, the prevalence of trichomoniasis has ranged from 3 % in adolescent and student to over 45 % in incarcerated women. Among men, the prevalence of trichomoniasis has ranged from 3 to 12 %
Giardiasis	*Giardia lamblia (or G. intestinalis or G. duodenalis)*	G*iardia duodenalis* (syn. *G. intestinalis*; *G. lamblia*) is the most frequently reported intestinal parasite in the world. According to estimations of WHO, giardiasis accounts for almost a billion cases worldwide with ~3 billion people living in areas in which the incidence of the infection is around 30 % (e.g., in developing countries). A prevalence range of between 2 and 8 % is estimated in developed countries. About 280 million people are infected each year worldwide. *Giardia* causes acute and chronic diarrhea, particularly among children in underprivileged communities
Amoebiasis	*Entamoeba histolytica*	Worldwide, approximately 50 million people develop colitis or extraintestinal diseases caused by amoebiasis. *E. histolytica* alone is responsible for 40,000–100,000 annual deaths worldwide. Amebic colitis and hepatic abscess are mostly responsible for the mortality, but the lung can be also infected which may also lead to death
Stramenopiles Parasites		
Blastocystosis	*Blastocystis hominis*	In some epidemiological surveys, *Blastocystis* is the most frequently isolated parasite; the prevalence varies between countries and between communities. In general, the estimated prevalence of *Blastocystis* spp. is higher in developing than developed countries (30–50 % and 1.5–10 %, respectively). This may be related to poor hygiene, animal exposure, and consumption of contaminated food or water

(continued)

Table 84.1 (continued)

Disease	Pathogen	Burden
Helminths		
Schistosomiasis (bilharziasis)	*Urogenital schistosomiasis is caused by S. haematobium and intestinal schistosomiasis by any of the organisms S. guineensis, S. intercalatum, S.mansoni, S. japonicum,* and *S. mekongi*	The schistosomes cause intestinal, hepatosplenic, pulmonary, urogenital, cerebral, and other forms of schistosomiasis. Schistosomiasis affects almost 240 million people worldwide and more than 700 million people live in endemic areas. DALYs burden is estimated at 3.31 million. The vast majority of the burden occurs in Africa
Lymphatic filariasis (also termed elephantiasis in extreme cases)	Filarial worms *Wuchereria bancrofti* and *Brugia malayi*	*W. bancrofti and B. malayi* are transmitted by mosquitos. Many patients are asymptomatic. Clinical features of *B. malayi* are similar to those of *W. bancrofti*. However in *B. malayi*, unlike *W. bancrofti*, genital involvement is rare. After recurring lymphangitis, a late complication resulting in thickening and verrucous changes in the skin known as elephantiasis may occur. An estimated 1.2 billion people are at risk in 83 countries throughout the tropics and subtropics of Asia, Africa, the western Pacific, and parts of the Caribbean and South America. An estimated 120 million people are infected worldwide with at least 40 million people severely affected. LF is marked by WHO for eradication by 2020. Lymphatic filariasis is responsible for 2.78 million DALYs
Onchocerciasis (river blindness)	Filarial worm *Onchocerca volvulus*	Onchocerciasis is one of the world's most distressing diseases of helminth origin, often resulting in blindness. The etiological agent *Onchocerca volvulus* is transmitted by the species *Simulium* or black flies whose breeding habitat is by fast flowing rivers or streams. The disease is prevalent in 30 countries of Africa, 13 countries in the Americas, and in Yemen. Worldwide, approximately 120 million people are at risk for the disease, over 35 million people are infected, 500,000 have visual impairment, and 270,000 people who have become blind as a consequence of long-term infection. DALYs burden is estimated at 0.49 million
Cysticercosis/ Taeniasis	*Taenia solium* (pork tapeworm) or *Taenia saginata* (beef tapeworm)	An infection due to an adult *Taenia,* in man or animals, is referred to as *taeniasis.* Only *T. solium* may cause cysticercosis in man. More than 50 million people are infected with *T. saginata* worldwide and about 60 million are infected with *T. solium*, causing ~50,000 deaths annually. Humans become infected by accidental ingestion of the embryonated ova (fecal-oral route) or by ingesting inadequately cooked beef or pork. Both humans and cattle or pigs are necessary to the complete life cycle of *Taenia* species. In the tropics, several other ruminants, e.g., goat, sheep, lama and giraffe, may serve as the intermediate hosts. DALYs burden is estimated at 0.5 million
Echinococcosis (Hydatid disease)	Caused by the larval stages of the *Echinococcus* spp. *(mainly **E. granulosus*** and *E. multilocularis but also **E. ortleppi**, **E. intermedius*** and **E. Canadensis**)[b]	Hydatid disease is most extensively found in East Africa, North Africa, South Africa, the Middle East, parts of South America, and Australia. The intermediate hosts are cattle, sheep, pigs, goats, or camels and the definitive host for this disease is the dog or other canids. Hydatid disease in humans is potentially dangerous depending on the location of the cyst (lung, liver, other tissues). Some 200,000 new cases of cystic echinococcosis are diagnosed annually. Echinococcosis are responsible for 0.14 million DALYs
Soil-transmitted helminthiases (intestinal worms)	*Ascaris lumbricoides* (roundworm), *Trichuris trichiura* (Whipworm), and hookworms (*Ancylostoma duodenale* and *Necator americanus*)	Soil-transmitted helminths infect a large proportion of people worldwide with significant morbidity in more than 450 million people, primarily children and pregnant women, resulting in over 39 million DALYs. Worldwide, over 950 million people are infected with *Ascaris* with 60,000 deaths annually. *Necator americanus* and *Ancylostoma duodenale* are hookworms classed as one of the most destructive of human parasitic helminths. Hookworms affect more than 700 million people across the globe. *Trichuris trichiura* is less prevalent (estimates are nonetheless close to 700 million people infected). *T. trichiura* is responsible for ~10,000 deaths each year
Foodborne trematode (FBT) infections	Over 100 species of foodborne trematodes are known to infect humans	The word trematode is derived from the Greek word "hole" which references to their two attachment organs also called suckers, an anterior oral one and a posterior ventral sucker. At least 56 million people suffer from one or more foodborne trematode infections (clonorchiasis, opisthorchiasis, fascioliasis, paragonimiasis, and others) worldwide. FBT infections are responsible for 1.88 million DALYs
Strongyloidiasis	*Strongyloides stercoralis* (also caused rarely by *Strongyloides fülleborni*)	*Strongyloidiasis* is a soil-transmitted disease. *Strongyloides stercoralis* infects ~40–100 million people worldwide. *Strongyloides fülleborni* is found sporadically in Africa and Papua New Guinea. The true prevalence of strongyloidiasis is unknown, because infection is often subclinical.

[a]DALYs, disability-adjusted life years

[b]These *Echinococcus* spp. were, until recently, all considered to be strains of one species (e.g., *E. granulosus*), but following a taxonomic revision, a number of species are now proposed

culture first, while others used directly freshly isolated parasites from patients into the test. Although cheaper, faster, and most of the time easier to perform in comparison to in vivo tests, in vitro tests have their intrinsic limitations also, the first one being the low correlation of in vitro response with clinical response observed in patients in several parasitic infections. While a lack of significant correlation between in vitro sensitivity of artemisinins and clinical response was found in some studies [3, 4], good correlation was observed with most antimalarial studies [5–10]. The imperfect nature of non-standardized techniques for measuring resistance/susceptibility in a large number of protozoan parasites may be one of the key factors contributing to this discrepancy in correlation between various studies.

Current molecular techniques have allowed to pinpoint several genes associated with drug resistance in protozoan (Table 84.2), at least when induced under laboratory conditions. The discovery of molecular targets and molecular

Table 84.2 Major drug treatments for human parasitic diseases, mode of action, and known resistance mechanisms

Disease	Drug	Mode of action	Mechanisms of resistance
Trypanosomatid parasites			
Chagas disease	Nitroimidazole (benznidazole)	Reduction of BZ results in the generation of the cytotoxic metabolite glyoxal which covalently modify macromolecules (reductive stress)	• Gene deletion of TcOYE • Overexpression of TcFeSODA • SNPs and gene deletion of NTR • TcABCG1 overexpression • TcAAAP069 overexpression • TcPGP1 and TcPGP2 overexpression • Overexpression of DNA repair proteins
	Nitrofuran (nifurtimox)	NFX reduction leads to the production of an unsaturated open-chain nitrile (reactive species) that leads to parasite death	• SNPs and gene deletion of NTR • TcAAAP069 overexpression
Human African trypanosomiasis (sleeping sickness)	Organic arsenical (melarsoprol)	Melarsoprol is degraded to melarsen oxide, a metabolite which is highly toxic Melarsoprol also interacts with TSH forming a stable complex called MelT, which in turn is an inhibitor of TR	• Mutations or loss of P2/AT1 • MRPA overexpression • ODC and γ-GCS overexpression • Loss of the high-affinity transporter AQP2 (alias HAPT1) • Generation of a chimeric AQP2/AQP3 with concomitant loss of AQP3
	Ornithine analogue (eflornithine)	Suicide inhibitor of ODC	• Mutations or loss of TbAAT6
	Diamidines (pentamidine)	Binds to kDNA and inhibits topoisomerase thus interfering with kinetoplast replication May also cause inhibition of multiple cellular targets including SAMDC	• Mutations or loss of P2/AT1 • Changes in the low-affinity pentamidine transporter LAPT1 • Loss of the high-affinity transporter AQP2 (alias HAPT1) • Generation of a chimeric AQP2/AQP3 with concomitant loss of AQP3 • Changes in nucleobase transporters NT11.1 and NT12.1
	Naphthalene derivative (suramin)	Inhibition of LDL uptake, prohibiting the parasite's supply of cholesterol and phospholipids	• Overexpression of TbMRPE
	Nitrofuran (nifurtimox)	NFX reduction leads to the production of cytotoxic species that cause damage to DNA, lipids, and proteins leading to parasite death	• SNPs and gene deletion of NTR
Animal African trypanosomiasis (Nagana)	Diminazene aceturate (Berenil)	The main biochemical mechanism of Berenil's trypanocidal actions is thought to be by binding to kinetoplast DNA, thereby inducing complete and irreversible loss of kDNA in certain strains of trypanosomes. In addition, diminazene aceturate modulates the host cellular and inflammatory responses to Trypanosome infection	• Loss of HAPT1 function
	Isometamidium chloride (e.g. veridium, samorin)	Mode of action of ISMM is not fully understood but evidence is there that kinetoplastic topoisomerase type II of *trypanosoma* is selectively inhibited by the drug	• Not well defined. Modulation of mitochondrial electrical potential has been pinpointed as a candidate mechanism for drug resistance • SNPs in mitochondrial topoisomerase enzymes of *T. congolense* are not involved in isometamidium resistance

(continued)

Table 84.2 (continued)

Disease	Drug	Mode of action	Mechanisms of resistance
Leishmaniasis	Polyene antibiotic (amphotericin B)	Binding to ergosterol creates a transmembrane channel, allowing cytoplasmic content including K^+ to leak out Autoxidation forms free toxic radicals	• Loss of SCMT increases membrane fluidity in resistant parasites with changes in lipid composition • Decreased AMB uptake • Increased efflux due to MDR1 overexpression • Upregulation of the tryparedoxin cascade • Increase in the reduced intracellular thiol content • Upregulation of Sir2
	Pentavalent antimonials (SbV) (sodium stibogluconate/ meglumine antimoniate)	Reduced in trivalent form in vivo Generation of oxidative stress which leads to the disruption of the synthesis of macromolecules	• Decrease or absence or drug reduction to the trivalent form • Mutations or loss of AQP1 • Detoxification of the trivalent form by conjugation with thiols (whose levels are increased in resistant parasites due to an increased activity in ODC and γ-GCS) • Intracellular drug sequestration of thiol-conjugates through the overexpression of MRPA • Efflux pump whose regulation is probably MAPK1-dependent, able to pump out the drug-thiol conjugate • ARM58 overexpression • Overexpression of the host MDR1 transporter at the macrophage cell surface
	Diamidines (pentamidine)	Accumulation within parasites leads to disintegration of the network of kDNA and collapse in the mitochondrial membrane potential	• Efflux pumps
	Aminoglycosides (paromomycin)	Inhibition of protein synthesis and interference with vesicle-mediated trafficking	• Increase in PM vacuolar sequestration followed by exocytosis • Other potential resistance mechanisms may exit, see text
	Azoles (itraconazole/ ketoconazoles/ metronidazole)	Inhibitors of cytochrome P-450-dependent lanosterol C14 α-demethylase, a step in ergosterol biosynthesis	• Overexpression of squalene synthase confers itraconazole resistance
	Alkyllysophospholipids (miltefosine)	Perturbation of the metabolism of lipids, especially phospholipids Inhibition of cytochrome c oxidase which causes mitochondrial depolarization resulting to an apoptosis-like death	• Decrease in miltefosine uptake due to point mutations in the P-type ATPase transporter or in its specific beta subunit • Increase in efflux through MDR1 • Role of ABCG4 and ABCG6 in phospholipid trafficking at the plasma membrane • Possible role of other ABC transporters • Role of HSP83 and SKCRP1 that both could protect against programmed cell death induced by MIL • Role of a pyridoxal kinase and alpha-adaptin like protein as well as a large 299 KDa protein
	Pyrazolopyrimidine (allopurinol)	Mainly used in canine leishmaniasis. Its conversion to ribonucleoside triphosphate analogues and further incorporation into RNA disrupts biosynthesis of macromolecules Allopurinol is known to inhibit enzymes of the purine salvage pathway	• Differences in the affinity of enzymes of the purine salvage pathway

(continued)

Table 84.2 (continued)

Disease	Drug	Mode of action	Mechanisms of resistance
Apicomplexan parasites			
Malaria	Quinolone derivatives (chloroquine, quinine)	Inhibition of heme polymerase resulting in accumulation of cytotoxic-free heme	• SNPs in pfCRT and pfMDR1 • Changes in pfMRP1 and pfNHE-1 • SNPs in pfMRP2 • Changes in pfMDR2
	Antifolates (sulfadoxine-pyrimethamine)	DHPS is the target of sulfadoxine DHFR is the target of pyrimethamine	• SNPs in DHPS • SNPS in DHFR • CNVs in GCH1
	Mefloquine	Interference with hemoglobin digestion by the parasite	• CNVs in pfMDR1 • SNPs in pfMRP1 and pfMRP2 • Changes in pfMDR2
	Artemisinins	Artemisinins act via the generation of free radicals (ROS) that are initiated by iron bioactivation of endoperoxides and/or catalyzed by iron-dependent oxidative stress	• Changes in pfMDR5 • SNPs in the kelch domain of the K13 propeller protein
	Atovaquone	Inhibition of the cytochrome Bc1 complex in the mitochondrial electron transport chain Indirect inhibition of DHODH	• SNPs in cytochrome b • Changes in pfMDR2
	Proguanil	Antifolate metabolized into cycloguanil which targets the malarial enzyme DHFR	• SNPs in DHFR
Toxoplasmosis	Antifolates (pyrimethamine)	DHFR is the target of pyrimethamine	• No SNPs detected in the therapeutic targets DHFR, nor to the ABC transporters TgABC.B1, TgABC.B2, and TgABC.C1. The mechanisms of resistance are unknown
	Sulfonamide (sulfadiazine)	DHPS is the target of sulfadiazine	• No SNPs detected in the therapeutic targets DHPS nor to the ABC transporters TgABC.B1, TgABC.B2, and TgABC.C1 • Differentially expressed proteins detected in sulfadiazine-resistant strains of *T. gondii*, but their formal role in resistance requires further investigation
	Atovaquone	Inhibition of the mitochondrial electron transport process (binding to the cytochrome bc1 complex)	• No mutation was found on the cytochrome b gene so the resistance mechanisms are unknown
Cryptosporidium	Paromomycin	Targets the ribosomes, where it binds to the A-site and disrupts protein synthesis	• Upregulation of Cgd1_1350 (e.g., CpABC4) and Cgd7_4510 transcript levels encoding ABC transporters
	Azithromycin	Macrolide that is probably acting by inhibition of protein synthesis	ND
	Nitazoxanide	Nitazoxanide and its two metabolites, tizoxanide and tizoxanide-glucuronide, inhibit the growth of *C. parvum* sporozoites and oocysts	ND
Coccidiosis (*Eimeria* spp., *Isospora belli*)	For *Eimeria*: Ionophores (e.g., iasalocid, monensin, narasin, salinomycin, and semduramicin)	Disruption of ion gradients across the parasite cell membrane	ND
	For *Eimeria*: Synthetic drugs (e.g., decoquinate, clopidol, sulfonamides, amprolium, diclazuril, halofuginone, nicarbazin, and robenidine)	In many cases, the mode of action is unknown	ND
	For *Isospora*: Sulfonamide (trimethoprim-sulfamethoxazole)	Inhibition of the folic acid pathway	ND

(continued)

Table 84.2 (continued)

Disease	Drug	Mode of action	Mechanisms of resistance
Anaerobe parasites			
Trichomoniasis	Metronidazole	Metronidazole is reduced by the pyruvate to ferredoxin oxidoreductase system in obligate anaerobes. Reduction of metronidazole creates a concentration gradient that drives uptake of more drug and promotes formation of intermediate compounds and free radicals that are toxic to the cell	*In* in vitro *resistant parasites:* • Shrinking of the hydrogenosome in laboratory-generated *Tv*-resistant strains • Downregulation of PFOR • Ferredoxin with an exceptional redox potential • Reduced amount of intracellular ferrodoxin • Reduced thioredoxin reductase activity and free flavins • Decrease in the activity of FR1 *In clinical resistant isolates:* • Decrease in FR1 and ADH1 • SNPs in the nitroreductase genes *ntr4Tv* and *ntr6Tv*
	Tinidazole	The nitro group of tinidazole is reduced in *Trichomonas* by a ferredoxin-mediated electron transport system. The free nitro radical generated as a result of this reduction is believed to be responsible for the antiprotozoal activity. It is suggested that the toxic free radicals covalently bind to DNA, causing DNA damage and leading to cell death	• Downregulation of PFOR in in vitro generated resistant strains
Giardiasis	Metronidazole	Same as Trichomoniasis	• Epigenetic regulation • Resistance to MTZ is negatively correlated with the intracellular concentration of PFOR, leading to a concomitant decrease in the uptake of free MTZ into the cell • Nitroreductases GlNR1 and GlNR2
	Tinidazole	The mechanisms by which tinidazole exhibits activity against *Giardia* species is not known but are probably similar to the one described for Trichomoniasis	• Cross-resistance to TDZ has also demonstrated with MTZ-resistant *Giardia* strains
	Albendazole (in combination with mebendazole)	The benzimidazole drugs bind selectively to beta-tubulin and inhibit microtubule formation Albendazole-induced ROS accumulation in the albendazole susceptible *Giardia* parasites, but not in the resistant ones	• Cytoskeletal changes but not with a mutations at amino acid 200 in β-tubulin • Eight proteins involved in energy metabolism, cytoskeleton dynamics and antioxidant response • Antioxidant enzymes are upregulated in ABZ-resistant clones, leading to an increase in the R-SH pool
	Quinacrine	The exact mechanism of antiparasitic action is unknown; however, quinacrine binds to DNA in vitro, inhibiting transcription and translation. Quinacrine does not appear to localize to the nucleus of *Giardia* trophozoites however, suggesting that DNA binding may not be the primary mechanism of its antimicrobial action. Fluorescence studies using *Giardia* suggest that the outer membranes may be involved. In other organisms, quinacrine inhibits succinate oxidation and interferes with electron transport	• Resistant parasites accumulate less drug
	Nitazoxanide	Nitazoxanide and its two metabolites, tizoxanide and tizoxanide-glucuronide, inhibit the growth of *Giardia*	• Nitroreductases GlNR1 and GlNR2 • Recombinant PDI2 and PDI4 are inhibited by nitazoxanide

(continued)

Table 84.2 (continued)

Disease	Drug	Mode of action	Mechanisms of resistance
Amoebiasis	Metronidazole	kill the trophozoites by alterations in the protoplasmic organelles of the amoeba, but are ineffective in the treatment of cysts	• Increased expression of Fe-SOD and peroxiredoxin • Decreased expression of flavin reductase and ferredoxin 1 (FR1)
	Tinidazole	kill the trophozoites by alterations in the protoplasmic organelles of the amoeba, but are ineffective in the treatment of cysts	• Increased expression of Fe-SOD and peroxiredoxin • Decreased expression of flavin reductase and ferredoxin 1 (FR1)
Stramenopiles parasites			
Blastocystosis	Metronidazole	Metronidazole induces programmed cell death in *Blastocystis* and apoptosis-like features are observable in growing axenic cultures	• Drug resistance in certain *Blastocystis* strains might result in fitness cost that manifested as impairment of parasite adhesion and, consequently, virulence • Tolerance of nitrosative stress
Helminths			
Albendazole		The benzimidazole drugs bind selectively to β-tubulin and inhibit microtubule formation	• SNPs which cause amino acid substitutions in β-tubulin • SNPs present in a drug transport glycoprotein
mebendazole		The benzimidazole drugs bind selectively to β-tubulin and inhibit microtubule formation	Same as albendazole
Levamisole		Agonist at nicotinic acetylcholine receptors of nematode muscle which cause spastic paralysis	• Modulation or loss of the levamisole-sensitive acetylcholine receptor • Mutations in modulatory proteins of the acetylcholine receptor
Pyrantel		Agonist at nicotinic acetylcholine receptors of nematode muscle which cause spastic paralysis	• Modulation of nicotinic acetylcholine receptor subunits that form the pyrantel-sensitive receptors • Mutations in modulatory proteins of the acetylcholine receptor
Macrolides lactone (ivermectin)		Ivermectin increases the opening of glutamate-gated chloride (GluCl) channel and produce paralysis of pharyngeal pumping	• Changes in the frequencies of two alleles of the glutamate-gated chloride channel • Modulation in P-glycoproteins
Praziquantel		A rapid influx of calcium upon treatment probably causes death. Praziquantel may block adenosine receptors of the worms, causing calcium influx PZQ can specifically bind to the intersubunit cleft of glutathione S-transferase (GST) of schistosomes, but it was demonstrated that GST is not the molecular target of PZQ	• Cytochrome-c oxidase (SCOXl) expression was increased in PZQ-resistant *Schistosoma* strains compared to sensitive strains, but the levels of SCOXl enzymatic activity were reduced in resistant worms. This raises the possibility of an involvement of mitochondrial/respiratory processes in resistance to PZQ • Alteration in calcium regulation or membrane composition (modulation or loss of the putative calcium receptor?) • *S. mansoni* expresses higher levels of SmMRP1 in response to praziquantel • Modulation in SmMDR2 expression
Diethylcarbamazine		DEC blocks host, and possibly parasite enzymes involved in arachidonic acid metabolism, and enhances the innate, nonspecific immune system by altering the parasite surface structure, making them susceptible to destruction by host defense DEC interferes with parasite signaling pathways, including the nitric oxide pathway	ND

ND, not defined; NTR, nitroreductase; AAT6, amino acid transporter 6; AT1, adenosine transporter 1; MRP, multidrug resistance protein; HAPT, high-affinity pentamidine transporter; LAPT, low-affinity pentamidine transporter; SNPs, single-nucleotide polymorphism; MDR, multidrug resistance; DHFR, dihydrofolate reductase; DHPS, dihydropteroate synthase; MRP, multidrug resistance protein; GCH1, GTP-cyclohydrolase; NHE-1, sodium hydrogen exchanger 1; CRT, chloroquine resistance transporter; SIR2, silent information regulator 2; PGP, P-glycoprotein; ABC, ATP-binding cassette; ODC, ornithine decarboxylase; γ-GCS, γ-glutamylcysteine synthase; AQP, aquaporin; SCMT, S-adenosyl-L-methionine-C24-Δ-sterol methyltransferase; AMB, amphotericin B; BZ, benzimidazole; NFX, nifurtimox; SAMDC, S-adenosylmethionine decarboxylase; kDNA, kinetoplast DNA; LDL, low-density lipoprotein; MAPK1, mitogen-activated protein kinase 1; ARM58, hypothetical protein ARM58; MIL, miltefosine; TR, trypanothione reductase; DHODH, dihydroorotate dehydrogenase; ROS, reactive oxygen species; SOD, superoxide dismutase; FR1, flavin reductase 1; PDI, disulfide isomerase; PFOR, pyruvate to ferredoxin oxidoreductase; ADH1, alcohol dehydrogenase-1; ex, example

resistant determinants in clinical isolates has been more complicated, but progresses are being made. In the molecular method, genetic markers, already known to be linked to resistance, are assessed by polymerase chain reaction (e.g., PCR or its variants) or by gene sequencing, allowing the prediction to some degree of resistance to drugs. Clear advantages of molecular tests over the other assays are the need for only small amounts of genetic material as opposed to live parasites (that need to be obtained in sufficient quantity) and the ability to conduct large number of tests in a relatively short period of time. Disadvantages include the obvious need for sophisticated equipment and training and the fact that the whole set of gene mutations that confer drug resistance are not completely known for the majority of the antiprotozoal drugs. Thus, the predictive value of these molecular tests is not always perfect and caution in interpretation is needed. Sometimes, in vitro bioassays need to be performed in parallel to confirm molecular assays.

2.2 Generalities: *Helminthes*

Helminths are a diverse group of parasitic worms, encompassing nematodes, cestodes, and trematodes. Collectively, parasitic worms are among the most common causes of chronic human infections worldwide, particularly schistosomiasis, filariasis, onchocerciasis, and intestinal roundworm infections (Table 84.1). The WHO estimates that 2.9 billion people worldwide are currently infected with one or more helminthic species. Current efforts to control parasitic helminthes rely on the use of a few active anthelmintic drugs, namely, macrocyclic lactones (e.g., ivermectin), benzimidazoles (e.g., albendazole, mebendazole), praziquantel, and levamisole/pyrantel derivatives. The high rate of reinfection in helminth infection after drug therapy means that vaccines remain the best hope for worm control in human. Although promising avenues exist [11], no vaccines are yet available. Periodic mass administration of anthelmintic drugs to school-age children and other at-risk groups has proven to effectively limit the burden of helminthes, particularly for soil-transmitted helminths. Laboratory diagnosis of helminth infections is usually performed by microscopical detection of eggs and in some cases larvae in urine or stool or by immunological methods, e.g., through antibody or antigen detection (Table 84.3).

The development of parasitic helminthes with resistance to one or more anthelmintics is an increasing problem, especially in livestock. Indeed, reports of drug resistance have been made in every livestock host and to every anthelmintic class. Sheep and goats are the most affected by parasitic nematodes in which a high prevalence of multidrug resistance (MDR) has been reported. Resistance in nematodes of horses and cattle has not yet reached the levels seen in small ruminants, but evidence suggests that the problems of resistance, including MDR worms, are also increasing in these hosts. In human helminthes, resistance is rare although there are more and more signs of an emergence of drug resistance as demonstrated by some studies reporting low cure rates and fecal egg count reductions in stool/urine samples [12–18].

Helminthes in general are much more difficult to culture than protozoan. They pass through a complex life cycle and it is not always possible to grow and test them for all stages of the parasite outside their natural hosts. Thus, similar to protozoan parasites, testing for resistance in parasite nematodes is difficult and hence not routinely available in diagnostic laboratories. Nonetheless, a variety of in vitro tests and few in vivo assays have been developed for the detection of nematode populations resistant to the main anthelmintic groups, but most of them suffer in reliability, sensitivity, and reproductivity because most of them are not well standardized. The majority of the assays are currently based on coprological methods (e.g., stool samples). From these, the most widely used method for detecting and monitoring the presence of anthelmintic resistance in nematodes is the so-called fecal egg count reduction test (FECRT) which is suitable for all types of anthelmintic and is essentially a measure of changes in egg output before and after drug treatment. Alternatively, a series of phenotypic assays as well as some molecular assays have been developed (see helminth's section).

The next sections will discuss about the various susceptibility tests that are currently used for specific parasites, starting with protozoan and followed by helminths.

3 Drug Susceptibility Testing in Trypanosomatid Parasites

Trypanosomatid parasites infect over 21 million people worldwide with over 2 million new cases per year [1, 19, 20]. The highest burdens are reported for *Trypanosoma cruzi* causing Chagas disease, *Trypanosoma brucei* causing African trypanosomiasis, and *Leishmania* spp. responsible for a group of clinical manifestations collectively known as leishmaniasis. Jointly, these three diseases cause over 4 million DALYs (Table 84.1).

3.1 Chagas Disease

Chagas disease (CD), also known as American trypanosomiasis, is a zoonosis caused by the protozoan parasite *Trypanosoma cruzi* [21, 22], an important parasitic burden that thrives since ancient times, mostly in Latin America. *T. cruzi* is a heterogeneous species population circulating in human, insect vectors, and animals, categorized recently in

Table 84.3 Diagnostic tests and examples of drug resistance assays in the control of NTDs

Disease	Diagnostic tests[a]	Drug resistance assays[b]
Trypanomatid parasites		
Chagas disease	**Multiple serological tests using different platforms (e.g., ELISA, indirect immunofluorescence antibody test (IFAT), and indirect hemagglutination (IHA)) but cross reactions occur especially with visceral and cutaneous leishmaniasis and HAT which co-exist in the same geographic region as Chagas disease.** Ex: Chagas Stat-Pak® Rapid Assay (RDT) from Chembio Diagnostic Systems Inc.; Chagas Immunochromatographic Strip (ICS) Test developed by PATH; Hemagen Chagas kit (ELISA); Chagas instantest (Silanes); Ortho *T. cruzi* ELISA test system; SD Chagas Ab Rapid (Standard Diagnostic); Serodia Chagas (Fujirebio Inc; OligoC-test and the *T. cruzi* kDNA OligoC-test (Coris BioConcept); several others RDTs **Microscopy of thin or thick blood or buffy coat films stained with Giemsa or other appropriate stains. Hemoculture using special media (e.g., Novy-MacNeal-Nicolle agar or Evan's modified Tobies's medium) can also be done** Various PCR-based assays including LAMP assays Radioimmunoprecipitation assay (RIPA) Trypomastigote excreted-secreted antigen immunoblot assay (TESA-blot) Abbott PRISM Chagas test (automated chemiluminescence analyzer) Xenodiagnosis (uninfected laboratory kissing bugs are allowed to feed on patients and are then examined for trypanosomes) In new born: the microhematocrit concentration method in capillary tubes or the Strout concentration method in eppendorf tubes Peptide-based lineage-specific serology-based assay Microfluidic/lab-on-chip-based detection (e.g., VereTrop from Veredus Laboratories Ltd)	**Lack of methodology that allows monitoring of drug susceptibility of *T. cruzi* at public health laboratories** In vitro susceptibility assay with epimastigotes based on the tetrazolium dye [MTT; 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] enzymatic micromethod (BZ resistance) In vitro epimastigote test combining hemoculture with quantification of BZ/NFX susceptibilities In vitro intracellular amastigote assay which involves the differentiation of hemoculture-derived epimastigotes into metacyclic trypomastigotes in order to establish infection in mammalian cell monolayers In vivo drug susceptibility assays in animals, mainly in the mouse model
Human African trypanosomiasis* (sleeping sickness)	CATT serological field tests for *T.b. gambiense* (e.g., the classical Card agglutination test on whole blood, the CATT-TP version and the CATT-D10 thermostable version). There is no comparable CATT test for *T.b. rhodesiense* The Immune trypanolysis tests LiTAT1.3 and LiTAT1.5 *for T. brucei gambiense* Coris BioConcept HAT Sero-strip (Dipstick) and HAT sero-*K*-SeT test (Lateral-flow device) for blood or plasma samples. These tests were developed by the NIDIAG consortium (http://www.nidiag.org/) and contain variant surface glycoproteins of the *T. brucei gambiense* variable antigen types LiTat1.3 and LiTat1.5 SD BIOLINE HAT test (immunochromatographic rapid serological test for *T.b. gambiense* detection in blood) IFA,ELISA and Dot-ELISA methods LATEX/*T.b. gambiense* serological test **Blood/lymph node/CSF microscopy and examination (e.g., thin or thick blood or buffy coat films stained with Giemsa or other appropriate stains. Fresh wet preparations of blood of buffy coat samples can also be used). Currently, stage determination in HAT relies on direct examination of CSF**; parasites in CSF are first centrifuged and examined by light microscopy in a mAECT viewing chamber or mAECT tubes. The HCT or QBC technique can also be used Various PCR and RT-PCR assays (conventional, TMA, NASBA, NASBA-OC, LAMP, RIME-LAMP, NEAR, HAD, RPA). However, molecular diagnostics are not yet developed to a level appropriate for widespread field use. A molecular diagnostic test for *T.b. rhodensiense* was developed based on the serum resistance associated (SRA) gene FISH test using peptide nucleic acid (PNA) probes Biomarkers in human plasma Light-emitting diode (LED)-based fluorescence microscope using acridine orange Nanobodies-based parasite antigen detection (co-developed by FIND and Standard Diagnostics) Single-chain variable fragment (scFv) engineered antibodies for trypanosome antigens detection in blood Microfluidic/lab-on-chip-based detection (e.g., VereTrop from Veredus Laboratories Ltd)	**No standardized methodology that allows monitoring of HAT drug effectiveness at public health laboratories** Molecular tests Assessment of drug sensitivity in mice Assay based on the metabolism of the dye Alamar blue (resazurin) by live cells to generate both a colorimetric and fluorescence signal Fluorimetric assay based on the interaction of propidium iodide with DNA The fluorescent diamidine DB99 test for melarsoprol resistance

Animal African trypanosomiasis (Nagana)	**Standard parasitological methods (Microscopy)** PCR-based assays (some based on 18S) Microsatellite loci analysis	Tests in ruminants **Tests in mice** in vitro assays (e.g., drug-ELISA technique) **Molecular detection** (e.g., the DpnII-PCR-RFLP assay or a similar BclI-PCR-RFLP assay specific for *T. congolense*. Several PCR-based assays are also available)
Leishmaniasis	Current rapid diagnostic tests for VL are antibody/antigen based. However, serological tests are positive in asymptomatic carriers and in past cases. Examples include the direct agglutination test (DAT), tests based on the K39 repeat antigen including the FDA-approved Kalazar Detect rapid test from InBios International Inc. and the urine latex agglutination test *KA*tex by Kalon Biological Ltd. RDTs based on the fusion synthetic protein rK28 (Chembio Diagnostics systems) **For VL: Microscopy (Giemsa or hematoxylineosin stained), culture of spleen, lymph node or bone marrow aspirates** **For CL and MCL: Microscopy (Giemsa or hematoxylineosin stained)/culture of biopsies/aspirate. Recently a Press-Imprint-Smear method was reported** Various PCR and RT-PCR assays including the Coris BioConcept *Leishmania* OligoC-test (e.g., PCR assay coupled to Oligochromatographic detection) and a LAMP assay The field-adaptable in-a-tube Liat/Cobas Analyzer (IQuum Inc. now Roche diagnostics) which is a simplified PCR assay that uses a colorimetric detection system and a portable instrument that can extract and amplify DNA as well as detect the PCR product PCR-ELISA assays Aptasensors Leishmanin skin test (LST); this assay measures delayed hypersensitivity response after 72 h Interferon-release assays (IGRAs); detect T-cells in peripheral blood reactive to *Leishmania* antigens IQuum Liat Analyzer, a four-color real-time PCR fluorescence detector For animal, biomarkers of leishmaniasis have been found in hair	**No standardized methodology that allows monitoring of antileishmanial drug effectiveness at public health laboratories** BALB/c mice infected with *Leishmania* strains and treated with antileishmanial drugs Amastigote/macrophage culture assays for SbV resistance Promastigote assay and the axenic amastigote culture assay Resazurin-based fluorimetric assay for promastigotes (see HAT section for details)
Apicomplexan parasites

Disease	Diagnostic tests[a]	Drug resistance assays[b]
Malaria	**Microscopy examination of thick and thin blood smears** Antigen detection (dipstick or ELISA formats) (antigens: HRP-II, Pan-malarial *Plasmodium* aldolase, pLDH) Antibody detection (ex: Pan malaria antibody CELISA from Cellabs) REED technology Micromagnetic resonance relaxometry Microarray-based techniques PCR and LAMP assays Aptasensors, immunosensors, and DNA biosensors Paper microfluidic Lab-on-chip-based detection (e.g., VereTrop from Veredus Laboratories Ltd) Flow cytometry and automated blood cell counting techniques to detect hemazoin or Plasmodium dsDNA in infected erythrocytes Focal Plane Array technology to detect the fatty acids in the parasite (infrared signature) Vapor nanobubbles technology (Rice University)	Rodent models for drug susceptibility testing Monitoring of the parasitological and/or clinical response over time in patients Spectroscopic analysis method In vitro assays based on [^{3}H]-hypoxanthine incorporation or other labeled precursors In vitro assays measuring parasite LDH activity, detecting antibodies against HRPII or LDH, or by staining parasite DNA with fluorescent dyes **The schizont maturation test/Mark III microtest** The "visual agglutination test" for detection of hemozoin production during parasite maturation Malaria Ag CELISA Double-site enzyme-linked pLDH immunodetection (DELI) assay In vitro and ex vivo phenotypic assays for artemisinin resistance PCR-based assays and pyrosequencing methods for detecting SNPs in target genes linked with resistance CDC is developing next-generation sequencing methods to detect resistant parasites rapidly Clamp-probe real-time PCR assay for detection of *Pfcrt* K76T SNP Gene Chip for drug resistance testing (can analyze ~7000 SNPs spaced throughout the parasite genome. Developed by Notre Dame's Eck Institute for Global Health)
Toxoplasmosis	**Isolation of *T. gondii* in stool, histological examination** Serological tests-immunoperoxidase stain toxoplasmin skin test antigen-specific lymphocyte transformation assay Inoculation of laboratory animals PCR-based and Lamp assays	**No standardized methodology that allows monitoring of anti-*Toxoplasma* drug effectiveness at public health laboratories** Sulfadiazine susceptibilities can be evaluated on Vero cells using an enzyme-linked immunosorbent assay (ELISA) Sulfadiazine susceptibilities can be evaluated on MRC-5 cells

Cryptosporidiasis	**Antigenic tests in stool specimens** (direct fluorescent antibody tests including the Meridian Merifluor kit for *Cryptosporidium*/*Giardia*, Crypto CELISA, PARA-TECT, Cryptosporidium Antigen 96 and ProSpecT from Remel, and several others) Modified acid-fast staining techniques and microscopy PCR assays	**No standardized methodology that allows monitoring of anti-*Cryptosporidium* drug effectiveness at public health laboratories** An in vitro model for *C. parvum* infection in human primary intestinal cells has been recently described but it has not been used yet for drug resistance testing Susceptibility testing for oocysts: inclusion or exclusion of fluorogenic vital dyes (DAPI/Propidium iodine, others) or by an excystation technique which reflects the metabolic potential of oocysts and their potential for infectivity Animal models available: *C. hominis* can be propagated in gnotobiotic piglets and immunosuppressed gerbils whereas *C. parvum* can be propagated in calves and lambs. In vivo drug screening/drug resistance testing has been done mostly in immunosuppressed rodents however
Coccidiosis	**Microscopic detection of oocysts in the feces** (acid-fast staining or use of fluorescence dyes, e.g., auramine-rhodamine) Examination of duodenal specimens by biopsy String test (Entero test) PCR assays	**No standardized methodology that allows monitoring of anti-coccidian drug effectiveness at public health laboratories** For *Eimeria*, in vivo assays in animal models (Chickens) Oocyst counts using a McMaster slide chamber or Neubauer counting chamber prior/post treatment Anticoccidial index (ACI), global index and optimum anticoccidial (OAA) index are commonly used to evaluate drug efficacies Experimental animal models (calves, Sinclair miniature pigs conventional pigs)
Anaerobe parasites		
Trichomoniasis	**Direct detection of trophozoites in vaginal secretions or urethral specimens by wet mount microscopic examination** Latex agglutination test for antigen detection in vaginal swab specimens OSOM Trichomonas Rapid Test (Genzyme Diagnostics, an immunochromatographic capillary flow dipstick) Aptima TV transcription-mediated amplification (TMA) test Direct fluorescent antibody staining culture (Pouch TV culture) PCR assays Rheonix CARD technology, an automated molecular diagnostic device	***T. vaginalis* susceptibility testing is not available routinely** In vitro susceptibility assays in aerobic conditions (initially developed by Meingassner and Thurne) In vitro susceptibility assays in anaerobic conditions in tubes or plates: • [^{3}H]-thymidine uptake assay • Anti-trichomonal activity colorimetric assays Anaerocult minisystems Mouse model and nonhuman primate animal models

(continued)

Table 84.3 (continued)

Disease	Diagnostic tests[a]	Drug resistance assays[b]
Giardiasis	**Fecal examinations in microscopy** Antigenic tests (Wampole, Antibodies Inc., Cellabs and Remel companies) Uni-Gold Rapid test (Trinity Biotech) Meridian Merifluor kit for *Cryptosporidium/Giardia* PCR-based and LAMP assays Wheatley's trichrome staining and microscopy in stool specimens Entero Test (e.g., the string test) Endoscopic aspiration and microscopy	**Susceptibility testing is not available routinely** Radiometric approaches to look for reduction in uptake of ^{3}H-thymidine (measuring parasite multiplication) or to look for reduction in parasite adherence with host cells Colorimetric assays for products released by killed trophozoites in the presence of drugs Colorimetric method of MTT (tetrazolium salts reduction to MTT-formazan) or on the fluorescent substrate resazurin Anaerocult assay Flow cytometry assay using propidium iodide Microfluidic devices In vivo Mongolian gerbil and mouse model assays Resistance to metronidazole and nitazoxanide has been detected using microarray technology and quantitative real-time PCR
Amoebiasis	**Immunoassay kits (antigen detection)** are commercially available that detect *E. histolytica.* Most tests detect the galactose-inhibitable adherence protein in the pathogenic *E. histolytica* in fresh stool specimens (ex: TechLab, Cellabs and Wampole are offering tests specific for *E. histolytica*). Currently, these tests require the use of fresh or frozen stool specimens and cannot be used with preserved specimens Trophozoites in trichrome stained smears and microscopy Rapid immunochromatographic cartridge assay: detects antigens of *E. histolytica*/*E. dispar*. However this assay does not distinguish between *E. histolytica* and *E. dispar*. This assay also detects antigens of *Giardia* and *Cryptosporidium.* Stool samples must be fresh or frozen	**Susceptibility testing is not available routinely** Nitro blue tetrazolium (NBT) reduction assay Experimental animal models (germfree guinea pig, hamsters)
Stramenopiles Parasites		
Blastocystosis	Microscopic observation (presence of vacuolar forms in feces and the amoeboid form in diarrheal stools) Direct smear, iodine stained smear, formalin-ether concentration techniques, and trichrome stained smear **In vitro cultivation using Jones' medium**	**Susceptibility testing is not available routinely** Caco-2 model of human intestinal epithelium Resazurin and XTT viability microassays
Helminths		
Schistosomiasis (bilharziasis)	**Microscopy of stool/urine/rectal biopsy (e.g., Kato-Katz fecal smear technique)** ELISA, Dot-ELISA, immunoblot tests Indirect hemagglutination test for *S. mansoni* Ether concentration technique Midi ParaSep SF solvent free fecal parasite concentrator PCR and RT-PCR assays including a OC-PCR dipstick assay for *S. mansoni* Immunological methods (antibody or antigen detection Urine-CCA and urine-CAA (circulating cathodic and anodic antigens) cassette test from rapid medical diagnostics; for *S. mansoni*, *S. haematobium*, and *S. japonicum.* Detection of antibodies directed against the soluble egg antigen (SEA) On-chip imaging of *S. haematobium* eggs in urine has been achieved by computer vision Thoracic imaging Luciferase immunoprecipitation system (LIPS) assay PCR-based assays On-chip imaging of eggs in urine by computer vision PCR-based assays	**Susceptibility testing is not available routinely** Animal models for praziquantel: worm count in treated infected rodents. A snail (*Biomphalaria glabrata*) model also exits Miracidial morphology and survival analysis in the presence of praziquantel Muscle contraction studies and $^{45}Ca^{+2}$ uptake FECRT (all anthelmintics) EHT (ivermectin) LFIA (ivermectin) assays xCeLLigence system (praziquantel)

Lymphatic filariasis* (also termed elephantiasis in extreme cases)	**Biopsy sample examination or microscopic examination of thick/thin blood film or buffy coat film stained with Giemsa or other appropriate blood stains** The ICT filariasis Antigen detection test (for *W. bancrofti* only) (BinaxNOW Filariasis; Binax) PCR and PCR-ELISA assays (Filariasis CELISA, Cellabs) TROPbio ELISA test for *W.bancrofti* *Brugia* rapid dipstick test Motile adult worms may be visualized by ultrasound exam of involved lymphatics	**Susceptibility testing is not available routinely** PCR assays for albendazole resistance
Onchocerciasis (river blindness)	**Microscopy of multiple Giemsa-stained Skin-snips** Observation of microfilaria in the eye by slit-lamp exam Ultrasonic detection Electromagnetic path (grant to Dr Manu Prakash, see: https://biox.stanford.edu/highlight/) Ov16 rapid test (POC prototype developed by PATH; detection of antibodies to the parasite antigen Ov16) SD BIOLINE Onchocerciasis IgG4 rapid POC test (developed by PATH and manufactured by Standard Diagnostics Inc.)	**Susceptibility testing is not available routinely** PCR assays detecting SNPs in β-tubulin selected in *O. volvulus* following repeated ivermectin treatment
Cysticercosis (taeniasis)	**Serology:** Various immunodiagnostic tests on serum or CSF (ex: RIDASCREEN *Taenia solium* IgG) PCR and LAMP assays for *Taenia solium* **Microscopy of tissue biopsies (recovery of the segments or scolex in the stool) or aspirate samples of cysts** CT or MRI scans of the brain or spinal cord for neurocysticercosis, plain radiographs of skeletal muscle	**Susceptibility testing is not available routinely** PCR, multiplex PCR Experimental encephalitis caused by *Taenia crassiceps* cysticerci in mice
Echinococcosis (Hydatid disease)	**Microscopy of tissue biopsies or aspirate samples of cysts** Serodiagnosis (ELISA-assays, indirect hemagglutination test, complement fixation test, western blot tests) Imaging—e.g., CXR, CT scan of the liver or abdomen, brain CT or MRI scan	**Susceptibility testing is not available routinely** PCR assays for BZ resistance testing Small laboratory animal models (mice and Mongolian jirds)
Soil-transmitted helminthiases (intestinal worms)	**Microscopy** The five most used techniques to detect eggs in feces are the FLOTAC method (hookworms), the Midi Parasep® SF Solvent Free Fecal Parasite Concentrator method, the McMaster Method, Kato-Katz technique (not very good for hookworms due to lysis of fragile hookworm eggs) and the formol-ether concentration technique A fully automated vision-based instrument called Ovaspec for *Trichuris* A Whipworm Antigen ELISA assay detects whipworm infections (in dogs)	**FECRT (all types of anthelmintics)** Egg hatch test (EHT) (BZ resistance in hookworms). EHT works well in hookworms but is not useful for *Ascaris* and *Trichuris* since they do not hatch externally to the host Larval development tests (BZ, levamisole, pyrantel and mebendazoles, ivermectin) Motility and the larval arrested morphology assay (LAMA) (Pyrantel, Levamisole and mebendazoles) PCR, real-time PCR and pyrosequencing assays (Benzimidazoles) In vitro assay using tritiated benzimidazole carbamates to tubulin extracts of third stage larvae
Foodborne trematode (FBT) infections	**Microscopy** ELISA and Dot-ELISA tests Immunoblot assays	**Susceptibility testing is not available routinely** In vivo animal model: dose and slaughter trial The murine model is the most commonly used animal model for fascioliasis

(continued)

Table 84.3 (continued)

Disease	Diagnostic tests[a]	Drug resistance assays[b]
Strongyloidiasis	Chest radiography and contrast enhanced scans **Parasitological diagnosis** (e.g., identification of larvae in stool using coproculture methods such as the Koga Agar culture method and the Baermann method, as well as the lesser known vermiculite stool culture. The sensitivity of these methods can be increased further by examining stool samples for several consecutive days. The direct saline smear method, and quantitative formalin ethyl acetate concentration technique can also be used Serological and molecular methods Luciferase immunoprecipitation system (LIPS) assay using a recombinant antigen (NIE)	**Susceptibility testing is not available routinely**

[a]Reference technique is given in bold

[b]Assays applied in field for treatment decisions are in bold. TMA, transcription-mediated amplification; NASBA, nucleic acid sequence-based amplification; LAMP, loop-isothermal amplification; NEAR, nicking enzyme amplification reaction; HAD, helicase-dependent amplification; RPA, recombinase polymerase amplification; mAECT, mini anion exchange centrifugation technique; HCT, microhematocrit centrifugation technique; NASBA-OC, nucleic acid sequence-based amplification coupled to an oligochromatographic dipstick detection. FISH, fluorescence in situ hybridization; QBC quantitative buffy coat; PATH, an international nonprofit organization; REED, rolling circle-enhanced enzyme activity detection; HRP-II, histidine-rich protein II; pLDH, parasite lactate dehydrogenase; CATT, card agglutination test for trypanosomiasis; CSF, cerebrospinal fluid; DAT, direct agglutination test; FECRT, fecal egg count reduction test; EHT, egg hatch test; LFIA, larval feeding inhibition assay; LDT, larval development test; LPT, larval paralysis test; MMT, micromotility test

six genetically defined groups, *T. cruzi* I to *T. cruzi* VI [23]. CD is usually a lifelong disease that is primarily transmitted by large blood-sucking insects (*Triatominae* spp.) widely known as "the kissing bugs" in endemic countries. Infection can alternatively results from blood transfusion, organ transplantation, vertical and congenital transmission, by ingestion of food or drinks contaminated by feces of insects or from domestic or wild mammal reservoirs of *T. cruzi*. CD presents three clinical stages in humans: the acute, indeterminate, and chronic phases. The acute disease is characterized by a number of symptoms which often spontaneously resolve in few weeks or months. In the asymptomatic "indeterminate" phase, patients can transmit the parasite to others while showing no signs of the disease. This asymptomatic phase can last for decades. An estimated 10–30 % of individuals infected with *T. cruzi* will develop the final phase known as the chronic symptomatic CD, which manifests as cardiac disease or pathological gut enlargement (e.g., megaesophagus and/or megacolon), with damage to the nervous system. If left untreated, patients infected with *T. cruzi* at this critical phase most often die precociously from heart (myocarditis) and gastrointestinal damages. The primary methods for diagnosing CD are serology and parasitology, but these tests have suboptimal sensitivity and low specificity (Table 84.3) [24]. Molecular techniques recently developed offer better sensitivity and specificity, although in the chronic phase, PCR seems less sensitive than serology. There is no effective vaccine for CD, and chemotherapy is restricted to two registered drugs, the nitroheterocyclics nifurtimox (NFX) and benznidazole (BZ). Considered as the gold standard treatment against *T. cruzi* for more than 40 years, NFX and BZ are nonetheless far from optimal; these treatments have low effectiveness (10–20 % of parasitological cure) in the chronic phase of the disease and limited effectiveness (60–80 % of parasitological cure) in the acute phase [25, 26]. In addition, *T. cruzi* treatment is often complicated by the natural variation in sensitivity in *T. cruzi* field strains, by differences in immune response among populations, and by the emergence of acquired drug-resistant strains which in fact are only suspected in the field since there are cases of treatment failure that are now documented in endemic areas [27–30]. Despite the urgent need for new CD therapies, only allopurinol and a few azoles (including fexinidazole currently in trials for African trypanosomiasis, posaconazole, and ravuconazole) have moved to clinical trials [31], but the results appear to be disappointing (80 % treatment failure) [32]. A number of preclinical promising agents are currently being evaluated (e.g., SCYX-6759, EPL-BS967, EPL-BS1246, SQ109 [33, 34], and few others [35–37]), but their potential clinical development is only expected in the medium- to long-term horizon [34].

3.1.1 Resistance and Diagnostic Assays

T. cruzi, in contrast to African trypanosomes and Leishmania, do not have a specific chapter on resistance and we will describe it here in greater details. Both NFX and BZ are prodrugs that are activated intracellularly in *T. cruzi* by mitochondrial NADPH-dependent type I nitroreductases (NTR) that are absent in human [38]. The reduction of BZ results in the generation of the cytotoxic metabolite glyoxal [39], while NFX reduction leads to the production of an unsaturated open-chain nitrile which has trypanocidal properties [40] (Table 84.2). Up to now, treatment failure in CD to these drugs has been largely attributed to variations in natural drug susceptibility of *T. cruzi* strains and not per se to drug-resistant isolates since no formal proof for true genetic-based resistance mechanisms in clinical isolates has been reported yet, despite the fact that resistance can be easily generated from in vitro selected clinical isolates [41–46] as well as in laboratory strains [38, 47] and animals [41, 48]. Several putative mechanisms of resistance to BZ have been however reported in in vitro generated cell lines (Table 84.2). Indeed, deletion of copies of the gene encoding the old yellow enzyme (TcOYE), a NAD(P)H flavin oxidoreductase associated with in vitro induced BZ resistance in *T. cruzi* was reported [49] as well as the overexpression of an iron-containing superoxide dismutase A (TcFeSODA) enzyme, possibly helping the detoxification of toxic metabolites [50] (Table 84.2). The tyrosine aminotransferase (TcTAT) was also overexpressed in strains of the parasite that were resistant to BZ [51]. Although not directly associated with the drug resistance phenotype, the overexpression of the TcTAT enzyme was considered as a general secondary compensatory mechanism or stress response factor in the parasite. Point mutations disrupting the flavin mononucleotide (FMN)-binding capacity of the NTR enzyme and gene deletion of NTR have been observed in BZ-resistant *T. cruzi* selected in vitro [52, 53] (Table 84.2). Interestingly, and although NTR genotypes in clinical isolates have never been tested yet, a stepwise BZ-induced resistance from a sensitive clinical isolate revealed that a resistant clone had lost a copy of NTR [46]. The participation of P-glycoprotein efflux pumps, TcPGP1 and TcPGP2, part of the ATP-binding cassette (ABC) transporter superfamily [54, 55] in *T. cruzi* BZ resistance has been also proposed recently in parasite lines submitted to in vitro induced resistance [56] (Table 84.2). Similarly, an AQBCG-like transporter gene, *TcABCG1*, was shown to be overexpressed in parasite strains naturally refractory to BZ. This gene in clinical BZ refractory strains exhibited several SNPs as compared to the CL Brener Bz-susceptible reference strain [57], but unfortunately the analysis revealed no direct correlation of any of these SNPs with the BZ resistance phenotype. It is thought however that

the overexpression of this ABC transporter in naturally *T. cruzi* BZ refractory strains (most likely favored by the high genome plasticity observed in *T. cruzi*) is a key determinant factor for the "natural drug resistance phenotype" observed in the field [57]. Recently, resistance to NFX and BZ in in vitro generated *T. cruzi* strains was also correlated with the overexpression of a D,L-proline transporter, the *T. cruzi* amino acid/auxin permease denoted TcAAAP069, located in a defined structure close to the flagellar pocket [58]. Augmented proline intracellular concentration in resistant parasites overexpressing this transporter not only improved resistance to trypanocidal drugs but also to reactive oxygen species (ROS), supporting the fact that proline is a free radical scavenger, radicals generated by the trypanocidal drug reduction [59] (Table 84.2). Interestingly in *T. brucei*, the etiological agent of African trypanosomiasis (see below), the orthologous protein TbAAT6 is not only capable of transporting proline but also the trypanocidal drug eflornithine and mutations in this gene are sufficient to generate resistance [60] (Table 84.2). Despite a clear involvement of aquaporin (AQP) homologs in drug response in several human parasites including African trypanosomes (see below), there is up to now no report of association between any of the four *T. cruzi* AQP homologs and drug response in *T. cruzi*, in neither in vitro drug-resistant selected strains nor clinical resistant isolates. Finally, although BZ is known to induce the formation of free radicals and electrophilic metabolites (e.g., glyoxal) in *T. cruzi* which potentially leads to cell death, its precise mechanism of action was still elusive until recently. Indeed, it was demonstrated that BZ preferentially oxidizes the nucleotide pool of *T. cruzi* during parasite growth and that the extensive incorporation of oxidized nucleotides during parasite DNA replication leads to potentially lethal double-stranded DNA breaks [61]. Moreover, it was elegantly shown that the overexpression of DNA repair proteins in BZ-treated cells increase resistance to BZ in vitro [61] (Table 84.2). It remains to be verified if the mechanisms of resistance detected in in vitro generated resistant *T. cruzi* strains are potentially operating in clinical isolates. Discrepancies may exit however between in vitro selected strains and clinical isolates as reported with the alcohol dehydrogenase enzyme TcADH that presented a decrease in expression in the in vitro induced BZ-resistant population, a situation that was not observed in naturally resistant strains [62].

Simple and rapid procedures to evaluate BZ and NFX "natural susceptibilities" of *T. cruzi* parasites isolated from humans have been difficult to standardize but are nonetheless possible in vitro on defined stages of the *T. cruzi* life cycle. Briefly, the life cycle of *T. cruzi* includes the non-replicative bloodstream trypomastigotes and the replicative intracellular amastigotes in mammalian hosts, and epimastigotes and mammalian infective metacyclic trypomastigotes in the triatomine vector. Currently, trypomastigotes are not widely used in drug resistance testing since their numbers are too low in the chronic phase of CD. A colorimetric method based on the tetrazolium dye MTT was developed more than 16 years ago to determine the susceptibility of *T. cruzi* epimastigotes in vitro and is still widely used [63] (Table 84.3). Briefly, the epimastigote forms obtained from in vitro culture in stationary phase are cultured in 96-well plates at 28 °C for 24 h, in the presence (or absence) of various concentrations of drugs. After this period, the MTT solution is added to each well, and the plate is incubated for 1 h. Then HCl and SDS are added to stop the MTT incorporation, and the plate is kept at room temperature for a further 30 min. The reading is performed on a spectrophotometer at 595_{nm}. The MTT assay should always include triplicate, and the results are normally expressed as IC_{50}, e.g., the concentration of the drug that kills 50 % of the parasites.

More recently, an in vitro procedure that couples the isolation of parasites by hemoculture with quantification of BZ/NFX susceptibilities in the resultant epimastigote form was reported [64, 65] (Table 84.3). This assay was also standardized with epimastigotes, as this developmental stage is predominant in hemocultures obtained from infected individuals. A reference strain, classified as resistant to BZ, is employed as positive control and incubated for 72 h with various BZ/NFX concentrations (serial dilutions 1:2) to determine IC_{50}. The assay is then applied to isolates from chronic patients prior to administration of BZ/NFX therapy and post-therapy. Suitable epimastigote density for the assay can be achieved after approximately 60 days in hemocultures derived from 30 mL blood. The IC_{50} of the isolates are determined as described above and values compared to the reference strain. It is important to mention however that this in vitro assay does not predict therapeutic outcome in CD [64]. The most obvious explanation of this disappointing conclusion would be that the epimastigote is not the infective stage in CD and its susceptibility to BZ/NFX does not reflect the susceptibility of other stages (e.g., trypomastigotes and amastigotes) encountered in the human host. Indeed, differences of several orders of magnitude of the IC_{50} values of epimastigotes and amastigotes were reported in *T. cruzi*. To alleviate this limitation, a robust intracellular amastigote model was developed (http://www.nature.com/protocolexchange/protocols/2240) (Table 84.3). The amastigote model involves the differentiation of hemoculture-derived epimastigotes into metacyclic trypomastigotes in order to establish infection in mammalian cell monolayers. Finally, drug susceptibility assays in animals exist in *T. cruzi*, and the majority uses the mouse model where the compounds are administered early in the acute phase of the infection [44, 66] (Table 84.3). More recently, an interesting real-time in vivo bioluminescence imaging method has been developed for drug screening [67, 68] which allows parasite burdens to be tracked

throughout the chronic stage of infection. This system is based on bioluminescent parasites expressing a red-shifted luciferase that emits light in the tissue-penetrating orange-red region of the spectrum. Although not suitable for drug resistance testing in clinical isolates (since no fluorescent reporter is present in clinical strains), this system may nonetheless accelerate drug discovery in CD.

3.2 Human African Trypanosomiasis

Human African trypanosomiasis (HAT), also known as sleeping sickness, is a vector-borne parasitic disease caused by two subspecies of the protozoan parasite *Trypanosoma brucei*, e.g., *T.b. gambiense* in Western and Central Africa and *T.b. rhodesiense* in Eastern and Southern Africa (Table 84.1). Other species, not infective to humans, causes animal African trypanosomiasis (see next section) [69, 70]. In humans, *T.b. gambiense* accounts for more than 90 % of reported cases and manifests as a chronic condition that claims its victims after several months. In contrast, *T.b. rhodesiense* causes an acute infection that may kill patients within a few weeks. HAT occurs in two stages which are linked with the location where the parasites proliferate in the human body. Stage 1 is called the hemolymphatic phase which includes nonspecific symptoms like headaches, joint pain, and bouts of fever. At this stage, the parasites proliferate in lymph and blood peripheral organs. Stage 1 is generally undiagnosed without active HAT surveillance. Stage 2 is termed the neurologic or meningoencephalitic phase and occurs when the parasite crosses the blood-brain barrier and invade the central nervous system. This later stage can lead to serious sleep cycle disruptions (hence the name), paralysis, progressive mental deterioration, confusion, and coma and ultimately results in death without effective treatment.

Diagnosis of sleeping sickness involves case detection followed by staging (Table 84.3), which is crucial in the decision of the treatment to be given. HAT case identification relies primarily on the use of microscopy to confirm the presence of parasites in body fluids (blood, lymph, or cerebrospinal fluid (CSF)). A rapid blood test under the acronym CATT is available for field diagnosis, but this test only detects *T.b. gambiense* infections but not *T.b. rhodesiense* cases. Very good markers for *T.b. gambiense* HAT (e.g., neopterin and CXCL13) have been found recently in CSF of HAT patients, and a dual purpose rapid test for both staging and monitoring treatments is being developed http://www.finddiagnostics.org/. This innovative test should bypass the need for lumbar puncture necessary for CSF examination during follow-up [71]. Numerous diagnostic methods have been recently reviewed for HAT and readers are encouraged to consult references to get more information on this topic [72]. Whatever the method, the earlier the disease is identified, the better the prospect of a cure.

Although cases of healthy carriers have been reported [73, 74] which suggests that prophylaxis should be possible, no vaccination exits for HAT. The control of HAT thus largely relies on chemotherapy for which there are only a few drugs that are old and toxic (Table 84.2): pentamidine and suramin for stage 1 and melarsoprol, nifurtimox, and eflornithine for stage 2. The latest regimen, introduced in 2009, is NECT that combines nifurtimox that is normally indicated for Chagas disease in combination with eflornithine. Unfortunately, NECT is active only against *T.b. gambiense* since *T.b. rhodesiense* is naturally tolerant to eflornithine [75–77]. Presently, fexinidazole is in clinical trial [78] while two other compounds (a benzoxaborole called Scyx-7158 and compound DB829) are being tested for the treatment of stage 2 HAT [79, 80] (see also http://www.dndi.org/diseases-projects/portfolio/oxaborole-scyx-7158.html). The research community is thus actively trying to improve therapy against trypanosomes and novel compounds should enter soon the market [35, 81].

Treatment failures have been reported for all of the currently licensed HAT monotherapies, though in the case of pentamidine, these are rare [82]. Small numbers of relapses have been also reported for the NECT combined therapy [83, 84]. It is though that trypanosomes develop resistance to trypanocidal drugs during asexual multiplication in the animal or human host or during the passage through the tsetse fly, genetic exchange (sexual recombination) may occur, contributing further to the high degree of genetic diversity observed in these parasites. Current data derived mainly from experiments on drug-resistant laboratory strains of *T. brucei* made resistant to the various antitrypanosomal drugs in vitro has highlighted multiple mechanisms of drug resistance in this parasite (Table 84.2). These have been reviewed in this book in the chapter of Graf and Maser.

The mediator of both melarsoprol and pentamidine uptake in African trypanosomes is the P2 adenosine transporter AT1 [85, 86]. Mutations or loss of TbAT1 renders *T. brucei* less sensitive to both drugs [87]. However, not all resistant clinical isolates have this locus modified [88, 89], suggesting that other resistance mechanisms may operate in resistant cells (Table 84.2). Furthermore, AT1 gene deletion only confers a twofold decrease in melarsoprol sensitivity [90], supporting addition resistance mechanisms against this drug. Indeed, the overexpression of the thiol conjugate transporter TbMRPA was reported to cause melarsoprol resistance in laboratory human strains of *T. brucei* [91] although MRPA overexpression in clinical strains doesn't seem to be a frequent event [92]. The overexpression of the trypanothione biosynthetic enzymes ornithine decarboxylase (ODC) and gamma-glutamylcysteine synthetase (γ-GCS) alone gave two- to fourfold melarsoprol resistance, but the overproduction of these enzymes is not apparently contributing synergically to the resistance caused by MRPA [91]. More recently, the

T. brucei aquaglyceroporin 2 (AQP2) was pinpointed as the main genetic determinant of resistance for pentamidine and melarsoprol since it corresponds to the high-affinity uptake transporter previously known as HAPT1 [93]. The loss of TbAQP2 leads to melarsoprol-pentamidine cross-resistance [94] (Table 84.2). Interestingly in some melarsoprol- and pentamidine-resistant clinical isolates, a chimeric AQP2/AQP3 was found, with concomitant loss of AQP3 alleles from the genome [94, 95]. Finally, apart from the AT1 transporter [96–98] and AQP2/HAPT1, a low-affinity pentamidine transporter (LAPT) [99–101] has been also described as well as two AT1-related nucleobase transporters, NT11.1 and NT12.1 [102]. These transporters seem specific for pentamidine uptake (Table 84.2).

NECT is the treatment of choice for the Gambian form of sleeping sickness due to the toxic combined effects of nifurtimox and eflornithine [76]. Eflornithine is an analogue of ornithine that blocks spermidine synthesis and thus the formation of TSH, the redox regulator, through the inhibition of ODC [103, 104] (Table 84.2). Eflornithine-resistant trypanosomes were generated in the laboratory, and these cells exhibited significant reduced drug uptake and accumulate less drug than the susceptible parasites [60, 105]. The amino acid uptake transporter TbAAT6 was identified as a key determinant of eflornithine uptake in *T. brucei*, and it was demonstrated that mutations in TbAAT6 or loss of this transporter causes resistance to eflornithine [60] (Table 84.2). The second active ingredient in NECT is NFX which is apparently not acting in synergy with eflornithine [104], although it increases oxidant stress in trypanosome parasites. NFX is believed to function as a prodrug requiring enzyme-mediated reduction by nitroreductases (NTRs) to generate cytotoxic species that cause damage to macromolecules (e.g., DNA, lipids, and proteins), a process linked with ubiquinone availability [106] (Table 84.2). Modulation of NTR levels within trypanosomes directly affects their sensitivity to nitro compounds, with reduced levels of the enzyme leading to nitro drug resistance. Resistance to NFX can be generated relatively easily in bloodstream trypanosomes in vitro and NFX-resistant cell lines are cross-resistant to a number of other nitro drugs including the lead compound fexinidazole [107]. In clinical isolates of *T.b. gambiense* from Sudan and West and Central Africa, a tenfold range of sensitivities to NFX was reported, but the levels of NTR have not been evaluated in these field isolates [108].

The last drug part of the antitrypanosomal arsenal is suramin, a sulfonated naphthylamine, exhibiting binding affinities to many plasma proteins including low-density lipoprotein (LDL) [109]. In fact, this drug cannot cross lipid membranes by passive diffusion due to strong negative charge and must be taken up via a bloodstream stage-specific invariant surface glycoprotein called ISG75 [106]. Once internalized, suramin has been shown to inhibit various glycolytic enzymes among other activities [110, 111], but its main trypanocidal action is probably due to inhibition of LDL uptake via ISG75, prohibiting the parasite's supply of cholesterol and phospholipids (Table 84.2). Few resistance mechanisms to suramin were described up to now, but one of these is the overexpression of the ABC transporter TbMRPE that was shown to give two- to threefold resistance [91] (Table 84.2). More recently, a genome-scale RNA interference (RNAi) target sequencing (RIT-seq) screen has been performed in *T. brucei*, and a number of proteins involved in the mode of action of suramin have been revealed [106]. Some of these proteins might be also involved in drug resistance, but further investigation is required.

Few PCR tests are available for drug resistance testing in African trypanosomes, e.g., for the detection of the genetic status of particular resistant determinants or for parasite detection posttreatment, although the majority of these were developed for animal trypanosomes [44, 112–115] (Table 84.3). Apart from molecular assays, two techniques are commonly used to identify drug resistance in these parasites: tests in mice and in vitro assays (Table 84.3). The mice test is conducted as following: groups of at least six mice are inoculated intraperitoneally with 10^5 parasites of the isolates of interest. Twenty-four hours after inoculation or at the first peak of parasitemia, a range of trypanocidal drug doses are administered, also intraperitoneally. A control group, e.g., not treated (only buffer), is also required. After treatment, the parasitemia is monitored daily during the first week, three times a week during the second week, and twice a week thereafter in wet smears of tail blood. The treated groups are monitored until relapse occurred or until 60 days posttreatment, when the mice are euthanized. A trypanosome isolate is considered as drug sensitive if at least five out of six treated mice were cured. If fewer than five mice were cured, the isolate is considered resistant. The ED_{50} or ED_{95} (the effective dose that gives temporary clearance of the parasites in 50 or 95 % of the animals, respectively) can be calculated, as can the CD_{50} or CD_{95} (the curative dose that gives complete cure in 50 or 95 % of the animals, respectively). These values are then compared with those obtained using reference-sensitive trypanosome strains.

A fluorimetric/colorimetric assay based on the metabolism of the dye Alamar Blue by live cell cultures in vitro in the presence of various concentrations of drugs is available [116] (Table 84.3). Briefly, the nonfluorescent dye Alamar Blue (resazurin) is reduced intracellularly to resorufin in live cells, a pink and fluorescent molecule (excitation and emission at 544_{nm} and 590_{nm}, respectively). Although very useful for drug resistance testing or drug screening, this assay does not easily distinguish between cell death and growth arrest. An alternative fluorimetric assay, based on the interaction of propidium iodide with DNA, that allows either real-time monitoring of cell viability or the generation of EC_{50} values

at a predetermined time-point was thus developed [117] (Table 84.3). This assay is highly sensitive and fluorescence readings easily correlate to numbers of parasites or DNA content.

For melarsoprol drug resistance testing, a quick, simple, and sensitive test was reported [118] (Table 84.3). The assay is based on the fact that resistant parasites are defective in a plasma membrane transporter responsible not only for drug uptake but also for the specific uptake of the fluorescent diamidine DB99 (2,5-bis-(4-amidinophenyl)-3,4-dimethylfuran) into trypanosomes. The two DNA-containing structures in the trypanosome, the nucleus and the kinetoplast, begin to fluoresce within 1 min of introduction of DB99 into the medium, unless parasites are resistant. With the molecular determinants of resistance being discovered, it is likely that numerous PCR-based assays will be developed in trypanosomes.

3.3 Animal African Trypanosomes

Animal African trypanosomoses (AAT) or Nagana is a disease transmitted biologically by tsetse flies and mechanically by various hematophagous biting flies [119–121]. The disease is caused by some species of the *Trypanosoma* genus, e.g., *T. vivax*, *T. congolense*, *T. brucei brucei*, *T. evansi, T. theileri*, and *T. equiperdum*. Together, these species contribute to considerable losses in animal production in Africa, Latin America, and Southeast Asia. Economically, *Trypanosoma congolense* is considered the most important species. To maintain livestock in acceptable health condition, farmers relies on either curative or prophylactic treatment of animals with diminazene aceturate (DA) or isometamidium chloride (ISM), respectively. However, since these two trypanocides have been on the market for several decades, treatment failures and drug resistance are now reported [122–126]. Drug resistance to ISM is more widespread than to DA, but increasingly there are reports of resistance to both drugs [126–128]. Similar to what have been described for human trypanosomes, in animal trypanosomes adenosine permeases (P1 and P2 types) turned out to play an important role in the uptake of, and resistance to, trypanocides. Changes in mitochondrial electrical potential have been also demonstrated in ISM-resistant *T. congolense* [129].

At present, four types of technique are commonly used to identify drug resistance in animal trypanosomes: tests in ruminants; tests in mice, in vitro assays, and molecular detection (Table 84.3). None of these is, however, an ideal test and other tests are still in the phase of development or validation. The in vivo assessment of trypanocidal efficacy in experimentally infected animals is one of the most useful ways to detect drug resistance in AAT isolates [130] (Table 84.3). Briefly, animals of a group are experimentally infected with an isolate. After all animal of the group became parasitemic, they are treated with the recommended curative doses of DA or ISM. From the treatment date, animals are then monitored for parasitemia by the buffy coat technique [131] twice a week for 100 days. When relapse (e.g., detection of trypanosomes by microscopy after drug treatment) is confirmed in an animal, the animal is treated with a second different drug. If no relapse is detected 100 days after the first and the second trypanocidal drug administration, the treatment is considered successful and the trypanosomes sensitive to drug treatment. Relapse infections detected within 100 days of administration of a trypanocidal drug are taken as indicative of resistance. If relapse occurred in more than 20 % of the animal tested, the isolate is considered resistant to the dose of drug used [130]. Since microscopic methods have poor sensitivity, follow-up for up to 100 days after treatment is recommended to increase the chance of detecting recurrent parasitemia waves. An alternative to this limitation is PCR-based detection assays [132]. For example, a touchdown PCR assay targeting the internal transcribed spacer 1 of the ribosomal DNA (ITS1 TD PCR) was developed as a useful tool in assessment of drug efficacy against *T. congolense* infection in cattle [113]. As the assay bears the potential for detection of mixed infections of various trypanosomal species, it may be applicable for drug efficacy studies and diagnostic applications.

The mouse test is performed by expanding an isolate in a donor mouse, which is then inoculated in groups of five or six mice. Twenty-four hours later, or at the first peak of parasitemia, each group except the control group is treated with a range of drug doses. Thereafter, the mice should be monitored three times a week for 60 days. The effective dose ED_{50} or ED_{95} can be calculated, as can the curative dose CD_{50} or CD_{95}. The advantage of the mouse test over the test in ruminants is that it is cheaper and less cumbersome. However, most *T. vivax* isolates, and also some *T. congolense* isolates, do not grow in mice. Secondly, higher dose of drug (normally ~ ten times higher) must be used in mice in order to obtain results comparable to those from cattle because of the vast difference in metabolic activity, in spite of the fact that there is reasonable correlation between drug sensitivity data in mice and cattle. Therefore, results in mice cannot be directly extrapolated to calculate the curative dose to be used in animals. Thirdly, a large number of mice per isolate are required in order to obtain a precise assessment of the degree of resistance. Finally, the test takes as long as 60 days to evaluate the drug sensitivity of an isolate.

DA resistance might alternatively be monitored by the *Dpn*II-PCR-RFLP resistance test (Table 84.3). Briefly, all positive samples from *Trypanosoma*-infected animals (usually based on 18S-PCR-RFLP) are amplified using two primers targeting the P1-type purine transporter TcoNT10 gene. Then, the PCR products are digested by *Dpn*II restriction

enzyme and the digestion pattern is analyzed for DA resistance [133]. This test remains a reliable readout for DA resistance although Munday et al. [134] showed that the target gene in this test (e.g., the P1-type purine transporter) is not directly involved in DA transport. In fact, the transporter HAPT1 was shown to be responsible for most of the P2-independent diminazene uptake in animal trypanosome, and its absence seems generally to correlate with high levels of diamidine resistance [135].

Finally, in vitro assays in animal trypanosomes are expensive to perform and require good laboratory facilities and well-trained staff. A competitive ELISA which allowed the detection of small amounts of isometamidium in serum of cattle is available [136–138]. The test is both sensitive, detecting subnanogram concentrations, and specific. It allows the monitoring of drug levels over extended periods from the plasma. The presence of trypanosomes in animals with an ISM concentration of >0.4 ng/mL suggests resistance. A similar test for DA has been developed [139].

3.4 Leishmaniasis

Leishmaniasis is caused by over 20 different species of the protozoan parasite genus *Leishmania* and is spread by the bite of the female sand fly (*Phlebotomus* and *Lutzomyia* spp.) (Table 84.1). Leishmaniasis is a complex disease, with visceral, mucosal, and cutaneous presentations, each of which varies in incidence and severity. Early case detection and resistance testing followed by adequate treatment is central to control leishmaniasis, especially the VL form which can be fatal within months if not adequately treated. For decades the direct demonstration of parasites in tissue (lymph nodes, bone marrow, spleen, or skin) smears has been the gold standard in *Leishmania* diagnosis, a technique that is invasive and requires considerable expertise (Table 84.3). Alternatively, the high levels of serum antibody specific for parasite antigens allow serological diagnosis of VL using ELISA. PCR is usually highly sensitive for detection of leishmanial infections, but since there are carriers of the infection in endemic areas, these molecular assays are not useful to discriminate between acute infections from asymptomatic cases.

The treatment options for leishmaniasis are limited and far from satisfactory (Table 84.2). For more than 60 years, treatment of leishmaniasis has centered on pentavalent antimonial (Sb^{V}) formulations (i.e., sodium stibogluconate or meglumine antimoniate). Widespread misuse has led however to the emergence of Sb^{V} resistance, notably in the hyperendemic areas of North Bihar in India. Other antileishmanials including amphotericin B (AmB), miltefosine (MIL), and paromomycin (PM) could also face the same fate as there are increasing reports of relapses [140–143]. Another factor contributing to the rise of drug resistance in *Leishmania* is certainly HIV/VL-coinfected patients that are extremely difficult to treat and have been reported in at least 35 countries worldwide [144, 145].

Antimonials mediate their antileishmanial activity via generation of oxidative stress which leads to the disruption of the synthesis of macromolecules in the parasite cell. To survive, the parasite must control this oxidative assault and this is achieved by a complex molecular and multifactorial response. It is generally accepted that Sb^{v} are prodrugs that require biological reduction to their trivalent form (Sb^{III}) in order to acquire antileishmanial activity [146]. Antimony reduction apparently may occur in both the host cell or in parasites. In macrophages, the reduced trivalent form enters the parasite cell through the aquaglyceroporin AQP1 [147]. It has been shown that a lower activity of AQP1 by point mutations acquisition or a complete loss of function through a telomeric gene deletion resulted in Sb^{III} increased resistance in *Leishmania* [147–149]. In contrast to Sb^{III}, the Sb^{V} form is speculated to enter into the parasite via a protein that recognizes a sugar moiety-like structure shared with gluconate [150]. Increased intracellular levels of the antioxidant molecule trypanothione (TSH) have been observed in antimony-resistant parasites, an event usually related to the overexpression of rate-limiting enzymes involved in the synthesis of glutathione (γ-GCS) and polyamines (ODC), the two building blocks of TSH. The ABC transporter MRPA confers resistance by sequestering Sb^{III}-TSH conjugates within an intracellular organelle near the flagellar pocket, where the antimonial target(s) are probably absent [151]. In addition, a protein localized at the parasite cell surface was reported to be responsible for the active efflux of TSH-conjugated antimonial compounds outside the parasite [152], although the identity of this plasma membrane thiol-X-pump remains elusive [153]. Several other markers of resistance have been described and are reviewed in the chapters of this book authored by Mandal and collaborators and by Sundar and Chakravarty. Several of the markers found while studying in vitro antimonial resistance were confirmed in natural antimony-resistant *Leishmania* clinical isolates recovered from patients unresponsive to sodium antimony gluconate [154–158]. Nonetheless, since different paths lead to resistance in *Leishmania*, alternative in vitro mechanisms other than those described here may also operate in field isolates [159–161]. Recently, it has been discovered that *Leishmania* parasites influence cell functions of the mammalian host cell via glycans deployed at their cell surface [162]. Indeed, particular glycans at the parasite cell surface outwit the immune system of the host and permit to resist to the toxic effect of antimonial drugs by making the human host cell expelling antimony drugs through the ATP-binding cassette (ABC) transporter MDR1 localized at the macrophage cell surface.

AmB is the current secondary treatment of choice against leishmaniasis and the best treatment against antimonials

refractive leishmaniasis in highly endemic regions. The mechanism of action of AmB is complex and based on the binding of the AmB molecule to ergosterol, the predominant sterol in the membranes of *Leishmania* parasites (Table 84.2). AMB binding to ergosterol produces an aggregate that creates a transmembrane channel, allowing the cytoplasmic contents to leak out, probably accelerating cell death [163–165]. The level of sensitivity to AMB is species dependent and depends on the variation in the ergosterol content in membranes [166]. Resistance in in vitro generated *Leishmania* promastigotes was shown to be caused by a significant change in plasma membrane sterols, with ergosterol being replaced by a precursor, cholesta-5,7,24-trien-3βol [167] (Table 84.2). This change is apparently due to a loss of function of the S-adenosyl-L-methionine-C24-Δ-sterol methyltransferase (SCMT) that impaired C_{24} transmethylation. In addition, AmB uptake was decreased in in vitro resistant cells and efflux, most likely due to the overexpression of an ABC transporter (MDR1), was increased (Table 84.2). To date, only few cases of AmB clinical resistance were reported [168, 169], but the analysis of one clinical isolate of *L. donovani* has shown that similar resistance mechanisms previously observed in in vitro AmB-resistant mutants are also operating in clinical isolates [169]. Finally, an upregulation of the silent information regulator 2 (Sir2) was associated with AmB resistance in clinical isolates by regulating MDR1, ROS concentration, and the apoptosis-like phenomena upon AmB treatment [170] (Table 84.2).

The mode of action of paromomycin (PM) against *Leishmania* has been investigated by proteomics and, like other aminoglycosides, appears to act by inhibition of protein synthesis and interference with vesicle-mediated trafficking [171] (Table 84.2). In vitro generated resistant strains have a higher number of vesicular vacuoles and an increase in a number of proteins involved in vesicular trafficking compared to the parental sensitive strain. Several other products may also be involved but awaits further confirmation [172]. Interestingly in a recent study [173], experimental PM resistance could be readily selected in amastigote stage of several species and strains, although promastigotes remained fully PM susceptible. This study strongly suggests that the use of intracellular amastigotes, at least for PM susceptibility testing, is strongly recommended as promastigote resistance mechanisms may differ from amastigotes.

Although miltefosine (MIL) is the latest antileishmanial agent to reach the market, field reports note an increasing trend in treatment failures [174–176]. The mode of action of MIL includes perturbing the metabolism of lipids (especially phospholipids) [177], inhibition of cytochrome c oxidase activity and mitochondrial depolarization resulting to an apoptosis-like death [178] (Table 84.2). Drug uptake is a prerequisite for MIL activity against *Leishmania*, and a common feature in all MIL-resistant lines is a decreased drug accumulation. This is achieved by a decrease in uptake and/or an increase in efflux. The MIL uptake machinery is composed of two proteins, the miltefosine transporter LdMT (a member of the P4-ATPase subfamily) and its specific beta subunit LdROS3 (reviewed in [179]). Both are essential for MIL uptake at the parasite cell surface, and any mutations inactivating or decreasing the expression of any of these two components render the parasite cells highly resistant to MIL [180–182] (Table 84.2). The leishmanial MDR1, a P-glycoprotein-like transporter part of the *Leishmania* ABC family was the first molecule shown to be involved in in vitro MIL resistance [183]. Two members of the ABCG subfamily were also reported to be involved in MIL resistance in *Leishmania*, namely, ABCG4 and ABCG6, whose localization is mainly to the parasite plasma membrane and flagellar pocket [184–186]. Other proteins were involved in experimental MIL resistance in *Leishmania*, but their roles in clinical isolates remain to be elucidated (Table 84.2).

Drug resistance in *Leishmania* parasites can be assayed in two major stage forms of the life cycle of the parasite (Table 84.3). *Leishmania* spp. are digenetic organisms shuttling between a flagellated promastigote in the gut of the sand fly vector and an intracellular amastigote, mainly in phagolysosomes of macrophages of the mammalian host. Both forms can be cultivated in vitro in culture flasks, and both these stages have been exploited in drug discovery and drug resistance assays, but the consensus is that the only reliable method for monitoring resistance of *Leishmania* isolates is the technically demanding in vitro amastigote-macrophage model [187] (Table 84.3). In fact, various in vitro host cell models such as murine peritoneal macrophages [188], human monocytes (U-937) [189], THP-1 [190], and Chinese hamster ovary (CHO) cells [191] have been investigated to test the antileishmanial activities of promising candidate drugs or to monitor drug resistance levels in clinical isolates. In all these in vitro models, infection rates are usually measured by microscopic examination of adherent cells, although the technique in THP1 and mouse peritoneal macrophages can also be performed with free non-adherent cells. Once infection is established and confirmed, infected cells are treated with drugs for a certain period of time and pathogen growth/multiplication or inhibition is recorded. Flow cytometry can also be used as an alternative way to microscopy to measure the extent of drug action on various infected mammalian cells [192–195]. A potential substitute to the amastigote-macrophage model, although not presently as reliable as the former in its actual format, is based on axenic amastigotes in the absence of macrophages, thus corresponding to a "semi-in vivo" condition [196–198] (Table 84.3). Although axenic *Leishmania* parasites are more easily obtained in large numbers compared to intramacrophagic amastigotes, axenic amastigotes apparently only mimic the real intramacrophagic amastigote form and thus may not lead to reliable conclusions in terms of clinical drug resistance levels as the ones obtained with the

amastigote-macrophage model. More recently, a novel *Leishmania*-macrophage 3D model has been reported that might be an interesting model for initial drug screens or to study drug resistance mechanisms in a more close to in vivo context [199].

Alternative to in vitro tests, in vivo systems exist in *Leishmania* which are based on experimental animal models (mainly for VL) like rodents (mice, rat, hamsters), dogs, and monkeys [200] (Table 84.3). However, they are not widely used for drug resistance monitoring in clinical isolates. Finally, despite their intrinsic limitations, the use of promastigotes grown in flasks is often used as the first drug resistance test to evaluate the susceptibility level of isolates to current treatments since it is simple, relatively cheap, and easily applicable in several settings (Table 84.3). Briefly for drug resistance profiling using promastigotes, parasites are diluted to a concentration of $1–2 \times 10^6$ per mL of cultivation medium, and the drugs in appropriate concentrations are added to the experimental cultures. The inhibition of promastigote multiplication is assessed after approximately 3 days, depending of the species. Results derived from this in vitro promastigote test would always need to be counter verified in amastigote models, however.

4 Drug Susceptibility Testing in Apicomplexan Parasites

Apicomplexan parasites impose devastating impacts on much of the world's population. The phylum includes several pathogens of clinical and veterinary importance, such as *Plasmodium*, *Toxoplasma*, *Cryptosporidium*, and *Eimeria*. In particular, apicomplexan diseases of domestic animals are associated mainly with farmed animals and are renowned for the large economic costs incurred by the agricultural industry. All apicomplexan parasites are characterized by the presence of a representative organelle, the apicoplast, a relic chloroplast-like organelle of uncertain function that contains hundreds of functional predicted proteins and gives the phylum its name. Most if not all apicomplexans are obligate intracellular parasites. They typically invade host cells by forming a ring-like junction with the host cell membrane through which the zoites will be internalized. It was estimated that out of a probable 1.2–10 million apicomplexan species, only about 0.1 % have been named and described to date [201].

4.1 Malaria

Each year an estimated 300–500 million clinical cases of malaria occur, resulting in nearly a million deaths, mostly young children under the age of five [202–204]. Malaria occurs in over a hundred countries (Table 84.1). The ever growing problem of drug resistance has hindered many malaria control programs. Transmitted from person to person by the bite of anopheline mosquitoes, malaria is caused by one of the five *Plasmodium* spp. *Plasmodium falciparum* is the main cause of severe clinical malaria and death, but the most common of all five human malarial species is *P. vivax*. Prompt diagnostic confirmation of malaria can be achieved through microscopy, serology, or rapid diagnostic tests (RDTs) with more than 200 malaria RDTs currently available on the market (representatives are listed in Table 84.2). Up to now, the most accurate tests to detect malaria parasites and for confirming the species are PCR-based tests but microscopy still remains the gold standard tool for malaria diagnosis although the accuracy and sensitivity of this method highly depends on well-trained and experienced technologists.

Drug resistance is now a major concern in the management of malaria. In addition to widespread resistance to chloroquine and sulfadoxine-pyrimethamine, parasite resistance to mefloquine, quinine, and other antimalarial drugs have been reported including to the last resort artemisinin-based combination therapies for which resistance has been reported in the Greater Mekong subregion of Cambodia, Laos, Myanmar, Thailand and Vietnam [205–208].

The mode of action and resistance mechanisms to several antimalarials have been extensively studied over the last decades and are reviewed in the chapters authored by Biagini and Ward and by Pradines (see also Table 84.2). Several molecular markers for chloroquine (CQ) resistance have been identified, including SNPs in the *pfCRT* (the digestive-vacuole transmembrane chloroquine resistance transporter) and *pfMDR1* (multidrug resistance 1) genes that are now well established [209–213] (Table 84.2). Other factors involved in modulating *P. falciparum* quinoline response include *pfMRP1* (multidrug resistance protein 1) [214] and *pfNHE-1* (sodium hydrogen exchanger) [215, 216], the latter specifically related to low levels of QN resistance. Mutations in other ABC transporters were associated to resistance [217, 218]. Mefloquine (MF) resistance was strongly associated with amplified pfMDR1 locus (e.g., copy number variations, CNVs). Both analyses of field isolates [219, 220] and cultured parasites [221] support a link between increased pfMDR1 CNVs and MF resistance. In fact, there is a complex relationship of CNVs and SNPs that contribute to MF resistance in the parasite. Some mutations in pfMRP1 as well as pfMRP2 were also found to be associated with reduced susceptibilities not only to MF but also to CQ [217, 222].

The sulfadoxine-pyrimethamine (SP) combination targets the folate pathway in malaria parasites. The primary determinants of resistance in *Plasmodium* against the SP combination are well-described point mutations in the enzymes dihydropteroate synthase (DHPS, the target of sulfadoxine) and dihydrofolate reductase (DHFR, the target of pyrimethamine)

(reviewed in [223]). Recent work has highlighted however the contributions of additional parasite adaptation to antifolate resistance (Table 84.2). Indeed, gene amplification (e.g., CNVs) of the first enzyme in the parasite folate synthesis pathway, GTP-cyclohydrolase (GCH1), was strongly associated with resistant parasites and potentially contributes to the development and even persistence of resistant parasites [223].

Atovaquone (ATQ) with proguanil is a component of Malarone that targets malaria respiration, more precisely inhibition of the cytochrome Bc1 complex in the mitochondrial electron transport chain. Resistance to ATQ in the field is associated with point mutations in cytochrome b, most notably near the conserved Pro(260)-Glu(261)-Trp(262)-Tyr(263) (PEWY) region in the ef loop [224] (Table 84.2). Even a single point mutation (at position Y268) in the active site of cytochrome b protein can rapidly render ATQ ineffective against *Plasmodium falciparum* parasites [225].

Artemisinins are the current cornerstone of effective therapy in malaria. These drugs are thought to act via the generation of free radicals (ROS) that are initiated by iron bioactivation of endoperoxides and/or catalyzed by iron-dependent oxidative stress [226, 227]. Recently, a molecular marker of artemisinin resistance, the K13 propeller protein in *P. falciparum* has been identified [228, 229] (Table 84.2). Mutations present in the kelch domain are now prevalent (>40 %) in parasite populations from the China-Myanmar border where artemisinin use has the longest history. In particular, a predominant mutation (F446I) and a prevalent microsatellite variation in the N-terminus were identified [230].

The three basic approaches routinely used to evaluate the antimalarial activity of compounds in malaria parasites are in vivo and in vitro assays along with molecular characterization. Of the available tests (Table 84.3), in vivo tests most closely reflect actual clinical or epidemiological situations, i.e., the therapeutic response of currently circulating parasites. Briefly, in vivo assessment of antiplasmodial activity, and thus resistance, can be achieved using rodent models in which assays measure mainly (a) the clearance of parasites as detected by optical microscopy or other more sensitive methods (e.g., PCR based), (b) the time that elapses between last drug dose and clearance of parasitemia, and (c) the drug dosage that clears parasites in a dose-response manner. In vivo studies can be conducted also in humans and usually represent the following of a selected group of symptomatic and parasitemic individuals that underwent carefully controlled treatment with subsequent monitoring of the parasitological and/or clinical response over time. Recently, a spectroscopic analysis method was proved to be sensitive for recognition of the effects of antimalarial treatment on the structure and composition of the parasites and infected red blood cells [231]. It is anticipated that this novel technology may aid and improve the accuracy and clinical relevance of laboratory or field testing for malaria drug resistance testing.

For *P. falciparum*, the in vitro assessment of parasite drug susceptibility, involving short-term culture of parasites in the presence of serial drug concentrations, has proved to be extremely useful in assessing intrinsic susceptibility to antimalarial drugs. Thus, in vitro tests in general consist by removing parasites from the host and placing them into a strictly controlled experimental environment. There are several in vitro tests that have been described over the last decades, but most of them are based on measuring parasite growth or growth inhibition under various drug concentrations either by counting parasites, measuring [^{3}H]-hypoxanthine incorporation [232] or other isotopic labeled precursors (e.g., palmitate, serine, choline, inositol, and isoleucine), measuring parasite lactate dehydrogenase (LDH) activity, detecting antibodies against histidine-rich protein II (HRPII) or LDH, or by staining parasite DNA with SYBR green, DAPI (4,6-diamidino-2-phenylindole), PicoGreen, or YOYO-1 dyes [233–238]. These malarial in vitro tests are demanding however and relatively expensive. A low-cost standardized in vitro assay called the schizont maturation test (SMT) also known as the Mark III microtest was developed by WHO more than 15 years ago (http://www.who.int/malaria/publications/atoz/ctd_mal_97_20_Rev_2_2001/en/) and is based on the maturation of parasites in a 24–36 h microculture (in the absence or in the presence of drugs) followed by microscopically counting the number of parasites that successfully develop from ring into schizonts (i.e., parasites with three or more chromatins) in Giemsa-stained thick films. The Mark III microtest (Table 84.3) was optimized for chloroquine, mefloquine, quinine, amodiaquine, sulfadoxine/pyrimethamine, and artemisinin susceptibility testing. Experienced microscopists should carry out this test however as it is prone to individual variability. The "visual agglutination test" for detection of hemozoin production during parasite maturation is also commonly used. In general all in vitro methods involve direct exposure of malaria parasites to drugs in culture plates. These were extensively described elsewhere [239]. A commercial kit (Malaria Ag CELISA) which takes only about 2.5 h to perform was developed, where if parasite growth is inhibited by antimalarial drugs, the inhibition is reflected in the HPR2 levels and can therefore easily be quantified by antibody-mediated detection. The drawback of this assay is that some isolates from a number of regions including the Amazon region of Peru lack the *pfhrp2* gene [240, 241] and will produce a false-negative result in this test. A double-site enzyme-linked pLDH immunodetection (DELI) assay has been also used to access *P. falciparum* antimalarial drug susceptibility [242, 243]. This assay is equally as sensitive as PCR and much simpler to perform compared to isotopic assays.

In 2013, two novel tests were developed that can discern within 3 days whether the malaria parasites in a given patient

will be resistant or susceptible to artemisinin, the key drug used to treat malaria [205] (Table 84.3). In both tests, young parasites are briefly exposed to a high dose of artemisinin, mimicking the way parasites are exposed to the drug in people being treated for malaria, and their survival is measured 72 h later. One test quickly determines how a malaria parasite from a specific patient responds to artemisinin. It involves taking a blood sample and treating it with artemisinin in a test tube for 6 h. The drug is washed and the treated parasites are incubated for another 66 h, and counted. The second test is designed to isolate the malaria parasite at an early stage of its life cycle, the so-called ring stage. At this stage, malaria parasites are uniquely susceptible to artemisinin so the test can determine how these immature forms are becoming resistant to the drug.

Finally in malaria, the presence of distinct point mutations in established molecular markers (e.g., chloroquine resistance transporter (*pfCRT*), dihydrofolate reductase (*dhfr*), dihydropteroate synthase (*dhps*), and cytochrome b (*cytb*)) is highly correlated with drug resistance, and PCR-based assays are now available for detecting drug resistance to most antimalarial drugs in clinical isolates, including artemisinin [244–246] (Table 84.3). However, when designing a molecular assay for drug resistance testing in malaria, one should always keep in mind that minor DNA alleles linked with resistance that are present in a parasite population at ≤10 % (e.g., in mixed *Plasmodium* genotype infections which are prevalent in endemic malaria areas) are hardly being detected by genotyping methods like RT-qPCR, pyrosequencing, or microsatellite typing. Thus, even if PCR is highly sensitive, it may present some difficulties to detect low-level resistance allele that may nonetheless influence the outcome of the treatment.

4.2 Toxoplasmosis

Toxoplasmosis is a widespread zoonotic coccidian disease that occurs in both animals and humans. Approximately one third of the global human population is infected with *Toxoplasma gondii* [247] (Table 84.1). Clinically, the lifelong presence of the parasite in tissues of a majority of infected individuals is usually considered asymptomatic. The definitive hosts are representatives of the felid family. There are three infective stages of *T. gondii*: a) a rapidly dividing invasive tachyzoite; b) a slowly dividing bradyzoite in tissue cysts; and c) an environmental stage, the sporozoite, which are protected inside an oocyst and are the product of a sexual cycle operating in the intestine of the cat. In human, *T. gondii* is usually transmitted by consumption of lightly cooked meat. It can also be acquired by inadvertent ingestion of oocysts containing sporozoites, which are remarkably stable environmentally. The diagnosis of toxoplasmosis may be established by serologic tests, amplification of specific nucleic acid sequences (i.e., PCR), histologic demonstration of the parasite and/or its antigens (i.e., immunoperoxidase stain), or by isolation of the organism [248] (Table 84.3). Other rarely used methods include demonstration of antigenemia and antigen in serum and body fluids, a toxoplasmin skin test, and antigen-specific lymphocyte transformation. To diagnose toxoplasmosis during pregnancy, a sample of amniotic fluid may be used to detect the parasite. Ocular disease is diagnosed based on the appearance of the lesions in the eye, symptoms, course of disease, and often serologic testing. The current treatment options for toxoplasmosis are limited and include only few compounds such as pyrimethamine and sulfadiazine, which act synergically to block the folate biosynthesis pathway by inhibiting DHPS and DHFR, and atovaquone which binds to the cytochrome bc1 complex and therefore inhibits the mitochondrial electron transport process (Table 84.2). Treatment failures have been reported for these drugs however [249–251] and "natural resistance" to sulfadiazine have been observed [252].

T. gondii strains are genetically highly diverse, but only a few lineages are widely spread. The three different genotypes of *T. gondii* show great diversity in pathogenicity and "natural" drug sensitivity. As mentioned previously, *T. gondii* strains "naturally resistant" to sulfadiazine have been reported [252], but sulfadiazine resistance, either "natural" or "acquired," doesn't seem to be related to changes in the expression levels or SNPs in none of the targets (e.g., DHPS and DHFR) [252, 253]. For atovaquone resistance, mutations (M129L and I254L) were found within the cytochrome b gene [254]. The mechanism of pyrimethamine resistance in *T. gondii* is currently unknown (Table 84.2).

Very few assays are available for drug susceptibility testing in *T. gondii* (Table 84.3). Sulfadiazine susceptibilities can be evaluated on Vero cells infected with tachyzoites in 96-well plates using an enzyme-linked immunosorbent assay (ELISA) [255]. Alternatively, pyrimethamine, sulfadiazine, and atovaquone can be evaluated on MRC-5 fibroblast-infected cells [256].

4.3 Cryptosporidiosis

Cryptosporidiosis is commonly a self-limiting disease in healthy hosts but represents a life-threatening disease in immunocompromised and young individuals (Table 84.1). The disease is caused by *Cryptosporidium* spp. which is recognized as major waterborne coccidian parasites worldwide [257–259]. Most infections worldwide have been attributed to *C. hominis* and *C. parvum*. Diagnostic tests for *Cryptosporidium* infection are suboptimum however, necessitating specialized tests that are often insensitive (Table 84.3). Antigen detection and PCR improve sensitivity.

There is no effective treatment against *Cryptosporidium* spp., although limited efficacies have been reported for paromomycin, azithromycin, and nitazoxanide which is the first FDA-approved drug for treating cryptosporidiosis in non-immunodeficient children and adults [259]. Resistance to paromomycin seems attributed to the modulation of ABC transporters [260]. No mechanism of resistance for azithromycin and nitazoxanide has been described in *Cryptosporidium* spp. (Table 84.2).

Many obstacles exist to the development of novel drugs for cryptosporidiosis, including difficulty in propagation of the organisms in vitro. Recently, a novel in vitro model for *C. parvum* infection in human primary intestinal cells has been reported [261]. Animal models for drug assessment and drug resistance testing are poorly standardized, however (Table 84.3). Gnotobiotic piglets and immunosuppressed gerbils are the only animal models available for *C. hominis* [259] whereas *C. parvum* can be propagated in calves and lambs. In vivo drug screening has been done mostly in immunosuppressed rodents. An assay that could be converted eventually in an in vitro drug resistance assay for current anti-cryptosporidial drugs is the enzyme-linked immunosorbent assay (ELISA) that has been initially described to examine the effects of 13 antivirals on the development of *C. parvum* in human ileocecal adenocarcinoma (HCT-8) cells [262]. Finally, the viability of purified *C. parvum* oocysts exposed for different period of time to different concentrations of drugs (or disinfectants) can be also evaluated by inclusion or exclusion of various fluorogenic vital dyes and by an excystation technique [263, 264].

4.4 Eimeria

Eimeria is the cause of important livestock diseases with a high impact in the poultry industry where parasite transmission is favored by high-density housing of large numbers of susceptible birds. Indeed, *Eimeria* spp. are responsible for a $1.5 billion loss to the poultry broiler industry each year worldwide [265]. Transmission of the disease to human is rare and proceeds via the fecal-oral route. Coccidiosis is usually diagnosed by demonstrating oocysts in the feces (Table 84.3). Because the oocysts may be passed in small amounts and intermittently, repeated stool examinations and concentration procedures are recommended. Acid-fast staining is the preferred method for *Coccidia* (Table 84.3). If stool examinations are negative, examination of duodenal specimens by biopsy or string test (entero test) may be needed. Alternatively, molecular tools have been developed for the diagnosis of *Eimeria* [266, 267].

In livestock, *Eimeria* has developed drug resistance against all the dozen or so drugs approved for use in avian, and varying levels of resistance are present for those currently employed [268, 269]. Relatively little is known about the mode of action of anticoccidial drugs and even less about the mechanisms of resistance (Table 84.2). Anticoccidial drugs used in avian can be broadly divided into two categories: the ionophores and the synthetic drugs and these are described in the chapter authored by Aubert et al. in this series.

The development of resistance in chickens can be detected by means of different indices and criteria, but the assays should include at least a group of medicated infected birds, a group of unmedicated infected birds, and a third group comprising unmedicated uninfected birds [270] (Table 84.3). The most useful criterion for evaluating the effects of anticoccidial drugs is body weight gain during the acute phase of infection. Gain can be measured from the day of inoculation until the sixth or seventh day postinoculation or during the period of maximum growth depression (3–7 or 4–8 days postinoculation). Weight gains in medicated infected birds may be compared directly with unmedicated infected and unmedicated uninfected controls. An isolate is considered resistant if the weight gain of medicated infected birds is not significantly different from that of unmediated infected birds. Apart from weight gain, a lesion score system is also available [271]. This procedure is inherently subjective since it requires visual assessment of the condition of different regions of the intestine of infected birds, medicated or not. One can also rely on oocyst counts from intestinal contents which estimate the magnitude of infection in terms of parasite numbers, although there may be considerable variation in the number of oocysts produced by individual birds (Table 84.3). An anticoccidial index (ACI) is also used to evaluate drug resistance in birds. A 50 % or greater reduction in the ACI for medicated infected birds compared with that of unmedicated uninfected birds is ascribed to resistance where as a 25–50 % reduction is considered to indicate reduced sensitivity. A global index and an optimum anticoccidial (OAA) index are two other usual anticoccidial efficacy indices useful to monitor drug efficacy in avian [272].

4.5 *Isospora belli*

Isospora belli is believed to be a species which only infects human and some primates. It has a worldwide distribution but is more common in tropical regions and areas with poor sanitation. Infections are often asymptomatic and those with symptoms tend to be self-limiting with a duration of a few weeks. Infections are more common and the symptoms more severe in AIDS patients. In general, symptoms are similar to those of cryptosporidiosis. The infection is acquired through the ingestion of sporulated oocysts contaminating the external environment, including food and water supplies. There is no accepted gold standard method for diagnosing isosporiasis, but infections are usually diagnosed

by the coprological examination of host feces for coccidial oocysts (concentrated using various sedimentation-flotation techniques) (Table 84.3). Feces from carnivores can also be pretreated with ether/chloroform to remove fatty material. Unstained oocysts are best observed by light microscopy using suboptimal transmitted illumination (condenser wound down to introduce diffraction), phase-contrast or interference-contrast optics. Alternatively, oocysts can be stained with Giemsa or acid-fast stains of dried smears or with fluorescence dyes (auramine-rhodamine) in wet preparations (Table 84.3). Fresh fecal samples may only contain unsporulated oocysts, so differential specific diagnosis may sometimes require short-term storage to facilitate sporulation (2 % potassium dichromate is often used to suppress microflora during storage, and refrigeration can slow the process down if so required for field samples). The recommended treatment for *Isospora* is the combination of trimethoprim-sulfamethoxazole [273]. Few failure treatment cases in human have been reported [274, 275]. Drug resistance in these cases is only suspected but not proven since parasite sequestration in immune privileged sites may also play a role in recurrent cases [276]. Monitoring susceptibility in *Isospora* is not well standardized and thus not performed routinely (Table 84.3).

5 Drug Susceptibility Testing in Anaerobe Parasites

Drugs and resistance mechanisms in anaerobic parasites have been reviewed in details in this series by Smith et al. and Orozco et al., and we will concentrate on salient points and on diagnostics.

5.1 Trichomoniasis

Trichomoniasis is the most common curable nonviral sexually transmitted infections worldwide, accounting for about 276 million cases annually [277] (Table 84.1). Diagnostic tools for *Tv* have improved significantly in the last decade and various laboratory methods are now employed routinely (Table 84.3). Trichomoniasis can be treated with metronidazole (MTZ) or tinidazole (TDZ), two 5-nitroimidazole compounds that are taken up by the parasite as a prodrug by passive diffusion and activated by reduction in the hydrogenosome, the *Tv* equivalent of a mitochondrion [278] (Table 84.2). Electrons required for the drug reduction are generated by the key hydrogenosomal enzyme pyruvate to ferredoxin oxidoreductase (PFOR). Electrons released in the PFOR reaction are accepted by ferredoxin that is subsequently reoxidized by a hydrogenase. This hydrogenosomal model for MTZ activation in *Tv* has been recently challenged however, since a flavin-based mechanism of MTZ activation has been suggested as an alternative mechanisms [279]. Whatever the activation pathway, drug activation always results in the production of toxic nitro-radical molecules that likely interfere with proteins and protein trafficking, leading to cell damage and ultimately parasite death [280] (Table 84.2).

Resistance to MTZ and TDZ has been demonstrated both in field isolates of *Tv* from patients refractory to treatment and in laboratory-developed strains obtained by exposing trichomonads to sublethal pressure of the drug in vitro. Clinical MTZ resistance in *Tv* is currently found in 2.5–10 % of isolates tested [281–285]. Fortunately, the prevalence of resistance to TDZ is lower but cross-resistance between MTZ and TDZ is of great concern as the two drugs are similar in modes of action. In laboratory-generated *Tv*-resistant strains, an altered conformation (shrinking) of the hydrogenosome was observed [286, 287], as well as a downregulation of enzymes required for drug activation including the enzyme PFOR [288], a ferredoxin with an exceptional redox potential [287] and a reduced amount of intracellular ferredoxin [289] (Table 84.2). However, resistant clinical isolates do not harbor downsized hydrogenosomes and do not exhibit reduced transcription of the PFOR or ferredoxin genes [290]. Laboratory-generated resistance was also associated with reduced thioredoxin reductase activity and free flavins, both of which are proposed to reduce MTZ as well [279, 291]. In clinical isolates a decreased flavin reductase activity (FR1, formerly known as NADPH oxidase) has been similarly observed [279, 292, 293] as well as a downregulation of alcohol dehydrogenase 1 (ADH1) (Table 84.2). MTZ resistance in clinical isolates was clearly associated with single-nucleotide polymorphisms in the nitroreductase genes *ntr4Tv* and *ntr6Tv* [294], although their formal role in resistance needs further investigation. Once confirmed, these SNPs may have clinical utility in identifying MTZ-resistant *Tv* in a rapid PCR-based assay. It is salient to point out however that MTZ resistance does occur in *Tv* isolates with intact *ntr4Tv* and *ntr6Tv* genes, indicating that alternative resistance mechanisms may also operate in clinical strains.

Resistance to nitroimidazole drugs has been studied by growing *Tv* strains in the presence of different drug concentrations under aerobic and anaerobic conditions in vitro (Table 84.3). Aerobic versus anaerobic resistance in *Trichomonas* isolates is an important consideration since most reports indicate significant levels of aerobic resistance and few cases of anaerobic resistance [295], the latest being characterized by very high minimum lethal concentration (MLC) values in vitro (over 1000 µg/mL MTZ) and has been demonstrated only in laboratory-developed strains up to now [296, 297]. Low-level resistance in *Tv* to MTZ is usually defined as aerobic MLC of 50–100 µg/mL, moderate-level resistance as 200 µg/mL, and high-level resistance as ≥400 µg/mL [298]. In general, elevated aerobic MLCs are associated with a greater likelihood of treatment failure, but inconsistency does exist [298].

The standard procedure to determine the in vitro aerobic MTZ (or TDZ) resistance among *Tv* isolates is performed as follows: swab specimens are obtained from infected person and parasites are cultured at 35–37 °C in the InPouch Tv (BioMed Diagnostics) culture media for 24–96 h. The cultures are examined at the microscope to visualize trichomonad parasites. Positive cultures are then incubated in multi-well plates (in triplicate) in TYM medium at 37 °C until axenic cultures are obtained. Axenic parasites are then assayed for MTZ and TDZ susceptibility under aerobic conditions, using serial dilutions of drug concentrations from 0.2 to 400 μg/mL [299, 300]. Briefly, stock solutions of MTZ or NTZ are prepared in dimethyl sulfoxide (DMSO) and diluted with TYM medium to obtain a stock solution, and then further serially diluted with the same medium in a multi-well plate. DMSO (0.05 %) in TYM is used as vehicle in control wells. Parasites (5×10^3 trophozoites/well) are added to the wells as well as control *Tv* strains (resistant and sensitive) and the plates are incubated at 37 °C. The MLC is the lowest dilution at which no motile trichomonads could be observed by microscopic observation, in at least two independent experiments.

For anaerobic condition, traditionally two major susceptibility assays have been optimized, e.g., tube assays and microtiter plate assays, and both have their own limitations. Microtiter plates are problematic due to the need to remove the plates from the anaerobic or low-oxygen environment to monitor the progress of the assay. On the other side, tube assays are much more cumbersome and time-consuming. Optimized in tubes or in plate format, a number of anaerobic susceptibility assays have been reported for *Tv* over the last decades, for example, [^{3}H]-thymidine uptake derived from a *Giardial* test [301]; colorimetric assays [302] based on the giardiasis colorimetric test [303] which employ synthetic substrates of purine salvage pathway enzymes [302, 303] are available (Table 84.3). Even a commercial system does exist for anaerobe parasites, the Anaerocult minisystems, which has been used for the determination of chemosensitivity in several anaerobic protozoan species including *Tv* [284] (Table 84.3). This system allows the use of multi-well plates in sealed bags or airtight jars for parasite culturing in low-oxygen environment. Finally, experimental animals employed in studies of *Tv* infection are available including a mouse model [304] and nonhuman primate animal models [305–307] (Table 84.3), but they are not routinely used for in vivo drug susceptibility testing.

5.2 Giardiasis

The anaerobe diplomonad parasite *Giardia lamblia* (also known as *G. duodenalis or G. intestinalis*) is a common enteric parasite spread all over the world in contaminated food and water (Table 84.1). Chronic infections of months to years can occur, but asymptomatic carriage of *Giardia* is common in human [308]. The fecal-oral route is regarded as the major source of infection. As few as ten cysts may establish infection in human [309]. The control of this infection requires both the inactivation of the infectious cysts disseminated in the environment and the elimination of pathogenic trophozoites attached to the small intestinal epithelium. The diagnosis of giardiasis is generally made by the identification of cysts or trophozoites in a total of three fecal samples over a period of several days. Enzyme immunoassays and fluorescent antibody assays of fecal specimens are available as well as the Entero Test (e.g., the string test) [310] (Table 84.3). Endoscopic aspiration from the small intestine is also possible in some patients with chronic diarrhea with repeatedly negative fecal examinations.

Giardiasis is treatable with metronidazole (MTZ) or tinidazole (TDZ), but alternatives such as albendazole (in combination with mebendazole), quinacrine, and nitazoxanide are available (Table 84.2). Treatment failures with MTZ occur in ~ 20 % of cases and resistance has been confirmed among clinical isolates of *Giardia* in in vivo Mongolian gerbils and mouse model assays [311] (Table 84.3). In in vitro generated MTZ strains, resistance was associated with DNA changes (epigenetic regulation) (Table 84.2). DNA probes which hybridize with specific chromosomes and repetitive sequences indicated that rearrangements both at the chromosome and repetitive DNA level occurred concurrently with the development of MTZ resistance [312]. Resistance to MTZ also is negatively correlated with the intracellular concentration of pyruvate to ferredoxin oxidoreductase (PFOR, which replaces pyruvate dehydrogenase in aerobic organisms) leading to a concomitant decrease in the uptake of free MTZ into the cell [313, 314] (Table 84.2). Similar to *Tv*, nitroreductases play a role in activating MTZ (and other nitronidazole drugs) and *Giardia* parasites encode two nitroreductases, GlNR1 and GlNR2, that were shown to be involved in this process [315]. Trophozoites overexpressing GlNR1 presented a higher susceptibility to MTZ and nitazoxanide [316] whereas trophozoites overexpressing GlNR2 were less susceptible to both nitro drugs as compared with control trophozoites [315]. Thus, susceptibility to nitro drugs in *Giardia* may depend not only on activation, but also on inactivation of the drugs by the two giardial nitroreductases (Table 84.2). Finally, it was shown that recombinant protein disulfide isomerases 2 and 4 (PDI2 and PDI4) are inhibited by nitazoxanide [317] (Table 84.2). In *Giardia*, resistance against nitazoxanide and MTZ is thus linked. Cross-resistance to tinidazole has also been demonstrated with MTZ-resistant *Giardia* strains [318, 319].

The emergence of albendazole resistance in giardiasis is also an issue of growing concern for public health. Albendazole resistance can be generated in vitro in Giardia

[320], and it was shown that resistance was correlated with cytoskeletal changes but not with mutations at amino acid 200 in β-tubulin, a common mutation found in almost every albendazole-resistant helminthic species (see below) [321]. Albendazole induces ROS accumulation in albendazole susceptible *Giardia* parasites, but not in resistant ones, and the accumulation of albendazole oxidant metabolites (e.g., sulfoxide/ABZ-SO and sulfone/ABZ-SOO) is lower in albendazole-resistant cultures compared to susceptible strains [322]. The NAD(P)H- and flavin-generating pathways, and possibly redox-sensitive epigenetic regulation are also probably involved in the complex albendazole resistance mechanism operating in *Giardia* [323]. It was thus suggested that the strong antioxidant response in resistant parasites may contribute to overcome the pro-oxidant cytotoxicity of albendazole observed in susceptible *Giardia* parasites, and thus may contribute to the resistance phenotype in this parasite (Table 84.2).

In vitro susceptibility assays are not easy to perform in *Giardia* and these difficulties result from the requirement for anaerobic growth and the difficulties in adapting the parasite strains to in vitro cultivation, e.g., excystation and axenization of trophozoites [324–326]. Nonetheless, a number of different methods have been developed to assay drug susceptibility in *Giardia,* which are similar to the ones developed for *Tv* (Table 84.3). In general, the axenized trophozoites are cultured in "large volume" airtight tubes [327], in vials [328], or in microtiter plates [329–332]. Some methods rely on a radiometric approach to look for a 50 % reduction in uptake of ^{3}H-thymidine measuring parasite multiplication [301, 333, 334], a 50 % reduction in parasite adherence [335–337], colorimetric assays for products released by killed trophozoites in the presence of drugs [303], assays based on soluble formazan production [338, 339], or the fluorescent substrate resazurin [330] (Table 84.3). In cases were anaerobic parasites are co-cultured with intestinal cells, *Giardia* trophozoites are normally quantified using real-time PCR with parasite-specific targets [340]. An Anaerocult assay is also available for drug susceptibility testing in *Giardia* [284], as well as a novel flow cytometry assay using propidium iodide [341] (Table 84.3). Recently, an integrated microfluidic device for culturing *Giardia* was reported, and this system also enables dose-response experiments for drug resistance monitoring [342]. A gerbil model [343] and mice model [311, 344] also exit for in vivo drug susceptibility testing.

5.3 Amoebiasis

Amoebiasis is caused by *Entamoeba* spp., anaerobes of worldwide high prevalence (Table 84.1). There are two distinct, but morphologically identical species of *Entamoeba*: *Entamoeba histolytica*, which is pathogenic and *Entamoeba dispar* which is non-pathogenic to human. Hepatic disease (amoebic liver abscess) is the most common symptomatic manifestation and occurs in 4–10 % of cases when organisms penetrate the bowel mucosa and enter the portal circulation. Antigen detection is the preferred tool in amoebiasis diagnosis (Table 84.3). Emetine, a plant alkaloid, was initially used to treat infections by *E. histolytica*, but MTZ/TDZ have become the drugs of choice following recognition of their amoebicidal properties in the mid-1960s (Table 84.2).

Emetine kills the trophozoites of *E. histolytica* mainly by inhibiting protein synthesis whereas MTZ and TDZ, two 5-nitroimidazoles, kill the trophozoites by alterations in the protoplasmic organelles of the amoeba. Both are ineffective however in the treatment of cysts [345]. Indiscriminate use of drugs has led to an increase in the minimum inhibitory concentration (MIC) of these therapeutic agents. In fact, MTZ/TDZ resistance in *E. histolytica* does not appear to be a serious problem since there are only occasional reports of failure with MTZ [346, 347]. Nonetheless, using stepwise incremental increases in drug dose, MTZ resistance can be induced in axenic lines of *E. histolytica* [348, 349]. In contrast to other anaerobes, resistant amoebae do not substantially downregulate pyruvate to ferredoxin oxidoreductase (PFOR) or upregulate P-glycoproteins, but exhibit increased expression of iron-containing superoxide dismutase (Fe-SOD) and peroxiredoxin and decreased expression of flavin reductase and ferredoxin 1 [348] (Table 84.2).

Because the organism is difficult to culture axenically from patients, there are very few assays to monitor drug resistance levels in clinical isolates (Table 84.3). Clinical isolates can be maintained in polyxenic cultures followed by monoxenic cultures. In vitro drug sensitivity of clinical isolates is usually assessed by nitro blue tetrazolium (NBT) reduction assay after exposure to various concentrations of each drug, in parallel with and standard reference strains [345]. Experimental animal models in the germfree guinea pig [350] and in hamsters [351] are also available using axenic or monoxenic cultures of *E. histolytica*.

6 Drug Susceptibility Testing in Stramenopiles (Heterokonts) Parasites

6.1 Blastocystosis

Blastocystosis is caused by a microscopic parasite, *Blastocystis hominis,* and the only stramenopile known to cause infections in humans [352] (Table 84.1). Several animals (e.g., cats, dogs, pigs, horses, cattle) can be also infected and infection in human often results from ingestion of contaminated food or water (fecal-oral route). In vitro cultivation is the most sensitive in detection of *B. hominis* than simple smear and concentration technique (Table 84.3) but is

not used routinely [353]. The taxonomy of *Blastocystis* remained elusive for many years, but there has been a sequence information on the complete SSU rRNA gene; *B. hominis* has been placed within an informal group, the stramenopiles, a branch of the *Chromalveolata* [354]. Once a person or animal has been infected with *B. hominis*, the parasite lives in the intestine and is passed in feces. Because the parasite is protected by an outer shell, it can survive outside the body and in the environment for long periods in some cases. Indeed, asymptomatic individuals with few cysts are usually not treated. Although MTZ is standard therapy for *Blastocystis* infections (Table 84.2), there have been accumulating reports of treatment failure, suggesting the existence of drug-resistant isolates [355]. One of the many reasons could be that the cyst forms, in addition to being genetically heterogeneous, are resistant to the cytotoxic effect of the drug [356] (Table 84.2). Alternatives include NTZ, trimethoprim-sulfamethoxazole, paromomycin, iodoquinol, ketoconazole, secnidazole, emetine, TDZ, and the probiotic *Saccharomyces boulardii* [355].

MTZ induces programmed cell death in *Blastocystis* and apoptosis-like features [357]. Reduction of ferredoxins in the mitochondrion-like organelle seems to play a role in the conversion of MTZ into its active state [357, 358]. A Caco-2 model of human intestinal epithelium also has been also developed for infection studies that may probably serve also in drug resistance testing [359] (Table 84.3). Rapid, in vitro high-throughput viability assays for *Blastocystis* spp. were optimized for MTZ resistance testing and extensive subtype-dependent variations in drug susceptibilities [360]. These are based on resazurin and XTT viability microassays (Table 84.3).

7 Drug Susceptibility Testing in Helminthes

There are a limited number of anthelmintic that can be used in medicine to treat helminthic infections, and most of them are also used since decades in animals. As a consequence of this long-term usage, resistance in livestock has been described for every anthelmintic available on the market. Resistance in helminthic infections in human, while not widespread, is now an emerging concern worldwide. There are only few broad-spectrum anthelmintic groups available for treatment and for the control of nematodes in human (Table 84.2). The first one is the benzimidazole class of drugs (e.g., albendazole and mebendazole), the second group includes imidazothiazoles (e.g., levamisole) and hydropyrimidines (e.g., pyrantel), and a third group corresponds to the macrocyclic lactones (MLs, e.g., ivermectin). In addition in the 1970s, the pyrazinoisoquinoline derivative praziquantel was successfully developed as a new broad-spectrum anthelmintic and is now used against most parasitic trematodes and cestodes on a large scale [361]. Praziquantel causes rapid contraction of the worm musculature of trematodes, which leads to a loss of worm movement, rapid bleb formation and vacuolization of the tegument, followed by rupture of the blebs and vacuoles [361]. Rare occurrence of allergic and hypersensitivity reactions after praziquantel administration may limit its use however [362]. The exact mechanism of action remains unclear [377]. Similarly, a synthetic derivative of piperazine, diethylcarbamazine (DEC), was discovered during the 1940s [363] and is now used as an antifilarial drug along with other drugs in mass drug administration programs (Table 84.2). DEC is part of the Global Program for the Elimination of Lymphatic Filariasis (GPELF) in human and is yearly administrated along with albendazole (or with ivermectin). DEC blocks host, and possibly parasite enzymes involved in arachidonic acid metabolism, and enhances the innate, nonspecific immune system by altering the parasite surface structure, making them susceptible to destruction by host defense. Each of these anthelmintic classes of drugs have their own mechanisms of action and resistance mechanisms (Table 84.2) that will be briefly described here.

The class of anthelmintic drugs that has been the most extensively studied up to now is certainly benzimidazoles (BZs). Members of this class bind selectively to β-tubulin and inhibit microtubule formation in parasites (Table 84.2). Parasites are thus immobilized and die slowly upon treatment. BZ resistance is characterized by single-nucleotide polymorphisms (SNPs), which cause amino acid substitutions in β-tubulin [364–366]. Mutations in β-tubulin inhibit drug binding and thus confer resistance (Table 84.2). More recently, SNPs present in a drug transport glycoprotein have been similarly involved in BZ resistance [367, 368]. Biologically, BZs prevent embryonation and hatching of nematode eggs. Therefore, a number of egg hatch/embryonation assays have been developed (see below) for the detection of resistance to this group of anthelmintics.

Levamisole and pyrantel are agonists at nicotinic acetylcholine receptors of nematode muscle and cause spastic paralysis (Table 84.2). Both drugs are used against nematodes of medical and veterinary importance, in particular soil-transmitted helminths. The molecular mechanism of resistance to such drugs is poorly understood however. In animals, reduced transcription of the mRNA coding for nicotinic acetylcholine receptor subunits that form the pyrantel-sensitive receptors was described as a component of the pyrantel resistance mechanism [369] (Table 84.2). A number of changes in several genes, which together encode the acetylcholine receptor, result in loss of the levamisole-sensitive acetylcholine receptor and thereby may cause resistance [370]. In *Haemonchus contortus*, a nematode infecting mainly sheep and goats, a potential marker for levamisole resistance has been discovered [371]. Indeed, the presence or absence of an indel of 63 bp located just downstream from

the splice acceptor site for the alternative third exon of a specific locus, Hco-acr-8b, was correlating with levamisole resistance status. Using this knowledge, a DNA-based assay for the detection and monitoring of levamisole resistance in parasitic nematodes of animals has been developed [371]. This test has not been validated for human nematodes yet.

Macrolide lactones (MLs) are primarily used against onchocerciasis, lymphatic filariasis, and strongyloidiasis. Most studies on the mode of action of MLs were based on the avermectins class of drug which includes ivermectin. Ivermectin resistance is now a serious problem for parasite control in livestock. Avermectins inhibits larval motility and the functioning of the pharyngeal pump which can inhibit feeding of nematodes. More specifically, ivermectin at certain concentrations increases the opening of glutamate-gated chloride (GluCl) channels and produces paralysis of pharyngeal pumping in nematodes through hyperpolarization of the target neuromuscular cell (Table 84.2). Changes in the frequencies of two alleles of this glutamate-gated chloride channel gene confer resistance [372] (Table 84.2). Interestingly in *Onchocerca volvulus*, changes in genotype frequencies in β-tubulin gene were associated with ivermectin treatments [373]. Finally, P-glycoproteins may be also involved in resistance to ivermectin [374–376] (Table 84.2).

7.1 Diagnostic Assays

A range of in vitro tests for both veterinary and human applications as well as few in vivo assays in animals have been developed for the detection of nematode populations resistant to the main anthelmintic groups (Table 84.3). Each suffers to some degree from reliability, reproducibility, sensitivity, and ease of interpretation however.

7.1.1 In Vitro Methods

The in vitro tests available to monitor drug resistance in helminths fall into three broad groups: (1) the Fecal Egg Count Reduction Test (FECRT) in which the fecal egg counts in pre- and post-drug treatment human samples are compared to indicate the percentage reduction in egg count as a result of the drug treatment [378]; (2) phenotypic assays in which the effects of drugs on free-living life cycle stages are examined with in vitro bioassays [378–380]; and (3) molecular tests in which the genotypic changes associated with drug resistance are monitored using polymerase chain reaction (PCR)-based methods [380, 381].

The FECRT assay measures changes in fecal parasite egg counts following chemotherapy and is currently the standard method for determining the therapeutic efficacy of all anthelmintic chemotherapy in human or animal use. The assay is valid however only when resistance becomes common place in the nematode population, e.g., when at least 20–25 % of the population developed resistance [382]. All FECRT protocols (e.g., FLOTAC, McMaster, Kato-Katz) start with fecal samples collected just before treatment with an antiparasitic drug and again after treatment. Parasites' eggs are counted in both the pre- and posttreatment fecal samples. If the egg numbers in the posttreatment sample are not reduced by at least 90 %, resistance may be suspected, although the proposed cut-off values have been set to 70 % and 50 % in the case of *Ascaris lumbricoides* and *Trichuris trichiura,* respectively [383]. The FECRT protocols can be used in human applications [384–386]. The Kato-Katz protocol is most widely used to detect eggs of *Schistosoma* spp., but less so for the detection of eggs of STHs and particularly for quantification of egg burden of hookworms (e.g., *Ancylostoma duodenale* and *Necator americanus)* due to lysis of fragile hookworm eggs during processing. The McMaster technique is the most common technique used in veterinary parasitology. Both the FLOTAC and McMaster techniques are designed to be quantitative, in comparison to the Kato-Katz method which can nonetheless be used for drug susceptibilities screening in helminths. Although very useful, one disadvantage of the FECRT is that some drugs, like ivermectin, may temporarily suppress egg laying so resistant worms appear to be susceptible in routine testing [387]. Furthermore, density-dependent fecundity effect among different worm populations is also a concern with this method. Indeed, egg output by females varies between species and changes under certain conditions which may complicate interpretation of results for this assay [388].

One of the phenotypic methods commonly used for drug susceptibility testing in parasitic helminths is known as the egg hatch test (EHT). This test assesses the ability of benzimidazole drugs (BZ), at given drug concentrations, to inhibit the embryonation and hatching of freshly collected nematode eggs, expressed as the dose required to inhibit 50 % of the eggs (ED_{50}). The EHT has been widely used with nematodes of livestock to detect resistance [389, 390], but several studies have tested human hookworm populations using this type of assay [391, 392]. The assay can be performed using the "agar-based protocol" or the "water-based" format. For the agar-based method, a stock solution of BZ is prepared in dimethyl sulfoxide (DMSO) and serially diluted twofold in the same solvent. Aliquots from a series of dilutions are added to 96-well microtiter plates, such that each row of the plate comprised a gradient of ten dilutions. The first two wells of each row are used as control wells (e.g., receive DMSO only). Each drug concentration is present in at least triplicate wells on each plate. Aliquots of a 2 % agar solution are dispensed into each well of the plate and allowed to set. Plates are placed into plastic press-seal bags and stored at 4 °C for no more than 3 months. Prior to use, plates are equilibrated to room temperature for 2 h before an aliquot of egg suspension in H_2O is dispensed onto the surface of the agar in each well.

Depending on the species, the number of eggs distributed per well may vary. For example, for *N. americanus*, it corresponds to ~30–35 eggs per well. Plates are then returned to a bag and incubated for 48 h at 26 °C. Lugol's iodine is then added to each well. The numbers of larvae present in each drug well are counted using an inverted microscope, and numbers of larvae and unhatched eggs are also counted in 12 control wells for each experiment. For some species, the amount of fecal material in each well prevents direct counting within the well. In those cases, the contents of each well are pipetted onto a slide for counting of larvae. Experiments are repeated three times. In the water-based assay, each drug well contains aliquots of the series of BZ solutions and control wells contain DMSO only. Egg solutions are added, the plates are sealed in plastic bags, agitated briefly and incubated at 26 °C for 48 h. Numbers of larvae and/or eggs are then counted as described previously for the agar assay. The EHT is the most appropriate test for use with human hookworms, since their eggs hatch rapidly. EHT is not useful for *Ascaris* and *Trichuris* which develop to the infective stage within the egg in the external environment but do not hatch externally to the host. As FECRT, low levels of resistance (below 25 %) are being hardly detected by EHT [382].

Another commonly used in vitro test for monitoring anthelmintic resistance is the larval development test (LDT) which allows the detection of resistance irrespective of the mode of action of drugs. Several different methods have been published, measuring the effect of different anthelmintic drug classes in various parasite species. There are currently two larval development tests, the liquid-based test described [393] and the agar-based test [394]. LDTs are mainly used to detect resistance to benzimidazoles (BZs), pyrantel/levamisole, and some macrocyclic lactones. The use of agar was reported to eliminate solubility problems with avermectins, including ivermectin [395]. Essentially LDTs measure either the morphology (or motility) changes upon treatment on a worm population. Briefly, these assays are performed with larvae in 96-well microtiter plates and LDT assays are performed as the EHT assays, but L1 stage larvae are used instead of eggs. Their development is followed up to the third larval stage (L3). LDTs are mainly useful to monitor drug resistance in *Necator americanus* and *Ancylostoma* spp., two soil-transmitted helminths.

A larval paralysis test (LPT) has been developed for the detection of levamisole (and morantel in animals) resistance [396]. In the assay, infective third stage larvae are incubated for 24 h in serial dilutions of the anthelmintic. After this time the percentage of paralyzed larvae is determined at each concentration and a dose-response line plotted and compared to known reference strains. Sutherland and Lee [397] described a modification of the larval paralysis assay, suitable for detecting thiabendazole resistance, a macrolide lactone.

A micromotility meter test (MMT) has been developed in which a micromotility meter is used [398]. On the base of the micromotility meter, a light is located, projecting upward through the test tube and its contents. It refracts horizontally from the meniscus to the outside of the tube, where the light signals are measured by a photodetector. Movement of the worms causes a variation of the reflected light rays and therefore a variation in the signals received. The average deviation of the signals from its mean value is determined by means of an amplifier, followed by a converter and a computer. The numerical representation of this signal is termed the motility index. Software is then used to record the readings which give a good measure of the motility of tested helminths in the presence or absence of drugs at various concentrations. Dead helminths generated a reading comparable to those obtained from pure liquid; active helminths caused higher indices than less active worms. MMTs have been proved useful for the detection of resistance to macrolide lactones (ivermectin) and levamisole, but not to BZ drugs [399].

Larval motility and larval migration (LMT) in the presence of drugs can alternatively be measured by migration through a sieve or by direct observation [400–405]. Most of these methods require visual scoring by skilled operators. To alleviate this limitation, an automated objective assay for drug screening and resistance diagnosis has been optimized [406]. A system called the xCeLLigence system (Roche) is currently available commercially which monitors cellular events in real-time without the incorporation of labels by measuring electrical impedance across interdigitated microelectrodes integrated at the bottom of tissue culture E-plates. Each time a parasite hit the electrode, it is monitored. As the action of many anthelmintics is reflected by their ability to affect the motility of the target parasites, the magnitude of the decrease in parasite motility for a particular sensitive strain is an indicator of compounds presenting therapeutic activities. In contrast, in the presence of a resistant strain, the motility will not be affected. Thus, the motility index generated by the statistical analysis of data using control strains clearly differentiates between resistant and sensitive strains of parasites.

Larval feeding inhibition assays (LFIAs) for detection of nematode anthelmintic resistance to macrocyclic lactones (ivermectin and imidazothiazoles) are available [407]. These assays consist in the study of the reduction of food ingestion (e.g., labeled bacteria) by first stage larvae (called L1) incubated in serial dilutions of an anthelmintic. The percentage of larvae fed is determined for each dilution by examination of the larvae's intestine, and the dose of larval feeding inhibition 50 (IC_{50}) (i.e., the concentration of anthelmintic required to inhibit the ingestion in 50 % of the L1) is calculated. Resistant strains tend to have higher IC_{50} values since they continue feeding at higher concentrations of the drugs being assayed. Control wells provided a qualitative measure of

larvae viability. Fed larval counts (observation of intestinal fluorescence) are carried out through a fluorescence inverted microscope. Feeding assays with adult worms are also possible [408].

A chemiluminescent assay for measuring avermectin binding sites has been described [409]. A biologically active chemiluminescent compound (ivermectin-luminol) provides an extremely sensitive nonradioactive probe to study avermectin binding sites.

The tubulin binding assay was specifically optimized for benzimidazole resistance testing [410]. The assay is based on the mode of action of BZ drugs that is associated with a reduced affinity of tubulins for the anthelmintics observed in resistant parasites. Briefly, the assay involves the incubation of a crude tubulin extract from adult parasites, infective larvae or eggs, with a tritiated benzimidazole for a certain period of time. The free, unbound drug still in suspension is removed using charcoal and the tubulin-bound label is counted by liquid scintillation spectrophotometry. Tubulin extracts from resistant parasites bind significantly less strongly than do those from susceptible parasites. Some drawbacks of this test are, besides requiring radiolabeled drug and access to expensive laboratory apparatus, that it requires relatively large numbers of starting material (worms, larvae, or eggs) making it nonoptimal for routine field assays.

Microfluidic chips for live whole worm sorting are also showing great promise for drug screening and resistance testing, as recently demonstrated for the model worm *C. elegans* [411–413]. With microchannels to direct worms and microsuction valves that trap individual worms, the microchip device can sort whole worms depending on drug sensitivity phenotype. The sorting chip is combined with fluorescence and digital imaging and permits screening down to a single cell worm resolution. Although very attractive, the limit of this system is that some adult parasites of many species are too large to be screened by this device.

The role of molecular diagnosis for resistance to antihelminthic drugs is currently considered as the way of the future. Indeed, several tests to detect antiparasitic resistance in worms are PCR or pyrosequencing-based tests, mainly for benzimidazoles resistance testing. Indeed, a number of tests have been applied in veterinary parasitology, especially for soil-transmitted helminths [376, 414–417] and some have been adapted to humans [418–420] (Table 84.3). However, with the exception of the benzimidazole class of drugs, the molecular basis of anthelmintic resistance is poorly understood at present for the other class of drugs, which limit the development of accurate and sensitive PCR/pyrosequencing-based assays. This may change through the leadership of a consortium carrying genomic characterization of resistant strains in a number of species [421]. Since the mechanism of benzimidazole resistance appears to be mainly associated with a reduced affinity of tubulin for the anthelmintic [422–424], a diagnostic assay for the detection of benzimidazole resistant nematodes in animals using the binding of tritiated benzimidazole carbamates to tubulin extracts of third stage larvae has been developed [410]. The assay is claimed to be rapid (~2 h), robust, highly reproducible, and sensitive to minor changes in the resistance status of parasite populations, but it requires relatively large numbers of larvae making it unsuitable for routine field assays. This assay has not been standardized yet for human nematodes.

7.1.2 In Vivo Methods

An in vivo test for monitoring suspected anthelmintic resistance in trematode- and cestode-infected animals is available which is called the controlled efficacy test (CET). The CET can assess anthelmintic resistance against any type of anthelmintic. After artificial infection followed by treatment with a flukicide, the animals are killed and the number of flukes in the liver (or in specific gastrointestinal regions) are counted [389]. By using various control groups (e.g., untreated and susceptible worm isolates), dose-response curves can be generated and then the ED_{50} calculated. There is, however, currently no agreed view on how to determine the occurrence of resistance on basis of these counts so this test is not routinely used.

The next sections will describe the main helminthic infections in human and discuss about the various susceptibility tests that are currently used for specific parasitic helminths (Table 84.3). It is important to mention here that very few in vitro assays to detect anthelmintic resistance in human nematodes have been validated so far, and most were adapted from assays previously developed for nematodes of veterinary importance. A major problem which limits the validation process is obviously the lack of human reference-resistant strains.

7.2 Schistosomiasis

Schistosomiasis is a parasitic worm disease carried by freshwater snails infected with one of the six species of the parasite *Schistosoma*, e.g., *S. mansoni, S. haematobium, S. japonicum, S. intercalatum, S. guineensis*, and *S. mekongi,* of which *S. haematobium* and *S. mansoni* are the predominant causes of disease (Table 84.1). Only *S. haematobium* causes vesical (urinary) human schistosomiasis that can lead to bladder cancer. The others are responsible for intestinal diseases (abdominal bleeding) but may also attack the liver, lungs, and spleen with concomitant damage to the intestines. Roughly 240 million people in ~80 countries suffer from schistosomiasis [425]. Transmission occurs by contact with contaminated freshwater (lakes and ponds, rivers, dams) inhabited by snails carrying the parasite. Parasites penetrate the skin during contact with freshwater or soil containing

contaminated snails. The quantitative Kato-Katz fecal smear technique is considered as the golden standard method for diagnosing schistosomiasis (Table 84.3). Praziquantel is the primary form of treatment against all schistosome species, and it can be safely coadministrated with albendazole or ivermectin. The expression of the schistosome P-glycoprotein SmMDR2 was found to be altered in worms exposed to praziquantel (PZQ) and was expressed at higher levels in worms from isolates with reduced PZQ susceptibility [426] (Table 84.2). A second ABC transporter, SmMRP1, was associated with PZQ resistance [426]. Drug resistance testing in schistosomes is usually performed using the FECRT (all anthelmintics), EHT (ivermectin), and LFIA (ivermectin) assays. The use of the xCeLLigence system has been also reported (praziquantel) [406], and animal models (snails [427, 428] and mice [429]) are available, although these models remain difficult to handle and interpret.

7.3 Lymphatic Filariasis

Lymphatic filariasis affects more than 120 million people in 80 countries worldwide and is a painful and debilitating disease (Table 84.1). The disease is caused by the threadlike parasitic filarial worms *Wuchereria bancrofti* and *Brugia malayi*, which live in the lymphatic system and can cause extreme swelling of the extremities and genitals. The disease is transmitted to humans by mosquitoes. The standard laboratory test for this infection is detection of the filarial worm in biopsy samples (Table 84.3). Lymphatic filariasis is treated with a combination of albendazole and diethylcarbamazine (DEC). Alternatively, ivermectin has proven to be effective. Although ivermectin is the only macrocyclic lactone approved for treating filarioid infections of humans, moxidectin appears to be effective against *B. malayi,* although resistance can be acquired in vitro by the modulation of ABC transporters [430] (Table 84.2). Few evidence of nonsusceptibility to DEC in *W. bancrofti* has been reported yet [431]. Drug resistance testing in filarial worms is usually performed using the FECRT and LMT assays. PCR and pyrosequencing assays for screening for albendazole resistance among *W. bancrofti* populations have been reported [15, 432–434].

7.4 Other Helminth Diseases

7.4.1 Onchocerciasis

Onchocerciasis, also known as river blindness, is caused by the filarial nematode *Onchocerca volvulus* which infects 26 million people living near the rivers and fast-moving streams of sub-Saharan Africa (Table 84.1). The disease is transmitted from person to person by infected *Simulium* black flies. Approximately 37 million people are estimated to be infected with onchocerciasis. Larvae enter the skin at the bite site and form nodules in the subcutaneous tissue where they mature. Adult females release millions of microscopic larvae—called microfilariae—into the surrounding tissue, that can lead to visual impairment and blindness. Onchocerciasis is treated with a biannual dose of ivermectin. In recent years there have been reports of persistent microfilaridermias despite multiple treatments with ivermectin suggesting that *O. volvulus* is becoming resistant to the anti-fecundity effects of the drug [18, 435–437]. Drug resistance testing in this parasite can be performed using the FECRT, LDT, LMT, MMT, and sometimes LFIA assays. Single-nucleotide polymorphisms in β-tubulin selected in *O. volvulus* following repeated ivermectin treatment can also be monitored though PCR assays [373].

7.4.2 Cysticercosis/Taeniasis

Two species of *Taenia* are frequent human intestinal parasites. *T. saginata*, the most frequent, is found in almost all countries where beef is eaten. *T. solium,* also called the pork tapeworm, is endemic in Latin America, Africa, and some Asian countries (Table 84.1). Infection occurs when one eats infected beef or pork. Eggs are passed in the human feces [438]. More than 60–70 million people worldwide are infected with a *Tania* spp. Taeniasis/cysticercosis are treatable with albendazole or praziquantel. Only few cases of treatment failure have been reported [439, 440]. Drug resistance testing in parasites causing cysticercosis/taeniasis is usually performed using the FECRT assay. An experimental encephalitis caused by *Taenia crassiceps* cysticerci in mice is also available [441] (Table 84.3).

7.4.3 Cystic Echinococcosis

Cystic echinococcosis (CE) or hydatid disease is a disease that affects both humans and animals (Table 84.1). CE is caused by the larval stage of *Echinococcus granulosus*, a tapeworm cestode that is common in Asia, Australia, East Africa, southern regions of Spain, South America, and North America. The primary carriers are dogs and wolves, and humans are accidental hosts. The liver is the most commonly involved organ in the body. The lungs are involved in approximately 10–30 % of adult cases. Pulmonary echinococcosis may remain asymptomatic for years and symptoms often develop only after cyst rupture or superinfection, most commonly by *Aspergillus fumigatus* [442, 443]. In humans, the disease is treated by surgery with a supplementary option of chemotherapy. Small (<5 cm) stage cysts (CE1 and CE3a) may be primarily treated with benzimidazoles, the first-choice drug being albendazole. In some situations the combination of albendazole and praziquantel may be preferred [444]. Out of three β-tubulin gene isoforms of *E. granulosus*, β-tubulin gene isoform 2 showed a conserved point mutation indicative of BZ resistance [445]. A second species, *E. mul-*

tilocularis, may also infect humans. The presentation is similar to *E. granulosus*, but the cysts are multilocular. *E. multilocularis* is resistant to praziquantel although high doses of albendazole or mebendazole may be effective. Drug resistance testing in CE parasites is usually performed using the FECRT and LDT assays, and PCR assays were also developed for BZ resistance testing. Small laboratory animals such as mice and Mongolian jirds are also used for in vivo drug susceptibility assays.

7.4.4 Soil-Transmitted Helminths

The major soil-transmitted helminths (STHs) are *Ascaris lumbricoides*/*Strongyloides stercoralis* (roundworms), *Necator americanus/Ancylostoma duodenale* (hookworms) and *Trichuris trichiura* (whipworm) (Table 84.1). The main intervention available for controlling STH infections is the periodic administration of one of the four anthelmintics recommended by WHO, mebendazole, albendazole, levamisole, or pyrantel. Of these, benzimidazoles (BZs) (e.g., mebendazole, albendazole) are the most frequently used anthelmintic for treatment of SHTs. Ivermectin is not recommended for STHs, except for strongyloidiasis (see below). The FECRT is by far the most commonly used test for diagnosis of resistance in human STHs. Phenotypic tests are also used in the livestock industries with some drug groups, most notably egg hatch assays with BZ [378, 380]. Phenotypic assays have been also developed to measure drug sensitivity in human hookworms [446]. Molecular tests are also available for detecting resistance to BZ drugs in some livestock nematode species [421]. For the nAChR antagonist drug group (pyrantel and levamisole), phenotypic tests have been described for livestock and companion animal gastrointestinal species [447, 448].

Strongyloidiasis is caused by *Strongyloides stercoralis*, a roundworm present mainly in tropical and subtropical regions but also in temperate climates (Table 84.1). Some 40–100 million people are estimated to be infected worldwide with more than 50 % of *S. stercoralis* infections being asymptomatic and most of them being chronic [449]. The two aggressive forms of the disease are hyperinfection syndrome or disseminated strongyloidiasis. In the first case, the infection occurs with a very heavy worm burden, while in the latter the larvae penetrate the intestine wall and reach the bloodstream, causing meningitis and septic shock. Severe strongyloidiasis carries a high mortality rate (up to 80 %) because the diagnosis is often delayed. Parasitological diagnosis of *S. stercoralis* infection relies on identifying larvae in stool. Alternatively, serological and molecular methods as well as chest radiography can also be used (Table 84.2). Today, ivermectin is the standard treatment for *S. stercoralis* infections, although many reports revealed an incomplete cure [450, 451]. Other drugs have been used for treatment, including mebendazole and albendazole [452, 453]. An in vitro larval motility assay is usually used to determine anthelmintic sensitivity for *Strongyloides* species [454]. A modified filter paper culture technique has been described for in vitro screening of *Strongyloides stercoralis* ivermectin sensitivity in clinical specimens [455]. This procedure does not require parasite isolation and is based on the principle of the drug effect on the motility of the infective-stage larvae, combined with a modified coproculture using the filter paper culture technique. Briefly, stool samples are collected from *S. stercoralis*-infected subjects and feces are smeared in the center of narrow filter paper strips. The strips are then placed in glass test tubes and various concentrations of ivermectin or of the control (distilled water) are added to the bottom of each tube at 25 °C. On the third and fifth days of culture at 25 °C, the tubes are examined for the effect of the drug on worm viability based on the motility of the infective-stage larvae at × 40 magnification. All control (no drug) tubes should show motile worms. The criterion for drug resistance is the demonstration of at least one motile worm in duplicate tubes either after 3 or 5 days of culture. Drug resistance testing in *S. stercoralis* can be alternatively performed using the FECRT, LFIA, LDT, and through the xCeLLigence platform.

There are two common species of hookworms, *Necator americanus* and *Ancylostoma duodenale*. Collectively, hookworms affect more than 700 million people across the globe, particularly in Africa and Latin America. Left untreated, hookworms cause internal blood loss leading to iron-deficiency anemia and protein malnutrition, particularly in pregnant women and children. Moreover, chronic hookworm infection in children contributes to physical and intellectual impairment, learning difficulties and poor school performance. Hookworm transmission is a complex, repetitive cycle. Larvae are found in human feces and transmitted to humans from contaminated soil through the skin or by accidentally ingesting contaminated soil. The worms mature in the small intestine of the host. A vaccine is currently in clinical trials [456, 457]. Hookworm infections are treated with anthelminthic drugs albendazole or mebendazole on an annual basis. Alternative treatment may include levamisole or pyrantel. Drug resistance testing in *Necator americanus* and *Ancylostoma duodenale* is usually performed using the FECRT and EHT assays, but PCR assays exist for the detection of SNPs in β-tubulin gene conferring BZ resistance.

Trichuriasis in human is caused by the species *Trichuris trichiura*. The disease affects close to 700 million people worldwide, particularly in warm, humid, tropical climates (Table 84.1). Symptoms include abdominal upset, diarrhea, and, depending on the number of worms, malnutrition, dehydration, and anemia. Adult worms live in the colon. Treatment is based on anthelminthic drugs albendazole or mebendazole on an annual basis. Alternative treatments include levamisole, pyrantel, and ivermectin. None of these drugs are opti-

mal however since they display only moderate cure rates when administered as single doses. Although this has not arisen as a problem yet, potential emergence of drug resistance in *Trichuris* is of concern [458]. The identification of potential new drug candidates currently relies on the adult *Trichuris* motility assay originally developed for the mouse whipworm *T. muris* [459]. A variant of this assay has been adapted for drug testing purposes based on L1 stage larvae, but the assay is also suitable for detecting resistance to levamisole and other drugs [460]. Alternatively, drug resistance in *Trichuris* may be detected using the FECRT (all anthelmintic) and LDT (BZs) assays. The xCELLigence system has been also used for levamisole, nitazoxanide, and ivermectin drug resistance testing in *Trichuris* [459] and molecular assays are available to detect BZ resistance [461]. The EHT is not useful for *Trichuris* which develop to the infective stage within the egg in the external environment but do not hatch externally to the host.

7.4.5 Foodborne Trematodes

Foodborne trematodes may cause fascioliasis, clonorchiasis, opisthorchiasis, and paragonimiasis (Table 84.1). These infections are treatable with praziquantel. The most notorious trematode is *Fasciola hepatica*, an hermaphroditic helminth of cattle and sheep. Human infection occurs occasionally, mainly in certain areas of Europe, Africa, and Latin America. The adult worm lives in the liver or bile ducts of the host, passing eggs in feces. The eggs hatch in fresh water, and the parasite completes its life cycle in a snail. Infection occurs by ingestion of metacercaria in vegetation or in water. Praziquantel treatment failure in human patients infected with *F. hepatica* has been reported [462, 463]. In sheep in cattle, *Fasciola* hepatica drug susceptibility testing can be performed by a coproantigen reduction test (CRT). The coproantigen assay (ELISA format) measures the levels of antigenic gut enzymes released from the fluke into the feces of the animal host. Coproantigen assays have been also tested in human [464, 465]. Alternative drug resistance assays include FECRT and EHT. The murine model is the most commonly used animal model for fascioliasis [466] (Table 84.3).

8 Point-of-Care (POC) Drug Resistance Testing

POC assays are rapid detection devices capable of determining whether a patient (clinically ill or asymptomatic) is infected with a particular pathogen. This type of assays either detects the pathogen itself or an alternative biomarker that is highly specific for the pathogen. With the threat of parasites developing resistance to the currently available drugs, the importance of POC assays for detecting parasites and simultaneously their resistance determinants is obvious. New or improved diagnostics including POC assays for parasite identification and drug resistance testing are needed. To facilitate the implementation of novel POC assays in resource limited settings, a series of criteria under the acronym "ASSURED" have been proposed [467, 468]. According to these criteria, an ideal POC assay should generate results within minutes; should not require a laboratory, electricity, or any special piece of equipment; should use heat-stable reagents with no special storage requirements; and should be easily performed by individuals with minimal training. The assay should also be highly sensitive and specific for the particular agent, inexpensive, and portable. In addition to speed up pathogen detection with high accuracy and sensitivity, the assay should also identify cases of drug resistance in order to ensure a better management of patients. This is no small challenge. The few POC assays currently available for infectious parasitic diseases commonly use the lateral-flow immunochromatographic format which is similar to the pregnancy strip test. Notorious examples in malaria diagnosis based on this format include the histidine-rich protein 2 (HRP2) of *P. falciparum*, the parasite-specific lactate dehydrogenase (pLDH), and a pan-malarial *Plasmodium* aldolase. Other POC assays use agglutination or solid phase processes. Currently, very few POC tests identify cases of drug resistance.

A particularly challenging issue when developing a POC assay for low-income resource settings is how to achieve high sensitivity or quantitative detection without dedicated instrumentation. Isothermal DNA amplification (e.g., LAMP) assays are gaining interest for empowering developing countries as they do not require sophisticated equipment and prove to be cost-effective. LAMP is unique among all isothermal amplification techniques as it is robust, rapid (can amplify a low copy DNA to more than 10^9 copies within an hour), and easy to perform. Moreover, LAMP is able to discriminate SNPs so drug resistance testing using this technology (when mutations are already known) appears very promising.

The LAMP assay is characterized by the use of a DNA polymerase (e.g., *Bst* or *Bsm* polymerases) that has low sensitivity to inhibitors and a set of primers specially designed to recognize different sequences on the target gene. Amplification occurs only when all primers bind, thus forming a product. The reaction allows the release of pyrophosphate that causes turbidity due to precipitations, which can be interpreted with naked eyes or by others means like agarose gel electrophoresis as well as by real-time monitoring in a relatively inexpensive turbidimeter. A DNA-binding dye can also be used to increase further the sensitivity of the assay or one can alternatively use a metal ion indicator like calcein or the coloring dye hydroxynaphthol blue (HNB) for product colorimetric detection without the need to run a gel.

LAMP assays can not only be used for detection of DNA but also can be used for detection of RNA which is known as RT-LAMP. LAMP assays can be carried on a microfluidic chip (microLAMP) or combined with lateral flow array (LFA-LAMP). Typical LAMP assays have been developed for a number of parasites including *Trypanosoma* species [71, 469, 470], Brugian filariasis [471], malaria [472–476]), *Wuchereria bancrofti* [477], and *Leishmania* [478–482]. Regarding resistance genotyping in parasites, few "home-made" LAMP assays have been developed [483], and some ready-to-use LAMP kits are available on the market, although none yet for parasite drug resistance genotyping.

Nanofluidics are being more and more used in POC assays as these technologies are compatible with inexpensive materials and fabrication methods. A European Union-funded public-private consortium, Nanomal (http://www.nanomal.org/), has developed a DNA testing microfluidic smartphone-like prototype device, the nanomal DNA analyzer. The first prototype is intended to quickly test a sample of blood (from a pinprick) for genetic markers of malaria. The assay is based on microfluidic PCR and nanowire sensing technology. The assay is able to identify in 10–15 min which species of malaria parasite is responsible for the infection and whether the parasite is resistant to antimalarial medications. To use it, a health professional would put a sample from a patient into a credit card-sized disposable cartridge and pop the cartridge into the device for analysis. Following a rapid mechanical lysis, the sample flows through a special filter that removes all non-nucleic acid blood constituents under 3 min. The purified DNA eluate then rehydrates lyophilized PCR reagents and is flowed through different temperature zones for rapid thermal cycling (30 cycles in less than 4 min). The amplicons then simply flow into the nanowire array channel. Detection happens when fragments of parasite DNA from the sample bind to complementary strands, or probes, in the cartridge. These probes are associated with nanowires. The binding produces an electrical change in the wires, which the device interprets as a positive result. The prototype device is currently known as Q-POC™ but is still not used in the clinic. The platform is battery powered and do not need special grade water.

A third interesting field of research for POC applications is paperfluidics also known as lab-on-paper. Lab-on-paper was introduced in 2007 [484, 485] and since the field has exploded as it represents an attractive platform for pathogen identification and drug resistance genotyping at very low cost. A number of elegant prototypes have been developed in the last few years [486]. Most of them were inspired from the convergence of fields such as nanotechnology, microfluidics, proteomics, and genomics. Several techniques can be used to create microchannels on paper chips, namely, photolithography, inkjet printing with polydimethylsiloxane (PDMS), the wax printing method, and hot roller embossing technique. These new paperfluidic assays would be valuable tools for routine screening of individuals for the presence of parasites and their resistance profiles in the near future.

9 Multiplex Resistance Testing in Parasite Coinfections

There are close to 150 countries where parasitic diseases are endemic, at least 100 of which are endemic for 2 or more diseases, and 30 countries that are endemic for 6 or more [487]. In areas where coinfections commonly occur, diagnostics should allow for testing related or multiple infections as well as multiple drug resistance profiles. Few assays have been optimized and commercialized to simultaneously detect several parasites and none of them offer drug resistance testing. One example of multiplex assays for pathogen identification is the VereTrop™, a molecular lab-on-chip device able to identify 13 different major tropical diseases, including the five pathogenic *Plasmodium* species, sleeping sickness, and Chagas disease from a single blood sample in less than 3 h (http://vereduslabs.com/products/clinical/veretrop/). The VereTrop™ chip is a PCR-microarray-based diagnostic test that needs to be processed on the portable VerePLEX™ Biosystem. The company claims that the Chip is customizable so there is a possibility to include SNPs linked with resistance, which are not included in the present format. Other multiplex assays include a multiplex real-time PCR assay for the detection in stool of eight gastrointestinal parasites [488], an assay allowing simultaneous detection of eight pathogenic parasites, and a number of bacteria causing gastroenteritis (Savyon Diagnostics and its proprietary NC400 NanoChip molecular electronic microarray, see http://www.savyondiagnostics.com/).

10 Promising Technologies in Parasite Diagnosis and Resistance Testing

The molecular diagnostics market is unquestionably the most rapidly growing segment of the in vitro diagnostics industry. The next 5 years should witness significant developments in nucleic acid amplification systems, automation, and miniaturization, as well as introduction of a wide range of new products facilitating product detection and drug resistance testing with an increased sensitivity. These promising technologies certainly represent the next generation of platforms for parasite diagnostics and drug resistance testing, and these will be briefly overviewed here.

10.1 Next-Generation Sequencing (NGS)

The DNA sequencing field has seen dramatic advances in recent years with companies reporting ever faster and cheaper sequencing methods collectively known as *next-generation sequencing (NGS)* methods. These NGS methods have different underlying biochemistries and different sequencing protocols, throughput, and sequence length output (reviewed in [489]). At present, sequencing-based approaches are the more expensive for drug resistance testing but represent one of the most powerful ways to screen a full genome (or transcriptome by RNAseq) for the detection of resistance genes and resistance determinants, even from unprocessed clinical specimens. Providing that a good genome coverage is obtained, mixed parasite genotypes and coinfections can also be easily detected in patient isolates. Current obstacles to a routine use of NSG technologies in diagnostic parasitology and resistance testing comprise the acquisition cost of the sequencer, scarcely available user-friendly bioinformatics platforms [490] and adequate computing resources (supercomputers). Indeed, the data analysis step is very time-consuming and requires a competent amount of manpower and expertise in bioinformatics. Nonetheless, NGS may revolutionize drug resistance testing on the long term, eventually replacing traditional culture-based approaches. Currently, NGS is successfully used in detection of antiviral drug resistance in clinical specimens [491, 492] but only rarely used in parasitology [493, 494]. In addition, the power and speed of NGS technologies in SNPs detection has recently prompted the CDC (Centers for Disease Control and Prevention) to develop NGS methods applied for the control and surveillance of the potential spread of artemisinin-resistant malaria parasites recently emerged in Southeast Asia (http://www.cdc.gov/amd/project-summaries/next-gen-malaria-methods.html). Their premise is that early identification of low levels of resistant parasites by NGS methods will make it easier and faster to choose the right drugs for treatment than the current practices allow, thus limiting the risk of spreading parasites resistant to artemisinin-based combination therapies to other regions. It is expected that the decrease of costs and improvement of turnaround time will lead to increase use of NGS for parasitological routine diagnostics.

10.2 DNA Pyrosequencing-Based Assays

Pyrosequencing provides a fast, inexpensive, and sensitive alternative to conventional resistance detection methods and can be easily adapted in a high-throughput format for molecular surveillance of drug resistance in human pathogens. Pyrosequencing [495] is a technology ideal for detecting SNPs and short-read sequencing. It is a flexible bioluminometric method which does not need labeled nucleotides or gel electrophoresis. In this technique an enzymatic cascade reaction is used to convert the inorganic pyrophosphate (PPi) released during the incorporation of deoxynucleotide triphosphate, into proportional amounts of visible light, which can then be measured. Interestingly, it has been reported that pyrosequencing assays can detect minor alleles down to a concentration as low as 5 % [496]. Recently, DNA pyrosequencing of PCR amplicons has been successfully applied for genotyping and species level identification of protozoan parasites [497–501] and nematodes [415, 502–504].

10.3 Luminex xMAP Technology

Co-occurring SNP mutations in resistance genes is challenging when using qPCR, multiplex PCR, or even pyrosequencing. In response to this challenge, the Luminex xMAP technology was developed which allows for simultaneous detection of multiple targets in a single reaction, e.g., up to 500 unique analytes within a single sample. In essence, the Luminex technology is a color-coded bead-based multiplex flow cytometric assay (http://www.luminexcorp.com/). Luminex beads, come into 500 distinct sets, each emitting unique fluorescent signals when excited by lasers. Each bead set can be coated with a reagent specific to a particular bioassay (e.g., antigens, antibodies, or oligonucleotides in the case of SNP detection), allowing the capture and detection of specific analytes from a sample. Within the Luminex compact analyzer, lasers excite the internal dyes that identify each microsphere particle, allowing target identification. Adapted to the study of parasites, the Luminex assay could either identify one particular organism, multiple organisms, or different genotypes (including drug resistance alleles) during the same reaction. The technology has been applied for parasitic diseases including malaria diagnosis [505] and intestinal parasites [506–508].

10.4 Oligonucleotide-Based DNA Microarrays

This methodology permits to rapidly and simultaneously identify a causative pathogen and generate its antimicrobial resistance profile based on its genome or transcriptome. Microarrays involve few up to several thousands of specific DNA sequences (probes) spotted in picomole amounts on any suitable surfaces. Hybridization of probes and target (e.g., the microbial DNA target) is usually detected and quantified via fluorophore labeling of the target sample. Most microarray imaging results are obtained by scanning of laser excitation coupled with photomultiplier tube light

detectors. At present, the DNA microarray technology is mostly used in the routine detection of antimicrobial resistance of TB, HIV, and influenza viruses [509–513] and has been used for *Leishmania* [514–516].

10.5 Minisequencing by Primer Extension Followed by Matrix-Assisted Laser Desorption/Ionization-Time of Flight (PEX-MALDI-TOF) and PCR-Electrospray Ionization Mass Spectrometry (PCR/ESI-MS)

PEX/MALDI-TOF is a method used to rapidly detect resistance, but for each reaction, a single-nucleotide polymorphism (SNP) can be detected. The technique requires a primer whose 3′-end is located directly at the site of the mutation to be detected. The extension reaction catalyzed by a polymerase is terminated in the case of a WT allele just after one nucleotide complementary to the mutated nucleotide and, in the case of a mutant, after two nucleotides by a dideoxynucleotide (ddNTP). Because of the molecular weight difference, mutant and WT alleles can be easily discriminated using MALDI-TOF. In contrast to *PEX-MALDI-TOF*, PCR/ESI-MS allows multiplexing that enables the parallel detection of a wide panel of resistant alleles or genes, as well as pathogen identification. As its name states, the technology combines broad-range PCR amplification with ESI-MS for the sensitive detection of amplicons by mass spectrometry. ESI-MS is used to determine the molecular mass of each amplicon, which is then used to calculate the base composition of each amplicon, and compared to an extensive database for pathogen and resistance SNPs identification. Another feature of the PCR/ESI-MS technology is that it allows a relative quantification of the microbe (and its resistance gene) present in the specimen. One current limitation of this technology is that there are still many gaps in our knowledge of the mechanisms and evolution of resistance in most parasites and the full panel of genes that control resistance to many drugs are not yet identified. The PCR/ESI-MS technology has been commercialized under the trade name PLEX-ID (www.abbott.com/).

10.6 Single Cell Mass Cytometry-Based Techniques

Mass cytometry is a recently developed technology platform that allows for high-content multiparametric analysis of single cells in complex biological systems [517]. Applications may include drug screening and drug susceptibility profiling studies, biomarker discovery, and time-course treatment analysis to name a few. Two important mass cytometric-based techniques were developed, namely, the fluorescent cellular barcoding (FCB) [518, 519] and mass-tag cellular barcoding (MCB) [520] methods. Both methods have the potential to impact the way drug resistance mechanisms are studied and assayed in cells. The first technique, FCB, uses fluorescent tags whereas the second one, MCB, uses metal isotope reporters. These techniques allow high throughput, minimize inter-sample variation, and reduce reagent consumption. Briefly in MCB, individual cell samples are labeled with a unique combination of mass tags before being combined into a single sample. The pooled samples is then stained with a single antibody mix and analyzed in one run on the mass cytometer. Roughly the same methodology stands for FCB. Measured cells are thereafter assigned to the corresponding source sample based on their unique "mass barcode" signatures. These two methods have been used in cancer cells studies but could be applied to a number of infectious diseases including parasites.

10.7 Aptamer-Based Multiplex Proteomics Assays

Aptamers are oligonucleic acids (ssDNA or RNA) that bind to a specific target. Oligonucleic acid aptamers are usually selected from a large random sequence pool through an in vitro iterative selection-amplification process called SELEX (standing for systematic evolution of ligands by exponential enrichment) [521, 522]. Similarly, peptide aptamers can be selected from combinatorial peptide libraries constructed by phage display and other surface display technologies such as mRNA display, ribosome display, bacterial display, and yeast display. Aptamers are attractive tools for multiple analytical and diagnostic applications. Recently, an emerging diagnostic technique based on aptamers called aptamer-based multiplex proteomics was reported [523, 524], commercialized by SomaLogic (http://www.somalogic.com/). This technology enables multi-biomarker protein measurements that can aid diagnostic distinction of disease versus healthy states or to predict treatment outcome [523]. For the moment, the technique has not been optimized to detect signatures from resistant versus sensitive pathogens, but the high specificity of aptamers emphasizes the feasibility of this type of assay, as recently demonstrated for drug-resistant HIV-1 [525] and MRSA [526]. In this context, the company Operational Technologies (OPTech) is working on a handheld aptamer-based-magnetic bead-quantum dot sensor for active and latent leishmaniasis [527] (see also http://www.sbir.gov/sbirsearch/detail/383773).

11 Conclusion

Drug resistance in parasites is inevitable, but the rate at which it develops is not. Increasing levels of pathogen resistance against available drugs aggravate the state of health worldwide, particularly in developing countries, where parasitic diseases are responsible for a high level of mortality and morbidity. Fighting parasites, especially resistant parasites, will require new and low-cost diagnostic tools as well as more sensitive and specific drug resistance assays, ideally POC assays. More research is needed into the mechanisms and genetics of resistance. Knowing the key players involved in resistance will certainly be the basis for more sensitive and accurate diagnostic tests, for the early detection of resistance, and will certainly accelerate the discovery of novel therapeutic targets to develop safer medicines.

Bacterial Genotypic Drug Resistance Assays

85

A. Huletsky and Michel G. Bergeron

1 Introduction

The rise in antimicrobial resistance has significantly reduced the effectiveness of current antibiotics in treating common infections. However, there have been no successful discoveries of novel antibiotics since 1987. During that period, hundreds of mechanisms of resistance have evolved to such an extreme level that the World Health Organization (WHO) has declared antibiotic resistance as a worldwide threat to human health [1]. In 2015, President Obama has released the *National Action Plan for Combating Antibiotic-Resistant Bacteria* (https://www.whitehouse.gov/sites/default/files/docs/national_action_plan_for_combating_antibotic-resistant_bacteria.pdf) and has offered a $20 million prize to facilitate the development of rapid, point-of-care diagnostic tests for healthcare providers to identify highly resistant bacterial infections.

These are dangerous times but also exciting as genomic technologies have evolved rapidly and will facilitate the development of tools to better diagnose antibiotic-resistant bacterial infections, evaluate the spread of resistance, and study its epidemiology. Practically speaking, hospital-acquired infections (HAIs), 70 % of which are caused by multidrug-resistant (MDR) organisms [2], are spreading rapidly so that our hospitals are no longer safe, killing more than 75,000 people each year in the United States [3] (http://www.cdc.gov/HAI/surveillance/). Some hospital-acquired MDR pathogens—the so-called superbugs—were recently named as the "ESKAPE" pathogens (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* spp.) to emphasize that they "escape" the effects of antibacterial agents [4–6]. Some strains of the ESKAPE pathogens group are not only MDR but also extensively drug resistant (XDR) or pandrug resistant (PDR) [5]. In the community, the prevalence of multidrug resistance in *Streptococcus pneumoniae* is increasing and includes resistance to ß-lactams (intermediate- and high-level resistance to penicillin and cross-resistance to cephalosporins), the macrolides, and, more recently, the fluoroquinolones [7–9]. Furthermore, virulent strains of MRSA that differ from the hospital strains, the so-called community-associated MRSA (CA-MRSA), have emerged in the communities and have now entered healthcare facilities causing HAIs [10, 11]. Another major public health problem is the increasing incidence of MDR *Mycobacterium tuberculosis* (MDR-TB) and the emergence of XDR *M. tuberculosis* (XDR-TB) [12–14].

Physicians practicing in both hospitals and the community must treat infections caused by multiresistant organisms, and new emerging antimicrobial resistances are becoming more complex to detect [15–17]. With the limited number of antimicrobial agents available to treat the infections caused by multidrug-resistant organisms, the need for rapid and reliable susceptibility testing methods or alternative resistance testing methods for detection of antimicrobial resistance becomes increasingly important. Conventional phenotypic culture-based susceptibility test results are usually obtained in 24–48 h or more after a bacterial culture has been isolated. Moreover, susceptibility tests are not always accurate to detect difficult-to-detect emerging antimicrobial resistance, and often more than one method is needed to obtain an accurate susceptibility profile. The lack of accurate and timely susceptibility data by the microbiology laboratory has consequences on antibiotic usage and prescription. Patients have to be treated empirically and often with broad-spectrum antibiotics which results in increased resistance rates and healthcare costs [18]. The advances in our understanding of the genetic mechanisms of antimicrobial resistance and the progress in sample preparation, nucleic acid-based amplification, and sensitive nucleic acid detection have allowed the development of genotypic methods for rapid detection of antimicrobial resistance. It is now possible

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_37

to identify a microorganism and its resistance to antimicrobial agents directly from clinical specimens in about 1 h [19, 20]. Some genotypic drug resistance assays are increasingly used in the clinical settings providing more accurate and rapid resistance testing.

This review describes the mechanism and the importance of this new plague and summarizes new rapid molecular diagnostic tests for the detection of antimicrobial resistance, some of which are having a great impact by allowing clinicians to intervene in real time (<1 h) not having to wait 2–3 days for the results of culture and susceptibility testing, this avoiding empirical treatment and the overuse of broad-spectrum antibiotics which is responsible, by disturbing the microbiota of patients, for the development of *C. difficile* infection and the spread of resistance. Microbes which have survived 4.2 billion years double their population in 20 min and are able to develop resistance very rapidly. Moreover, this resistance can be passed over to other pathogens through mobile genetic elements (plasmids, transposons, etc). The molecular diagnostic revolution has started in 2002 when our group has developed the first real-time PCR assay cleared by the FDA (IDI-Strep B, now BD GeneOhm StrepB from BD Diagnostics), a test that can be used to detect Group B *Streptococcus* in pregnant women during delivery [21]. In 2004, our second real-time PCR test (IDI-MRSA, now BD GeneOhm MRSA from BD Diagnostics) was the first molecular MRSA test cleared by the FDA for use directly on clinical specimens [19, 22].

Today, 10 years later, there are many molecular tests available and "the change in culture without culture" (using nucleic acid-based tests) [23] is occurring slowly but surely and hopefully will insure a better use of antibiotics and less empirical treatment. Rapid molecular tests at point of care are now also appearing and within the next 5–10 years will have great impact on clinical practices.

2 Mechanisms of Resistance to Antimicrobial Agents

Different strategies have been developed by bacteria to evade the action of the antimicrobial agents. In general, antimicrobial resistance results from:

(a) Production of enzymes that inactivate or destroy the antimicrobial agent or the target gene
(b) Acquisition of exogenous resistance genes that are not inhibited by the antimicrobial agent
(c) Reduced uptake of the antimicrobial agent
(d) Active efflux of the antimicrobial agent
(e) Overproduction, loss, or mutation of cellular target genes reducing the binding of the antimicrobial agent

Here are described the major resistance mechanisms for the important antimicrobial classes.

2.1 Resistance to Aminoglycosides

The aminoglycosides constitute a large family of antimicrobials that inhibit the translation process by binding to the bacterial 16S rRNA of the 30S ribosomal subunit. Five mechanisms of resistance to aminoglycosides have been described [24–26] including:

(a) Enzymatic inactivation by aminoglycoside-modifying enzymes (AMEs)
(b) Mutations in the ribosomal target site (*rrs* gene encoding 16S rRNA and *rpsL* gene encoding the S12 protein) that prevents binding
(c) Decreased cell membrane permeability
(d) Expulsion by efflux pumps
(e) Methylation of 16S rRNA target site

Inactivation by AMEs is the most important in terms of frequency and level of resistance [26]. Aminoglycosides are modified by three types of enzymes classified as: aminoglycoside phosphotransferases (APHs), aminoglycoside adenylases (ANTs), and aminoglycoside acetyltransferases (AACs). These enzymes covalently modify specific amino or hydroxyl groups, resulting in aminoglycosides that bind poorly to the target ribosomes. Within each class, there are enzymes with different specific sites of modification. More than 100 aminoglycoside-modifying enzymes have been described [26].

2.2 Resistance to β-Lactams

The β-lactams are a structurally diverse group of antimicrobials that interfere with the synthesis of the bacterial cell wall as a result of their interaction with penicillin-binding proteins (PBPs). Resistance to β-lactam antibiotics can be caused by four different mechanisms: (a) acquisition or hyperexpression of β-lactamases which is considered the most common resistance mechanism; (b) alteration, overexpression, or acquisition of PBPs; (c) permeability change in the outer membrane; and (d) active efflux of the antimicrobial [27, 28]. More than 1300 β-lactamases have been described to date [29]. β-Lactamases can be grouped on the basis of either their molecular structure or function. Four different molecular classes of β-lactamases have been defined based on the similarities in amino acid sequences. Class A, B, and C are serine β-lactamases, whereas class B are metallo-β-lactamases [30, 31].

2.3 Resistance to Glycopeptides

Glycopeptide antibiotics such as vancomycin and teicoplanin inhibit cell wall synthesis by binding to the terminal D-alanyl-D-alanine of the pentapeptide peptidoglycan precursor molecule. This binding prevents the cross-linking of peptidoglycan precursors necessary for the formation of cell wall. Acquired resistance to vancomycin in Gram-positive bacteria differs depending on the bacterial species where they have been described: (a) altered precursor formation in enterococci and staphylococci, (b) mutational cell wall changes in staphylococci, and (c) tolerance in *S. pneumoniae* [32–35]. To date, nine gene clusters conferring different glycopeptide resistance phenotypes have been described in enterococci; eight are acquired (*vanA*, *vanB*, *vanD*, *vanE*, *vanG*, *vanL*, *vanM*, and *vanN*), while the ninth (*vanC*) is usually intrinsic to *Enterococcus gallinarum* and *E. casseliflavus/flavescens* [32]. However, recent studies reported the presence of *vanC* genes in *E. faecalis* and *E. faecium* showing the ability of these genes to be transferred between bacteria [36–38]. The *vanA*, *vanB*, *vanD*, and *vanM* genes encode D-alanine-D-lactate ligases whereas the *vanC*, *vanE*, *vanG*, *vanL*, and *vanN* genes encode D-alanine-D-serine ligases. Bacterial species other than enterococci have been described to contain *van* genes [39–55]. The world's first isolate of *S. aureus* containing *vanA* (vancomycin-resistant *S. aureus* (VRSA)) was reported in June 2002 in the United States [39]. Nowadays, the number of VRSA isolates worldwide is still low [34, 56–58]. Recently, *S. aureus* isolates containing *vanB* and both *vanA* and *vanB* were described in India, Iran, and Sudan [57–59].

2.4 Resistance to Macrolides, Lincosamides, and Streptogramins

Macrolides, lincosamides, and streptogramins (A and B) inhibit protein synthesis by reversibly binding to the peptidyl-tRNA binding region of the 50S ribosomal subunit, stimulating dissociation of the peptidyl-tRNA molecule from the ribosome during elongation [60, 61]. Three different mechanisms of macrolide, lincosamide, and streptogramin resistance have been described:

(a) Alterations in the ribosomal target site by several different acquired erythromycin ribosomal methylases (*erm*) that methylate the same adenine residue in 23S rRNA or by mutations in chromosomal genes (e.g., *rrl* gene encoding 23S rRNA), resulting in resistance against macrolides, lincosamides, and streptogramin B antibiotics (MLS_B) (alteration in the target site has not been described for streptogramin A resistance)
(b) Active efflux of the antimicrobial (e.g., *mef*(A) conferring macrolide resistance, *vga*(A) conferring streptogramin A resistance, and *msr*(A) conferring both macrolide and streptogramin B resistance)
(c) Drug inactivation by several different enzymes including esterases (*ere*), phosphorylases (*mph*), lyases (*vgb*), and transferases (*vat*) [62, 63]

2.5 Resistance to Quinolones

Quinolones interact with two type II topoisomerases, DNA gyrase, and topoisomerase IV, both of which are essential for bacterial DNA replication. Inhibition appears to occur by interaction of the drug with complex composed of DNA and either of these two target enzymes. The GyrA and GyrB subunits of DNA gyrase are respectively homologues with ParC and ParE subunits of topoisomerase IV. Quinolone resistance results mostly from chromosomal mutations in the drug target and alterations of drug access to target enzymes, either by altered permeation mechanism or increased drug efflux [64, 65]. Low-level resistance may also be mediated by (a) plasmid-encoded Qnr proteins which protect DNA gyrase from quinolone action, (b) an aminoglycoside acetyltransferase encoded by the *aac(6′)-Ib-cr* that acetylates quinolones, and (c) plasmid-mediated quinolone efflux pumps encoded by *qepA* [65, 66].

2.6 Resistance to Trimethoprim and Sulfonamides

Trimethoprim and sulfonamides are inhibitors of two enzymes (dihydrofolate reductase [DHFR] and dihydropteroic acid synthase [DHPS], respectively) that act sequentially in the formation of tetrahydrofolate (THF). The most common mechanism of trimethoprim resistance is the acquisition of low-affinity *dhfr* genes, of which approximately 20 have been described [67]. Resistance to trimethoprim can also be conferred by promoter mutations, leading to overproduction of DHFR, point mutations within the *dhfr* genes, or both mechanisms. Resistance to sulfonamides can be caused by acquisition of different low-affinity *dhps* genes and by point mutations in chromosomal *dhps* genes [67].

2.7 Resistance to Tetracyclines

The tetracyclines are a group of bacteriostatic antibiotics that act by binding reversibly to the 16S rRNA near the ribosomal acceptor A site, inhibiting the attachment of aminoacyl-tRNA to this site, thereby preventing the elongation step of protein

synthesis [68]. Tetracycline resistance is caused by four mechanisms: (a) active efflux which keeps tetracycline out of the cytoplasm, (b) ribosomal protection which prevents tetracycline from binding to the ribosome, (c) inactivation of the tetracycline molecules, and (d) rRNA mutations which prevents tetracycline from binding to the ribosome [68, 69].

2.8 Resistance to Chloramphenicol

Chloramphenicol binds to the 50S ribosomal subunit and inhibits prokaryotic peptidyl transferase. The most common mechanism of resistance to chloramphenicol is the production of chloramphenicol acetyltransferases (CATs) which inactivate the antibiotic. A large number of CAT genes have been reported, and these determinants generally confer high levels of resistance to chloramphenicol [70]. Resistance to chloramphenicol can also be caused by target site mutations, permeability barriers, phosphotransferase inactivation, and active efflux [71].

2.9 Resistance to Linezolid

Linezolid, an oxazolidinone antimicrobial, inhibits bacterial protein synthesis by binding to the domain V region of the 23S rRNA [72]. Resistance to linezolid is principally mediated by mutations in the central region of domain V of one or more alleles of the *rrl* gene encoding 23S rRNA [73]. Mutations in the *rplC* and *rplD* genes encoding the riboproteins L3 and L4, respectively, as well as methylation of the 23S rRNA base A2503, have also been described [73].

2.10 Resistance to Rifampin

Rifampin acts by binding to the beta subunit of the bacterial DNA-dependent RNA polymerase encoded by the *rpoB* gene resulting in transcription inhibition [74]. Resistance to rifampin is conferred by chromosomal mutations or short deletions and insertions in the central region of the *rpoB* gene [75].

2.11 Resistance to Isoniazid

Isoniazid is a synthetic antimicrobial agent used for the treatment of infections caused by *M. tuberculosis* complex. The precise mechanism of action is still unclear but the target seems to be inhibition of mycolic acid synthesis [76, 77]. Resistance to isoniazid may result from mutations in six different genes:

(a) The *katG* gene encoding a catalase-peroxidase
(b) The *inhA* gene encoding an enoyl reductase and its promoter
(c) The *ahpC* gene encoding an alkyl hydroperoxide reductase subunit and its promoter
(d) The *kasA* gene encoding a β-ketoacyl-acyl-carrier-protein synthase
(e) The *ndh* gene encoding a NAD dehydrogenase
(f) The *nat* gene encoding an arylamine N-acetyltransferase [75, 77–79]

2.12 Resistance to Ethambutol

Ethambutol is a synthetic antituberculosis agent. This compound alters outer mycobacterial membrane formation by inhibiting the synthesis of arabinogalactan [74, 80]. Resistance to ethambutol often results from mutations in the *embB* encoding the arabinosyltransferase [81].

2.13 Resistance to Pyrazinamide

Pyrazinamide, the pyrazine analog of nicotinamide, is a prodrug for *M. tuberculosis*, which requires conversion to the active pyrazinoic acid by the bacterial pyrazinamidase. Resistance to pyrazinamide is usually caused by mutations in the *pncA* gene encoding the pyrazinamidase or in the putative regulatory region upstream of the gene [82].

3 Methods to Detect Resistance

The clinical microbiology laboratory has the responsibility to provide reliable, accurate, and susceptibility data of significant bacterial isolates in a time frame that is useful to the clinicians to prescribe the most appropriate antimicrobial agent (least expensive and/or narrower spectrum) for a particular infection and, when possible, to reduce the development of resistance. Determining the antimicrobial susceptibility profile of a pathogen is considered as important as the identification of the pathogen involved in the infection. This is becoming even more essential with the increasing antimicrobial resistance in which treatment options are more limited. The antimicrobial susceptibility of a clinical isolate measured by conventional phenotypic susceptibility methods is presently the parameter provided to clinicians. However, an isolate which is defined as sensitive to an antimicrobial agent is not always treated with success, but most resistant isolates result in treatment failure. Therefore, it is important to develop methods that will allow detection of resistance mechanisms and to better understand which resistance mechanisms are the most difficult to detect

[83]. During the past years, optimization of conventional susceptibility tests and development of novel phenotypic methods for resistance mechanisms that are difficult to detect have been carried out [84, 85]. Moreover, several innovative phenotypic methods for antimicrobial susceptibility testing, such as matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF MS), could provide valuable novel options in the near future [86, 87]. As alternative or complement to these phenotypic methods, several genotypic drug resistance assays have been developed and are increasingly used in the clinical microbiology laboratory offering rapid, accurate, and sensitive methods to detect the presence of antimicrobial resistance [16, 86, 88, 89].

3.1 Phenotypic Assays/Susceptibility Tests (Culture)

Conventional culture-based susceptibility methods measure the in vitro phenotypic expression of resistance which can be interpreted quantitatively as the minimum inhibitory concentration (MIC) or interpreted qualitatively as sensitive, intermediate, or resistant. MIC is defined as the lowest concentration of an antimicrobial agent that inhibits the visible growth of an organism over a defined interval. Several methods for routine antimicrobial susceptibility testing are used in the clinical microbiology laboratory [90]. The phenotypic resistance can be quantitatively reported as the MIC for dilution methods (broth and agar dilution) and antibiotic gradient diffusion (e.g., Etest) or may be expressed qualitatively with disk diffusion method (e.g., Bauer-Kirby disk diffusion). Broth microdilution methods have been adapted to automated instrument-based systems facilitating the reading and interpretation of results. These instruments can provide species identification and/or antibiotic susceptibility results within 24–48 h. The most common systems currently available include the Microscan WalkAway system (Siemens Healthcare Diagnostics), the Vitek 2 system (bioMérieux), the BD Phoenix system (BD Diagnostics), and the Sensititre system (TREK Diagnostic Systems). Detailed descriptions as well as advantages and limitations of these systems can be found in recent reviews [91, 92].

Regardless of the microorganism and antibiotic tested as well as the method used, the results obtained by in vitro antibiotic susceptibility testing can vary greatly depending on the culture medium, inoculum concentration of the organism tested, and the conditions of incubation (duration, temperature, and atmosphere). The Clinical and Laboratory Standards Institute (CLSI, formerly NCCLS) [93–96] (clsi.org) and the European Committee on Antimicrobial Susceptibility (EUCAST) [97] (eucast.org) are the major bodies which contribute to antimicrobial susceptibility testing providing up-to-date guidelines on methodologies and standardized control procedures to ensure accuracy and reproducibility within and between laboratories [98]. Different national standardized methods may also be used including those published by the British Society for Antimicrobial Chemotherapy (BSAC) in the United Kingdom and equivalents in other countries [98, 99].

3.1.1 Clinical Significance of Breakpoints

The goal of antimicrobial susceptibility testing is to predict the clinical outcome by classifying a bacterial strain into clinically relevant categories (i.e., susceptible, intermediate, or resistant) on the basis of established breakpoints based on MIC. A breakpoint for an antibiotic is usually selected as the therapeutic concentration in blood that can be readily achieved with usual dosing regimens, but this is not easily determined. Several factors must be taken in consideration in establishing MIC breakpoints such as MIC distributions, pharmacokinetics and pharmacodynamics, clinical and bacteriological response rates, and zone diameter distributions for disk diffusion methods [100]. Breakpoints must be periodically reevaluated following change in bacterial resistance, susceptibility test methods, or antibiotic regimens. Determination of MIC is influenced in vitro by a number of variables such as the composition of the test medium, the inoculum size, the incubation time, and the presence of resistant subpopulations of the organisms. Moreover, the condition tested in vitro for determining MIC cannot mimic other factors that can influence the in vivo antimicrobial activity including sub-MIC effects, postantibiotic effects, protein binding, variations in redox potential at sites of infection, and differences in drug levels in blood and at the site of infection [100]. Nevertheless, when the MIC is determined under standardized condition, it provides a convenient reference point for the setting of breakpoints to predict the efficacy in vivo.

The interpretative breakpoints assigned to an antimicrobial agent can have a significant impact on the prescribing of that drug for empiric therapy by influencing the resistance rates measured at the local, regional, national, or international level [101]. In North America, the CLSI has the responsibility to establish breakpoints. However, different countries have defined different breakpoints to define resistance [98] (see Sect. 3.1). This difference may be related to different dosages or administration intervals or can result from technical aspects such as different susceptibility test media and test conditions [102]. Moreover, some countries may be more or less conservative in determining susceptibility. Therefore, it is sometimes confusing to compare resistance rates among countries if different methods have been used. In Europe, MIC breakpoints have been harmonized by EUCAST. However, there is an urgent need that susceptibility methods and MIC breakpoints be harmonized at the international level [98, 103].

3.2 Special Phenotypic Susceptibility Methods

Conventional susceptibility testing methods or automated systems are not reliable for certain fastidious organisms or organisms with difficult-to-detect resistance mechanisms. Fastidious organisms (e.g., *Mycobacterium* species, *Streptococcus* species including *S. pneumoniae*, *Haemophilus* species, *N. gonorrhoeae*, and anaerobic bacteria) require special growth media and conditions, and certain organisms with inducible resistance or subtle change in MICs (at or near the breakpoint) (e.g., methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci (VRE), vancomycin-intermediate *S. aureus* (VISA), as well as carbapenemase-producing *Enterobacteriaceae* (CPE)) require special phenotypic testing methods for detection of antimicrobial resistance. A complete description of susceptibility test methods used for these fastidious organisms and difficult-to-detect resistance mechanisms can be found in recent reviews [77, 84, 104, 105]. Some examples of phenotypic methods used for difficult-to-detect resistance are further described.

3.2.1 Detection of Oxacillin Resistance in Staphylococci

Oxacillin resistance in *S. aureus* results from at least three different resistance mechanisms:

(a) Acquisition of a mobile genetic element, the staphylococcal cassette chromosome (SCC*mec*) carrying the *mecA* gene which encodes an altered PBP—PBP2a/PBP2′—which has reduced affinity for β-lactam antibiotics (a new *mecA* homologue named *mecC* (originally $mecA_{LGA251}$), has been recently described [106–108].
(b) Inactivation of the drug by increased production of ß-lactamase which results in low-level or borderline resistance (BORSA).
(c) Production of modified intrinsic PBPs (MOD-SA) with altered affinity for the drug which also results in borderline resistance [84, 109, 110].

It is important to differentiate isolates that have *mecA*- and *mecC*-positive resistance from isolates that have the two other types of resistance because *mecA* and *mecC* genes confer resistance to all ß-lactams. Moreover, isolates carrying *mecA* are also usually multidrug resistant which is not the case for the two other types of resistance and for *mecC* isolates [108]. Although the majority of MRSA isolates are susceptible to the novel anti-MRSA extended-spectrum cephalosporin ceftaroline that has been approved recently in the United States and elsewhere in the world [111], some *S. aureus* isolates resistant to this new drug were recently described [112–114]. Moreover, some new emerging community-associated *mecA*-positive MRSA strains (named CA-MRSA) are usually susceptible to non-β-lactam antibiotics [115].

Some isolates carrying *mecA* are either homogeneous or heterogeneous in their expression of resistance. Contrary to isolates with homogeneous resistance, heterogeneous resistance results in MICs that appear to be borderline and can be confused with BORSA or MOD-SA isolates for which MICs are also borderline. To detect heterogeneous subpopulation, conventional susceptibility test with oxacillin requires special media, incubation temperature, and time. Moreover, some rare MRSA strains are inducibly resistant and need specific procedures to be detected [111]. BORSA resistance can usually be distinguished from *mecA* resistance by the addition of a ß-lactamase inhibitor (e.g., clavulanic acid) to the oxacillin MIC test, which lowers the MIC by two dilutions or more [84]. During the past years, cefoxitin has been shown to be more sensitive than oxacillin for detection of isolates containing *mecA* and is now widely used to predict *mecA*-mediated oxacillin resistance as a surrogate for oxacillin in MIC and disk diffusion methods [84, 93]. Moreover, cefoxitin is more reliable than oxacillin to detect *mecC* MRSA [116]. However, this test does not detect BORSA and MOD-SA isolates [84]. Therefore, both CLSI and EUCAST recommend testing both oxacillin and cefoxitin to detect all possible oxacillin resistance mechanisms [111].

Other commercially available methods are widely used in the clinical microbiology laboratory for rapid confirmation of oxacillin resistance in *S. aureus* isolates such as latex agglutination tests that detect the presence of PBP 2a in about 15–20 min including the MRSA-Screen test (Denka Seiken Co., Ltd.), the PBP 2′ latex agglutination test (Oxoid Limited), the Mastalex-MRSA test (Mast Diagnostics), and the Slidex MRSA detection test (bioMérieux) [84]. However, these methods do not detect isolates containing *mecC* [106]. The automated instruments described in Sect. 3.1 for bacterial identification and susceptibility testing have been improved during the past years and can now identify MRSA isolates reliably.

Rapid and accurate identification of MRSA isolates is essential not only for patient care but also for effective infection control programs to limit the transmission of MRSA [117–122]. Active surveillance for identification of MRSA carriers, either targeted or universal, is one of the most common and effective measure to prevent the spread of MRSA in healthcare facilities [2, 118, 123, 124]. However, culture-based methods for identification of *S. aureus* combined with susceptibility testing, as described above, usually requires at least 48 h. In recent years, several commercial chromogenic media containing a selective antibiotic (e.g., cefoxitin) have been developed (e.g., BBL-CHROMagar MRSA from BD Diagnostics, CHROMagar MRSA from CHROMagar Microbiology, Brilliance MRSA agar from Oxoid,

MRSA*Select* from Bio-Rad, and ChromID MRSA from bioMérieux) allowing direct colony identification of MRSA from the primary screening culture, obviating the need for subculture, and reducing the time to results to 20–26 h. The performance of these different media has been evaluated in several studies and is described in recent reviews [111, 121, 125, 126]. Sensitivity and specificity of these media are highly variable. A prolonged incubation time of 48 h or a selective enrichment broth prior to inoculation of the sample to these chromogenic media has been shown to improve sensitivity but increasing time for MRSA detection.

3.2.2 Detection of Vancomycin Resistance in Enterococci and Staphylococci

Among the nine glycopeptide resistance phenotypes described to date in enterococci [32] (see Sect. 2.3), three are most commonly found in the clinical settings: (a) high-level vancomycin resistance with teicoplanin resistance (VanA phenotype); (b) moderate- to high-level vancomycin resistance, usually without teicoplanin resistance (VanB phenotype); and (c) intrinsic low-level resistance associated with *E. gallinarum* and *E. casseliflavus/flavescens* (VanC phenotype) [84]. In the past, standard culture-based methods (especially disk diffusion) and automated systems commonly used in clinical laboratories sometimes failed to detect low-level vancomycin resistance (VanB and VanC phenotypes) in certain enterococcal strains. However, some automated systems such as the Vitek 2 (bioMérieux) and BD Phoenix (BD Diagnostics) systems have now been enhanced, and new recommendations have been added by the CLSI to improve vancomycin disk diffusion method [35, 84]. The use of the vancomycin agar screening test is recommended by the CLSI to detect low-level vancomycin resistance in enterococci [93]. However for an infection control perspective, it is important to distinguish the *vanC*-containing enterococcal species that can grow on the agar screening plate from the clinically important vancomycin-resistant enterococci (VRE), which include *E. faecalis* and *E. faecium* [93] (see Sect. 3.3.3). Special phenotypic tests are needed to differentiate these enterococcal species [84].

Active screening of VRE using rectal/perirectal specimen or stool specimen to detect carriage in at-risk patients has been shown to contribute to reducing VRE colonization, infections, and healthcare costs [127, 128]. Several selective agar media are commercially available (e.g., *Brilliance* VRE agar from Oxoid, chromID VRE from bioMérieux, CHROMagar VRE from CHROMagar Microbiology, and VRE*Select* from Bio-Rad) for VRE screening and have been shown to reduce time to identify VRE carriage. The performance of these selective media for detecting VRE has been evaluated in several studies [129–133]. While most agar media demonstrated excellent specificity, the sensitivity of these media (especially when assessed at 24 h versus 48 h) was suboptimal for detecting *vanB*-VRE with low vancomycin MICs.

Three types of vancomycin resistance phenotypes have been described in *S. aureus*: (1) vancomycin-intermediate resistant (VISA), (2) heterogeneous VISA, and (3) vancomycin resistant (VRSA) [33]. Whereas resistance to vancomycin in VRSA usually results from acquisition of the *vanA* gene (see Sect. 2.3), diverse mutations in a small number of staphylococcal chromosomal regulatory genes have been associated with VISA and hVISA, resulting in changes in cell wall volume and composition. The cell wall of these strains is usually thickened and is thought to prevent the diffusion of vancomycin to its active site in the cytoplasmic membrane in the division septum [33]. VRSA strains can be detected accurately with standard disk diffusion and broth microdilution methods as well as with the vancomycin agar screening test used to detect VRE and most commercial methods. However, detection of VISA strains is reliably detected only with the broth microdilution method [84]. Recently, some *S. aureus* isolates containing *vanA* or *vanB* with vancomycin-intermediate resistance or vancomycin-susceptible phenotype have been reported [57, 134].

3.2.3 Detection of Carbapenemase Producers in Gram-Negative Bacteria

Resistance to carbapenems in Gram-negative bacteria mainly results from the acquisition of carbapenemase-encoding genes, although other resistance mechanisms may be involved such as decreased permeability of the outer membrane due to porin alteration or high efflux pump activity [135]. Carbapenemases are β-lactamases being able to hydrolyze carbapenems (imipenem, ertapenem, meropenem, and doripenem) and most other β-lactams and are located on mobile genetic elements carrying many other resistance determinants, thus giving rise to transmissible multidrug resistance and even pandrug resistance and limiting the choice of antibiotic treatment [136]. Carbapenemases belong to three classes of β-lactamase, namely, class A (e.g., KPC type), class B or metallo-β-lactamases (MBLs) (e.g., IMP, NDM, and VIM types), and class D (e.g., OXA-48 type), each class harboring specific hydrolytic properties against β-lactams [135, 137]. Carbapenemase-producing Gram-negative bacteria (CPGN), mainly *Enterobacteriaceae*, *P. aeruginosa*, and *A. baumannii*, are associated with increased mortality and have become a major concern worldwide [138–141]. The high rate of transmissibility of plasmid-encoded carbapenemase genes and their association with multiple antibiotic resistance determinants explain the need for detection of carbapenemase producers both for selecting the appropriate therapy and implementing effective infection control measures [142].

Detection of carbapenemases is usually performed on isolates which are resistant to carbapenem based on MIC

breakpoints [143]. However, carbapenem resistance in Gram-negative bacteria can usually be detected reliably only based on susceptibility testing results obtained with standard broth microdilution and disk diffusion methods since automated antimicrobial testing systems or gradient diffusion technologies such as the Etest have shown poor performance [144]. Nevertheless, some carbapenemase producers with MICs for carbapenems lower than the established CLSI breakpoints may not be detected, especially OXA-48-type producers [136]. It has recently been proposed that a search for carbapenemase production should be performed on any enterobacterial isolate that exhibits even a slight decrease in susceptibility to carbapenems compared with a wild-type phenotype [136].

Several phenotypic methods can be used to confirm carbapenemase activity. The CLSI recommends the modified Hodge test (MHT) to screen for production of carbapenemases in *Enterobacteriaceae* [93]. However, some isolates producing AmpC-type β-lactamases or ESBL coupled to porin loss can give false positive, and a lack of sensitivity has been reported for detection of class B carbapenemases [136, 144]. Other tests can also be performed to identify carbapenemase producers with molecules inhibiting carbapenemases and/or other types of β-lactamases using double-disk synergy and combined-disk methods [136, 144, 145]. Combination-disk tests based on the specific inhibition properties of the different carbapenemases are commercially available (e.g., KPC/MBL and OXA-48 Confirm Kit from Rosco Diagnostica and Carbapenemase Detection Kit from Mast Diagnostics). The sensitivity and specificity of these methods are highly variable depending on the carbapenemases detected [136, 143–147].

Recently, Nordmann et al. described a new rapid (<2 h) chromogenic carbapenemase detection assay based on hydrolysis of the β-lactam ring of imipenem, the Carba NP test [148–150]. This assay has been validated in several studies for detection of carbapenemase producers among *Enterobacteriaceae*, *Pseudomonas* spp., and *Acinetobacter* spp. Reported sensitivities varied between 78.9 and 100 %, whereas specificity was generally reported to be 100 % [148–155]. Two commercial versions of this test are now available (RAPIDEC CARBA NP from bioMérieux and Rapid CARB Screen Kit from Rosco Diagnostica). The performance of the Rapid CARB Screen Kit has been recently evaluated for detection of carbapenemase producers in *Enterobacteriaceae* and *P. aeruginosa* and was shown to perform less well than the Carba NP test [156].

Recently, several studies have reported methods to identify carbapenemase activity with Gram-negative bacterial isolates using MALDI-TOF-MS which detect hydrolysis of the carbapenem ring [145]. MALDI-TOF-MS has also been evaluated to detect cabapenemase activity directly from positive blood cultures [157]. These methods appear to be simple, rapid, and reliable to identify carbapenemases.

To cope with the increasing emergence and high transmission potential of carbapenemase producers, screening of stools or rectal swabs is recommended by the Centers for Disease Control and Prevention to identify carriers of carbapenemase-producing *Enterobacteriaceae* (CPE) and initiate appropriate infection control measures [158]. To screen for CPE carriers, the stools or rectal swabs are usually plated on selective media containing carbapenems [159, 160]. Selective chromogenic culture media are commercially available (e.g., Brilliance CRE from Oxoid, CHROMagar KPC from CHROMagar, and chromID Carba from bioMérieux) for detection of carbapenemase producers. The performance of these culture media has been evaluated in several studies which are described in recent reviews [136, 144, 145, 161]. These media showed variable specificity, and their sensitivity depends on the MICs of the carbapenemase-producing isolates. Carbapenemase producers growing on selective culture media should be confirmed by susceptibility testing and carbapenemase activity by the methods described above.

3.3 Genotypic Assays

Phenotypic methods for susceptibility testing are usually simple, and automated systems have greatly facilitated the susceptibility testing procedures and data analysis [91, 92]. Even though incubation time to obtain susceptibility data is reduced to 3–5 h with some automated systems or shorter (15–20 min) with special susceptibility tests (e.g., MRSA-Screen test) (see Sect. 3.2.1), all the phenotypic susceptibility methods require bacterial isolation, and hence the results are not available until 24 h or more after a treatment is started. Several of the presently performed susceptibility tests are highly dependent on experimental conditions, and special phenotypic tests must often be performed to obtain an accurate susceptibility profile. Moreover, there is presently no international agreement on susceptibility methods and interpretation of breakpoints in antimicrobial susceptibility testing (see Sects. 3.1 and 3.1.1).

There are several advantages of using genotypic methods for resistance testing compared to conventional susceptibility methods [86, 88, 162]:

(a) Detection of resistance genes is more accurate for detection of isolates with difficult-to-detect resistance profiles (MICs at or near the breakpoint or inducible resistance) since it does not depend on the variable gene expression under laboratory conditions [85].
(b) Genotypic tests can provide resistance profiles rapidly (less than 1 h with some molecular methods) since they

can be performed directly from clinical specimens; this is particularly important not only for organisms that cannot be cultured and are not easily cultured or for slow-growing organisms but also to choose the most appropriate therapy early in the course of disease before cultures are positive.

(c) Genotypic tests may diminish the biohazard risk associated with the propagation of a microorganism by culture.

(d) Genotypic tests are a powerful tool for epidemiological study of antimicrobial resistance in a hospital or the community by providing an immediate insight into the genetic mechanism underlying the resistance phenotype.

(e) Genotypic tests can be used as a gold standard for evaluating new improved susceptibility methods for testing clinical isolates with difficult-to-detect resistance profiles.

With the progress in the understanding of antimicrobial resistance mechanisms and the increasing number of resistance gene sequences available in public databases [163], several genotypic assays have been developed for detection of bacterial genes and mutations associated with resistance. Some reviews provided more details on several genotypic resistance assays [16, 86, 88, 89, 164–166]. Table 85.1 shows the most common antibiotic resistance genes for which genotypic resistance assays have been developed. For the majority of these genes, the genotypic resistance assays developed to date are in-house tests that have not been necessary validated through a thorough process by clinical microbiology laboratories. However, guidelines which described validation of laboratory-developed tests have been published by the CLSI [167]. Moreover, the number of commercially available kits which are Food and Drug Administration (FDA)-cleared and/or European Community (CE)-marked (Table 85.2) as well as analyte-specific reagents (ASRs) has considerably increased in recent years and has facilitated the use of these technologies. Nevertheless, ASRs still need to be optimized and validated by the users in the clinical microbiology laboratories under the Clinical Laboratory improvement Amendments (CLIA) [168], making it more and more difficult for laboratories to use ASRs [88].

Genotypic resistance assays usually target a nucleic acid sequence containing a part of, or the entire resistance gene, or the mutations associated with resistance which can be detected by DNA probe techniques or amplification technologies. However, non-amplified probe technologies are not sensitive enough to detect the small number of bacterial cells found in most clinical specimens and are therefore limited for direct detection of pathogens in specimens in which the number of organisms is large. For example, the *mecA Xpress*FISH (AdvanDX), a fluorescence in situ hybridization (FISH) assay using PNA probes, detects *mecA* from positive blood cultures [169]. Amplification techniques used for genotypic testing comprise:

1. Nucleic acid target amplification [e.g., polymerase chain reaction (PCR) including reverse transcriptase PCR (RT-PCR), nested PCR, multiplex PCR, real-time PCR, and digital PCR, as well as several isothermal amplification methods such as strand displacement amplification (SDA), self-sustaining sequence replication, transcription-mediated amplification (TMA), nucleic acid sequence-based amplification (NASBA), helicase-dependent amplification (HAD), loop-mediated isothermal amplification (LAMP), and recombinase polymerase amplification (RPA)]
2. Probe amplification (e.g., ligase chain reaction, cycling probe technology, and cleavase-invader technology)
3. Signal amplification (e.g., signal-mediated amplification of RNA technology (SMART) and branched DNA (bDNA) assay) [165, 170, 171]

The amplification product or amplicon can be detected following amplification by different methods; the most common are hybridization arrays, line probe assays, gel and capillary electrophoresis methods, colorimetric microtiter plate systems, restriction fragment length polymorphism (RFLP) analysis, DNA sequencing, or mass spectrometry. A comprehensive description of these technologies is provided in recent reviews [170–172].

PCR amplification is the most commonly used nucleic acid amplification technique for the detection of antimicrobial resistance genes. However, the combination of PCR amplification with post-PCR amplicon detection have found limited acceptance for diagnostic laboratory testing due to the time-consuming nature of these post-PCR detection approaches and the problem of carry-over contaminations [173]. Real-time PCR is the most widely used technology for genotypic resistance testing in routine microbiology laboratories because this closed-tube amplification process, which is monitored in real time by using fluorescence techniques, is fast due to ultrarapid thermal cycling and easy to perform, while the risk of carry-over is minimized [174]. A variety of in-house or commercial real-time PCR assays have been developed for detection of antibiotic resistance genes and mutations (Tables 85.1 and 85.2). Real-time multiplex PCR can be used when there is a need to detect several bacterial species and/or antimicrobial resistance genes. However, real-time multiplex PCR is limited by the number of genetic targets that can be simultaneously detected because of the restricted number of fluorophores that can be discriminated by the optical detection systems. To detect a broader range of microbes and antimicrobial resistance genes present in some

Table 85.1 Common bacterial drug resistance genes detected by genotypic methods

clinical samples, multiparametric technologies are needed. Comprehensive reviews of such technologies have recently been published [16, 175, 176].

Array technologies represent one of the most powerful multidetection technologies, having the capacity to identify multiple targets, up to thousands, depending on the system [176–178]. However, because of the poor analytical sensitivities of array technologies, most of them include PCR amplification prior to array detection. Several in-house DNA probe arrays combined or not with PCR amplification have been developed to detect multiple antibiotic resistance genes and mutations [179–205] (Table 85.1). Different types of array technologies are also commercially available and increasingly used in the clinical microbiology laboratories including low-density PCR arrays such as the FilmArray technology (bioMérieux), liquid bead arrays such as the xTAG technology (Luminex), DNA microarrays such as the Check MDR technology (Check-Points) and the Verigene technology (Nanosphere), and line probe arrays such as the DNA strip technology (Hain Lifescience), some of which detect both antibiotic resistance genes and bacterial species whereas others also detect virulence genes (Table 85.2). Most commercial array technologies used PCR amplification prior to array detection, especially for detection of bacterial and drug resistance targets directly from clinical specimens. However, the potential of amplicon carry-over contamination of two-step non-integrated PCR/array technologies has pushed the development of new systems in which PCR amplification and multidetection on arrays are performed in a closed system (e.g., FilmArray Blood Culture Identification Panel from bioMérieux). The Verigene Gram-Positive (BC-GP) and Gram-Negative (BC-GN) Blood Culture Nucleic Acid tests from Nanosphere allow direct detection on DNA microarrays of bacterial and drug resistance targets from positive blood cultures without amplification by using a sensitive gold nanoparticle probe-based hybridization technology [206]. Though, the lack of prior amplification is possible because of the large bacterial load in positive blood cultures.

In the next section, some genotypic resistance assays that are increasingly used in the clinical microbiology laboratories are further described.

3.3.1 Genotypic Detection of Drug-Resistant *Mycobacterium tuberculosis*

The increasing rates of MDR-TB (resistance to rifampin and isoniazid) and the emergence of XDR-TB (MDR plus additional resistance to fluoroquinolones and at least one of the injectable drugs amikacin, kanamycin, or capreomycin) is a serious global health problem causing an important rise in morbidity and mortality [12–14]. The rapid identification of MDR-TB and XDR-TB is essential to improve TB treatment, prevention, and control [207]. However, because *M. tuberculosis* is slow growing, identification and determination of the susceptibility profile of this organism can take several weeks. In the last few years, broth-based methods,

either manual or fully automated, have allowed to accelerate the culture of mycobacteria and the availability of antibiogram. Nevertheless, culture-based drug susceptibility testing (CDST) methods may still take few weeks after the primary culture results are available. Reviews of susceptibility methods for mycobacteria were recently published [77, 208].

Advances in our understanding of the genetic mechanisms of drug resistance in *M. tuberculosis* have made possible the development of several different rapid genotypic drug resistance assays. Recent reviews describing these assays have been published [25, 89, 209, 210] (see Sect. 2). Most molecular methods for detecting resistance are based on determining the presence/absence of the mutations associated with resistance (Table 85.1). Comprehensive databases of mutations associated with antibiotic resistance in *M. tuberculosis* are available providing access to up-to-date information on mutations [211–213]. A few years ago, genotypic assays were mostly developed for detection of rifampin resistance because the genetic basis of rifampin resistance in *M. tuberculosis* is simple and well characterized, being caused by specific mutations in the *rpoB* gene in more than 95 % of rifampin-resistant TB [75] (see Sect. 2). Moreover, resistance to rifampin can often be used as a marker of MDR-TB since more than 90 % of rifampin-resistant TB are also resistant to isoniazid [75]. However, in the past few years, in-house molecular methods have been developed to detect mutations in most known target genes conferring resistance to rifampin (*rpoB*), isoniazid (*katG*, *inhA*, *ndh*, *kasA*, as well as *inhA* and *ahpC* promoters), ethambutol (*embB*), pyrazinamide (*pncA*), fluoroquinolones (*gyrA* and *gyrB*), streptomycin (*rrs* and *rpsL*), amikacin/kanamycin (*rrs*), kanamycin (*eis* and *eis* promoter), and capreomycin (*rrs and tlyA*) (Table 85.1) (see Sect. 2). Several molecular methods have been used to detect these mutations including Sanger sequencing, pyrosequencing, whole-genome sequencing (WGS), PCR-single-strand conformation polymorphism (PCR-SSCP), PCR-restriction fragment length polymorphism (PCR-RFLP), PCR hetero-duplex formation (PCR HDF), multiplex allele-specific PCR (MAS-PCR), real-time PCR using different types of fluorescent probes, LAMP, and hybridization on strips and on microarrays; and most of these methods have been described in recent reviews [25, 172, 209, 214–216].

Three molecular assays, namely, GenoType MTBDR*plus* and GenoType MTBDR*sl* (Hain Lifescience) and GeneXpert MTB/Rif (Cepheid) are commercially available for detection of TB drug resistance directly from specimens, concentrated specimens, and cultures (Table 85.2). The INNO-LIPA rif. TB assay (Fujirebio) that has been widely used in the past is now discontinued. GenoType MTBDR*plus* and GenoType MTBDR*sl* are line probe assays based on a multiplex amplification in combination with reverse hybridization to identify either wild-type sequence or specific mutations, whereas the GeneXpert MTB/Rif assay is a nested real-time PCR assay which uses molecular beacon probes to detect mutations. GeneXpert MTB/Rif assay detects *M. tuberculosis* complex (MTBC) and rifampicin resistance (*rpoB* mutations), whereas GenoType MTBDR*plus* detects MTBC as well as rifampin (*rpoB* mutations) and isoniazid resistance (*katG* and *inhA* promoter mutations). GenoType MTBDR*sl* assay detects resistance to fluoroquinolone (*gyrA* mutations), aminoglycosides/cyclic peptides (*rrs* mutations), and ethambutol (*embB* mutations). The advantages and limitations as well as the performance of these tests have been recently reviewed [25, 209, 214–218].

Noncommercial sequencing methods such as pyrosequencing and Sanger sequencing are increasingly used as they can provide, directly from specimens or from cultures, gene sequence information for specific targeted loci to identify known mutations as well as new unknown potential mutations that must be confirmed by CDST [209]. In recent years, WGS has emerged as a promising technology for characterizing antibiotic resistance in *M. tuberculosis* isolates [216]. Several studies have used WGS on hundreds of clinical isolates for identifying known and novel mutations conferring antibiotic resistance [219–223]. In a recent study, WGS was also used for TB diagnosis and drug-resistance screening (for 39 antibiotics), as well as strain typing on a sputum sample that became positive after 3 days [224]. This study showed that in well-resourced countries, rapid whole-genome sequencing may replace current methods of identifying and typing TB as well as rapidly identifying resistance when mutation known to confer resistance is detected.

The use of molecular methods to detect resistance markers in mycobacteria is an area of great potential benefit to the clinical mycobacteriology laboratory allowing diagnosis of MDR-TB and XDR-TB in the same day or a few days after sample collection. However, the correlation between phenotypic and genotypic resistance testing is not always accurate because the genetic mechanism of resistance for certain antituberculous drugs is still not fully known [209]. Therefore the "gold standard" for identification of resistant TB remains CDST.

3.3.2 Genotypic Detection of Oxacillin Resistance in Staphylococci

Despite improvement and development of phenotypic methods to detect oxacillin resistance (see Sect. 3.2.1), molecular detection of the *mecA* gene is considered the "gold standard" for detection of oxacillin resistance in *S. aureus* as it does not depend on the variable expression of the PBP 2a [109]. Unfortunately, the newly described *mecC* homologue of *mecA* (see Sect. 3.2.1) is usually not detected with *mecA*-specific primers since these two genes share <70 % identity [106]. Numerous molecular-based tests have been developed to increase the sensitivity, the specificity, and the speed for

MRSA detection. Most of these methods are in-house tests that detect an *S. aureus*-specific gene and/or *mecA* (Table 85.1). In-house molecular assays detecting *mecC* have also been developed recently [225, 226] (Table 85.1). Several commercial assays are also available for detection of MRSA, but only a few also detect *mecC* (Table 85.2). Molecular methods detecting *S. aureus* and *mecA*/*mecC* can be used to detect MRSA from pure cultures or directly from sterile specimens such as cerebrospinal and peritoneal fluids, endotracheal aspirates, blood, and blood cultures [169, 227–244] but can hardly be applied for detection of MRSA from nonsterile specimens such as nasal screening specimens containing a mixed flora of CoNS and *S. aureus*, because both can carry *mecA* [245–247]. During the past years, novel strategies, mainly PCR-based, have been developed to rapidly identify MRSA from nonsterile screening specimens. One of the most common PCR strategy used was pioneered by our group [22] and is based on our increasing knowledge of the genetic element containing *mecA* (see Sect. 3.2.1). PCR assays, which are based on this approach, generally include a primer specific to the *S. aureus* chromosomal *orfX* gene combined with primers specific to the right extremity sequences of the different staphylococcal cassette chromosome *mec* (SCC*mec*) containing *mecA* in proximity to the *orfX* junction, thus providing a link between *mecA* and *S. aureus*. By linking *mecA* to *S. aureus*, these PCR tests allow detection of MRSA directly from clinical specimens containing a mixture of staphylococci without previous isolation or enrichment of the bacteria, thereby reducing the number of sample preparation steps and time to results. Our original assay [22] led to the first real-time PCR test (IDI MRSA, now BD GeneOhm MRSA) cleared by the FDA for rapid detection of MRSA from nasal swabs (~2 h) and was initially commercialized by Infectio Diagnostic Inc. (IDI) (now BD Diagnostics). Several PCR assays based on this strategy are now commercially available on different system platforms to meet different clinical needs (batch processing or on demand) (Table 85.2). These assays reduce time for identification of MRSA from clinical samples from <1 to 3 h. The description and clinical performance of these different assays can be found in recent reviews [111, 121]. Some system platforms are fully automated including the sample preparation steps, thus requiring minimal hands on time (e.g., BD MAX MRSA, BD Diagnostics and Xpert MRSA, Cepheid) (Table 85.2). Some PCR assays also contained primers for identification of *S. aureus* and *mecA* in addition to SCC*mec*/*orfX* primers and can be used for detection of both MSSA and MRSA. Addition of *mecA* primers to the *S. aureus* SCC*mec*/*orfX* primers could reduce the number of false positive resulting from the presence of some *S. aureus* isolates harboring SCC*mec* but lacking *mecA* [22, 248–250]. Some assays have been adapted for detection of these microorganisms either in nasal swabs, wound swabs, or blood cultures (Table 85.2). False negative has also been described with some assays due to sequence variants of SCC*mec* not detected by the primers used [251, 252]. With the recent description of new SCC*mec* sequences and the new *mecC* gene in some MRSA isolates [108, 253], new versions of assays which now include primers specific to new SCC*mec* and *mecC* sequences have recently been cleared by the FDA (e.g., BD MAX MRSA XT, BD Diagnostics).

A new FDA-cleared PCR assay (MRSA/SA ELITe MGB, Epoch Biosciences) used another strategy to detect MRSA in nasal swabs. This PCR assay contains primers specific to *S. aureus* and *mecA*/*mecC*. MRSA identification is based on the presence of both markers at the same relative quantity measured by a difference in cycle threshold (Ct) value. This new test has not been evaluated in several studies, but the company claims clinical sensitivity and specificity of 92.3 and 95.2 % for detection of MRSA in nasal swab specimens when compared to conventional broth culture methods (Food and Drug Administration. Medical Device. MASA/SA ELITe MGB. 510 (k) Summary. http://www.accessdata.fda.gov/cdrh_docs/pdf11/K112937.pdf).

By providing an immediate detection of MRSA carriers (1–3 h), many studies have shown the positive impact of rapid molecular tests for reducing the transmission of MRSA [117, 254–256].

3.3.3 Genotypic Detection of Glycopeptide Resistance in Enterococci and Staphylococci

Most conventional phenotypic susceptibility methods can detect accurately high-level vancomycin resistance in enterococci (VanA and VanD phenotypes); however, detection of low-level vancomycin resistance (VanB, VanC, VanE, VanG, VanL, VanM, and VanN phenotypes) and differentiation between different Van types are difficult by phenotypic methods (see Sect. 3.2.2). Numerous in-house or commercial amplification or probe hybridization assays have been developed to detect the various *van* genes conferring glycopeptide resistance in pure cultures of enterococci (Tables 85.1 and 85.2). A multiplex PCR detects six types of glycopeptide resistance genes (*vanA*, *vanB*, *VanC*, *vanD*, *vanE*, and *vanG*) [257]. This multiplex PCR also contains primers specific to *E. faecium*, *E. faecalis*, *S. aureus*, and *S. epidermidis* allowing detection of both glycopeptide-resistant enterococci and *vanA*-containing *S. aureus* (VRSA). Other groups have used PCR assays for detection of *vanA* and/or *vanB* in *S. aureus* isolates [57, 58, 258–260]. However, the description of new *van* genes in recent years (e.g., *vanL*, *vanM*, and *vanN*) in enterococci emphasizes the need for more universal *van* gene primers in the future [261–263].

Despite development of various selective culture media and novel susceptibility testing methods for detecting VRE from screening specimens, it still takes at least 72 h to iden-

tify VRE by culture methods (see Sect. 3.2.2). Moreover, the sensitivity of selective culture media for detecting VanB-type VRE with low-level vancomycin resistance remains low [130, 133] (see Sect. 3.2.2). From the nine different glycopeptide resistance genes described in VRE, *vanA* and *vanB* are the most prevalent and clinically important from an infection control perspective because of the transmissibility of these genes. Since *vanA* and *vanB* are generally associated with *E. faecalis* and *E. faecium*, different in-house PCR assays, including gel-based PCR assays and real-time PCR assays, have been developed to detect these two resistance genes (some assays also include *vanC*) directly from fecal specimens or following enrichment in broth culture (for increased sensitivity) without the need to include PCR primers specific to these two bacterial species [264–269] (Table 85.1). Real-time PCR assays detecting *vanA* and *vanB* directly from fecal specimens are also commercially available (e.g., BD GeneOhm VanR, BD Diagnostics and Xpert *vanA*/*vanB*, Cepheid) (Table 85.2). The clinical performance of these commercial tests has been evaluated in several studies for detection of VRE in fecal specimens [270–276]. While the sensitivity of these assays is usually good, the specificity was limited in some studies largely due to false-positive results obtained for *vanB* [51, 271, 274–276]. These can be explained by the presence of *vanB*-containing anaerobic bacterial species in fecal specimens [50, 52, 53]. In this case, the presence of VRE must be confirmed by culture in stools that are positive for *vanB* [274–276]. A recent study has shown that rapid real-time PCR assays for VRE detection contributed to rapid decision about the best infection control measures and resulted in substantial cost savings [278].

3.3.4 Genotypic Detection of Carbapenemases in Gram-Negative Bacteria

The high mortality rate observed in infections caused by CPGN urges for rapid detection of these microorganisms [139–141] (see Sect. 3.2.3). However, culture-based methods for detection of carbapenemases in Gram-negative bacteria are time-consuming having a time to result of at least 24–48 h, often lack sensitivity and specificity, and cannot identify the type of carbapenemases [136, 144, 279–282] (see Sect. 3.2.3). Currently, the most prevalent carbapenemases include KPC, NDM, OXA-48-like, VIM, and IMP. The prevalence of each gene varies depending on countries or regions [135, 138, 283, 284]. Each carbapenemase type includes several variants, VIM and IMP harboring the greatest number of variants (http://www.lahey.org/Studies/access). To overcome limitations of the phenotypic culture-based methods, several in-house or commercial molecular tests (e.g., real-time and conventional simplex and multiplex PCR, DNA microarrays, and LAMP assays) which allow detection of a single or several carbapenemase genes in carbapenemase producers have been developed (Tables 85.1 and 85.2). These molecular assays are described in recent reviews [136, 144, 145, 161, 285]. Some in-house assays have been used to detect carbapenemase genes directly from clinical specimens such as urine, sputum, fecal, blood, or surgical site samples [286–291]. For example, the sensitivity and specificity of a real-time PCR used to detect KPC in 187 perianal/rectal swabs were shown to be 97.9–100 % and 96.4–95 %, respectively, depending on the nucleic acid extraction method used [286]. This study showed that the time to detect KPC carriers was reduced from 24 h to 4 h.

The different commercial molecular technologies available for detecting carbapenemase genes (Table 85.2) include real-time PCR assays such as the Xpert Carba-R kit (Cepheid) and the Check-*Direct* CPE kit (Check-Points), LAMP assays such as the eazyplex SuperBug CRE kit (Amplex BioSystems), and capture probe hybridization on microarrays (combined with multiplex PCR) such as the different Check-MDR kits (Check-Points). The type of carbapenemase genes and the variants detected depend on the different kits. These tests can be used for detection of carbapenemase genes from bacterial cultures, but some can be used directly from clinical specimens such as the Xpert Carba-R kit, the Check-*Direct* CPE kit, and eazyplex SuperBug CRE kit. The performance of some of these commercial assays has been assessed for detecting the major families of carbapenemase in pure cultures [292–294]. Most assays detect all isolates containing the carbapenemases included in their assays. However, the first version of the Xpert Carba-R kit which includes OXA-48 did not detect the common OXA-48 variant named OXA-181 [292, 294]. The new version of this kit now detects OXA-181 and OXA-232. The Xpert Carba-R kit is the only test detecting IMP carbapenemases, but it only detects IMP-1 subgroup [293]. The Check-*Direct* CPE kit combined with the NucliSENS easyMAG Extraction kit (bioMérieux) has been evaluated for detection of carbapenemase genes using spiked rectal samples and was shown to be comparable to the ChromID CARBA agar (bioMérieux) [295]. The use of molecular tests for rapid detection of carbapenemase producers directly in clinical samples should help to rapidly detect infected or colonized patients, improve treatment caused by these resistant microorganisms, and control their dissemination.

3.3.5 Potential Artifacts of Genotypic Resistance Testing

There are some potential artifacts of genotypic resistance testing to determine the resistance profile of a microorganism. For example, the presence of a resistance gene may not be always indicative of a resistant bacterium and does not necessarily lead to treatment failure, because the level of expression may be low. For example, the development of resistance by ß-lactamase production among members of

Enterobacteriaceae depends on the mode and level of expression [296]. However, the presence of a gene can be indicative of the potential to develop resistance. For example, in a study of antimicrobial resistance in *S. aureus*, it has been shown that the presence of *mecA* did not necessarily result in oxacillin resistance phenotype; however oxacillin-susceptible *S. aureus* isolates carrying this gene were easily selected for resistance expression by exposure to increasing antibiotic concentrations suggesting that, at least for certain resistance genes, the presence of a gene is sufficient for a bacterium to eventually become resistant to the drug [297, 298]. Another limitation of the resistance testing is that the absence of a gene coding for a resistance to a drug does not always mean that the bacterium is susceptible to that drug because resistance testing only identifies genes or mutations that have been characterized and other unknown resistance mechanisms may exist. Therefore, continuously updated epidemiological studies of resistant bacteria based on susceptibility testing and study of novel resistance mechanisms would help to develop genotypic tests for detection of the new types of resistance that undoubtedly will arise in bacteria in the future.

4 The Future of Genotypic Drug Resistance Detection

During the past decade, there has been enormous progress in the development of genotypic drug resistance assays that provide more accurate and rapid antimicrobial resistance testing. Genotypic drug resistance assays are increasingly used in the clinical microbiology laboratories, especially for detection of antimicrobial resistance in microorganisms that grow slowly such as MDR and XDR *M. tuberculosis* or for rapid detection of difficult-to-detect resistance mechanisms such as those found in MRSA, VRE, and carbapenemase-producing microorganisms. With the increasing prevalence of MDR and XDR pathogens, there is an urgent need for novel rapid genotypic diagnostic tests for detection of resistance without the need of the time-consuming culture-based systems. For infection control programs, the use of specific genotypic tests that can be used directly from screening clinical specimens to detect rapidly patients colonized with antimicrobial-resistant pathogens (e.g., MRSA, VRE, and carbapenemase-producing microorganisms) will help to prevent or reduce transmission [117, 139–141, 254–256, 278]. However, for diagnostic purpose, genotypic tests for detection of antimicrobial-resistant pathogens will have to detect and identify rapidly (in less than 1 h) all possible causative pathogens for a specific infection or syndrome (e.g., meningitis, nosocomial pneumonia, septicemia, etc.) as well as the associated genes or mutations conferring resistance to potentially effective therapeutic agents [175, 299, 300].

Several genome sequences as well as sequences of many conserved genetic targets for bacterial identification and antimicrobial resistance genes and mutations are available in public databases [163]. Though, the development of genotypic tests that will allow sensitive detection of multiple pathogens as well as multiple antimicrobial resistance genes and mutations directly from clinical specimens will pose major challenges. PCR-based techniques, especially multiplex real-time PCR, remain today the most common molecular methods when there is a need to detect a limited number of bacterial species and/or antimicrobial resistance genes and mutations. However, array technologies represent the most powerful tools for multiple target detection [176, 178]. To overcome the problem of amplicon carryover and the lack of sensitivity of array technologies, new array platforms are now available combining arrays to prior PCR amplification in closed systems (e.g., FilmArray technology from bioMérieux and eSensor technology from GenMark) [206, 301]. Other platforms enabling PCR amplification and array detection in a single closed chamber or closed systems combining amplification and innovative detection technologies are under development and should help to solve the challenge of sensitive multidetection [302–309]. Moreover, the development of ultrasensitive biosensors for nucleic acid analysis is another promising tool that could obviate the need for multiple target amplification in the future [310–313].

In recent years, the decreasing cost of next-generation sequencing (NGS) and the development of various rapid desktop sequencers have allowed these technologies to make significant impact in infectious diseases [176, 314–317]. It is now possible to rapidly sequence a whole bacterial genome in less than 1 day directly from a single colony on a primary isolation plate [318]. Whole genome sequencing (WGS) has found numerous applications in the clinical field of antimicrobial resistance [317] such as characterizing the genetic determinants of antibiotic resistance in clinical isolates and predicting antimicrobial susceptibilities [319, 320], measuring the rate at which resistance emerges [321], improving genotypic resistance tests [108], typing multidrug-resistant isolates for epidemiological surveillance [322, 323], and tracking outbreaks [324–326]. However, despite the high concordance between whole genome-based resistance genotypes and phenotypes observed in some studies [319], WGS will not be implemented for routine susceptibility testing of pure bacterial culture in the near future, considering the turnaround time, the lack of automated sequence analysis system, and still elevated cost of these technologies compared to traditional phenotypic methods and new molecular tests. Unbiased metagenomic NGS can also be performed directly from clinical specimens to identify antibiotic-resistant pathogens [327, 328], but this approach is very expensive, is less sensitive than phenotypic and molecular methods, and can-

not ascertain which pathogen harbors a plasmid-borne resistance gene in mixed cultures [176, 318, 328]. Nevertheless, the continuous technical advances (ultimately entirely automated) and the falling costs and turnaround time of NGS technologies as well as automation of sequence data analysis to generate data relevant for clinical use should push forward implementation of these diagnostic platforms in clinical and public health microbiology laboratories by providing unprecedented information on clinical isolates on a single platform [317, 329].

Finally, the next generation of genotypic tests for detection of antimicrobial-resistant pathogens should be fully automated with integrated sample preparation and nucleic acid detection (sample-to-answer). Indeed, automation of standard culture-based methods is steadily spreading throughout clinical microbiology laboratories [330], and genotypic tests should follow this trend while offering new faster technologies. Eventually, some molecular tests should be used at the point of care (POC) (i.e., close to a healthcare user) in low-complexity settings, such as the emergency rooms, for example, when rapid results (ideally less than 1 h) matter for patient outcomes or for infection control practices [331]. Although fully automated or integrated systems are commercially available for detection of bacteria and antibiotic resistance genes (e.g., BD MAX technology from BD Diagnostics, the Xpert technology from Cepheid, and the FilmArray technology from bioMérieux), there are no POC molecular tests available for detection of antibiotic resistance. Indeed, in January 2015, the 15-min molecular Alere I Influenza A & B test on the Alere I platform (Alere) was the first nucleic acid-based test ever to receive FDA CLIA waiver. In May 2015, a second nucleic acid-based POC test, the Strep A assay on the Liat system (Roche) was approved by the FDA. Other tests from these two companies have now received FDA CLIA waiver as well as tests for other companies (e.g., Xpert Xpress Flu/RSV from Cepheid and FilmArray Respiratory Panel EZ from bioMérieux). Several POC diagnostics devices are currently in development that can identify a variety of nucleic acid targets from multiple types of samples in under an hour [175, 332–334]. GenePOC, a Canadian company, has developed a simple microfluidic centripetal platform which enables a fully automated nucleic acid-based testing for infectious microorganisms within 1 h and less than 1 min of hands-on time. This system has the ability to process a wide range of clinical samples with up to 12 genetic targets [331]. Recent advances in nanotechnology and microfluidic "or lab-on-a-chip" systems should revolutionize the detection antimicrobial-resistant pathogens in the future [305–307, 331–336].

Genotypic Assays for Monitoring Drug Resistance in HIV-1 Infection and for Other Chronic Viral Diseases

86

Ying-Shan Han and Mark A. Wainberg

1 Introduction

The routine introduction of genotypic drug resistance assays in the clinical microbiology setting represents a significant milestone in the treatment of HIV-1 infection; it has had practical utility in guiding antiviral therapy. These laboratory methods permit characterization of specific changes in the genomic nucleotide sequence of viral isolates in comparison to a HIV-1 reference strain to monitor the development of resistance to antiretroviral therapy [1, 2]. With genotypic testing, mutations that emerge spontaneously as a result of error-prone viral replication and/or that are selected by drug pressure in the HIV-1 polymerase (*pol*) or envelope (*env*) genes are commonly detected by automated techniques based on the Sanger method for dideoxy-terminator nucleotide sequencing [1] or, alternatively, with hybridization tests such as the line probe assay (LiPA) that monitor point mutations at codons known to be important for resistance to specific antiretroviral agents (ARVs) [1, 3, 4]. The effective utilization of genotypic drug resistance assays for HIV-1 infection also requires expert clinical interpretation of often complex mutational patterns. This task has been greatly facilitated by the use of several computerized algorithms that have been specifically designed for HIV-1 genotypic analysis [5–7].

Resistance-conferring mutations that encode single or multiple amino acid substitutions in the reverse transcriptase (RT) or protease (PR) enzymes or the heptad repeat 1 (HR-1) domain of gp41 in the HIV-1 envelope have been shown to be directly responsible for diminished susceptibility to the inhibitors of these viral targets and may, therefore, be viewed as important molecular markers that are predictive of drug resistance [8]. The prognostic value of genotypic resistance testing in improving virological outcomes to antiretroviral therapy for HIV-1 infection has been documented in several prospective and retrospective clinical studies, including comparisons against standard of care [9–12]. In addition, health economics analyses from the CPCRA 046 [13] and VIRADAPT [14] studies have confirmed the benefit conferred by genotypic resistance testing when used for guiding therapy choice decisions in patients who experienced virological failure on an initial antiretroviral regimen. In CPCRA 046, patients receiving standard antiretroviral therapy regimens were randomly assigned to one of two study groups in which therapeutic decisions were determined by clinical judgment alone or, alternatively, using genotypic antiretroviral resistance testing (GART) as an adjunct to clinical judgment [9]. With GART, 34 % of patients were reported to achieve a successful virological response compared to 22 % of patients in which therapy choice decisions were based entirely on physician clinical judgment [9–12]. Similar results have also been reported from the VIRADAPT study [10], in which 32 % of patients assigned to the drug resistance genotyping (DRG) group responded satisfactorily to antiretroviral therapy compared to a response rate of 14 % in patients without DRG [10, 13].

The benefit conferred by HIV-1 genotyping in treatment-experienced patients has also been further corroborated by the Havana trial [15]. In this study, a significantly greater proportion of patients in whom genotyping was used to guide therapy choice decisions achieved undetectable plasma viremia (i.e., HIV-1 RNA <400 copies/mL) after 24 weeks of therapy as compared to patients managed in accordance with the standard of care alone [15]. Additionally, the use of expert advice to assist with treatment decisions was also shown to be associated with improved virological response, especially in patients who had experienced a second virological failure [15]. Thus, the results from CPCRA 046, VIRADAPT, and Havana, as well as those from other related studies conducted in settings that more closely reflect current

clinical practice [16], support the use of genotypic drug resistance assays and expert advice as important interventions to improve the sustained effectiveness of antiretroviral therapy in patients with HIV-1 infection.

The scope of utilization of genotypic drug resistance assays is increasing, and this technology is also being used, albeit on a more limited basis, to monitor resistance to antiviral drugs used for the treatment of hepatitis B virus (HBV) infection as well as a limited number of other chronic viral diseases associated with certain herpes viruses, e.g., cytomegalovirus (CMV) [1, 2, 17]. Although antiviral drugs have also recently become available for some other viral infections such as influenza, the routine use of genotypic drug resistance tests may not be equally practical or feasible in all situations [1]. Interestingly, molecular genotyping of validated tumor molecular markers, akin to drug resistance testing for HIV-1 infection, may also be of value in the future to help predict the development of resistance to novel targeted anticancer drugs [18]. For example, genotypic surveillance of the Bcr-Abl/c-kit tumor marker in chronic myelogenous leukemia (CML) may be used to detect resistance to targeted anticancer drugs such as Gleevec (imatinib mesylate, STI571) that are now used to treat this disease [19]. This therapeutic strategy could be advantageous with respect to the selection of alternate courses of therapy in patients with CML that has become refractory to treatment with Gleevec and, therefore, may also result in improved therapeutic outcomes compared to patients in whom genotypic drug resistance testing was not used for guidance of chemotherapy [18].

Although many of the techniques associated with genotyping were first developed for use in HIV-1 disease, these methods will also prove useful for other viral diseases including those associated with human cytomegalovirus (CMV) and herpes simplex viruses (HSV) among others; there is also likelihood that these techniques may prove useful in the management of certain types of cancer. This chapter reviews the methods available for detection of drug resistance by genotyping and the clinical utility of the testing procedures available at this time.

2 Genotypic Drug Resistance in HIV-1 Infection

The development of resistance to antiretroviral agents (ARVs) is largely thought to be a consequence of incompletely suppressive regimens and, moreover, constitutes a serious limitation in regard to the sustained effectiveness of these drugs for the treatment of HIV-1 infection [20–23]. HIV-1 variants that harbor resistance mutations to drugs from any of the currently approved classes of antiretroviral agents including the recently introduced fusion inhibitor, enfuvirtide (T-20), may precede the initiation of therapy because of spontaneous mutagenesis or transmission of drug-resistant viruses and are subsequently selected by antiretroviral therapy [8, 24]. Genotypic analysis has shown that prolonged exposure to combination therapy is associated with complex and often overlapping patterns of resistance-conferring mutations commensurate with increasing levels of resistance and, for that matter, cross-resistance, to some of the antiretroviral drugs comprising the therapeutic regimen. In general, multiple drug mutations to any single or combination of ARVs need to be selected in order to produce clinical resistance to most ARVs. However, this is not the case for a limited number of nucleoside reverse transcriptase inhibitor (NRTIs) such as lamivudine (3TC) and a closely related compound, emtricitabine (FTC), and also for most non-nucleoside reverse transcriptase inhibitors (NNRTIs) of HIV-1 reverse transcriptase (RT). These compounds possess relatively low genetic barriers for the development of drug resistance compared to the protease inhibitors (PIs) and can often experience substantial loss of antiviral activity following the appearance of a single primary drug resistance mutation in RT [25–29]. Table 86.1 shows most HIV-1 drug resistance mutations that are usually associated with antiretroviral therapy.

3 Nucleoside Reverse Transcriptase Inhibitor (NRTIs)

Unlike ARVs from other drug classes, NRTIs are administered to patients as precursor compounds that are phosphorylated to their active triphosphate form by host cellular kinases [30, 31]. NRTIs mimic the naturally occurring deoxynucleotide triphosphates (dNTPs) and can effectively compete with these intracellular substrates for binding to RT and incorporation into proviral DNA. However, NRTIs lack a 3′ hydroxyl group that is necessary for DNA polymerization, and, therefore, the antiviral activity of these compounds results from their ability to cause chain termination of nascent viral DNA strands [30, 32–34].

Mutations associated with drug resistance have been reported in response to the use of any single NRTI [8]. However, not all drugs elicit the same mutagenic response, and, consequently, resistance patterns and sensitivity must be considered on an individual drug basis. For example, resistance to 3TC develops quickly both in vitro [27, 29] and in patients treated with 3TC-containing regimens [35, 36]. High-level resistance to this nucleoside analogue (i.e., 500–1000-fold increase in IC_{50}) is mediated by a single mutation that encodes substitution of a methionine amino acid residue for either isoleucine (M184I) or, more commonly, valine (M184V) at position 184 in HIV-1 RT [29, 37–39]. Moreover, a novel mutational pattern in RT consisting of V118I alone or in association with E44A/D has also been shown to confer

Table 86.1 Common antiretroviral drug resistance mutations

Nucleoside (tide) reverse transcriptase inhibitor (NRTI) mutations associated with HIV drug resistance				
NRTI				
Abacavir	K65R, L74V, Y115F, M184V			
Didanosine	K65R, L74V			
Lamivudine/emtricitabine	K65R, M184V			
Stavudine	M41L, D67N, K70R, L210W, T215YF, K219KE			
Tenofovir	K65R, K70E			
Zidovudine	M41L, D67N, K70R, L210W, T215YF, K219KE			
TAMs	M41L, D67N, K70R, L210W, T215YF, K219KE		Affect all NRTIs	
69 insertion	TAMs plus T69X + X or XX		Affect all NRTIs	
151 complex	A62V, V75I, F77L, F116Y and Q151M		Affect all NRTIs except tenofovir	
Non-nucleoside (tide) reverse transcriptase inhibitor (NNRTI) mutations associated with HIV drug resistance				
NNRTI				
Delavirdine	K103N, V106AM, Y181C, Y188L, P236L			
Efavirenz	K103N, V106AM, V108I, Y181C, Y188L, G190SA, P225H			
Nevirapine	K103N, V106AM, V108I, Y181CI, Y188CLH, G190A			
Protease inhibitor (PI) resistance mutations according to the IAS-USA panel for antiretroviral drug resistance				
PI	Cross-resistance mutation		Unique mutations	
	Major	Minor	Major	Minor

Raltegravir	Y143R/C, Q148R/H/K, N155H			
Elvitegravir	E92Q, Y143R/C, Q148R/H/K, N155H			
Dolutegravir	G118R, R263K			

moderate phenotypic resistance (i.e., 3- to 4-fold increase in IC_{50}) to 3TC in the absence of M184V [40, 41]. Increased prevalence of both V118I and E44A/D is associated with long-term ZDV/d4T usage.

In contrast to these findings with 3TC, resistance to zidovudine (ZDV) and other NRTIs may become clinically important only about 6 months after initiation of therapy [42, 43]. Furthermore, prolonged exposure to ZDV is characterized by a stepwise accumulation of resistance mutations referred to as thymidine analogue mutations (TAMs) that can result in progressive loss of antiviral activity to this compound. The TAMs comprise a group of six drug resistance mutations (i.e., M41L, D67N, K70R, L210W, T215Y/F, and K219Q) in RT that were initially described in connection with ZDV resistance and have also been implicated in reduced sensitivity to stavudine (d4T) [8, 44–47]. In addition, TAMs can also confer moderate levels of resistance to other NRTIs such as didanosine (ddI) and zalcitabine (ddC), depending on the mutational pattern that is present. However, L74V is the primary resistance-conferring mutation that is selected by ddI that is responsible for the greatest loss of antiviral activity with this drug [8, 42, 44, 46]. Similarly, the selection of various TAMs is also associated with decreased susceptibility to ddC, although, as with ddI, other resistance-conferring mutations (i.e., K65R and T69N) are also important in this regard [8, 42, 45, 46]. It is also noteworthy that whereas discriminatory mutations in RT such as M184V confer resistance primarily against the drugs that select them, TAMs, on the other hand, can mediate diminished drug susceptibility against an extended array of unrelated NRTIs [8, 44–47].

Genotypic analysis of viral isolates from patients treated with antiretroviral regimens that included d4T or ZDV has pointed to the existence of two major genetic pathways in regard to the development of resistance to thymidine analogues as evidenced through the detection of differential patterns of TAMs over time [48–51]. Initially, each of the M41L and T215Y/F mutations is commonly present in both pathways (50), and they are followed by the stepwise accumulation of other TAMs at positions 210 and 215 (i.e., 41 L-210 W-215Y pattern) or, alternatively, positions 67, 70, and 219 (i.e., 67 N-70R-219Q/E pattern) [48, 49, 51]. Furthermore, the specific sequence of TAM accumulation observed may be dependent on whether ZDV monotherapy or dual-NRTI combinations were used for initiation of antiretroviral therapy. Monotherapy with ZDV has been shown to be more commonly associated with the K70R mutation appearing first, leading predominantly to selection of the 67 N-70R-219Q/E pattern [48], whereas patients who started treatment with either ZDV/ddI or ZDV/ddC usually initially developed 215Y/F followed by 41 L and 210 W [48]. Moreover, the 41 L-210 W-215Y pattern appears to be more prevalent than 67 N-70R-219Q/E [52]. The V118I and E44A/D mutations frequently cluster jointly with the 41 L-210 W-215Y pathway but have only been observed individually in association with the 67 N-70R-219Q/E pattern [52]. TAMs from the 41 L-210 W-215Y pathway generally yield higher levels of cross-resistance to other NRTIs when present together with other mutations than do the same number of TAMs from the 67 N-70R-219Q/E pathway [52].

Another less frequently observed resistance mutation, K65R, has been shown to be associated with prior treatment with abacavir (ABC)-containing regimens and results in reduced antiviral susceptibility to both ABC and the nucleotide analogue reverse transcriptase inhibitor tenofovir (TDF). Hence, resistance to these ARVs can develop independently via genetic pathways involving either the TAMs or K65R as the signature drug resistance mutations [53]. K65R is also selected by TDF in vitro [54] and has been observed with low frequency (i.e., 3 % of cases) in clinical trials of patients with HIV-1 infection who were treated with a TDF-containing regimen for up to 96 weeks [55].

The simultaneous presence of K65R together with TAMs is very rare in clinical samples. One study found only a negative association of K65R and TAMs (except for Q151M [positive association] and K70R [no association]) [56]. Site-directed mutagenesis experiments that introduced both TAMs and K65R into clinical isolates determined a reciprocal antagonistic phenotypic effect. TAMs reduced the resistance conferred by K65R to TDF, ABC, and ddC, and K65R decreased the resistance conferred by TAMs to AZT. TAMs had no effect on the resistance conferred by K65R against 3TC or FTC, but enhanced the resistance of M184V against each of ABC, ddI, and TDF [56]. This finding adds support to the sequential use of AZT- and TDF-based NRTI backbones.

Mutational patterns that are associated with broad cross-resistance to multiple NRTIs have also been identified. The Q151 multidrug resistance (MDR) complex is encoded by five mutations in RT: A62V, V75I, F77L, F116Y, and Q151M. These mutations were initially observed in viral isolates from patients with HIV-1 infection who received combination therapy with ZDV plus either ddC or ddI for over 1 year [57, 58]. Primary resistance mutations that are usually associated with resistance to ZDV, ddI, or ddC in monotherapy were not present in these isolates. Q151M is the first of these five mutations to develop in vivo and compared to the other Q151M MDR substitutions also produces the most resistance to additional NRTIs [57]. In addition, it has been shown that a family of insertion mutations between codons 67 and 70 in RT can cause resistance to a variety of NRTIs including ZDV, 3TC, ddI, ddC, and d4T. Usually, these mutations confer resistance to multiple NRTIs when present in a ZDV-resistant background [59, 60]. The development of these mutations is also correlated with prior treatment with ZDV/ddI and ZDV/ddC combination therapy regimens. However, the prevalence of the insertion mutations has been reported to be lower than that for the substitutions comprising the Q151M MDR complex [61].

4 Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Non-nucleoside RT inhibitors (NNRTIs) act as noncompetitive antagonists of enzyme activity by binding to a hydrophobic pocket that is located adjacent to the catalytic site of RT [62, 63]. NNRTIs reduce the catalytic rate of polymerization without affecting nucleotide binding or nucleotide-induced conformational change [64]. These drugs are particularly active at template positions at which the RT enzyme naturally pauses and, moreover, do not appear to influence the competition between dideoxynucleotide triphosphates (ddNTPs) and the naturally occurring dNTPs for insertion into the growing proviral DNA chain [65].

Diminished sensitivity to NNRTIs appears quickly both in tissue culture selection protocols and in patients [25, 62, 63]. NNRTIs share a common binding site, and mutations that encode NNRTI resistance are located within the binding pocket that makes drug contact [62–69]. This explains the finding that extensive cross-resistance is observed among all currently approved NNRTIs [25, 70, 71]. A substitution at codon 181 (i.e., Y181C) is a common mutation that encodes cross-resistance among many NNRTIs [25, 68, 70, 72]. Replacement of Y181 by a serine or histidine also conferred HIV resistance to NNRTIs [73]. A mutation at amino acid 236 (i.e., P236L), conferring resistance to a particular class of NNRTIs that include delavirdine, can also diminish resistance to nevirapine and other NNRTIs, particularly if a Y181C mutation is also present in the same virus [74]. Y188C and Y188H are other important mutations that can also confer resistance to NNRTIs.

Another drug resistance mutation, namely, K103N, is also commonly observed and is responsible for reduced susceptibility to all approved NNRTIs [25, 68, 70, 72]. Substitution of K103N results in alteration of interactions between NNRTIs and RT. The K103N mutation shows synergy with Y181C in regard to resistance to NNRTIs, unlike antagonistic interactions involving Y181C and P236L [75].

5 Protease Inhibitors (PIs)

Drug-resistant viruses have been observed in the case of all protease inhibitors (PIs) developed to date [76–78]. In addition, some strains of HIV have displayed cross-resistance to a variety of PIs after either clinical use or in vitro drug exposure [76–78]. In general, the patterns of mutations observed with PIs are more complex and extensive than those observed with RT antagonists [8]. This involves greater variability, as well, in temporal patterns of appearance of different mutations and the manner in which different combinations of mutations can give rise to phenotypic resistance. These data suggest that the viral protease (PR) enzyme can adapt more easily than RT to pressures exerted by antiviral drugs. At least 70 mutations in PR have been identified as responsible for resistance to PIs [8, 76–79].

In general, several mutations are necessary in order for PIs to lose activity against HIV-1. Certain of the mutations within the HIV-1 PR affect the enzyme more than others and can on their own confer resistance to certain PIs [76–78]. In particular, D30N and D50L are unique to nelfinavir and atazanavir, respectively. Saquinavir, an early PI, predominantly selects for the mutations L90M and G48V. Amprenavir and fosamprenavir can select for D50V, which can confer some degree of cross-resistance to darunavir (DRV) [80]. Regarding lopinavir, the accumulation of at least five mutations in PR is required for high-level resistance to develop this drug [81, 82]. Recently, the presence of mutation I47A, although uncommon, was shown to result in very high levels of resistance to lopinavir (>100-fold increase in IC50) and hypersusceptibility to saquinavir [83, 84]. Unique signature mutations have not been well defined for either tipranavir or darunavir.

A variety of mutations may confer cross-resistance among multiple drugs within the PI family. Cross-resistance mutations can lower the affinities of PIs, but the specific effects of these mutations vary according to each individual PI. As a classical example, the mutations V82F/I84V can contribute to resistance against almost all PIs currently available for therapy. These two positions are located in the β-sheet of the active site cavity of the PR, a structure to which all PIs must bind to inactivate the enzyme. Interestingly, the IAS-USA Drug Resistance Mutation Panel considers that mutations at position 82 can affect all PIs in clinical use to date, except DRV (although the resistance profile of DRV is not yet completely determined) [79]. Similarly, the I84V mutation affects all PIs in clinical use and is a major mutation for five of them. Despite being located outside the active site, the L90M mutation also affects all PIs except DRV and, on its own, does not contribute to tipranavir (TPV) resistance [79]. Extensive reviews on the effect of each resistance mutation on each particular PI goes beyond the scope of this review and can be found elsewhere [85].

On the other hand, wide arrays of secondary mutations have been observed that, when combined with primary mutations, can cause increased levels of resistance. Mutations such as L90M and L63P (a common polymorphism) have no discernible effect on binding affinity, but can partially restore PR catalytic activity and hence viral fitness [86]. It should be noted that resistance to PIs can also result from mutations within the substrates of the PR enzyme. The gag and gag-pol precursor proteins of HIV can acquire mutations at or close to their cleavage sites that render them more susceptible to hydrolysis by PR [87–90]. Thus, cleavage occurs more efficiently and viral fitness can be restored to some degree. Some of the gag and gag-pol mutations that have been

reported in treatment-experienced patients include the p7/p1mutations A431V, K436R, and I437V and p1-/p6-gag mutations L449F/V and P452S-P453L/A [91]. At least one of these mutations was detected in 60 % of therapy-experienced patients compared to 10 % in treatment-naïve patients [91]. Nevertheless, the full clinical significance of these cleavage site mutations in regard to PI resistance remains to be elucidated.

6 Fusion Inhibitors (Enfuvirtide, T-20)

Enfuvirtide (T-20) is the first entry in a novel class of antiretroviral agents known as HIV-1 entry inhibitors and has recently been approved for the treatment of HIV-1 infection [92]. This compound is a synthetic peptide consisting of 36 amino acids that are homologous to the residues located at positions 127–162 from the C-terminus of the heptad repeat 2 (HR-2) domain in the gp41 transmembrane glycoprotein of the viral envelope. T-20 binds competitively to the HR-1 domain within gp41, thus preventing interaction with HR-2 and formation of the hairpin-like structure that is required for fusion of the viral and host cell membranes [92, 93].

In the TORO-1 and TORO-2 studies, the addition of T-20 to optimized background therapy consisting of three to five active antiretroviral drugs, which were selected using genotypic drug resistance testing, was shown to result in significant reduction of plasma HIV-1 RNA and CD4 cell count increases compared to optimized background therapy alone in heavily treatment-experienced patients with HIV-1 infection that was resistant to NRTIs, NNRTIs, and PIs [94, 95]. The results from additional open-label and controlled clinical trials with this drug have similarly demonstrated improved treatment outcomes for up to 48 weeks in HIV-1 patients that were experiencing virological failure on previous regimens [96, 97]. In phase 1 clinical testing, resistance to T-20 developed rapidly and shown by rebounding plasma HIV-1 RNA after 14 days of monotherapy in four patients receiving an intermediate dose (i.e., 30 mg twice daily) of T-20 [98]. Genotypic analysis of cloned virus from these patients showed that resistance to T-20 was produced by substitutions in the highly conserved GIV motif which comprises a three-amino-acid sequence between residues 36–38 within the HR-1 domain that is essential for fusion of viral and cellular membranes to occur. Mutants that harbored a single amino acid substitution in GIV (i.e., G36D, I37V, and V38A/M) were frequently detected [98] (84). G36D and, in particular, V38A both exhibited significant fold increases in the IC_{50} for T-20 compared to HIV-1 strains with wild-type envelope sequences. In addition, dual mutants that contained G36D together with substitutions at other amino acid residues within HR-1 (i.e., Q32H/R and Q39R) were also observed and were shown to confer reduced susceptibility to T-20 to an extent similar to that produced with G36D by itself [98]. Interestingly, variability in the HR-1 domain at positions that are associated with resistance to T-20 has been demonstrated in both subtype B (i.e., residues 37, 39, and 42) and in non-B (i.e., residue 42) HIV-1 strains isolated from T-20-naïve patients [99]. However, the major GIV mutants commonly associated with T-20-resistant isolates were not observed in the absence of drug treatment, suggesting that primary genotypic resistance to this drug is uncommon [99]. Further study is needed to better understand the long-term implications of these uncommon resistance mutations in HIV-1 patients undergoing therapy with fusion inhibitors.

7 Integrase Inhibitors

HIV integrase inhibitors are the latest class of antiretroviral agents and inhibit the strand transfer reaction leading to the insertion of viral DNA into target host DNA and are therefore called integrase strand transfer inhibitors (INSTIs). INSTIs specifically and tightly bind to the active site of integrase and chelate the divalent metal ions located in the catalytic triad of integrase. Currently approved INSTIs include raltegravir (RAL), elvitegravir (EVG), and dolutegravir (DTG) [100, 101]. All approved INSTIs are well tolerated and highly efficacious against variants resistant to other classes of drugs with well-tolerant safety.

The development of resistance to INSTIs to varying extent has been reported both in vitro and in patients [102–104]. Genotypic studies showed that resistance to RAL and EVG develops rapidly both in cell culture selection and in the clinic. Resistance to RAL (i.e., FC 10–100) often occurs due to three primary mutations at positions N155H, Q148H/K/R, and less frequently Y143R/C/H in the active site of integrase, resulting in reduced integrase activities and virological failure. The primary mutations in combination with one or more secondary mutations are often observed after virological failure involving raltegravir, e.g., G140S/Q148H and G140S/Q148R conferring high-level resistance to RAL. The mutation at N155 commonly appears early in RAL therapy and is often replaced by other primary mutations (e.g., Q148H, K, or R) with secondary mutations. Cross-resistance between RAL and EVG has been observed. Major primary mutations that confer resistance to EVG have been found at positions T66I, E92Q, N155H, and Q148H/K/R. The addition of G140S to Q148H/R/K resulted in increased levels if resistance to EVG (i.e., FC $\geq$100). However, DTG, the second-generation INSTI, can still be either partially or completely active against RAL- and EVG-resistant viruses in vitro, and it is the only anti-HIV drug against which HIV has not developed resistance mutations in clinical practice. In treatment-naïve patients, only

low-level resistance to DTG (i.e., FC <10) has been observed on the basis of a primary mutation at R263K, accompanied by impaired viral replication fitness. However, so far no virological failure resulting from R263K or any other mutation has been reported since the approval of this drug in 2013.

8 Limitations of Genotypic Resistance Testing for Treatment of Infection with HIV-1

Although genotypic resistance testing represents an important advance in HIV therapy, it adds complexity to the management of HIV infection, since interpretations of results are not straightforward and clinical correlates do not yet exist for all resistance mutations. The limitations for genotypic resistance tests include inability to detect virus archived in viral reservoirs, insensitivity to viral minority populations (populations that are less than 20 % of the total viral mixture), and the requirement of a minimum viral load (500–1000 plasma HIV RNA copies/mL) for detection to be achieved. However, it is generally accepted that genotype is more sensitive for minority populations than phenotype testing. For instance, genotyping can detect sentinel mutations (e.g., M184V) before changes in phenotypic resistance become evident. Importantly, several studies have clearly demonstrated that expert advice adds benefit to results from resistance testing [12, 15, 16, 105–107].

On the other hand, large databases of paired genotype-phenotype assays have allowed the construction of "virtual phenotype" estimators that quantify HIV-1 resistance to ARV drugs based on a statistical prediction of the phenotype for a given genetic sequence. The accuracy of such estimations depends on the frequency of genotypes in the database that match the problem genotype and the variability in drug susceptibility of the phenotypes used to create the predicting pool. Uncommon sequences and those with suboptimal matches will have less accurate predictive value than those that are more frequent and better matched. Although a good correlation of virtual phenotypes with "real phenotypes" has been reported [108, 109], it should be kept in mind that "virtual phenotype" is a probability estimation. Further research is advancing in order for informatic aids to be able to display options of antiretroviral regimens starting from the computerized evaluation of a viral nucleic sequence.

Finally, there is subrepresentation of non-B subtype genetic sequences in current HIV resistance databases that have been used to generated resistance algorithms. Therefore, resistance pathways and mutations may be limited in the interpretation of resistance of non-B subtype clinical isolates. A classical example in subtype C HIV-1 exposed to efavirenz in tissue culture is the emergence of the V106M mutation which was observed to arise in the place of the V106A substitution, more commonly seen with subtype B viruses [110]. It is not yet known to which extent natural polymorphisms of different non-B subtypes can lead to different mutation patterns of frequency of individual mutations. For instance, a rapid emergence of K65R has been reported in tissue culture of subtype C HIV-1 in the presence of TDF. A high prevalence of this mutation has also been described in Botswana patients taking ddI [111, 112].

9 Hepatitis B Virus (HBV) Infection

Antiviral treatment of chronic hepatitis B has regained importance since only a small proportion of actively infected patients achieve the desirable outcomes with interferon-based therapy. Also new data suggests that higher viral loads are associated, at least in Asian populations with increased risk of developing cirrhosis and hepatocellular carcinoma [113, 114]. Hence, suppression of viral load with the use of antiviral drugs in chronic HBV infection emerges as a promising option for reduction of patient morbidity.

Four nucleoside reverse transcriptase inhibitors are currently licensed for treatment of chronic HBV infection: lamivudine (3TC), adefovir and entecavir, and telbivudine. They are used either alone or in association with immunotherapy, i.e., interferon-α (regular or pegylated) in treatment of HIV/HBV coinfection. All are highly active against HBV and are frequently used together with antiretroviral therapy directed against chronic HIV-1 infection. Other drugs, not yet specifically licensed for HBV treatment but that have excellent anti-HBV activity, are famciclovir, tenofovir, emtricitabine, clevudine, pradefovir, ANA 380, myrcludex, and valtorcitabine.

Lamivudine is a widely utilized antiviral drug often used in initiation of therapy in patients with hepatitis B virus (HBV) infection. In both immunocompetent and HIV/AIDS patients with HBV coinfection, the prevalence of lamivudine (3TC)-resistant hepatitis B virus (HBV) variants has been reported to be approximately 16–43 % after 1 year and up to 70 % at 4 years of treatment [115, 116]. The rtM204V (previously position M552V) mutation induces a 1000-fold decrease in susceptibility to lamivudine in vitro in comparison to wt HBV [117]. Drug-resistant virus can be selected after 6 months of lamivudine therapy in these patients, and its presence has been shown to increase with the duration of exposure to this drug [115, 118]. As is also the case with HIV-1, genotypic analysis has shown that resistance to lamivudine results principally from either isoleucine (I) or valine (V) amino acid substitutions in place of methionine (M) at position rt204 within the C domain of the highly conserved tyrosine-methionine-aspartate-aspartate (YMDD) motif of the HBV DNA polymerase [1, 115]. Compensatory mutations associated with lamivudine resistance (rtV173L, rtL180M) are found in the B domain [119, 120]. This mutation and similarly the M184V/I substitution in HIV-1 RT are responsible for high-level resistance to lamivudine.

In addition to rtM204I/V, several other mutations in the HBV polymerase gene have been shown to emerge following prolonged exposure to lamivudine and are associated with diminished susceptibility to this drug. Specific patterns of these mutations are used to assign lamivudine-resistant HBV variants to one of two genotypic groups. HBV group I mutants contain lamivudine resistance mutations that are located in both the polymerase B and C domains that include predominantly the rtL180M (previously L528M) and rtM204I/V (previously M552I/) substitutions, respectively. Group II viruses on the other hand are characterized by the presence of rtM204I in the C domain as the main lamivudine resistance-conferring mutation and have been shown to occur less frequently than their group I counterparts [115].

Resistance to other nucleoside analogues used for the treatment of HBV infection has also been documented. Compounds such as ganciclovir (GCV) and famciclovir (FCV) are potent inhibitors of the HBV polymerase both in vitro and in vivo, and, although they appear less effective than lamivudine [1, 118], both of these antiviral agents have been used on an investigational basis to treat HBV infection. Genotypic analysis has revealed that the most important resistance-conferring mutations to these drugs are selected outside of the YMDD motif and include the rtV173L (previously V521L), rtP177L (previously P525L), rtL180M (previously L528M/V), T184S (previously T532S), and rtV207I (previously V555I) substitutions in the B domain of the HBV polymerase gene. Furthermore, it has been shown that the rtV207I substitution produces the highest attenuation of antiviral susceptibility to FCV and that both this mutation and rtP177L are associated with cross-resistance to lamivudine [1].

Adefovir dipivoxil (PMEA), a novel antiviral drug from a class of compounds known as nucleotide analogue reverse transcriptase inhibitors (NtRTIs) [121], has been licensed for the treatment of chronic hepatitis B [122–124]. Resistance to adefovir appears to develop infrequently in vivo, and, in two large placebo-controlled trials that included 700 patients with HBV infection [122, 123], treatment with adefovir for 48 weeks did not select for mutations associated with resistance to this compound [125]. Substitutions in the conserved domains of HBV polymerase (i.e., rtS119A, rtH133L, rtV214A, and rtH234Q) were infrequently detected as minority species in the clinical isolates of four adefovir-treated patients from these studies. Moreover, these secondary mutations did not confer phenotypic resistance to adefovir and were not associated with diminished virological response to this drug during the treatment period [125]. However, continued exposure to therapeutic levels of adefovir for up to 96 weeks resulted in selection of an adefovir resistance mutation within the HBV polymerase D domain (i.e., rtN236T) in one patient [126]. Other reports from patients receiving 10 mg/d as monotherapy registered 2, 5.9, 18, and 29 % of resistant mutants after 2–5 years of treatment [126–128]. Clinical isolates that harbored this substitution were shown to have reduced antiviral activity to adefovir in vitro but remained susceptible to lamivudine and entecavir [126]. The mutation rtA181V in the B domain of the polymerase has been more recently described and can confer some loss of susceptibility to lamivudine [128, 129]. Also, adefovir resistance has been seen to emerge more frequently in lamivudine-resistant patients than in those without previous lamivudine resistance (10 % vs. 0 %) [130]. However, adefovir resistance is less likely to occur when adefovir is given in addition, rather than as a substitute, for lamivudine [131]. Therefore, the addition of adefovir to lamivudine-failing patients has become widely accepted. Importantly, a virus variant carrying the mutation rtI233V which occurs naturally appears to have lower susceptibility to adefovir [132]. This mutation has not been selected in vitro nor seen in patients experiencing virological breakthrough. In general, these data point to the essentiality of always initiating the therapy of HBV disease with combination therapy.

The nucleoside analogue entecavir was approved for treatment of HBV infection in 2005. Virologic breakthrough confirmed by genotypic analysis has been seen during phase II and III clinical trials in 5.8 % of patients treated by entecavir after lamivudine failure for 1 year, 10 % for 2 years, and 25 % for 3 years [133–136]. The patients reported with resistance to entecavir had two signature lamivudine resistance mutations in the HBV polymerase, the rtL180M and rtM204V, along with the novel mutations rtM250V or rtS202I and rtT184G. The mutation more closely linked to entecavir resistance appears to be rtM250V within a background of lamivudine resistance mutations [133]. To date, primary resistance to entecavir in the absence of previously existing lamivudine resistance has not been reported [133]. Also, recent studies indicate that entecavir possesses activity against HIV-1 as well as against HBV and can select for the M184V mutation in HIV-1 [137]. This finding my lead to revision of current guidelines of treatment in HIV/HBV coinfected patients.

Emtricitabine (FTC) is an L nucleoside very similar to lamivudine. When administered as monotherapy for HBV infection, it selects for the rtM204I/V (YIDD/YMDD) mutations in the C domain of the HBV polymerase. The rate of YMDD mutations emerging in patients receiving 200 mg of FTC per day has been reported to be 9–13 % at week 48 of treatment and 19 % at week 96 of treatment [138]

Telbivudine is a potent L-analogue and the latest antiviral drug to be approved for treatment of chronic hepatitis B. Resistance was seen in about 5 % of patients after 1 year of treatment and is attributable to a rtM204I mutation in the HBV polymerase "YIDD," but this does not seem to be linked to the rtM204V mutation in the "YMDD" motif of the HBV polymerase [139]. Telbivudine resistance mutations do not overlap with the entecavir resistance mutations, leaving a

full option for patients failing therapy with either of these agents. Finally, the emergence of resistance to all drugs used to date for the treatment of HBV provides testimony to the need for combination therapy in clinical practice.

10 Herpes Virus Infections: Cytomegalovirus (CMV) and Herpes Simplex Virus (HSV)

The incidence of opportunistic infections associated with HIV/AIDS has significantly declined as a result of the introduction of highly active antiretroviral therapy (HAART). However, in certain clinical settings, such as in patients with severe primary combined immunodeficiency (SCID) and patients requiring organ transplantation, the development of cytomegalovirus (CMV) infection remains a serious complication that generally requires the use of antiviral therapy [1, 140]. In the pre-HAART era, the rate of resistance to each of the anti-CMV drugs was estimated to be approximately 25 % per person-year [141–144].

Regarding human CMV therapy, a diverse array of drugs that includes acyclovir, ganciclovir (GCV), oral prodrug of valganciclovir (a prodrug which is transformed into GCV first-pass metabolism), foscarnet (FOS), nucleotide analogue, cidofovir (CDV), and fomivirsen are used to treat CMV disease [1, 121, 140]. These compounds have been shown to suppress viral replication through inhibition of the viral DNA polymerase which is encoded by the CMV UL54 gene. Sequence analysis has demonstrated that mutations in this gene can confer resistance to each of these three drugs. In addition, GCV, like all other nucleoside analogues, needs to be activated to its virologically competent form, GCV-triphosphate. This process initially involves the phosphorylation of GCV to its monophosphate moiety by a viral-encoded phosphotransferase (see Fig. 86.1). This enzyme is expressed by the UL97 gene. Studies have shown that resistance to GCV can manifest as early as 10 days following initiation of therapy with this drug and that numerous mutations, many of which are located between amino acid residues 590–606 or at position 460 or 520 [145] in UL97, may contribute to reduced susceptibility to GCV in some immunocompromised patients [140]. Similarly, a novel deletion mutant involving an eleven amino acid sequence between positions 590–600 in UL97 has also been identified in GCV-resistant isolates from a patient with SCID [146]. In other studies, GCV-associated mutations in UL97 were found to be highly prevalent in viral isolates that displayed varying degrees of resistance to GCV [147]. However, sequence analysis of UL97 alone cannot be used to predict the level of resistance to GCV without knowledge of additional genotypic and/or phenotypic information obtained in regard to UL54 [1]. During prolonged GCV therapy, UL97 mutations appear early and result in lower-level resistance, whereas UL54 mutations appear later and confer higher-level resistance [147–150].

Recent studies of clinical isolates from AIDS and solid organ transplant patients have documented that the most frequent UL97 mutations present in GCV-resistant mutants were A594V, L595S, M460V, and H520Q [150–152]. Other common UL97 mutations related to resistance include C592G and C603W. The mutations associated with the highest rate of increase in GCV resistance have been M460V, C603W, deletion of codons 595–603, H520Q, L595S, A594V, C607Y, and deletion of codon 595 with a fold change in resistance from 4.9 to 13.3 depending on the mutation [145, 153–156]. In contrast, mutations C592G, A594T, and E596G and deletion of codon 600 confer a lower decrease in drug susceptibility [145].

The CMV DNA polymerase, which is encoded by the gene pUL54, can also mutate in response to drug pressure, and such mutations can potentially affect all currently approved antivirals. Some of the most frequent DNA polymerase mutations

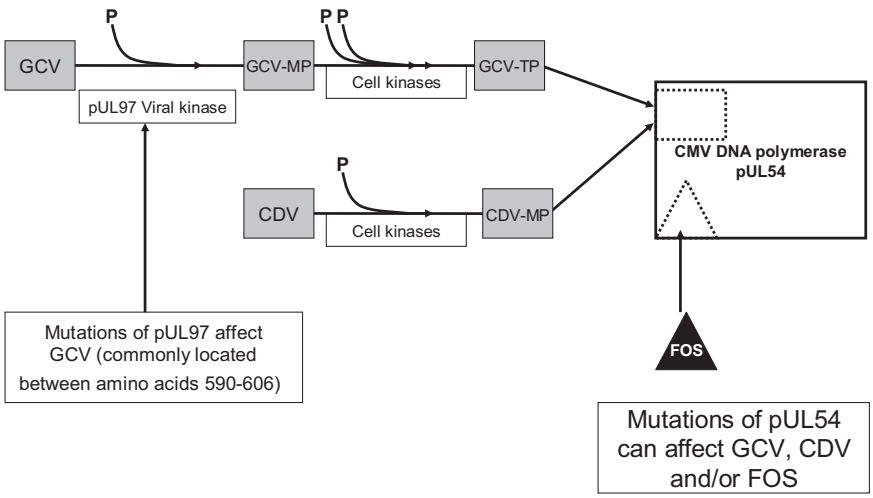

Fig. 86.1 Anti-CMV drugs: mechanisms of action and resistance. (Ganciclovir) GCV needs to be first phosphorylated by a viral kinase encoded by the gene UL97. The CMV DNA polymerase, encoded by the gene UL54, can also mutate and potentially cause resistance to CGV, cidofovir (CDV), and foscarnet (FOS)

causing drug resistance are V715M, V781I, and L802M, which confer resistance to FOS, and F412C, L501I/F, and P522S, which result in resistance to GCV and CDV. The mutation A809V, which confers resistance to GCV and FOS, the mutation N408K which confers resistance to GCV and CDV, and the mutation A834P which causes resistance to GCV, FOS, and CDV have also been reported [157, 158]. Some mutations (A834P, E756K, and V812L and the deletion of codons 981 and 982) can cause resistance to all three of those antivirals [157–159]. The effect of combined mutations can be synergistic, as it is the case with mutations N408K and A834P. N408K and A834P cause a 4.2-fold and a 5.4-fold increase in resistance against GCV, respectively. When present together, the resulting fold increase in resistance is 22.7, rendering the virus highly resistant to this drug [158]. The mutations L501I and K513N and deletion of codons 981–982 result in six- to eightfold decrease in GCV susceptibility, and mutations F412C/V, K513N, and A987G have been associated with a 10- to 18-fold decrease in CDV susceptibility [157, 159, 160]. In addition, the substitutions D588N, V715M, E756K, L802M, and T821I can reduce the susceptibility to FOS from 5.5- to 21-fold [157, 159–162].

Fomivirsen (ISIS 2922) is a 21-base oligonucleotide with phosphorothioate linkages that are complementary to human CMV immediate-early 2 (IE2) mRNA. Hence, fomivirsen binds to this complementary CMV mRNA sequence and inhibits translation of several CMV immediate-early proteins [32, 163]. Although a resistant virus has been isolated in vitro, the mechanism of resistance was not due to loss of encoded complementarity with the oligonucleotide. To date, no report has been published on fomivirsen resistance in patients [164].

As is also the case with CMV disease, the prevalence of drug-resistant herpes simplex virus (HSV) variants is both highest and of greatest concern in immunocompromised hosts [165]. It has been reported that up to 30 % of allogeneic bone marrow transplant patients may be infected with acyclovir (ACV)-resistant HSV [166] (97). These mutants arise spontaneously and are selected by exposure to antiviral agents. Resistance to ACV and also to related drugs such as penciclovir that are used for the treatment of HSV infection arises predominantly from mutations in the virally encoded thymidine kinase (TK) gene. The TK gene product is responsible for the phosphorylation of ACV to ACV-monophosphate, an important initial step that is essential for the activation of nucleoside analogues such as ACV in HSV-infected cells. ACV resistance mutations in TK involve nucleotide additions, deletions, or substitutions that often occur in regions that contain a high density of guanine-cytosine (G-C) sequences and which are thought to be more prone to mutagenesis. Examples of common ACV resistance mutations in TK include repeated nucleotides at codon 92; a frameshift mutation at codon 146 that is detected in the majority of ACV-resistant clinical isolates; an arginine substitution at codon 176 in HSV type 1 or, alternatively, at codon 177 in HSV type 2; and an amino acid substitution at codon 336 that is observed in both clinical and laboratory HSV strains with reduced sensitivity to ACV [166]. Furthermore, genotypic studies have shown that TK possesses an unusually high propensity for the development of mutations associated with polymorphisms that do not confer resistance to ACV. These polymorphisms are located throughout the TK gene but do not involve conserved domains or the nucleotide sequences that encode the ATP and nucleoside binding sites within TK. Lastly, mutations in the conserved domains of the HSV DNA polymerase gene have also been shown to be involved in resistance to ACV [166, 167]. For example, the L774V substitution in the polymerase conserved region VI has been shown to be associated with diminished susceptibility to both ACV and the pyrophosphate analogue foscarnet [168].

11 Future Perspectives

As reviewed herein, the application of genotypic resistance testing has proven to be instrumental for the clinical monitoring of antiretroviral drug resistance and now constitutes an important component of the standard of care for patients with HIV-1 infection in industrialized nations. Furthermore, the results of several studies including CPCRA 046 and VIRADAPT and the Havana trial have confirmed the prognostic value and cost-effectiveness of genotypic resistance testing for guidance of therapy in patients who experience virological failure during the second or later regimens. In particular, HIV-1 genotyping is an essential strategy for the optimization of combination therapy used in salvage regimens that include the fusion inhibitor T-20.

However, despite these significant advances, the high cost and complexity associated with genotypic drug resistance assays remain important economic and technological barriers in regard to their wider implementation, especially in resource-poor countries [169]. Careful planning and prioritized use of genotyping are essential in order to achieve the best cost-benefit in these circumstances. There are also several other potential applications for genotyping that may represent opportunities for further improvements in therapeutic outcomes for HIV-1 infection. An example concerns the use of genotypic analysis for monitoring polymorphisms in non-B HIV-1 subtypes that may be important in regard to differential patterns of antiretroviral susceptibility compared to HIV-1 subtype B viruses. For instance, some subtype C HIV-1 variants are known to possess naturally occurring polymorphisms at several RT and PR codons that are implicated in drug resistance [170, 171]. Studies have showed that the presence of these polymorphisms did not significantly reduce susceptibility to ARVs nor diminish the effectiveness of an initial antiretroviral therapy regimen for a period of up

to 18 months [170, 172]. However, it has also been suggested that polymorphisms at resistance positions may facilitate selection of novel pathways in some cases, leading to drug resistance especially with incompletely suppressive antiretroviral regimens [170]. This, in turn, may have important clinical implications with respect to the choice and long-term benefit of antiretroviral therapy that may indeed warrant increased genotypic surveillance, particularly as the worldwide prevalence of non-B HIV-1 infection is increasing rapidly [173]. HIV-1-infected pregnant women who have previously received antiretroviral therapy represent another important situation in whom genotypic drug resistance testing may be a perinatal strategy for guidance of therapy to prevent HIV transmission to infants [174, 175].

Genotypic monitoring may also be of prognostic value in the clinical management of patients with primary HIV-1 drug resistance. The prevalence of primary HIV-1 drug resistance (RT and PR resistance-associated mutations) in recently infected individuals in Europe [176] and North America [177, 178] has been estimated to be approximately 7 and 20 %, respectively. In addition, recent reports suggest that a trend exists toward worldwide transmission of drug-resistant HIV-1 variants in antiretroviral therapy-naïve individuals [179]. Of particular interest and concern is the transmission in primary HIV-1 infection of highly resistant and of multidrug-resistant (MDR) HIV-1 variants that harbor resistance-conferring mutations to two or three classes of ARVs. Studies have shown that these viruses display in vivo replication competence that is often comparable to that of drug-sensitive species and, moreover, that they are able to establish persistent infections in the absence of antiretroviral drug pressure [170–182]. The use of HIV-1 genotyping in this clinical setting may allow for earlier detection of HIV-1 MDR variants and, therefore, increase the likelihood for improved therapeutic outcomes during chronic infection. Furthermore, such testing may help to reduce overall the spread of HIV-1 drug resistance.

As mentioned previously, the use of interpretative algorithms in conjunction with HIV-1 genotyping has facilitated prediction of drug resistance from the plethora of mutational patterns that are frequently associated with failing antiretroviral regimens. Two types of computer-based algorithms have been developed for analysis of HIV-1 genotypic data; these are rule-based algorithms and a virtual phenotype [183]. Rule-based algorithms are derived from knowledge of in vitro drug susceptibility assays, the relationship between specific resistance-associated mutations and virological responses in HIV-1 infected patients, and expert opinion [184]. The virtual phenotype, on the other hand, utilizes databases that correlate various mutational patterns with actual in vitro phenotypic resistance and clinical response in order to infer the level of drug resistance (i.e., sensitive, intermediate, or resistant) to ARVs that is displayed by a viral isolate on the basis of its HIV-1 genotype [183]. Discordant results among widely used interpretative algorithms, in which a viral isolate is scored as sensitive by one program and resistant by another, are frequent. This situation constitutes an important limitation of current technology and, moreover, underscores the technical challenges associated with the coding and interpretation of complex patterns of drug resistance mutations.

Several studies have shown that discordance between various algorithms is greatest with NRTIs, with the exception of 3TC, as compared to NNRTIs and most PIs, where the level of disagreement is usually less [185–187]. For example, in one study that examined the Stanford University Database (HIV db), Bayer Diagnostics TRUGENE (BDT), and the Virco VirtualPhenotype (VP) HIV-1 genotyping programs, discordant results for interpretation of drug susceptibility to ddI, ddC, d4T, and ABC were reported in excess of 50 and 40 % of cases in comparisons between the HIV db and VP and BDT and VP algorithms, respectively [186]. In contrast to these findings, concordant scores for 3TC were obtained with all three genotyping programs in >90 % of cases studied [186]. It has also been suggested that the discordance that exists between algorithms reflects a need for increased clinical validation and better consensus in interpretation of drug resistance data during the development of these tools, especially for some drugs such as NRTIs [185, 186].

In addition, the use of phenotypic drug resistance assays in conjunction with genotyping may be of further predictive value in some situations [184, 188]. Unlike genotyping, phenotypic tests represent a more direct method for detection of HIV-1 drug resistance that is based on changes in the 50 % inhibitory concentration (i.e., IC_{50}) for a particular ARV in regard to a viral isolate in comparison with a HIV-1 reference strain [7, 184, 189, 190]. However, discordances between genotypic and phenotypic tests are not uncommon and can arise as a result of several circumstances [82, 184, 191]. In instances of either genotypic-phenotypic discordance or disagreements between different HIV-1 genotypic interpretative systems, access to expert advice on HIV-1 drug resistance may be invaluable in order to help reduce uncertainty with respect to decisions about a subsequent therapeutic regimen.

Lastly, genotypic drug resistance testing has also been successfully implemented for other chronic viral infections (i.e., HBV, CMV, and HSV) and may also hold promise for guiding therapy choice decisions to improve treatment outcomes for certain types of cancer. The development and future availability of antiviral therapy for additional viral diseases as well as the identification of novel molecular markers for cancer are likely to be key determinants in regard to the extended utilization of genotypic drug resistance assays.

Acknowledgments Research performed in our laboratory is funded by the Canadian Institutes for Health Research.

Part XIII

Public Health Issues of Drug Resistance

Antimicrobial Resistance: An International Public Health Problem

87

Joseph D. Lutgring, Carlos A. Diaz Granados, and John E. McGowan Jr.

1 Introduction

In recent years, the problem of antimicrobial resistance has been recognized and addressed by international, regional, and national public health agencies, authorities, and professional societies [1–4]. Antibiotics have saved millions of lives and have enabled many other medical advances since their discovery and introduction into clinical practice. The worsening problem of antimicrobial resistance now jeopardizes many of these advances. However, action plans to minimize this threat have been developed by many public health agencies around the globe [5–8]. This focus is likely to increase among public health agencies in the coming years. Several facets of the problem involve the relationship between human and animal use of antimicrobial agents [3, 9]. This chapter summarizes the components of the cost of resistance from a public health perspective and contrasts this perspective to other societal perspectives. It then reviews strategies at several different levels of responsibility, ranging from the patient care provider to international agencies. Finally, it considers appropriate public health responses according to the resources available for control. In an era of globalization, antimicrobial resistance represents an international concern that demands a concerted effort from multiple health and industry sectors. Public health must be at the forefront of these efforts. Antimicrobial resistance is widely recognized as a complex international problem. Antibiotics have saved millions of lives and have enabled many other medical advances since their discovery and introduction into clinical practice. The worsening problem of antimicrobial resistance now jeopardizes many of these advances [1, 2, 4, 7, 8, 10–13]. The number of pathogens resistant to multiple classes of antimicrobials has increased worldwide [14]. There have been reports of infections with *Pseudomonas aeruginosa* and *Acinetobacter* species which are resistant to all available antibiotics [15]. Other pathogens, such as *Neisseria gonorrhoeae*, that were previously relatively easy to treat, are now becoming much more difficult to treat due to antimicrobial resistance [16]. There is also evidence that resistant organisms that were previously confined to the acute care hospital setting are now sources of community-acquired infections [17]. Resistance is not only an issue for bacterial pathogens like staphylococci, enterococci, *Escherichia coli*, *Klebsiella*, *Neisseria*, and *Mycobacterium tuberculosis* but also the problem of resistance is increasingly being recognized in nonbacterial pathogens like *Candida*, HIV, malaria, and influenza [14].

The worldwide increase in the prevalence of resistance is a concern because it threatens both the optimal care of patients with infections and the viability of current healthcare systems [18]. For individual patients, antimicrobial drug resistance has a clear impact on patient morbidity and mortality [5, 19, 20]. Of concern for healthcare systems is the economic impact of resistance [20–23]. In the United States, resistance is especially costly for the healthcare system and for the third-party payers that support such systems [20, 22]. Costs are also burdensome for national-based healthcare programs [23]. The incremental cost of caring for patients infected with resistant organisms has several aspects [19, 20, 22]. As the prevalence of resistance increases, physicians often substitute older and less expensive drugs for newer and more expensive agents [24]. Such costs in the United States are absorbed only in part by third-party payers, which often reimburse on the basis of head count, diagnosis-related groups, or other formulas unrelated to specific services provided to an individual patient. Thus, most costs

associated with resistant infections must be absorbed by the healthcare system itself [25]. As the prevalence of drug-resistant organisms increases, these additional costs will mount and become a threat to the financial stability of local, regional, and national healthcare systems, many of which are already struggling to survive.

2 Public Health as a Perspective on Resistance

Public health involves the population as a whole. It focuses on what we as a society do to assure conditions in which we can be healthy [26]. The goal of public health, the health of a population, can be distinguished from the goals of medical care, the health of a patient [27]. The public health goal, fueled by an aim of social good, is much broader in scope. It can encompass the health of neighborhoods, cities, countries, or even the entire world [21]. Using the public health perspective of health, a long time frame for evaluation is usually appropriate. Since antimicrobials can both prevent and treat infections in society, society considers them a valuable resource [28]. As resistance diminishes this resource, a societal goal should be to minimize resistance and therefore to reduce the forces that produce resistance [6, 29, 30].

All use of antimicrobials increases the likelihood of resistance developing [13]. From a societal viewpoint, the use of antimicrobials to appropriately treat infections would be an appropriate rate of depletion of this valuable resource [25, 31]. Overuse or misuse of antimicrobials would be an inappropriately increased depletion of this resource [32]. The costs of resistance from a public health perspective can be summarized as those resulting from treatment of patients infected with resistant organisms, those resulting from treatment of patients not infected with resistant organisms, and those resulting from antimicrobial use in agriculture, animal breeding, aquaculture, and industry (Table 87.1).

The impact of antimicrobial resistance includes an increase in morbidity, mortality, and added costs for patients with resistant organisms. The added costs include those derived from the use of scarce healthcare resources: the care of patients with infections of resistant organisms, preventing transmission, maximizing appropriate empiric therapy, and resistance surveillance. In addition, excess loss of productivity and excess intangible costs such as patient and physician anxiety, pain, suffering, and inconvenience are also increased with antimicrobial resistance. Antimicrobial drug markets may also be affected by increasing resistance. Older, cheaper, and more narrow-spectrum drugs often become less useful, while the marketability of newer, more expensive, and more broad-spectrum drugs is favored [33].

2.1 Morbidity and Mortality

Numerous studies have demonstrated that antimicrobial-resistant organisms are associated with a higher morbidity and mortality than susceptible organisms. This has been shown for many different types of resistant organisms [34–40]. Invasive infections with methicillin-resistant *Staphylococcus aureus* (MRSA) have frequently been shown to be associated with a higher mortality and an increase in hospital length of stay when compared to methicillin-susceptible *Staphylococcus aureus* (MSSA) [35, 36, 38]. Similar associations are found when looking at enterococci. Vancomycin-resistant enterococci (VRE) bloodstream infections are associated with a higher mortality than vancomycin-susceptible enterococci bloodstream infections [38]. Although prior studies had not shown a higher mortality with penicillin-resistant pneumococcal infections [38, 41], a more

Table 87.1 Factors contributing to the public health impact of antimicrobial resistance

Resulting from antimicrobial use in infected patients with resistant organisms	Added deaths[a]
	Added pain/suffering/inconvenience/anxiety
	Added costs for increased hospital stay: resulting work absence and loss of productivity
	Added costs for antimicrobial drug purchase (use of more expensive agents)
	Added costs for diagnostic and therapeutic procedures dealing with initial treatment and complications
	Added costs for infection control activities
	Loss of markets for old drugs (minus gain in markets for new drugs)
Resulting from antimicrobial use in patients not infected with resistant organisms	Added costs for substitution of a drug in empiric treatment because resistant organisms may be present (usually broader coverage, selecting for new emergence of resistance)
	Added costs for substitution of a drug in empiric treatment because resistant organisms may be present (usually more expensive)
	Added costs for infection surveillance
	Added anxiety about treatment failure
Resulting from nonhuman antimicrobial use (animals, aquaculture, agriculture, industry, etc.)	Emergence of resistance in human populations by transfer of resistance determinants from nonhuman settings

[a]Beyond that of a similar infection with a susceptible organism

recent meta-analysis has shown penicillin-resistant pneumococcal infections to be associated with a higher mortality compared to penicillin-susceptible infections [38, 42].

Similar outcomes have been noted for antibiotic-resistant gram-negative infections. *Escherichia coli* and *Klebsiella pneumonia*e strains resistant to extended-spectrum cephalosporins, multidrug-resistant (MDR) *Pseudomonas aeruginosa* strains, and carbapenem-resistant *Acinetobacter* infections have all been associated with an increased length of stay and mortality when compared to their more susceptible counterparts [34, 35, 37, 43]. Specifically, this mortality is noted to be higher when study antibiotic-resistant gram-negative bacilli in the setting of septic shock [40]. One plausible reason for this finding is the difficulty in selecting an appropriate empiric antibiotic regimen in the era of highly drug-resistant gram-negative infections. It is well established that the duration of hypotension without appropriate antimicrobial therapy is a crucial factor in the probability of survival in septic shock [44].

In addition to gram-positive and gram-negative pathogens, drug-resistant tuberculosis has also been shown to have a higher mortality compared to drug-susceptible tuberculosis [39]. For all different types of drug-resistant infections, an increase in mortality affects more than just the patient when examined using the public health perspective. Although difficult to quantify, the consequences of premature death include a loss of productivity (number of productive years lost multiplied by the average yearly productivity) and the pain and suffering of family members and friends [25].

2.2 Added Healthcare Costs

In addition to an increase in morbidity and mortality, antimicrobial resistance is associated with added healthcare costs. These costs correspond to the direct and indirect costs of patient care (healthcare professionals' time, medications, devices, tests, administration, space, utilities, and patient travel costs) [45]. For infections that require hospital admission, these costs have been estimated by comparing total hospital expenditure for patients infected with resistant microbes to total hospital expenditure for those infected with susceptible organisms. These studies sometimes control for confounding factors such as comorbidities and severity of illness. In a 2012 study, hospitalizations with a resistant organism were on average US$15,626 more expensive than hospitalizations with a susceptible organism. This study included *Staphylococcus aureus*, *Enterococcus*, *Klebsiella pneumonia*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii* [20]. Findings were similar in a 2009 study with the added cost ranging from US$18,588 to 29,069 [22].

In addition to hospitalization costs, healthcare costs can be estimated by looking at length of stay, which can be used as a surrogate measure. Length of stay has been found to be longer for resistant strains of *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterococcus* compared to susceptible strains. These increases in length of stay have ranged from 3.3 to 39.6 days in various studies of various organisms [20, 22, 34, 36, 37].

Tuberculosis is another example of an infection in which the drug-resistant strain has clearly been associated with higher healthcare costs compared to the drug-susceptible strain. A recent study showed multidrug-resistant (MDR) tuberculosis cases to cost US$134,000 on average compared to extensively drug-resistant tuberculosis cases at US$430,000. Both of these numbers are compared to an average cost of US$17,000 for non-MDR tuberculosis [46].

The costs of infection control activities and antimicrobial stewardship programs should also be considered because these programs largely exist due to antimicrobial resistance. These expenses include personnel costs, equipment costs, surveillance costs, and microbiology laboratory costs [21]. Antimicrobial resistance also leads to the phenomenon of resistance-induced antimicrobial substitution [21, 24]. In the setting of empiric therapy, when treating septic shock, for instance, the physician feels obligated to attempt to cover all possible pathogens. As antimicrobial resistance worsens, the number of drugs that are needed increases. The cost of the medications also often increases, and new drugs are often more broad spectrum. In addition to the direct costs of this phenomenon, the overall problem of antimicrobial resistance is also worsened [21, 24].

3 Contrasts Between the Public Health View of Resistance and Other Views

There are multiple stakeholders when it comes to antimicrobial resistance. These various groups have different viewpoints about resistance and its impact (Table 87.2) [21]. The view of antimicrobial resistance from a public health perspective will be contrasted with the view of physicians and other medical providers, patients, healthcare businesses (both providers and payers), and pharmaceutical companies.

3.1 Physicians

Physicians and other healthcare providers are focused on treating individual patients [21]. They seek to cure disease and alleviate suffering by treating medical conditions. The time frame of most patient-provider relationships is short (at least in regard to treating infections). From the perspective of physicians, the loss of effectiveness of a single antimicrobial agent would typically be of little concern assuming

Table 87.2 Differing perspectives on the importance of antimicrobial resistance[a]

	The public	Medical professional	Patient	Healthcare business	Industry
Focus	Population	Individual	Individual	Care group	Potential clients
Desired outcome	Maximize health	Absence of disease	Absence of disease	Reduce cost of care	Increase sales
Time frame	Long	Short	Short	Short	Short, long
Motivation	The social good	Professionalism	Personal well-being	Profit	Profit
Approach	Reduce the forces leading to resistance	Treatment	Treatment	Cost containment	Develop new drugs, keep old drugs viable

[a]Adapted in part from [18]

there were other antimicrobials that could be used. However, as microbes accumulate resistance mechanisms that render multiple classes of antimicrobials ineffective, medical providers will become alarmed. Providers may be left with alternative therapies that are more toxic or no therapies at all. An example of this situation is the spread of carbapenemase-producing gram-negative bacteria throughout the world [47–51]. As the incidence of these very resistant pathogens increases, medical providers will very much take notice.

3.2 Patients

Patients are interested in antimicrobial resistance to the point that it affects their personal well-being. They would be concerned to know that antimicrobial-resistant infections are associated with a higher mortality than susceptible infections [34–40]. They may also be concerned about the increases in cost associated with resistance (especially if patients pay retail prices for their healthcare).

3.3 Healthcare Businesses

For the administrators who control healthcare system financial resources (both systems that provide healthcare services and the agencies that pay for such services), the major impact of resistance is the increasing healthcare costs associated with resistance [19–23]. Managers of these groups are also concerned about a reduction in morbidity and mortality, but they look to accomplish this goal in a fiscally efficient manner. They aim to minimize the costs of increasingly scarce financial resources. Antimicrobials are usually a cost-effective method of caring for patients who these groups are responsible for [25]. Measures that must be taken to deal with antimicrobial resistance may lead to incremental increases in the costs of drugs, diagnostics, and therapeutic services. The institution must also fund costs for personnel time, supplies, and equipment for institutional programs to deal with resistance (infection control programs, antimicrobial stewardship programs, etc.).

One example of a healthcare system intervention to deal with antimicrobial resistance and increasing costs was the decision in October 2008 for the Centers for Medicare and Medicaid Services to discontinue payments to hospitals for certain hospital-acquired infections. This decision was made in an attempt to curb costs and reduce the rates of hospital-acquired infections. Unfortunately (at least so far), this policy doesn't appear to have reduced infection rates in the United States [52, 53].

3.4 Industry

The focus for pharmaceutical firms, diagnostic instrument manufacturers, and other industry groups providing products for treatment and prevention of infectious diseases (antimicrobial agents, products to stimulate host defenses, vaccines, etc.) is similar in some ways to that of healthcare business. In this case, however, the clients of interest are the potential users of their products, both directly (patients) and indirectly (healthcare systems, governments, etc.). Product sales are the desired outcome, and a short-term view of sales is part of their outlook. However, industry also must take a longer view of the subject and consider the impact of resistance as a potential opportunity for introduction and sales of new products. This sometimes leads to antagonistic and conflicting views of the problem. On the one hand, the firms wish to maintain the life of their current antimicrobial products, a goal that is threatened by new patterns of antimicrobial resistance. On the other hand, resistance may make render competitor's products obsolete. It may also open up new potential markets for either new drugs or new uses of old drugs [54]. An interesting phenomenon is the reemergence of old antimicrobials like colistin that were previously seldom used due to high rates of toxicity that have found a new market due to increasing antimicrobial resistance [55]. Thus, the consequences of resistance to industry are varied and depend on the individual situation. Diagnostic instrument manufacturers, for example, may benefit by antimicrobial resistance as their products may become more in demand.

3.5 Summary: A Dramatic Difference in Viewpoints

It is clear that different stakeholders concerned about antimicrobial resistance have different focuses, motivations, and approaches to the problem. This discrepancy between the public health perspective and the perspective of others' informs how these different groups act.

4 Influences on Resistance and Control Strategies

The forces that influence the rates of antimicrobial resistance are several (Fig. 87.1). Antibiotic resistance is a naturally occurring phenomenon, and antibiotic resistance genes are present in nature long before those antimicrobials are used in humans. This is because environmental organisms often produce substances very similar (if not identical) to antimicrobials, and bacteria have evolved to survive these naturally occurring substances [56]. The spread and proliferation of antimicrobial use is certainly heavily influenced by human behavior. Attempts to minimize antimicrobial resistance include appropriate antibiotic prescribing, antimicrobial stewardship programs, infection control programs, education, limiting use of antimicrobial use outside of human populations, and novel antimicrobial drug development [57, 58]. Different individuals and groups have different focuses to combat antimicrobial resistance (Table 87.3). While certain principles for controlling antimicrobial resistance apply to all organisms, other principles are organism specific [59]. For example, the prevention strategies for controlling the spread of gram-negative antimicrobial resistance are different than those for controlling resistance in HIV. In the paragraphs that follow, the strategies that various interested parties use to combat antimicrobial resistance will be examined.

4.1 Providers

Regardless of which resistant organisms are of interest, healthcare providers are crucial to combating antimicrobial resistance. Providers have a responsibility to attempt to educate their patients about the issue of antimicrobial resistance [7]. In addition to education, medical providers have a tremendous impact on antimicrobial resistance by their prescribing behavior. Antibiotic overuse, misuse, and underuse are all examples of inappropriate use of antimicrobials that contribute to resistance [60]. Antibiotics are overused when prescribed for noninfectious inflammatory processes like pancreatitis, when given for an unnecessarily long duration or when used to treat bacterial colonization rather than infection. Antibiotics are misused when unnecessarily broad-spectrum agents are chosen or when antibiotics aren't appropriately narrowed after culture results return. Antibiotics are underused when dosing is inappropriately used or when antibiotics are prematurely discontinued [60]. Despite providers' best intentions, the inappropriate use of antibiotics is rampant. Many hospitals have developed antimicrobial stewardship programs (usually lead by medical providers) to attempt to optimize the use of antimicrobials [61–63].

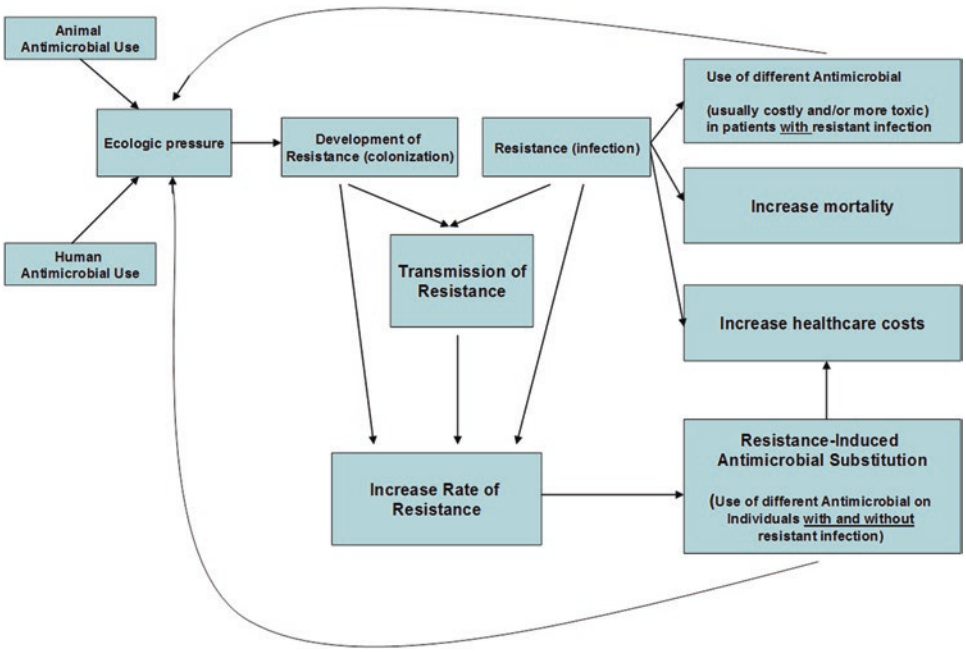

Fig. 87.1 Forces influencing antimicrobial resistance and its consequences

Table 87.3 Possible control strategies for controlling resistance, by levels of responsibility within the public health and healthcare systems

Strategy	Provider level	Local health department/ hospital level	Regional health department level	National level	International level
Patient education	Conduct	Provide materials	Provide materials	Provide materials	Provide materials
Prescriber education	Self-education	Provide materials	Provide materials	Provide materials	Provide materials
Resistance and antimicrobial use of surveillance	Report cases	Aggregate and disseminate resistance and antibiotic use summaries	Aggregate and disseminate resistance and antibiotic use summaries	Aggregate and disseminate resistance and antibiotic use summaries	Aggregate and disseminate resistance and antibiotic use summaries
Treatment	Implement	Community programs	Provide guidelines and resources; ensure drug supply/quality	Provide guidelines and resources; ensure drug supply/quality	Provide guidelines and resources; ensure drug supply/quality
Preventing spread	Implement isolation, quarantine, and vaccination	Contact tracing, vaccination campaigns	Provide guidelines and resources, vaccination campaigns	Provide guidelines and resources, vaccination campaigns	Provide guidelines and resources
Research	Study individual patients or a group of patients (case reports and case series)	Study effective provision of services	Study effective provision of services	Support local and regional studies; study drug, diagnostic test, and vaccine development	Support local and regional studies; study drug, diagnostic test, and vaccine development

4.2 Local Health Departments and Hospitals

Local health departments and hospitals should participate in education, generating useful tools and disseminating them to providers and patients. As mentioned previously, antimicrobial stewardship programs (usually run by hospitals) have an important role in attempting to optimize the use of antimicrobials [61–63]. Over the past decade, the number of antimicrobial stewardship programs in the United States has increased [64]. The goals of antimicrobial stewardship programs are several. They seek to reduce the rates of antimicrobial resistance (or at least slow the increase). They also seek to improve the care of patients (ensuring infections are appropriately treated), to minimize adverse drug toxicities, and to decrease the incidence of *Clostridium difficile* infection. They may also have the ability to reduce healthcare costs [65]. The possible strategies to achieve these goals are several. Antimicrobial stewardship programs have attempted to develop clinical guidelines, educate providers and patients, require prescription approval, and use computer-based decision support systems [65, 66].

In addition to antimicrobial stewardship programs, hospitals and local health departments play a significant role in surveillance. Using *Neisseria gonorrhoeae* as an example, local health departments play a critical role in the surveillance of drug-resistant strains. For this infection, diagnosis in the clinical setting is usually made by nucleic acid amplification tests (which cannot detect resistance). Thus, local health departments have a role in continuing to collect cultures to monitor for drug-resistant *N. gonorrhoeae* [67]. Tuberculosis is another infection where surveillance for drug resistance is important. Optimally, in all cases of tuberculosis, the isolate should undergo drug susceptibility testing. This is especially imperative when the patient is failing therapy or in locations with very high rates of resistance [68].

4.3 Regional, National, and International Health Organizations

All of these groups have similar responsibilities in the effort to control resistance. One important role is antimicrobial resistance surveillance. They should aggregate, summarize, and disseminate surveillance reports to help providers make patient care decisions and to help governments and health organizations make policy decisions [69–74]. These groups also have a role in generating "calls to action" and mobilizing the political will to bring about legislation that tackles the problem of antimicrobial resistance [75–78].

Another role that national and international organizations have is in the development of guidelines to reduce antimicrobial resistance. One example of such guideline development is the Centers for Disease Control and Prevention's Ventilator-Associated Pneumonia Surveillance Definition Working Group. This group was formed to improve ventilator-associated pneumonia surveillance with the ultimate aim of reducing such events [79–81].

5 Public Health Perspectives of Antimicrobial Resistance According to Resource Limitation Levels

Since antimicrobial resistance is both a cause and a consequence of resource utilization, forces that drive the emergence and spread of resistance are clearly different according to the

Table 87.4 Public health perspectives of antimicrobial resistance according to resource limitation levels

Resource limitation level	Extreme resource limitation	Significant to moderate resource limitation	Minimal to moderate resource limitation	Minimal resource limitation
Resource use	Minimal to none	Some (inconsistent and/or insufficient)	Inappropriate (excessive use and poor compliance)	"Perfect" use
Antimicrobial use and consequence	No antimicrobial use— minimal antimicrobial resistance (naturally occurring)	Inconsistent antimicrobial use (interrupted supply, suboptimal dosing, use of counterfeit drugs, and nonprescription antimicrobial use)—excessive emergence of resistance	Excessive use of antimicrobials (including those not used by humans) and excessive use of broad-spectrum agents—excessive emergence of resistance	Appropriate (indication and dosing) and consistent (uninterrupted supply) use of good quality antimicrobials—unavoidable emergence of resistance
Infection control activity and consequence	No infection control activities—minimal resistance transmission	Inconsistent and incomplete infection control activities—excessive resistance transmission	Inappropriate use of infection control activities (noncompliance, slow implementation, etc.)—excessive resistance transmission	Appropriate use of isolation practices and other infection control strategies—minimization of resistance transmission
Public health consequences	Excess mortality due to treatable infections, excessive public health costs	Excess morbidity, mortality, and excess healthcare costs caused by infections due to resistant organisms	Excess morbidity, mortality, and excess healthcare costs caused by infections due to resistant organisms	Unavoidable but justifiable emergence of resistance and public health costs
Possible responses	Scale up antimicrobial agents, surveillance, vaccination, and infection control strategies (limited by resource availability)	Optimize appropriate and consistent use of good quality antimicrobials, surveillance, vaccination, and infection control practices	Optimize appropriate antimicrobial use, surveillance, vaccination, infection control practices, drug development, vaccine development, and diagnostics development	Surveillance, drug development, vaccine development, and diagnostics development
Setting	Extremely poor or low-income countries	Mainly middle-income countries	Mainly high-income countries	Nonexistent (utopia)

different levels of resource limitation. Similarly, the public health consequences and the appropriate public health policy responses are different for each scenario. Table 87.4 shows a somewhat simplistic categorization of the emergence and spread of resistance, its public health consequences, and the possible responses according to resource limitation levels.

5.1 Settings with Extensive Resources

For comparison purposes, let's suppose a utopia where there is minimal resource limitation, antimicrobials are always used appropriately, and infection control practices are timely and adequately implemented. In this scenario, some resistance will emerge unavoidably because of the use of antimicrobials, but its spread will be limited as a consequence of good infection control strategies. The excess resistance and costs derived from antimicrobial use are justified since deaths from infection are being prevented by the rational use of antimicrobials. In this scenario, the benefit derived from antibiotic use outweighs the risks of emerging resistance. Resources can also be allocated to optimize active surveillance and to develop new diagnostic tests, new antimicrobials, and new vaccines. Of course, this utopia does not exist.

5.2 Settings with Minimal Resources

In settings in which resource limitation is extreme, antimicrobials are not available, and antimicrobial resistance only emerges as a natural phenomenon. For the 1 billion people in the world who live on less than $1.25 per day, paying for antibiotics may not be possible [3]. Excessive deaths result from treatable infections due to a lack of antimicrobials. In these settings, scaling up antimicrobial use, vaccination, surveillance efforts, and infection control activities should be done.

5.3 Settings with Significant Resource Limitations

This scenario may predominate in many of the low-resource countries and some rural areas of high-income countries. In these settings, antimicrobials are available, but are frequently misused due to overprescribing, use without a prescription or self-medication, and lack of diagnostic testing [82–84]. As a consequence of these practices, antimicrobial resistance is excessive. Additionally, infection control practices and antimicrobial stewardship programs have not been optimized, so the emerging resistance is easily transmitted [85]. In this scenario, the infections caused by resistant organisms lead to an

increase in morbidity, mortality, and healthcare costs. Appropriate public health responses for this scenario include optimization of the use and supply of good quality antimicrobials, active resistance surveillance, prioritization of vaccination, and improved infection control practices.

5.4 Settings with Minimal to Moderate Resource Limitations

This situation predominates in the high-income countries throughout the world and in high-complexity medical centers. In these settings, antimicrobials are readily available. However, antimicrobials are often used inappropriately. This includes excessive use and use of agents that are unnecessarily broad [60]. Antimicrobials are also used commonly in animals, agriculture, aquaculture, and industry [9, 76]. The ecologic pressure created by excessive antimicrobial use leads to an excessive amount of resistance. In these settings, significant resources are devoted to infection control practices [21], but these practices are often not followed or implemented appropriately. The net effect is excessive transmission of resistance. The excessive resistance leads to an increase in resistant organism-related mortality and an increase in healthcare costs. Appropriate public health responses include optimization of antimicrobial use [61–63], active resistance surveillance, improved vaccination, and improved infection control practices. Resources can also be directed toward new drug, diagnostics, and vaccine development.

6 Conclusion: Antimicrobial Resistance in the Era of Globalization—An International Concern for Public Health

Human migration, animal and vector movement, and food markets may facilitate the spread of antimicrobial resistance across almost any geographic or political boundary [76]. Methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *Enterococcus* were first reported in the United Kingdom. After becoming widespread in North America and Europe, the same resistance patterns were noted in Asia. Today, novel gram-negative carbapenem resistance mechanisms such as OXA-48 and NDM-1 (New Delhi metallo-β-lactamase) were first discovered in Asia and have since spread to Europe and North America [86]. The global spread of antimicrobial resistance demands effort of multiple health and industry sectors (in both low-resource and high-resource countries) to strengthen multinational/international partnerships and regulations. Public health must be at the forefront of these efforts.

Hospital Infection Control: Considerations for the Management and Control of Drug-Resistant Organisms

88

Summer Donovan and Gonzalo M.L. Bearman

1 Introduction

The prevalence of hospital-acquired, antibiotic-resistant organisms has increased significantly over the last 20 years. Data from the National Healthcare Safety Network (NHSN) report published in 2013 revealed an alarming proportion of drug-resistant pathogens [1]. The NHSN system report represents data from more than 4000 medical facilities throughout the United States. Reports of hospital-acquired infections and microbiology data from participating institutions are published annually. From the sample, in 2009–2010, 43.7–58.7 % of all *S. aureus* isolates were resistant to methicillin, depending on the site of infection. *Enterococcus faecalis* and *Enterococcus faecium* were 6.2–9.8 % and 62.3–82.6 % vancomycin resistant, respectively [1]. An increase in drug-resistant staphylococci and enterococci has also been reported in Europe and South America [2–4].

As hospital-acquired infections with drug-resistant pathogens become increasingly more common and endemic, healthcare systems have taken various infection control measures to limit both their frequency and spread (Table 88.1, summary). Three parameters define the prevalence of drug-resistant bacteremia: how much enters the institution from outside, how much is selected by antibiotic use and misuse, and how much spreads from person to person [5]. The early recognition and isolation of incoming patients harboring resistant pathogens, appropriate antibiotic control programs, and assiduous infection control are necessary to minimize cross infection. Within the infection control domain, there may be specific efforts to minimize patient, healthcare worker (HCW), and environmental reservoirs and efforts to create meticulous hand hygiene and glove and gown use. In addition, surveillance systems for infection with hospital-acquired pathogens are essential for establishing endemic rates and for defining outbreaks. Aggressive surveillance for asymptomatic reservoirs may be of value but is not without controversy. Other considerations for an infection control program include hospital design considerations and antibiotic control programs.

1.1 The Importance of Patient and Healthcare Worker Colonization with Drug-Resistant Pathogens: Reservoirs for Infection

Colonization serves as a significant reservoir of drug-resistant, hospital-acquired pathogens. Patient colonization by drug-resistant pathogens such as VRE and MRSA has been well described. Thirty to 50 % of healthy adults have nasal colonization with *S. aureus*, with 10–20 % persistently colonized [6, 7]. Both methicillin-sensitive *S. aureus* (MSSA) and MRSA isolates can be persistent colonizers. Colonization with MRSA has been well documented in various healthcare settings. It has been reported that 25 % of patients admitted to a hospital will become nasally colonized with *S. aureus* [8]. This figure varies widely based on different populations and risk factors. Rates as high as 40–60 % have been reported in select populations including patients with diabetes and HIV. Certain populations are predisposed to colonization with *S. aureus* at the time of admission. Dupeyron et al. prospectively analyzed *S. aureus* colonization in a cohort of 551 cirrhotic patients. Screening nasal and rectal swabs were performed within 48 h of admission to the

Table 88.1 Summary of selected infection control measures for the management and control of drug-resistant organisms

Infection control measure	Rationale	Comment
Nasal decontamination with mupirocin	• 25 % of patient admitted to a hospital will become nasally colonized with *S. aureus* • Compared with MSSA colonization, both MRSA colonization and MRSA acquisition during hospitalization increased the relative risk of infection	• In one prospective study, the use of intranasal mupirocin in a surgical cohort was effective in reducing the frequency of *S. aureus* hospital-acquired infections only in patients previously colonized with *S. aureus* • Mupirocin decreased the rate of *S. aureus* infections in hemodialysis patients
Chlorhexidine bathing	• Colonization of bacteria on patients' skin leads to environmental contamination • Environmental contamination increases the risk of transmission of hospital-acquired infections	• Chlorhexidine bathing decreases rates of colonization and hospital-acquired infections • Chlorhexidine-impregnated cloths provide a convenient no-rinse option • Studies revealed no significant toxicity associated with chlorhexidine bathing • Use is not approved for infants <2 months old
Environmental decontamination	• The inanimate environment can be contaminated with MRSA, *C. difficile*, VRE, and drug-resistant gram-negative rods. This is a potential reservoir for cross-transmission of hospital-acquired pathogens via the hands of HCWs	• All healthcare facilities should develop policies for the terminal and periodic disinfection of patient care areas and environmental services • This policy should include input from infection control practitioners, industrial hygienists, and environmental services supervisors • Ultraviolet light and hydrogen peroxide vapor are useful options for whole-room terminal cleaning
Hand hygiene	• Hand hygiene is the single most effective method to limit the spread of drug-resistant pathogens and hospital-acquired infections • Multiple opportunities exist in the hospital environment for the contamination of healthcare worker hands including direct patient care and contact with environmental surfaces	• Increased accessibility to hand hygiene agents is associated with improved compliance • Medicated hand washing agents are bactericidal (alcohol, chlorhexidine gluconate, triclosan) and effectively reduced bacterial counts on the hands • Chlorhexidine has the advantage of producing a residual antibacterial effect, thereby limiting hand recontamination until the time of the next hand hygiene episode • Sustained improvements in hand hygiene compliance should be achieved through a multimodal approach, which includes efforts that stress increased use of accessible, easy to use, medicated hand hygiene products, coupled with a hospital-wide, administration-backed, high-priority hand hygiene campaign • Novel hand hygiene technologies are emerging as useful methods for monitoring hand hygiene compliance
Gloves	• Gloves should be worn to prevent healthcare worker exposure to blood-borne pathogens and to prevent contamination of hands with drug-resistant pathogens during patient care activities	• Even with proper glove use, hands may become contaminated during the removal of the glove or with micro-tears that allow for microorganism transmission • Glove use should not be used as a substitute for hand hygiene
Gowns	• Several studies have documented colonization of healthcare worker apparel and instruments during patient care activities without the use of gowns	• The use of gloves *and* gowns is the convention for limiting the cross-transmission of hospital-acquired pathogens; however, the incremental benefit of gown use, in endemic settings, may be minimal
Healthcare worker apparel	• Contamination of healthcare worker apparel occurs throughout the course of a normal work day • Biological plausibility suggests that contaminated apparel could lead to transmission of organisms between patients	• Expert guidance by SHEA recommends implementing hospital-wide policies that include "bare below the elbows," restriction of white coats during patient care activities, and frequent laundering of apparel
Contact precautions	• Contact precautions are for selected patients who are known or suspected to harbor certain infections	• Contact precautions are commonly employed for the endemic control of MRSA, VRE. *C. difficile*, and multidrug-resistant gram-negative rods • Contact precautions are typically employed along with other infection control measures during hospital outbreaks of drug-resistant infections • Controversies in contact precautions include low compliance rates, increased rates of adverse events and anxiety/depression, and decreased satisfaction of care among patients on contact isolation

(continued)

Table 88.1 (continued)

Infection control measure	Rationale	Comment
Screening for asymptomatic patient colonization with drug-resistant pathogens	• Some authorities advocate active surveillance cultures to identify the reservoirs of MRSA and VRE • The goal of active surveillance is to identify every colonized patient so that infection control interventions such as contact isolation and cohorting can be implemented to reduce the risk of cross-transmission	• This measure is controversial • The majority of the studies had multiple interventions and major methodological weaknesses. As such, the quality of evidence in many studies was considered weak • The use of strict isolation practices may have a detrimental impact on the process and quality of patient care
Antibiotic control program	• Prolonged antibiotic prophylaxis with cephalosporins was an independent risk factor on logistic regression analysis for infections with cephalosporin-resistant gram-negative rods • Enteric VRE colonization has been associated with cephalosporin use • MRSA colonization has been associated with fluoroquinolone use	• The degree in which antibiotic pressure directly contributes to the cross-transmission of hospital-acquired infections remains poorly defined • All healthcare facilities are encouraged to implement multidisciplinary antibiotic stewardship teams, which should include a physician, pharmacist, clinical microbiologist, and infection preventionist

hospital. The investigators reported carriage rates of 19 % for MSSA and 16 % for MRSA. When comparing nasal carriers vs. non-carriers, the investigators documented a greater frequency of prior MRSA bacteremia and urinary tract infections, respectively, 8.3 % vs. 0.8 % and 11.4 % vs. 0.6 %. Additionally, the colonizing MRSA strain matched the invasive strain by pulsed-field gel electrophoresis [9].

In a different prospective series, however, only 2.7 % of the isolates were identified as MRSA [10]. Using a case control study and multivariate analysis to determine risk factors for MRSA colonization, independent predictors for colonization with MRSA were prior admission to a nursing home (OR 16.5) and a prior hospitalization of greater than 5-day duration within the past year [10].

Surveillance in nursing home settings reveals an increasing prevalence of *S. aureus* colonization. A prospective study in the mid-1980s by Sheckler et al. failed to document MRSA colonization in a cohort of community-based nursing homes [11]. Another study of community-based nursing homes from the early 1990s revealed 24 % of patients with *S. aureus* colonization, while 8.7 % of all patients were colonized with MRSA [12]. Lee et al. reported *S. aureus* colonization and infection in a 149-bed skilled nursing facility over a 1-year period. In this series, nasal and stool or rectal screening cultures were done on admission and then on a quarterly basis for a year. At the conclusion of the study, 35 % of all patients were colonized with *S. aureus* at least once during the period of analysis. Of the positive cultures, 72 % were MSSA, 25 % were MRSA, and 3 % were mixed phenotype. Only a minority of patients colonized developed an infection with *S. aureus*. The authors reported no association between MRSA colonization and frequency of *S. aureus* infection [13].

MRSA colonization has been studied in the intensive care setting. Garrouste-Orgeas et al. prospectively studied MRSA colonization and infection in a medical-surgical ICU of a tertiary care medical center [14]. In this prospective, observational study, cultures were obtained within 48 h of hospitalization, then weekly thereafter. Five percent of all patients were colonized with MRSA at the time of admission, and 4.9 % were newly colonized with MRSA during the course of their ICU stay. After multivariable analysis, factors associated with MRSA infection were severity of illness (HR 1.64), male gender (HR 2.2), and MRSA colonization (HR 3.84). However, MRSA colonization was not associated with increased mortality [14]. Overall, 10 % of patients in the cohort were colonized with MRSA. A similar rate of MRSA colonization has been documented by other investigators [15].

Co-colonization or coinfection with multidrug-resistant pathogens has been reported in several different populations. A point prevalence survey of antimicrobial-resistant pathogens in skilled care facility residents revealed a high rate of MRSA colonization. Of the 177 patients surveyed, 24 % were colonized with MRSA. Additionally, ESBL-producing organisms were discovered in their patient population, including *K. pneumoniae* (18 %), *E. coli* (15 %), and VRE (3.5 %). As these patients were asymptomatic, the investigators discovered a large, unrecognized pool of antimicrobial-resistant pathogens in their nursing home population [16]. Warren et al. determined the occurrence of co-colonization and coinfection with VRE and MRSA among medical patients in a medical ICU of a tertiary care medical center. Screening cultures were obtained in adults requiring at least 48 h of intensive care therapy. The study evaluated 878 consecutive patients. Of these, 40 % were either colonized or infected with VRE, 4.4 % were either colonized or infected with MRSA, and 9.5 % had either co-colonization or coinfection with MRSA and VRE. Risk factors for co-colonization or coinfection were increasing age, prior hospitalization within the preceding 6 months, and admission from a long-term care facility [17]. In a study of patients at high-risk

wards at an urban academic center, almost 30 % of patients carrying VRE were co-colonized with MRSA [18].

1.2 The Impact of Colonization Status on Hospital-Acquired Infections

An association between MRSA colonization and the subsequent development of MRSA hospital-acquired infections exists. Pujol et al. prospectively analyzed the relationship of MRSA nasal colonization and bacteremia [19]. During a 1-year period in an ICU, nasal swabs were obtained on all patients within 48 h post admission and then weekly. Thirty percent of all patients were nasal *S. aureus* carriers: 17 % with MSSA and 13 % with MRSA. Bacteremia was observed in 38 % of the MRSA carriers and 9.5 % of the MSSA carriers. Using Cox proportional hazard modeling, the relative risk (RR) of *S. aureus* bacteremia was 3.9 when comparing MRSA to MSSA nasal carriers [19].

Other investigators have confirmed the significance of MRSA colonization and its predilection for subsequent infection. Davis et al. investigated MRSA colonization at hospital admission and its subsequent effect on MRSA infection rates [20]. Nares cultures were obtained on admission on patients admitted to various hospital units, including medical, surgical, and trauma ICUs. The patients were followed for the study period and then 1 year thereafter. Nasal colonization with MSSA far exceeded that with MRSA (21 % vs.3.4 %). However, 19 % of patients with MRSA colonization at admission and 25 % with subsequent colonization developed infection with MRSA. Reported infections included line sepsis, bacteremia, and skin and soft tissue infections. Compared with MSSA colonization, both MRSA colonization and MRSA acquisition during hospitalization increased the relative risk of infection (RR 13 and RR 12) [20].

Nasal carriage of both MRSA and MSSA has been associated with increased risk of vascular access-related infections in patients with type II diabetes on dialysis. In this series, nasal swabs were performed in 208 patients enrolled for long-term hemodialysis between 1996 and 1999 [21]. Persistent nasal carriage was defined as two or more positive cultures. Diabetic patients had higher MSSA and MRSA carriage rates (54 and 19 %) than nondiabetics (6 %). Overall, 73 % of all diabetic patients were colonized nasally with either MRSA or MSSA. Additionally, when compared to nondiabetic hemodialysis patients, the relative risk for vascular access-associated bloodstream infection was significantly greater [21].

Lastly, published data suggest that healthcare workers colonized with drug-resistant pathogens may be associated with cross-transmission and hospital-acquired infections. Wang et al. investigated a hospital-acquired outbreak of MRSA infection initiated in a surgeon carrier [22]. Over a 4-month period, five patients who had undergone open-heart surgery developed surgical wound infections and mediastinitis with MRSA. Investigation by the infection control team led to MRSA nasal screening of all ICU staff and of the surgical team. Pulsed-field gel electrophoresis technology was employed for isolate typing. Of the five hospital-acquired MRSA infections, all had the same attending surgeon and 2–3 assistant surgeons. Surveillance cultures of the staff were all negative save for one assistant surgeon, present in all of the five cases. The typing profile of the surgeon's isolate was identical to that of three of the cases. The remaining two isolates were lost and hence not typed; however, these were presumed to be identical to the others owing to the same antibiogram [22]. Other investigators have reported healthcare colonization and its effect on cross-transmission and subsequent MRSA infection and colonization. Boyce et al. reported the spread of MRSA within a hospital. A healthcare worker with chronic sinusitis was the purported source [23]. In addition, outbreaks of MRSA infections in a burn unit have implicated nursing staff as sources [24, 25].

1.3 Strategies for Staphylococcal Decolonization

Given the importance of *S. aureus* as a hospital-acquired pathogen, decolonization of carriers has been attempted in various populations. Early investigations employed both topical and systemic therapy for the eradication of *S. aureus* nasal colonization. In the 1980s, in experimental studies, it was shown that mupirocin was effective in reducing nasal carriage of volunteers with methicillin-sensitive *S. aureus* [26]. Subsequently it was shown that mupirocin was active against methicillin-resistant strains of *S. aureus* [26]. In the early 1990s, Darouich et al., as part of a multidisciplinary approach, attempted to control the spread of MRSA within a spinal cord unit [27]. Eleven patients in the spinal cord unit were colonized with MRSA. The sites of colonization varied but included nares, axilla, tracheostomy site, urethra, wounds, and urine. Ten of the colonized patients received a 2-week course of 100 mg of minocycline twice daily and 600 mg of rifampin once daily. The remaining patient was treated for only 1 week with the minocycline/rifampin combination. For those that were nasally colonized, nasal mupirocin ointment was applied twice daily for 5 days. The authors reported eradication of MRSA colonization in 10 of the 11 patients [27].

Subsequent data suggest that for nasal MRSA, mupirocin alone may be sufficient for decolonization. In one, 6-month, two-step, prospective study from France, the efficacy of nasal mupirocin for the prevention of *S. aureus* nasal carriage was assessed [28]. In the first 4 months, all patients in the surgical ICU were cultured without the nasal decontamina-

tion protocol. Nasal and surgical wound swabs and tracheal secretions were collected on admission and then once weekly. In the following 2 months, all patients admitted to the SICU were given twice daily intranasal mupirocin for 1 week. In the comparison, 31.3 % of untreated patients and 5.1 % of mupirocin-treated patients subsequently acquired nasal *S. aureus* while in the surgical ICU. In addition, nasal carriers were more commonly colonized in the bronchopulmonary tract and surgical wounds (62 %) than were nonnasal carriers (14 %). When compared to the nontreatment group, the bronchopulmonary tract infection rate was reduced in the group receiving mupirocin treatment. Thus, in a surgical ICU cohort, the use of prophylactic mupirocin treatment reduced the rate of both MRSA nasal colonization and subsequent MRSA colonization bronchopulmonary infection [28]. Additionally, the use of mupirocin has successfully decreased the rates of *S. aureus* infections in dialysis patients, even though most of these isolates were methicillin sensitive [29].

Intranasal mupirocin has been employed to prevent postoperative *S. aureus* infections. Perl et al. conducted a randomized, double-blind, placebo-controlled study to determine the efficacy of mupirocin in both the reduction of surgical site infections and in the prevention of other hospital-acquired infections [30]. A total of 3864 patients were included in an intention to treat analysis, and of these, 891 patients (32.1 %) were *S. aureus* colonized in the anterior nares. The cohort underwent either general, gynecologic, neurologic, or cardiothoracic surgery. At the conclusion of the study, 2.3 % of the mupirocin recipients and 2.4 % of the placebo recipients had *S. aureus* infections at the surgical site. However, in a subset analysis of *S. aureus* nasal carriers who received mupirocin, there was a statistically significant reduction in the rate of *S. aureus* hospital-acquired infections, 4.0 % versus 7.7 % for recipients of placebo. Thus, in this analysis, the use of intranasal mupirocin in a surgical cohort was effective in reducing the frequency of *S. aureus* hospital-acquired infections only in patients previously colonized with *S. aureus*. For patients known to be nasal carriers of *S. aureus*, consideration should be given to the preoperative application of mupirocin.

The above studies used a targeted approach to decolonization of patients colonized with MRSA, which requires active detection and isolation of the organism. This approach can be costly, both directly and indirectly [32]. Universal decolonization, which involves the broad use of infection prevention practices throughout populations that are at high risk of hospital-acquired infections, is favored by some as a preferred approach[31]. Huang et al. conducted a pragmatic, cluster-randomized trial to assess which approach is superior [32]. The study randomized 74,256 patients from 43 hospitals into three groups. The group that underwent universal decolonization had significantly lower rates of MRSA-positive clinical isolates when compared to either screening and isolation or targeted decolonization groups. Universal decolonization also resulted in decreased rate of bloodstream infections due to any pathogens. There was no significant difference in the number of MRSA bloodstream infections between the groups.

1.4 The Role of Chlorhexidine (CHG) Bathing for Prevention of Hospital-Acquired Infections

Chlorhexidine is an antiseptic that has activity against a broad spectrum of organisms, including gram-negative bacteria, gram-positive bacteria, and fungi [33]. Chlorhexidine bathing has been employed as a means to decrease bacterial burden on patient skin. Bathing or showering with a 4 % solution is effective in reducing bacterial density on the skin of patients [34, 35]. Recently, cloths impregnated with 2 % CHG have become widely available as a no-rinse option as well. One study demonstrated that 2 % CHG cloths may perform superiorly to topical application of 4 % CHG [35]. Chlorhexidine-impregnated cloths have also demonstrated effectiveness in reducing bacterial burden of multidrug-resistant organisms like *K. pneumonia* and MDR GNR on skin surfaces [36]. In 2012, Karki and Cheng published a systematic review that assessed the impact of CHG bathing (with CHG-impregnated cloths) on the incidence of healthcare-associated infections and colonization. The authors included 20 studies in the analysis: 15 quasi-experimental studies, 3 cohort studies, 1 crossover study, and 1 randomized controlled study. The final analysis demonstrated reduced rates of MRSA and VRE colonization and reduced rates of hospital-acquired infections with CHG bathing. There were no reports of significant toxicity for patients who underwent daily CHG bathing [37]. Subsequently, a multicenter, cluster-randomized, nonblinded crossover trial also concluded that CHG bathing reduces rates of colonization and CLABSI. The overall rate of acquisition of multidrug-resistant organisms was lower with the use of CHG-impregnated cloths than with the use of nonantimicrobial washcloths (5.10 cases per 1000 patient days versus 6.60 cases per 1000 patient days, respectively). This same study demonstrated significantly reduced rates of hospital-acquired bloodstream infections with the use of CHG-impregnated washcloths versus nonantimicrobial cloths (4.78 cases vs. 6.60 cases per 1000 patient days, respectively). Interestingly, central line-associated fungal bloodstream infections were also reduced with CHG bathing [38].

Two studies support the use of CHG bathing in children as well. One quasi-experimental study that included adult and pediatric patients found a significant reduction in *Clostridium difficile* infections with the use of CHG bathing. Compared to the baseline period when no CHG bathing was done, all cohorts that used CHG bathing had a lower relative risk of *C.*

difficile infection [39]. A multisite, cluster-randomized, crossover trial which was conducted in ten pediatric ICUs and involved 4947 patients demonstrated a reduction in the rate of bacteremia in patients receiving daily CHG bathing compared to those receiving standard bathing practices. Although reduction in the rate of bacteremia using intent to treat analysis was not statistically significant, the per protocol analysis did reveal a significant reduction in the rate of bacteremia. No serious adverse events were reported. However, more patients in the intervention group reported skin irritation [40]. Of note, these studies assessed tolerability and effectiveness of CHG in children greater than 2 months of age. Chlorhexidine is not currently approved by the US Food and Drug Agency for use in children less than 2 months of age due to the possibility of irritation or chemical burns [41].

Some concern for development of bacterial resistance to CHG and selection of resistant organisms with the use of CHG exists. There is a paucity of data on this topic, but reduced in vitro susceptibility to CHG have been reported [42, 43]. One study demonstrated higher MICs to CHG among a multidrug-resistant strain of *K. pneumonia*. Of the multidrug-resistant *K. pneumonia* isolates, 99 % had MICs >32 μg/mL, compared with 52 % of other *K. pneumonia* strains [42].

1.5 Environmental Contamination

It is well documented that patients colonized or infected with drug-resistant pathogens, such as MRSA, VRE, or multidrug-resistant gram-negative rods, contaminate the inanimate environment. Contaminated objects can include but are not limited to floor, bed linens, patient gowns, overbed tables, bedrails, urinary containers, enteral feeding tubes, light switches, bathroom faucets, IV pumps, telephones, and blood pressure cuffs [23, 44–46]. In addition to objects in patient rooms, contamination can extend beyond the immediate patient care area. Devine et al. surveyed two acute care hospitals (A and B) in the United Kingdom with a focus on contamination of ward-based computer modules [47]. In total, 24 % of sampled computer terminals were positive for MRSA. Five of the six positive computer terminal cultures were from hospital A. In contrast to hospital A, the infection control team of hospital B reviewed handwashing compliance regularly with doctors and nurses. Hospital B also reported a greater rate of paper towel consumption, a surrogate marker for hand hygiene compliance. Although the direction of transfer is impossible to define from such studies, the data suggest that inanimate reservoirs have the potential to contaminate the hands of healthcare workers. Furthermore, hand hygiene compliance may be essential in minimizing this risk of environmental contamination [47]. Contamination of gowns and gloves from hospital personnel (those performing nursing care activities on colonized patients and those with no direct patient contact) has also been documented [23].

The environment likely represents a potential source for healthcare worker hand contamination, an important step in the cross-transmission of hospital-acquired pathogens. A study by Duckro et al. gave credence to this idea [48]. Cultures were obtained from the intact skin of 22 patients colonized with VRE and from various environmental sites before and after routine care by 98 healthcare workers. Cultures were obtained from the hands of the HCWs before and after patient care, and pulsed-field gel electrophoresis typing of the isolates was performed. In this analysis, VRE was transferred from contaminated sites in the environment or on the patient's intact skin to clean, previously non-contaminated environmental and body sites via the HCW in 10.6 % of the opportunities. Of these 16 VRE transfer sites, 12 were patient body sites [48]. These data suggest that the hospital environment is a potentially important reservoir for cross-transmission of drug-resistant pathogens.

As patients colonized with resistant pathogens can contaminate the environment, proper environmental disinfection is an important step for minimizing the risk or cross-transmission. An extensive review of approved disinfectants and environmental cleaning practices is beyond the scope of this chapter. However, several general principles are of note. Terminal cleaning of patient rooms should aim to minimize the persistence of drug-resistant pathogens. Hospital environmental services personnel should clean the bed frame and handrails, mattress, and all other patient room furnitures with an Environmental Protection Agency (EPA)-approved disinfectant and use according to manufacturers' guidelines [49]. Suction containers should be removed and prepared for disposal or reprocessing, and all other reusable equipment should be decontaminated using an (EPA)-approved disinfectant. The bathroom in an isolation room should be thoroughly cleaned and disinfected, with particular attention paid to the sink, toilet, and doorhandle areas. Environmental surfaces with a high degree of patient body and hand contact such as bedrails, doorknobs, bathrooms, light switches, and wall areas should be cleaned with greater frequency and not exclusively at the time of patient discharge.

Traditional room decontamination may not be sufficient to eliminate environmental bioburden. Therefore, alternate methods for terminal disinfection of patient rooms are needed. Ultraviolet (UV) light irradiation has the ability to inactivate a wide range of biological agents. Rastogi et al. studied the effectiveness of UVC light for decontamination of three hospital surfaces (aluminum bed railings, stainless steel operating tables, and laboratory coats) [50]. *Acinetobacter baumannii* was inoculated onto small coupons of each of the three types of materials. Fifteen minutes of

UVC light exposure (at a fluence of 90 J/m [2]) resulted in ≥4-log reduction and complete killing of organisms on the two metal surfaces. However, UVC light was ineffective for laboratory coat disinfection [50]. In addition to inadequate penetration of fabrics, the use of UV light for whole-room disinfection has the disadvantage of providing only "line-of-site" killing.

Like UV irradiation, hydrogen peroxide vapor (HPV) inactivates a wide range of biological agents through production of oxygen free radicals. Its effectiveness was demonstrated in one prospective cohort intervention study [51]. The intervention (HPV) was implemented after routine cleaning and disinfection of rooms with a quaternary ammonium compound. All rooms were previously occupied by patients with known infection or colonization with multidrug-resistant organisms. Patients admitted to rooms that underwent HPV decontamination were 64 % less likely to acquire any multidrug-resistant organisms than those that were in rooms with no HPV decontamination. Specifically, patients in rooms with HPV decontamination were 80 % less likely to acquire VRE [51].

Several potential strategies exist for monitoring compliance and assessing environmental hygiene. Boyce et al. compared three methods of monitoring with a prospective observational study of 100 hospital rooms [52]. In this study, five high-touch surfaces were marked with different brands of fluorescent markers prior to terminal cleaning and were checked after cleaning with a black light to assess whether the marker had been partially or entirely removed. Aerobic colony counts (ACCs) and adenosine triphosphate (ATP) bioluminescence assays were performed on the same surface before and after terminal cleaning. The ATP method was much less likely than either fluorescent markers or ACC to classify a room as clean. This result is not surprising since ACC measures only contamination by aerobic bacteria, whereas ATP bioluminescence assays detect many ATP-containing organic substances such as secretions, blood, and food. The authors concluded that each method has utility for different situations. Fluorescent markers are simple to implement and are useful for providing feedback to housekeepers regarding adequacy of cleaning. Aerobic colony counts provide a quantitative measurement of surface contamination and provide information about specific organisms causing contamination, but are costly and time consuming. Advantages of ATP bioluminescence assays are ease of use, rapid results, and provision of quantitative measurements that can be used for trends and feedback [52].

All healthcare facilities should develop policies for the terminal and periodic disinfection of patient care areas and environmental services. This policy should include input from infection control practitioners, industrial hygienists, and environmental services supervisors.

2 Hand Hygiene

Hand hygiene, either by conventional handwashing or disinfection, is the single most effective method to limit the spread of drug-resistant pathogens and hospital-acquired infections [53]. Conceptually, the cross-transmission of hospital-acquired pathogens is summarized as follows [54]:

- Organisms present either on the patient's skin or from the inanimate environment must be transferred to the hands of the healthcare worker.
- Hospital-acquired pathogens must be capable of surviving on the hands of the healthcare worker.
- Hand hygiene must be either inadequate or omitted.
- The contaminated hands of the healthcare worker must then come into contact with another patient or into contact with an inanimate surface that will later come into contact with the patient.

The microorganisms of the hand can be divided into transient flora and resident flora [55]. The resident flora is typically of low virulence pathogens such as *Micrococcus*, coagulase-negative *Staphylococcus*, and *Corynebacterium*. These organisms are difficult to remove by handwashing yet are rarely pathogenic except when introduced to the patient by invasive procedures. Transient flora is acquired largely by contact with either the patient or an inanimate object, is loosely attached to the skin, and is easily removed by handwashing [55]. These organisms include MRSA, VRE, and MDR GNR. Additionally, these bacteria are important causes of hospital-acquired infections.

Numerous studies have shown that multiple opportunities exist in the hospital environment for the contamination of healthcare worker hands. Hospital-acquired pathogens can be recovered from a variety of patient care scenarios. Patient contact, including contact with wounds and intact skin, can result in healthcare worker hand contamination [56–67]. Areas of high hospital-acquired pathogen concentration on patient skin include the axillae, trunk, perineum, inguinal region, and hands [59, 61, 62, 64, 66–68]. As previously mentioned, the inanimate environment is a source of contamination.

Healthcare workers should practice hand hygiene before and after each patient contact. Methods of hand hygiene include washing with plain soap and water, or using an antibacterial agent such as alcohol, chlorhexidine gluconate, or triclosan as either detergent washes or waterless hand-rubs. Conventional soap and water may have various shortcomings and barriers to compliance. Although soap and water can remove loosely adherent transient skin, these agents have minimal antimicrobial activity [54]. For effective bacterial reduction, a 30 s hand rub is recommended; unfortunately, this time length of handwashing is rarely practiced. In

addition, several studies have demonstrated that handwashing with both plain soap and water can result in skin irritation, dryness, and a paradoxical increase in microbial counts on the skin [69–73]. Medicated handwashing agents are bactericidal (alcohol, chlorhexidine gluconate, triclosan) and effectively reduce bacterial counts on the hands. Moreover, chlorhexidine has the advantage of producing a residual antibacterial effect, thereby limiting hand recontamination until the time of the next hand hygiene episode [74].

At least one study supports the effectiveness of chlorhexidine as a hand antiseptic agent with regard to infection control endpoints. Doebbling et al. compared different hand hygiene agents with the end result of hand hygiene compliance observation and the reduction of hospital-acquired infections in an intensive care unit setting [75]. During an 8-month period, a prospective, multiple crossover trial was conducted in three intensive care units. The trial involved 1894 adult patients exposed to alternate months of either chlorhexidine or 60 % alcohol solution with the optional use of a non-medicated soap. A greater frequency of hospital-acquired infections was seen with the combination of alcohol and soap compared to the chlorhexidine hand hygiene agent (202 vs. 152). However, during periods of chlorhexidine use, there was a decrease in the rate of hospital-acquired infections and an increase in the observed frequency of hand hygiene compliance coupled with a volume of chlorhexidine consumption that exceeded that of the alcohol-based agent. The difference in hospital-acquired infections may have been partly due to increased compliance with hand hygiene practices. Regardless, owing to their bactericidal properties, medicated hand hygiene agents, including chlorhexidine, alcohol, and triclosan, should be highly considered especially in environments with elevated rates of drug-resistant pathogens.

Unfortunately, data on healthcare worker hand hygiene practice are discouraging. The reasons for poor compliance are multiple and have been studied by numerous investigators. Observational studies of hand hygiene compliance report compliance rates of 5–81 % [76–108]. Factors cited that may influence poor adherence with hand hygiene include insufficient time, understaffing, patient overcrowding, lack of knowledge of hand hygiene guidelines, skepticism about handwashing efficacy, inconvenient location of sinks and hand disinfectants, and lack of hand hygiene promotion by the institution [54].

In the intensive care units, where critically ill patients are particularly susceptible to hospital-acquired infections, hand hygiene is poor. A British study performed a detailed survey of hand hygiene practices in 16 ICUs [55]. Additionally, 381 (non-nurse) healthcare professionals were observed for hand hygiene compliance. Compliance with hand hygiene and proper glove use ranged from 9 to 25 %. Survey responses suggested that poor compliance with hand hygiene in the ICU was secondary to multiple issues including ineffective communication of infection control recommendations, insufficient promotion of hand antisepsis, and a deficiency of infection control education [55]. Poor compliance with hand hygiene was similarly observed by Kaplan et al. in a tertiary care American hospital [81]. Physician compliance with hand hygiene was 19 %, while compliance by the nursing staff was 63 %. Greater compliance with hand hygiene was observed among the nursing staff with a 1:1 bed to sink ratio than those with a greater bed to sink ratio (76 % vs. 51 %) [81].

Efforts to improve hand hygiene both in the ICUs and hospital-wide likely require simultaneous interventions on multiple levels. In a study by Bischoff et al. where alcohol-based hand sanitizers were introduced to an ICU, the greatest increment in hand hygiene compliance was observed when the hand sanitizer to healthcare worker ratio went from 1:4 to 1:1, thereby underscoring the importance of accessibility [82]. As such, the CDC now suggests promoting alcohol-based hand sanitizer access both by bedside dispensers and healthcare worker pocket-sized dispensers [54]. Pittet and colleagues improved overall compliance with hand hygiene by implementing a hospital-wide program with special emphasis on bedside, alcohol-based hand disinfection. The campaign ran from December 1994 to December 1997 and consisted primarily of hand hygiene promotion through large, conspicuous posters promoting hand hygiene throughout patient care areas. The project was supported and heavily promoted by senior hospital management. Additionally, alcohol-based handrub solutions were distributed in large amounts, mounted on beds/walls, and given to healthcare workers to encourage pocket carriage for convenience of use. During this time frame, seven institution-wide hand hygiene observational surveys were performed twice yearly. Additional measures included hospital-acquired infection rates, the rate of MRSA infections, and overall consumption of handrub disinfectant. In this 3-year study, 20,000 opportunities for hand hygiene were observed. Compliance with hand hygiene improved from a baseline of 44 % in 1994 to 66 % in 1997. Of note, hand hygiene improved markedly among nursing staff but remained poor for physicians. Additionally, over the study period, the overall prevalence of hospital-acquired infections decreased from 16.9 to 9.9 %, MRSA transmission rates decreased from 2.16 to 0.93 episodes per 10,000 patient days, and the consumption of alcohol-based hand rub increased from 3.5 to 15.4 L per 1000 patient days [109]. Unfortunately, as multiple interventions were employed simultaneously, the relative effect of each component was difficult to properly assess. Thus, although the most efficient and effective means for sustained improvements in hand hygiene compliance have yet to be defined, measures should at least include efforts that stress increased use of accessible, easy to use, medicated hand hygiene products, coupled with a hospital-wide,

administration-supported, high-priority hand hygiene educational and promotional campaign.

2.1 Hand Hygiene Bundles

Bundles are commonly used multimodal approaches in infection prevention practice that aim to improve patient care and outcomes. They combine several interventions concurrently in order to optimize outcomes more than any one intervention could achieve alone. Possible components of a hand hygiene bundle include administrative support, education and training, availability of hand hygiene resources (e.g., hand sanitizer, soap, etc.), and ongoing monitoring and feedback of hand hygiene compliance [110]. One commonly used bundle that is promoted by the WHO includes administrative support toward improved hand hygiene, access to alcohol-based hand rub (ABHR), performance feedback, education, and reminders [111]. Several studies have assessed the use of bundles in order to improve hand hygiene compliance. A recent meta-analysis reviewed the literature with the aim to assess utility of hand hygiene bundles [112]. Forty-six studies were included in the final analysis. There were 39 quasi-experimental, four cluster-randomized, and two randomized controlled trials. Two bundles were associated with improved hand hygiene compliance. One bundle included education, reminders, feedback, administrative support, and access to ABHR, while the other included education, reminders, and feedback. Interestingly, increasing the number of interventions in a hand hygiene bundle was not associated with improved compliance. This review was limited by study heterogeneity. Furthermore, most studies were quasi-experimental in design, which are subject to bias. Robust randomized controlled trials assessing hand hygiene bundles are lacking. Currently underway is a multicenter randomized controlled trial with the aim to identify an optimal hand hygiene bundle [113]. Combinations of three interventions (hand-hygiene point-of-use reminder signs to serve as an environmental cue to action, individual hand sanitizers, and healthcare worker hand cultures) will be assessed.

2.2 Emerging Technologies for Monitoring Hand Hygiene Compliance

Monitoring of hand hygiene provides important information about baseline and ongoing rates of compliance among healthcare workers. Several different methods of monitoring have been tried. Direct observation is the traditional method of monitoring and provides detailed information about adherence to the various components of hand hygiene (e.g., proper technique and compliance before and after patient contact). However, the reliability of direct observation is limited by observer bias as well as the Hawthorne effect [114, 115]. This practice is also time consuming and expensive to carry out. The use of novel hand hygiene technology has become a recent topic of interest and represents a possible alternative to direct observation. Measuring product consumption and electronic monitoring systems have been studied. Boyce recently published a thorough review of these emerging technologies [116]. Measurement of product consumption is accomplished via volume or weight of product used or amount of product purchased. Most studies have shown a direct relationship between amounts of product consumed and observed compliance rates [76, 117–119]. However, several other studies have shown no correlation between product consumption and observed hand hygiene rates [120, 121]. One prospective observational study compared direct observation, product usage, and electronic counting devices as methods of monitoring in a tertiary care hospital 40-bed ICU in Brazil. There were 2249 opportunities for hand hygiene observed with an overall compliance rate of 62.3 %. Direct observation did not correlate with the amount of product used. The authors concluded from this study that direct observation is an inaccurate method of monitoring [120]. Another quasi-experimental study by Morgan et al. similarly concluded that direct observation did not correlate with dispenser counts [121]. Despite this conflicting data, monitoring of product usage is likely to be a useful adjunct to monitoring by direct observation. Monitoring of product usage is less time consuming and less labor intensive, but also provides less detail about each episode. Once baseline product usage for an institution is established, trends can be followed.

Product use can also be monitored with electronic counting devices. These devices record a hand hygiene event every time sanitizer is dispensed. They supply additional important data, including frequency of use, and specific date, time, and location of use. One quasi-experimental study suggested that electronic counting may be a better method of monitoring than direct observation. Over a period of 30 weeks, 424,682 dispenser counts, 338 h of human observation, and 1783 room entries were recorded. Hand hygiene rates were monitored before and after feedback intervention, which included posters displaying unit-specific compliance rates and educational sessions for healthcare workers. Rates significantly increased according to electronic counters (average count/patient day increased 22.7 in the NCICU and 7.3 in the CCU), but were not significantly changed according to direct observation [121]. Larson et al. studied hand hygiene compliance (with the use of electronic counting devices) in response to changes in the hospital's organizational culture [122]. In this quasi-experimental study in two mid-Atlantic hospitals (one hospital received the intervention, while the other served as the control), 860,567 hand hygiene events were recorded over a period of 8 months. The intervention implemented in the study hospital included establishment of leadership support

and role modeling of proper hand hygiene, positive deviance, and feedback to units of current compliance rates. While the hand hygiene rate increased in both hospitals, the difference was greater in the intervention hospital. In addition to improvements in hand hygiene, rates of VRE infections were significantly reduced in the intervention group compared to the control group (85 % vs. 44 %, respectively) [122]. Other studies demonstrated that counting devices provide useful information about patterns of sanitizer use [123, 124]. For example, higher rates of sanitizer use outside of patient rooms than inside patient rooms were recorded [123]. Touch-free dispensers were preferred over manual dispensers [124].

Other technologies, such as dedicated hand hygiene systems and real-time location devices, target hand hygiene at the individual level. Marra et al. conducted a two-phase trial [125]. The first phase assessed baseline rates of hand hygiene using an electronic counting device. The second phase used real-time feedback with a wireless identification device (badge) that flashes red when the healthcare worker approaches the patient bed and has not performed hand hygiene and flashes green when hand hygiene has been performed. There was a significant increase in hand hygiene after implementation of the real-time feedback technology (74.5 episodes/patient day prior to intervention vs. 90.1 episodes/patient day during intervention) [125]. Another two-phase study used real-time feedback in the form of three consecutive beeps and the prerecorded voice prompt, "Please wash your hands," when healthcare workers failed to comply with hand hygiene upon entering or exiting a patient room. Hand hygiene improved from 36.3 % during phase 1 (prior to intervention) to 70.1 % during phase 2 (after intervention) [126]. Other studies reported similar improvements in hand hygiene rates after implementation of feedback technology [127, 128].

Another novel hand hygiene technology is real-time location systems. These systems use technologies such as Wi-Fi, active radio-frequency identification (RFID), infrared, and ultrasound to communicate information from special badges worn by healthcare workers. They have the advantage of being able to locate individual healthcare workers and the dispensers they access. This data is communicated back to a central server for real-time analysis [116]. Pineles et al. compared direct observation of hand hygiene to an RFID system. When compared to recorded data by the RFID system, direct observation was only 52.4 % accurate [129].

Video monitoring has also been used to assess healthcare worker hand hygiene compliance. Armellino et al. used video monitoring as a way to remotely assess hand hygiene in a medical ICU prior to and during a feedback period. Hand hygiene rates were 6.5 % during the 16-week pre-feedback period and 81.6 % during the 16-week post-feedback period. More importantly, the increase was maintained through 75 weeks at 87.9 % [130]. This study was extended to the surgical ICU and achieved similar results [131]. Video monitoring, similar to direct observation, requires significant man-hours, but may have the advantage of improved accuracy.

Possible barriers to implementing these technologies include upfront and maintenance costs, and healthcare worker buy-in. While these new technologies may improve hand hygiene monitoring accuracy and healthcare worker compliance rates, they continue to have shortcomings. They do not provide the level of detailed monitoring achieved by direct observation, such as hand hygiene technique, and hand hygiene practices prior to aseptic procedure or when hands are soiled.

2.3 The Use of Gloves and Gowns to Limit Cross-Transmission of Hospital-Acquired Pathogens

Gloves should be worn to prevent healthcare worker exposure to blood-borne pathogens and to prevent contamination of hands with drug-resistant pathogens during patient care activities. Nevertheless, even with proper glove use, hands may become contaminated during the removal of the glove or with micro-tears that allow for microorganism transmission [132]. Glove use should not be used as a substitute for hand hygiene. The promotion of glove use may increase compliance with hand hygiene protocols. A recent study by Kim and colleagues observed the rate of hand disinfection with glove use and patient isolation [133]. In this prospective, observational study, hand hygiene and glove use compliance rates were measured in two ICUs of a tertiary care hospital. Over 40 h of observation and 589 opportunities for hand disinfection were noted. Overall hand hygiene compliance was 22 %. The investigators found a statistically significant, positive association between glove use and subsequent hand disinfection (RR 3.9). Isolation precautions did not significantly increase hand hygiene compliance. For infection control purposes, glove use should be promoted as a means of limiting hand contamination with drug-resistant pathogens such as MRSA and VRE. Additionally, glove use and hand hygiene should be promoted concurrently.

2.4 Gowns

Gowns have been used as part of contact precaution protocols to limit the spread of hospital-acquired pathogens. Several studies have documented colonization of healthcare worker apparel and instruments during patient care activities without the use of gowns [134–136]. One study by Boyce et al. demonstrated the efficacy of disposable gowns in the prevention of HCW clothing contamination [136]. In another study, Srinivasen et al. prospectively measured the effect of gown and glove use in a 16-bed medical ICU of a tertiary care medical center. Over a 3-month period, all admissions

to a medical ICU were screened for VRE by perirectal swab. Patients who were culture positive for VRE were isolated by hospital policy, requiring the use of gown and glove for patient care. For the following 3 months, precautions were changed to glove use alone. The VRE acquisition rate was 1.8 cases per 100 patient days at risk in the gown/glove group and 3.78 per 100 patient days during glove use alone [137].

Not all studies, however, support the routine use of gowns for infection control measures. In addition, with regard to the endpoint of colonization and cross-transmission, there may be little incremental benefit to gown use over proper glove use and hand hygiene alone. Pelke et al. studied the effect of gowning in a neonatal intensive care unit over an 8-month time frame employing an alternating 2-month gowning and non-gowning cycles. The outcomes of interest were colonization patterns, necrotizing enterocolitis, respiratory syncytial virus, other hospital-acquired infections, mortality, and handwashing. The investigators failed to document any significant difference between the gowning and non-gowning cohorts with respect to the rates of bacterial colonization, infection type, or mortality. In addition, no significant difference in hand hygiene practice was observed [138].

Other investigators have compared gown use in addition to gloves and the effect on hospital-acquired transmission of VRE. Slaughter et al. compared the universal gloving versus universal gown and glove use on the acquisition of VRE in a medical intensive care unit. This prospective study involved 181 consecutive admissions. Half of the 16-bed ICU was designated for universal gown and glove use during patient care activities, and the other half was universal gloving for patient care activities. Rectal surveillance cultures were taken daily from patients along with monthly environmental cultures of bed rails, bedside tables, and other common objects in patient rooms. The investigators found no superiority in the universal use of gowns and gloves versus use of gloves only in preventing the rectal colonization of VRE in a medical ICU cohort [102]. Trick and colleagues compared the impact of routine glove use versus contact isolation on the transmission of multidrug-resistant bacteria in a skilled nursing home environment [139]. Over an 18-month period, all residents admitted to the skilled care unit of an acute and long-term care facility were randomly allocated to two different contact isolation precautions (gown and glove use) vs. routine glove use during patient care. No differences were observed in the transmission of antimicrobial-resistant bacteria, including MRSA, VRE, and extended spectrum beta-lactamase producing *K. pneumonia* and *E. coli* between the two study groups. Of note, greater compliance with proper glove use and hand hygiene was seen in the routine glove use section [139]. Harris et al. conducted a cluster-randomized trial among 20 medical and surgical ICUs. All healthcare workers in the ten ICUs assigned to the intervention groups were required to wear gloves and gowns for all patient contact and when entering any patient room. The ten ICUs in the control groups continued to follow their usual standard of care, which involved contact precautions (gloves and gowns) for patients known to be infected or colonized with multidrug-resistant organisms. Surveillance cultures for MRSA and VRE were performed at the time of ICU admission and at the time of discharge. A total of 92,241 swabs were collected for surveillance cultures from 26,180 patients. Intervention and control ICUs experienced a decrease in patient acquisition of antibiotic-resistant organisms between the baseline and study periods. The difference in change was not statistically significant between the groups, however. In this same study, universal glove and gown use resulted in increased room-exit hand hygiene compliance (62.9% pre-intervention vs. 78.3% post-intervention). Of potential concern, healthcare worker room entry was also decreased (5.24 entries per hour pre-intervention vs. 4.28 entries per hour post-intervention). However, no change in the rate of adverse events was experienced [140]. Thus, although the use of gloves *and* gowns is the convention for limiting the cross-transmission of hospital-acquired pathogens, the incremental benefit of gown use, in endemic settings, may be minimal.

2.5 The Role of Healthcare Worker Apparel in Hospital-Acquired Transmission of Pathogens

Contamination of healthcare worker apparel has been well documented [141–147]. The most commonly isolated organisms include *Staphylococcus aureus*, *Enterococci* (including VRE), and gram-negative organisms. Although evidence that transmission of organisms occur via contaminated clothing is lacking, there remains concern that healthcare worker apparel can act as a fomite for transmission of harmful organisms. The Society for Healthcare Epidemiology of America (SHEA) recently issued expert guidance regarding healthcare worker attire in acute care hospitals [148]. Despite the lack of firm evidence, these recommendations confer low cost and low likelihood of harm. Based on thorough review of the literature and expert opinion, they offered guidance for voluntary adoption of the following policies:

- Bare below the elbows (BBE): This is defined as wearing short sleeves, no wristwatch, no jewelry, and no ties while performing clinical duties. While direct evidence of transmission of organisms from clothing to patients is lacking, this practice is supported by biological plausibility and low risk of harm, according to the authors.
- White coats: If white coats are used, facilities should provide access to two or more coats with easy access to on-site laundering. Hooks should also be provided by the facility as a place where white coats can be hung during patient contact.

- Frequency of laundering: Clothes that come into contact with patients should be laundered daily, while white coats should be laundered at least weekly and when soiled. Preferably, items laundered at home should go through a hot-water wash cycle (with bleach if feasible), followed by a dry cycle. Less frequent laundering of clothing may be indicated for healthcare workers who engage in direct patient contact less often.
- Footwear: For healthcare worker safety, shoes with closed toes, low heels, and nonskid soles should be worn. This practice also confers less risk of exposure to blood, other potentially infectious materials, and injuries due to sharp objects.
- Identification: Identification badges should be worn by healthcare personnel and be clearly visible at all times for identification and security purposes.
- Other recommendations: Equipment used on multiple patients, such as stethoscopes, should be cleaned between patients. No other recommendations were made on additional personal items such as cellular phones, pagers, or other clothing items. In general, any item that comes into contact with multiple patients should be cleaned in between patients.

3 Contact Precautions

Contact precautions prevent spread of organisms from an infected patient through direct (touching the patient) or indirect (touching surfaces or objects that that been in contact with the patient) contact. This type of precaution requires the patient either be placed in a private room or be cohorted with a roommate with the same organism. Healthcare workers should don gloves upon entering the room. After patient care or environmental contact, the gloves should be removed and hand hygiene should be performed prior to leaving the room. In addition, the use protective gowns have been advocated to decrease the risk of healthcare worker garment contamination. Patient care items used for a patient in contact precautions, such as a stethoscopes and blood pressure cuffs, should not be shared with other patients unless they are properly cleaned and disinfected before reuse. Patients should be restricted to the isolation room [150].

Contact isolation is recommended for diarrheal illnesses of infectious origin and for infections with *C. difficile*. Traditionally, contact precautions have also been recommended for patients with drug-resistant pathogens such as MRSA, VRE, and multidrug-resistant gram-negative rods. However, controversies with the use of contact precautions exist.

3.1 Controversies in Contact Precautions

Effectiveness of contact precautions has been exhibited in outbreak situations [151–153]. Extrapolation of these results has led to the use of contact precautions as a control measure for transmission of multidrug-resistant organisms, such as MRSA, VRE, and multidrug-resistant gram-negative rods, in healthcare settings. While some studies have documented reduced rates of transmission of drug-resistant organisms when contact precautions are used, others fail to show this association [140, 161–163]. In addition to conflicting outcomes, well-designed, robust studies are lacking.

Several studies have noted suboptimal compliance with contact precautions. A large prospective cohort study analyzed compliance with various components of contact isolation practices, including hand hygiene prior to donning gloves, gowning, using of gloves, doffing of gown and gloves, and hand hygiene after removal of gown and gloves. Out of the 1013 healthcare workers observed, only 28.9 % adhered to all components of contact precautions [161]. Another prospective observational study involving a 900-bed tertiary care teaching hospital observed 73 % overall compliance with routine gown use. Specifically, healthcare workers were 76 % compliant, while visitors were 65 % compliant [162]. On the other hand, it has been argued that gown use may actually improve hand hygiene compliance. Golan et al. studied this hypothesis with an interventional study in two ICUs in the same tertiary care hospital. The intervention ICU eliminated the use of gowns for contact precautions, while the other ICU continued with the usual use of both gowns and gloves for contact precautions. Of concern, a very low rate of overall hand hygiene compliance was observed (10.1 % before patient care, 35.6 % after patient care, and only 5 % both before and after patient care). Hand hygiene compliance was no different between the intervention and control groups [163]. Another observational study demonstrated improved rates of hand hygiene on exiting the room of patients on contact precautions (63.2 %) vs. patients not on contact precautions (47.4 %), $p < 0.001$ [164]. Notably, a recent prospective cohort study found that as the burden of isolation increased from ≤20 to >60 %, hand hygiene compliance upon room entry decreased from 43.6 to 4.9 % [161].

Of some concern, adverse events associated with the use of contact precautions have been documented. In a prospective cohort study, Saint et al. reported in a prospective cohort study that patients on contact precautions are examined by the attending physician less often than their non-isolated controls (35 % vs. 73 %, respectively) [165]. In 2009, Morgan et al. conducted a review of the literature on adverse outcomes related to contact precautions. Four main outcomes were recognized. Isolated patients experienced less contact with healthcare workers, delays in care and increases in adverse events, increased anxiety and depression, and more dissatisfaction with care [164]. Since that time, several other reports have reinforced these results. A prospective observational study reported that patients on contact precautions had 36.4 % fewer hourly healthcare worker visits and 17.7 % less patient contact time with healthcare workers. These patients also had fewer outside visitors. Another study compared 150

patients on contact precautions to 300 controls. The patients on isolation were more likely to experience preventable adverse events, such as falls and pressure ulcers, experience less satisfaction with care, and have less physician progress notes [166]. Another study surveyed 1876 adult patients. Those on contact precautions had higher depression and anxiety scores [167]. Additionally, patients on contact precautions experience more medication errors, such as erroneous insulin and anticoagulant administration [168].

4 Measures to Control Hospital-Acquired Outbreak of Drug-Resistant Pathogens

Data published by the CDC report that more than 70 % of bacterial pathogens implicated in hospital-acquired infections are resistant to at least one commonly used anti-infective [169]. In addition, current evidence suggests that the proportion of MRSA and VRE attributable to cross-transmission is significant. Transmission of clonal MRSA strains within a healthcare setting has been confirmed by pulsed-field gel electrophoresis and has occurred in various healthcare settings including general hospital wards, neonatal intensive care units, and surgical intensive care units [155, 170–178]. Similarly, the clonal transmission of VRE within healthcare settings has been documented via molecular typing [179–189].

There is no one size fits all approach to the control of hospital-acquired drug-resistant pathogens such as MRSA or VRE. The literature is replete with reports of intervention and programs to limit the spread of drug-resistant pathogens. These examples, occurring in diverse patient populations such as hospital wards, intensive care units, and neonatal units, typically involve different combinations of multiple interventions such as surveillance cultures, pulsed-field gel electrophoresis typing of isolates, patient isolation, cohorting, gloving, gowning, antibiotic restriction, and healthcare worker decolonization [10, 190–195]. The best approach for controlling the hospital-acquired spread of pathogens such as MRSA or VRE should take into account the frequency of transmission of hospital-acquired infection, the reservoirs, the patient risk factors, and the resources of the healthcare system for implementation of varied infection control measures.

5 Screening for Asymptomatic Patient Colonization with Drug-Resistant Pathogens

As the incidence of both patient infection and colonization with drug-resistant pathogens such as MRSA or VRE has increased, the management of this phenomenon has evolved. Aggressive strategies include screening to detect asymptomatic carriers and the strict use of isolation measures to control spread. Nevertheless, there has been much debate about the rationale and efficacy of this practice to control the endemic spread of potential hospital-acquired pathogens.

In the latest guidelines by the Society for Healthcare Epidemiology of America (SHEA) for the prevention and spread of antibiotic-resistant pathogens, the use of active surveillance cultures to identify the reservoirs of MRSA and VRE is strongly recommended [196]. The ultimate goal of active surveillance is to identify every colonized patient so that infection control interventions such as contact isolation and cohorting can be implemented to reduce the risk of cross-transmission. As per the SHEA guidelines, these active surveillance cultures are indicated at the time of hospital admission for patients at high risk for carriage of MRSA and/or VRE [196–201]. For patients with ongoing or prolonged hospitalization, or high risk for VRE or MRSA carriage due to hospital location, underlying comorbidities, and concurrent antibiotic therapy, periodic re-culturing is recommended, typically on a weekly basis [176, 187, 202–209]. Furthermore, for facilities with high endemic rates of VRE or MRSA, as determined by surveillance of high-risk patients, an institution-wide survey should be conducted so that these patients are identified and placed in either contact isolation or cohorted [196].

However, a recently published review of isolation policies by the British National Health Service highlighted the strong evidence for the effectiveness of different isolation and screening policies for MRSA [210]. Data were extracted from articles reporting infection control mechanisms, policies, and interventions for MRSA-related outcomes, including colonization or infection. From 4382 abstracts, 254 full article appraisals were made with 46 papers included in the final review. Of the 46 studies, 18 included the use of isolation wards, 9 used nurse cohorting, and 19 involved other isolation policies including multiple combinations of different interventions such as patient cohorting in single or multiple occupancy rooms, strict use of gown, glove and mask, changes in antibiotic formulary, screening on admission and weekly thereafter, prompt patient discharge, mupirocin for decolonization, hand hygiene education with and without feedback to healthcare workers, and antibiotic restriction. Although the review concluded that concerted efforts, including isolation, can reduce the rates of MRSA in both endemic and epidemic settings, several other findings were noteworthy. The majority of the studies had multiple interventions and major methodological weaknesses such as lack of measures to prevent bias, the absence of consideration for confounding, and inappropriate statistical analysis. As such, the quality of evidence in many studies was considered weak, many alternative and plausible explanations for the reduction in MRSA could not be excluded, and the role and impact of isolation measures were not assessed by well-designed studies.

At least one recently published, well-designed, prospective study evaluated the efficacy of single room and cohort isolation for MRSA in the intensive care unit setting [211]. In this 1-year analysis conducted in the intensive care units of two teaching hospitals, MRSA screening was performed both on admission and then weekly for all patients. During the first 3 months and the last 3 months, all MRSA-positive patients were moved either to a single occupancy isolation room or cohorted with other MRSA-positive patients. During the middle 6-month period, MRSA-positive patients were not placed in isolation or cohorted unless they were co-colonized with another multidrug-resistant pathogen. Patient characteristics, hand hygiene compliance, and MRSA acquisition rates were similar in the periods when patients were moved and not moved. Using Cox proportional hazard modeling to control for confounders such as gender, age, APACHE II score, antibiotic use, number of intravascular catheters, and colonization pressure, no significant reduction in MRSA acquisition was observed between the two groups [211].

The use of strict isolation practices may have a detrimental impact on the process and quality of patient care. Evans et al. prospectively observed surgical patients in both the ICU and on a general surgical floor. In both the ICU and surgical floor, surgical patients on contact isolation had fewer healthcare worker visits and less contact time overall despite a higher severity of illness as measured by APACHE II score [212]. Stelfox et al. studied the quality of medical care received by patients isolated for MRSA-related infection control precautions using a case control study design. Although isolated and control patients had similar baseline characteristics, isolated patients were twice as likely as non-isolated patients to experience adverse events during their hospitalization. These adverse events included supportive care measures and process of care measures such as days with incomplete or absent vital signs and days without documented nursing and physician progress notes. Additionally, patients on MRSA contact isolation expressed greater dissatisfaction with the quality of their treatment [166]. Similarly, Saint and colleagues observed, in a prospective cohort study of two in-patient medical services, that patients on contact isolation were half as likely to be examined by an attending physician as non-isolated patients [165].

Contact isolation may have a detrimental psychological impact on patients. One cross-sectional matched case control study compared contact isolated versus non-isolated elderly patients [213]. The level of depressive and anxiety symptoms exhibited by the contact isolation group exceed that of the noncontact isolation group. Catalano et al. prospectively studied the impact of contact isolation on anxiety and depression in non-critically ill hospitalized patients [214]. Patients on contact isolation for either MRSA or VRE were compared to other hospitalized patient with infectious diseases not requiring isolation. All patients were evaluated with the Hamilton Anxiety and Depression Rating Scale at baseline and then later during the hospital course. Although no significant differences in baseline anxiety and depression scores were noted, for patients in contact isolation, statistically significant higher scores on both scales were reported later during the course of hospitalization.

Thus, the optimal strategy for control of endemic, resistant pathogens such as MRSA or VRE is yet to be defined. Aggressive measures involving surveillance cultures for colonized patient reservoirs may not effectively reduce the rate of pathogen cross-transmission. Additionally, surveillance cultures with consequent the implantation of isolation measures may have the impact of increased patient depression and anxiety, and may be detrimental to the both the process and quality of care.

6 Antibiotic Control Programs and Surveillance for Hospital-Acquired Infections

The implications of widespread antibiotic use, including the impact on public health, are beyond the scope of this chapter. The reader is referred to other chapters within this textbook for further information on the topic. Although the degree to which antibiotic pressure directly contributes to the cross-transmission of hospital-acquired infections remains poorly defined, several studies and observations are worth mentioning. Harbath and colleagues prospectively studied surgical site infections in cardiovascular surgical patients. In this cohort, prolonged antibiotic prophylaxis with cephalosporins was an independent risk factor on logistic regression analysis for infections with cephalosporin-resistant gram-negative rods [215]. Additionally, in a prospective, non-randomized, cohort study in a neonatal ICU, a change to a new empiric antibiotic regimen resulted in a decrease in colonization or infection by gram-negative organisms resistant to the standard or prior empiric regimen [216]. Donskey and colleagues showed that enteric VRE colonization was significantly associated with colonization pressure, presence of feeding tube, and cephalosporin use [217]. Similarly, MRSA colonization has been associated with antibiotic use. A significant risk factor for prolonged MRSA colonization, as defined by multivariate regression analysis, was fluoroquinolone use [218]. Additionally, using an ecologic study design, investigators from Belgium reported a direct association between fluoroquinolone use and MRSA infections [219]. Consideration should be given to antibiotic restriction and control programs in the event of elevated rates of hospital-acquired drug-resistant pathogens.

According to the Society for Healthcare Epidemiology of America (SHEA), antimicrobial stewardship refers to coordinated interventions designed to improve and measure the appropriate use of antimicrobials by promoting the selection

of the optimal antimicrobial drug regimen, dose, duration of therapy, and route of administration [220]. All healthcare institutions in the United States are urged to adopt antimicrobial stewardship programs. The goal of these programs is to improve clinical outcomes by optimizing antimicrobial use in order to minimize toxicity, reduce adverse events, and reduce selective pressure that leads to antibiotic resistance. In 2012, SHEA, the Infectious Diseases Society of America (IDSA), and the Pediatric Infectious Diseases Society (PIDS) issued a joint policy statement regarding antimicrobial stewardship [221]. Several recommendations are given.

First, antimicrobial stewardship programs should be required through regulatory mandates (through a combination of state and federal mandates, and via the Centers for Medicare and Medicaid Services (CMS)). However, objectives should be flexible enough so that resource-limited facilities are able to maintain participation in such programs. Requirements of a program should include:

- A multidisciplinary antimicrobial stewardship team, which is physician directed and has at least one team member trained in antimicrobial stewardship. At the least, the team should include a physician, a pharmacist, a clinical microbiologist, and an infection preventionist.
- A medication formulary limited to non-duplicative antibiotics of clinical need.
- Institutional guidelines for the use of antibiotics for management of common clinical syndromes.
- Methods for detecting and eliminating the use of antibiotics in a manner that is redundant, inappropriate, or inadequate (e.g., the use of antibiotics for the treatment of nonbacterial illness and the use of antibiotic regimens that are either too broad, not broad enough, or not appropriately targeted for the pathogen).
- Processes for monitoring antibiotic use for internal benchmarks.
- Periodic distribution of facility-specific antibiograms to clinicians.

In addition, CMS should require institutions to report to the National Healthcare Safety Network's (NHSN) Antimicrobial Use and Resistance option of the Medication-Associated Module, conduct prospective surveillance and concurrent interventions to optimize antimicrobial use, establish national benchmarking of antimicrobial use at the institutional level based on acuity of care and patient mix, and report other indicators of effective antimicrobial use such as incidence rates of drug-resistant organisms and *C. difficile* infections.

Second, validated antimicrobial stewardship interventions do not exist for ambulatory healthcare settings. Therefore, pilot projects should be designed to develop and implement antimicrobial stewardship interventions in these settings. National organizations, such as the Agency for Healthcare Research and Quality (AHRQ), CMS, National Institutes for Health (NIH), and the Centers for Disease Control and Prevention (CDC) should provide funding for such projects. Suggested areas of research include integration of clinical decision support into electronic health records and e-prescribing systems. Once validated, interventions should become CMS requirements.

Third, mechanisms should be put into place to educate physician trainees (e.g., medical students, residents, and fellows) about antibiotic resistance and antimicrobial stewardship. Furthermore, practicing clinicians should receive education as well. Educational materials can be distributed through specialty societies, the FDA, and individual institutions, for example.

Fourth, there should be a national system for collecting antimicrobial use data, which can then be used to benchmark institutions. The data could potentially be used as part of an incentive-based payment system.

Fifth, research on antimicrobial stewardship is needed in order to understand antimicrobial resistance and how interventions affect it. This is best accomplished via translational research. Research should focus on:

- Development of a standard definition of appropriate and inappropriate antimicrobial use, measures of use, and the factors that contribute to misuse. In addition, standardized data collection tools should be developed for purposes of measurement and interpretation of antimicrobial use.
- Determination of the most effective and cost-efficient means of implementing antibiotic stewardship programs in various settings, using robust study design.
- Development and validation of process and outcome measures that allow comparison of antimicrobial use within and across healthcare settings. Measures may include surrogate markers of effective and appropriate antibiotic use, such as rates of infections due to drug-resistant organisms and *C. difficile* infections, adverse effects of antibiotics, and hospital/ICU length of stay.
- Understanding how generic versus trade name antimicrobial agents affects use.
- Evaluation of the impact of rapid diagnostic tests and biomarkers, such as procalcitonin, on the use of antibiotics, and whether or not unnecessary antibiotic use (e.g., for viral infections) is decreased.

7 Conclusion

The prevalence of hospital-acquired, antibiotic-resistant pathogens has increased significantly over the last 20 years. Hospital infection control programs are seen as increasingly important for the control of antibiotic-resistant organisms. Strategies to control the spread of hospital-acquired infections by drug-resistant pathogens are multiple. The patient, the healthcare

worker, and the environment are reservoirs for drug-resistant pathogens. For high-risk patients colonized with MRSA, such as surgical candidates and those in intensive care units, decolonization with nasal mupirocin should be considered. Patients colonized with resistant pathogens such as MRSA, VRE, and drug-resistant gram-negative rods can contaminate the environment. As such, all healthcare facilities should develop policies for the terminal and periodic disinfection of patient care areas and environmental services. Cross-transmission of hospital-acquired pathogens by the hands of healthcare workers has been well documented. Meticulous hand hygiene should be practiced with medicated handwashing agents (alcohol, chlorhexidine gluconate, triclosan) that are bactericidal and effectively reduced bacterial counts on the hands. Measures to promote hand hygiene compliance should include efforts that stress increased use of accessible, easy to use, medicated hand hygiene products, coupled with a hospital-wide, administration-backed, high-priority hand hygiene campaign. Glove use is beneficial in limiting the contamination of healthcare worker hands but is not a substitute for hand hygiene. Concerns about the contamination of personnel clothing with hospital-acquired pathogens has led to the use of gowns for patients in contact isolation. The incremental benefit of gowns and glove use may be minimal. Transmission-based precautions are useful for the control of hospital-acquired infections and include contact, airborne, and droplet precautions. Aggressive surveillance for asymptomatic reservoirs may be of value but is not without controversy including questions about efficacy and effect on quality of care. Other considerations for an infection control program include antibiotic control programs and surveillance systems for infections with hospital-acquired pathogens. This type of surveillance is essential for establishing endemic rates, defining outbreaks, and developing institution-specific antibiograms. In the end, the purpose of a hospital infection surveillance program is to define endemic rates, recognize outbreaks, and obtain data of value in recognizing the extent and causation of the infections. This data is later applied for the planning and implementation of risk reduction policies and interventions.

Controlling the Spread of Resistant Pathogens in the Intensive Care Unit

89

Tara N. Palmore and David K. Henderson

1 Introduction

As is detailed carefully throughout this text, antimicrobial resistance has surfaced as a major challenge to modern medicine in the twentieth and twenty-first centuries. The challenges presented by burgeoning antimicrobial resistance are magnified in the intensive care unit (ICU), where aggressive, invasive care of severely ill patients sets up a perfect storm for resistant pathogens. ICU patients frequently develop nosocomial infections, which are often severe, difficult to treat, and, in some populations, recurrent [1]. Extensive exposure to antimicrobial agents, colonization with nosocomial bacteria, and prolonged immunosuppression put ICU patients at high risk for infection from resistant pathogens. Some of the most aggressive resistant pathogens have become endemic in hospital environments, and many of these pathogens have established residence in intensive care units [2–4]. Examples of such pathogens are methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus*, and some carbapenem-resistant Gram-negative bacilli (e.g., *Klebsiella pneumoniae*, *Enterobacter* spp., *Acinetobacter baumannii*). The rise of extensive drug resistance and pan-resistance among nosocomial Gram-negative bacteria has made controlling the spread of these organisms in the ICU environment even more important. In addition, some consider *C. difficile* infection a multidrug-resistant pathogen because it is selected out by antibacterial therapy.

This chapter discusses the special issues relating to the ICU that make antimicrobial resistance a major problem confronting critical care clinicians. The chapter addresses (1) reservoirs of infection in the ICU, (2) common nosocomial infections encountered by intensivists, (3) resistant pathogens that particularly affect ICU patients, and (4) approaches to preventing infections caused by resistant pathogens in the ICU setting.

2 Reservoirs

The nosocomial reservoirs for resistant organisms vary by the pathogen and the clinical setting. Organisms can be transmitted from person to person on the hands of healthcare personnel or spread via contaminated surfaces or equipment. All persons are colonized with bacteria on the mucous membranes and skin and within the fecal flora. The flora of hospitalized patients quickly change during hospitalization, often incorporating locally endemic multidrug-resistant bacteria [5]. The source of these new flora may be the patient, a provider, or the inanimate environment of the ICU. Little evidence suggests that hospital visitors are a significant source of multidrug-resistant bacterial transmission, though family members who provide extensive care to colonized patients certainly may become colonized themselves [6–8]. The endogenous flora of hospitalized patients may become more resistant with antibiotic exposure or may acquire new resistant pathogens that are spread within the ICU. Patients colonized with resistant bacteria are potential reservoirs for transmission to other patients via the hands of healthcare personnel or contamination of the environment. Identification and isolation of colonized patients, hand hygiene, environmental disinfection, and other infection control precautions are key to preventing or interrupting this cycle of transmission.

Staphylococci are often carried on the skin and mucous membranes of staff and patients [9]. *Staphylococcus aureus* may colonize several sites on the body, including the face, hands, throat, axillae, and groin, but are most frequently

D.L. Mayers et al. (eds.), *Antimicrobial Drug Resistance*, DOI 10.1007/978-3-319-47266-9_41

found in the epithelium of the anterior nares [10]. Patients who are colonized and/or infected with resistant staphylococci can serve as reservoirs for the spread of these organisms within healthcare institutions [11]. Studies suggest that 30–60 % of healthy adults carry *S. aureus* and that 10–20 % of these individuals are chronically colonized [12, 13]. Many patients are identified as nasal carriers of *S. aureus*, including methicillin-resistant strains, at the time of hospital admission [14, 15]. Healthcare personnel have higher rates of MRSA carriage than are found in the general population, with as many as 44 % of healthcare personnel carrying *S. aureus* and up to 15 % carrying MRSA in some studies [16–19]. The primary route of MRSA transmission within the hospital appears to be from patient to patient, with healthcare personnel the likely vector, carrying the organisms on their hands. In addition, some studies have suggested that resistant staphylococci can establish an inanimate environmental reservoir and can persist on contaminated objects in the environment. When these objects are used for subsequent patients, they may serve as vehicles of transmission for the resistant pathogens as a result of the patient having direct contact with the contaminated objects or a healthcare worker handling the object and then touching the patient [20–22]. Some respected investigators believe that environmental or fomite spread may be substantially underestimated as a potential nosocomial route of transmission of resistant organisms.

Some pathogens (e.g., *Clostridium difficile*, *Enterococcus faecium*, resistant Gram-negative organisms, etc.) can be carried in the fecal flora of patients. The bacteria may not invade and cause infection unless the intestinal epithelium is damaged, the intestinal microbiome is subjected to antibiotics, or both. Antibiotic pressure can give multidrug-resistant bacteria a selective advantage (e.g., the administration of antimicrobial agents to which the majority of the fecal flora—and especially the fecal anaerobes—are susceptible, but to which the pathogen is not). Similarly, organisms can be carried as part of the cutaneous flora, causing few problems until the normal flora are perturbed by external forces, such as antimicrobial agents.

In the ICU environment, healthcare personnel who exercise inadequate hand hygiene may carry multidrug-resistant bacteria on their hands; carriage may be transient but last long enough to spread the bacteria with facility to the ICU environment or directly to patients. Personnel can have longer-term carriage of bacterial pathogens under long or artificial fingernails, and the recurrent role of long and artificial nails in outbreaks has led the Centers for Disease Control and Prevention (CDC) to recommend against them [23].

2.1 The Inanimate Environment

Certain organisms have a proclivity for establishing reservoirs in the inanimate environment in healthcare settings. Some such organisms find moist places in the environment and establish residence in biofilms. Examples include *Stenotrophomonas maltophilia*, species of *Pseudomonas*, *Aeromonas*, *Sphingomonas*, and others. Other organisms are resilient and able to tolerate a range of conditions of temperature and humidity, including spores of *Clostridium difficile*, *Acinetobacter* species, and enterococci. The latter hardy bacteria may survive for months in the hospital environment and, in the absence of effective disinfection, may spread to patients long after they were shed, creating a prolonged transmission cycle. Multidrug-resistant bacteria, once established in an environmental reservoir, may cause recurring clustered infections in the ICU. In multiple ICU outbreaks with multidrug-resistant bacteria, the outbreak organism has been identified in sink drain biofilms. Although circumstantial evidence may implicate the sink drain colonization in the outbreak, transmission from sink drains to patients has not been definitively proven [24–27]. In cases of sporadic infection and even some outbreaks, identifying the precise environmental reservoir may be extremely difficult [28].

3 Major Infectious Disease Syndromes Commonly Encountered in the ICU

Whereas virtually any infectious syndrome may occur in patients hospitalized in the ICU, several categories are worthy of special mention because of the frequency with which they occur, as well as the frequency with which these syndromes are associated with resistant pathogens: catheter-associated bloodstream infections, ICU-acquired nosocomial pneumonia, *Clostridium difficile* infection, and sepsis in immunosuppressed patients. The intensivist must be particularly attuned to the pathogenesis of these infectious syndromes in the ICU patient population, as well as the factors that increase the likelihood that these infections will involve resistant organisms.

Most, if not all, of these syndromes are by-products of medical progress. We are able to prolong life though the use of aggressive chemo- and immunotherapies, the use of sophisticated life-support devices, and other invasive diagnostic and therapeutic approaches. Use of each drug or device is associated with increased risks for complications, including infection. Seriously ill ICU patients often sustain repeated bouts of infection and are therefore exposed to multiple courses of antibacterial, antiviral, and antifungal agents. With inadequate host defenses and multiple invasive devices in place, these patients are essentially incubators for microbial resistance.

3.1 Central Venous Line-Associated Bloodstream Infection (CLABSI)

The occurrence of CLABSI in ICU patients has become commonplace. Microorganisms reach the circulation via the catheter insertion site, along hubs [29, 30], junctions, and

connectors, and via intrinsic or extrinsic contamination of the infusion fluid. Insertion site colonization and infection are facilitated by conditions that favor the growth and proliferation of skin flora, thereby accelerating the migration of organisms from the skin surface along the catheter insertion tract. Contamination may occur at the time of insertion or, more likely, weeks to months later. This type of contamination will most commonly result in colonization along the external surface of catheter and is facilitated by fibrin sheath/platelet deposition on the external catheter surface and organism-produced biofilm at the catheter surface in the circulatory channel. Similarly for contamination introduced into the system via the catheter hub and the catheter's junctions and connectors, the resident skin flora are the most common pathogens producing device-associated infection. Again, the source of these organisms may be the patient, a healthcare provider, or the ICU environment. These organisms are typically introduced into the system at the time the device is being manipulated. This pathway is more likely to produce colonization of the catheter lumen. Because infection is introduced as the device is being manipulated, this route of infection becomes increasingly important as a source of infection as the duration of catheterization increases. The likelihood of contamination and colonization may relate to the design of the device and also will be facilitated by fibrin sheath production, platelet deposition, and/or biofilm development on the catheter surface.

Contamination introduced via the infusion fluid itself occurs less commonly. Such contamination may be intrinsic (i.e., due to contamination during manufacture or processing) or extrinsic (i.e., contamination introduced at the time the fluid is hung or at the time additives are injected into the container).

3.2 Ventilator-Associated Pneumonia

The reservoir for ventilator-associated pneumonia is again most commonly the patient's own oropharyngeal flora. Patients' oral flora change quickly, often in critically ill patients within 24 h of hospitalization, from the normal, primarily anaerobic flora to an oral flora that is dominated by aerobic Gram-negative bacilli and *S. aureus* [7]. When the patient is intubated and placed on a ventilator, risk for pulmonary infection increases dramatically. The endotracheal tube itself contributes to this risk. Direct inoculation through the respiratory apparatus may occur, either as a result of cross-contamination or from breaks in sterile technique.

The inner lumen of an endotracheal tube also rapidly develops a biofilm containing microorganisms [31, 32], such as aerobic Gram-negative rods and *S. aureus*, at very high concentrations. This biofilm can be inoculated directly into the lower respiratory tract either by ventilatory flow or by inserting suction catheters through the tube and producing infectious emboli [33, 34]. Additionally, in the critically ill, supine, ventilated patient, oral secretions pool in the oropharynx and subglottic space above the tracheal tube cuff, forming a reservoir of secretions contaminated with the altered flora [33, 34]. Without measures to drain subglottic fluid, leakage of pooled secretions around the cuff occurs almost uniformly in these patients.

If the patient has a nasotracheal tube or has had a nasogastric tube inserted, the risk of nosocomial sinusitis is increased. In a patient with a substantially altered mental status, such sinus infections often are unsuspected and undiagnosed. Predominant pathogens for these sinus infections are aerobic Gram-negative bacilli. More importantly, the development of nosocomial sinusitis increases the risk of ventilator-associated pneumonia by a factor of four [35, 36].

Positioning of the patient is also associated with risk for ventilator-associated pneumonia. Aspiration of gastric contents occurs four times more frequently when the patient is in the supine position, rather than when the head of the patient's bed is elevated at a 45° angle [37]. Isolation of the same organisms from the stomach, pharynx, and endobronchial samples occurred in 32 % of semirecumbent patients in one study compared with 68 % of patients in the supine position [38]. Unfortunately, gastric reflux occurs irrespective of body position in mechanically ventilated patients who have nasogastric tubes.

Ventilated patients are frequently placed on proton pump inhibitors to decrease gastric acidity to reduce the risk for gastric hemorrhage. Decreased gastric acidity (which is clearly appropriate for ventilated patients) increases the microbial colonization of the stomach [39]. Enteral feedings (often administered to such patients) also increase the risk for gastric colonization with Gram-negative bacilli. The use of either continuous or intermittent enteral feeding increases gastric pH and is associated with an 80 % risk for Gram-negative colonization of the stomach [40]. Conversely, the maintenance of adequate nutritional status is clearly associated with a reduced risk for ventilator-associated pneumonia, and enteral nutrition is clearly the route of choice for these patients. In ICU patients who have received multiple courses of empiric and/or therapeutic antimicrobials, the likelihood that the organism colonizing the stomach is a multidrug-resistant pathogen is increased substantially. VAP caused by multidrug-resistant bacteria prolongs ICU stay compared with VAP caused by antibiotic-susceptible organisms [41].

3.3 Catheter-Associated Urinary Tract Infections

Urinary tract infections are among the most common of all healthcare-associated infections. The overwhelming majority (approximately 75 %) of these infections are related to the use of indwelling urethral catheters [42]. The use of such

indwelling catheters is extremely common in the ICU setting. Catheter-associated urinary tract infection (CAUTI) rates among adult patients in ICUs reported to the CDC's National Healthcare Safety Network have been reported to be between 1.2 and 4.7 infections per 1000 urinary catheter-days [43]. Factors associated with a risk for CAUTIs among adult ICU patients include the duration of catheterization, increased age, female sex, and failure to maintain a closed drainage system [44].

3.4 Sepsis in Immunosuppressed ICU Patients

Immunosuppressed patients lack some of the normal physical barriers to infection. Impaired integrity of the skin and mucous membranes that accompanies some immunosuppressed states allows these surfaces to become portals of entry for pathogens that colonize the skin or intestinal tract. The skin and mucous membrane damage that accompanies radiation therapy, chemotherapy, burns, graft-versus-host disease, surgery, trauma, and many other conditions facilitates colonization with nosocomial pathogens. Again, ICU patients have been exposed to multiple courses of antimicrobials, and the likelihood that the organisms colonizing the skin are multidrug-resistant pathogens (e.g., MRSA, VRE, Gram-negatives) is increased substantially. Following radiation therapy or chemotherapy, patients' oral, pharyngeal, and intestinal mucous membranes experience accelerated apoptosis without cell renewal, ultimately resulting in an ulcerative phase (mucositis) that may permit entry of nosocomially acquired microflora into the circulation. This ulcerative phase is followed by a healing phase that restores the integrity of the mucous membrane barrier. Additionally, the administration of antimicrobials may facilitate colonization of the gut with resistant pathogens. Additional possible portals of entry for resistant nosocomial pathogens include the respiratory tract, the genitourinary tract (particularly if the tract has been instrumented), and a variety of others.

For all of these reasons, these patients are at extreme risk for infection. Pathogens causing infections in these patients may originate from the patient's endogenous flora, from the hands of their healthcare providers, from fomites and equipment, from the inanimate healthcare environment, and even from the air. As rough approximations, about 80 % of bacterial pathogens causing infection in neutropenic patients originate from patients' endogenous flora, and approximately half of patients' endogenous microbial flora are acquired nosocomially. For the reasons noted above, the normal flora of the oropharynx, the skin, and the lower gastrointestinal tract are perturbed, and, particularly because of the frequent exposures to broad-spectrum antimicrobials, resistant organisms play an increasingly important role in colonization and infection in this setting. Resistant pathogens frequently encountered in the ICU causing these infections include MRSA, VRE, and multidrug-resistant Gram-negative bacteria, including carbapenemase-producing strains and organisms that have other mechanisms of resistance.

4 Resistant Pathogens of Particular Interest to ICU Staff

Certain resistant pathogens are worthy of special mention as particularly problematic for patients hospitalized in the ICU. Whereas a wide range of bacterial, viral, and fungal pathogens can affect patients hospitalized in the ICU, four bacterial pathogens have emerged as particularly challenging for critical care staff in the past two decades: methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus faecium*, *Clostridium difficile*, and highly resistant Gram-negatives, including carbapenemase-producing *Acinetobacter baumannii* and carbapenemase-producing Enterobacteriaceae. ICU infections associated with each of these pathogens will be discussed in more detail.

4.1 Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Resistant *Staphylococcus aureus* organisms are often spread to patients from the hands of healthcare personnel; these organisms may be acquired from an infected or colonized patient and then transferred to another patient when hand hygiene procedures are inadequate to remove the organisms. In addition, unlike other resistant nosocomial organisms, MRSA is also spreading extensively in the community setting—such that many patients now may be colonized due to acquisition outside the healthcare setting. The ICU environment, with its attendant urgencies and immediacy of care, is an ideal environment for the spread of MRSA. Thus, starting in the 1980s, MRSA became predominant pathogens in the ICU [11]. As noted above, resistant staphylococci can also establish transient residence on objects in the environment and be spread from these objects to patients, often via healthcare personnel's hands [20–22]. Since staphylococci are primarily considered skin and nares colonizers, environmental or fomite spread of resistant staphylococci may be substantially underestimated as a route of nosocomial transmission.

Resistant staphylococci, as is the case for relatively susceptible staphylococcal organisms, possess essentially the same number of toxins and virulence factors and, hence, are aggressive human pathogens, capable of producing significant infections in even immunologically normal patients. In the ICU setting, MRSA is primarily encountered as a pathogen causing skin and soft tissue infections, wound

infections, CLABSIs, and, somewhat less frequently, respiratory infection. The propensity for MRSA to cause CLABSIs is well established. Several studies have demonstrated that resistant staphylococcal infections are associated with prolongation of hospitalization and increased costs of hospitalization [45–50].

The critical care practitioner has several options for treatment of MRSA infections. Antimicrobial selection should be governed by disease severity, susceptibility patterns, clinical response to therapy, and cost. Current parenteral therapeutic options include vancomycin, linezolid, daptomycin, ceftaroline, teicoplanin, and telavancin. An occasionally overlooked but nonetheless important therapeutic intervention for resistant staphylococcal infections is the assurance of adequate drainage of purulent fluid collections.

4.2 Vancomycin-Resistant *Enterococcus* (VRE)

Vancomycin-resistant *Enterococcus faecium* (VRE) was first detected in Europe, as early as 1987, but its appearance was preceded by substantial resistance to other antimicrobials (e.g., resistances to β-lactam antibiotics, such as ampicillin, as well as extremely high-level resistance to aminoglycosides) among enterococcal isolates.

In North America, VRE is a significant nosocomial pathogen. Colonization with VRE is common in the ICU, especially among chronically ill, critically ill, and immunocompromised patients who have prolonged hospitalization and have received multiple courses of broad-spectrum antimicrobials. Because the organism can be carried on healthcare personnel's hands and survives well in the inanimate environment, cross-transmission in the complex ICU environment has become a substantial problem over the past 15 years.

In US hospitals, and particularly in US ICUs, the inanimate environment is likely a significant source of VRE transmission. Hayden and colleagues demonstrated that VRE was highly prevalent in the inanimate environment in their ICU and also subsequently demonstrated that reducing environmental contamination had a statistically significant effect on the spread of VRE in their ICU [51]. As discussed elsewhere in this text, the increasing use of vancomycin and antimicrobial drugs that target anaerobes has likely applied substantial antimicrobial pressure on enterococcal isolates in US ICU patients [52]. To date, to our knowledge, no community reservoir for VRE has been identified in the United States.

Unlike MRSA, VRE is not a very aggressive pathogen. Nonetheless, due to the dramatically immunosuppressed state of many twenty-first century critically ill patients, the frequency with which ICU patients receive multiple courses of broad-spectrum antimicrobials, and the extent to which such patients are exposed to invasive techniques, these pathogens commonly cause infection, particularly in tertiary referral centers. In 1993, the prevalence of VRE had increased 20-fold in the ICUs of US hospitals participating in the National Nosocomial Infections Study (NNIS) [53]; however, in recent years the proportion of enterococcal infections resistant to vancomycin has plateaued at approximately 30 % [54].

Although several antimicrobial agents have activity against VRE, resistance to some of those agents has made treatment of VRE infections difficult. Agents currently marketed with efficacy against VRE include linezolid, an oxazolidinone, and daptomycin, a lipopeptide. Telavancin, a lipoglycopeptide that is approved for treatment of skin and soft tissue infections, has low potency against VanA strains of VRE [55]. The combination streptogramin, quinupristin-dalfopristin, has fallen out of favor because of its poor side effect profile. Tigecycline, a glycylcycline, is not generally used for enterococcal infections because of lack of evidence of clinical efficacy against VRE and an overall increased mortality among its recipients [56]; its use may be appropriate as a component of salvage therapy for those without better treatment alternatives.

4.3 *Clostridium difficile* Enterocolitis

Clostridium difficile enterocolitis is an extremely common sequela of broad-spectrum antimicrobial therapy. Approximately 3 % of healthy adults [57] and 14–40 % of hospitalized patients are colonized with *C. difficile* (usually in the metabolically inactive spore form) [58–61]. Because of *C. difficile's* remarkable ability to persist in the environment and resist standard cleaning and disinfecting agents in its spore form, transmission from the hospital environment may play a significant role in the organism's nosocomial spread. Development of *C. difficile* infection typically occurs after exposure to broad-spectrum antimicrobial agents. Other risk factors include colonization density of *C. difficile* infection in the patient care unit and underlying gastrointestinal disease (such as inflammatory bowel disease [62, 63] and intestinal graft-versus-host disease [64]), as well as gastric acid suppression [65].

The past decade has seen a dramatic resurgence of *C. difficile*-associated disease in North America and Europe, such that it has become the most prevalent healthcare-associated pathogen in the United States [66]. Although the rate is lower in Europe [67], variation in testing may underestimate its prevalence in that part of the world [68]. *C. difficile* infection is particularly severe in older adults, in whom the vast majority of attributable mortality occurs [69]. Toxins, A and B, are primarily involved in the pathogenesis of *C. difficile*-associated disease; however, a hypervirulent strain that emerged in the past decade contains a binary toxin, increased toxin production, and high-level resistance to fluoroquinolones

[70]. Polymorphisms in the *tcdC* gene, which downregulates toxin production, may explain toxin production that is 16–23 times higher than that of other strains [71]. Experts have speculated that widespread fluoroquinolone use may have selected this strain and led to its emergence. The increased virulence of this now-dominant hypervirulent strain (BI/NAP1/027) has been associated with higher rates of fulminant and fatal *C. difficile* infection [70, 72].

Environmental persistence combined with the substantial antimicrobial agent use among ICU patients and other host factors that place ICU patients at risk makes *C. difficile* one of the most challenging ICU pathogens to control.

4.4 Carbapenemase-Producing Gram-Negative Bacteria

Gram-negative bacteria harboring carbapenemase enzymes have emerged over the past decade and disseminated around the globe, changing dramatically the epidemiology of nosocomial infections in many countries. The predominant bacterial etiology of ICU-acquired bloodstream infections is, in many centers, shifting from Gram-positive to Gram-negative organisms, with a high proportion of multidrug-resistant Gram-negative strains [73, 74]. Although a wide range of Gram-negative species can harbor plasmid-borne genes for carbapenemase enzymes (discussed in Chapter 56), the most common in North America and Europe are *Klebsiella pneumonia* and *Enterobacter* species. Globally, *Pseudomonas aeruginosa* and *Acinetobacter baumannii* are also important pathogens whose multidrug-resistance is often, but not always, attributable to carbapemenase genes.

Clinically significant carbapenemase genes include bla_{KPC}, $bla_{OXA\text{-}48}$, $bla_{OXA\text{-}23}$, and the metallobetalactamase genes $bla_{NDM\text{-}1}$ bla_{VIM}, and bla_{IMP}. The genes that encode these enzymes are often found in organisms that already harbor other resistance genes, such as extended-spectrum beta-lactamases, and the carbapenemase thus confers extensive or even pan-drug resistance. These bacteria have caused numerous ICU-based outbreaks in every inhabited continent and profoundly affected the epidemiology of ICU-acquired infection in patients of all ages in countries with the highest prevalence of carbapenemase-producing organisms [73, 75–78].

Infections caused by Gram-negative bacteria that are carbapenem resistant due to the presence of carbapenemase or other mechanisms of resistance are frequently very difficult to treat. In contrast to multidrug-resistant Gram-positive infections, for which typically several antibiotics retain activity, treatment options for resistant Gram-negative infections may be drastically narrowed, frequently leaving one, two, or no antibiotic options (typically, these organisms may be initially susceptible to colistin and an aminoglycoside). Colistin, a polymyxin antibiotic previously of primarily historical interest and limited use, has become the last line of therapy for many Gram-negative species. The drug has substantial side effects, including the potential for significant neurotoxicity and renal toxicity, particularly in critically ill patients and especially when administered with aminoglycosides or other nephrotoxic drugs that may be necessary to treat these bacteria. Colistin-resistant strains have developed during therapy [77] and have caused nosocomial outbreaks [79]. Because resistant Gram-negative organisms disproportionately affect susceptible hosts, the mortality rate from infection with carbapenemase-producing bacteria in highly immunocompromised hosts is reported to be 40–80 % [77, 80, 81].

As is the case for other healthcare-associated bacteria, highly resistant Gram-negative bacilli are likely transmitted on the hands of healthcare personnel, with a probable lesser role of environmental contamination in nosocomial spread. Transmission is rampant in long-term acute care hospitals in some geographic areas. Patients transferred to hospitals from those facilities may arrive with colonization or infection; if surveillance or clinical cultures do not identify their carriage, those patients can serve as the sources of nosocomial spread. The organisms join the fecal flora of susceptible patients who may subsequently develop infection or become reservoirs for transmission to other patients, via the personnel or environment of the hospital. Without development of novel antimicrobial treatments or implementation of better infection control, these organisms are likely to pose an enormous challenge for intensivists for years to come.

4.5 Multidrug-Resistant *Acinetobacter baumannii*

Acinetobacter baumannii, an aerobic, nonfermenting, Gram-negative coccobacillus, has, in the past decade, become a formidable problem for intensivists. Although other *Acinetobacter* species can cause infections in the community or hospital, *Acinetobacter baumannii* is predominantly a healthcare-associated pathogen and, worldwide, typically harbors significant antimicrobial resistance. *A. baumannii* is a particular problem in surgical and medical ICUs. *A. baumannii* has been estimated to be responsible for two to 10 % of all Gram-negative infections in intensive care units in both the United States and Europe [82]. *A. baumannii* was frequently identified as a significant wound pathogen in US troops returning from the Middle East with battlefield injuries [83], leading to nosocomial transmission in US military healthcare facilities [84, 85]. The pathogen is ubiquitous in some parts of the world, where it has become a dominant cause of infection in ICUs [86].

A. baumannii has the remarkable ability to develop durable antimicrobial resistance with alarming speed; resistance genes can be acquired from transposons, integrons, or plasmids carrying large clusters of resistance genes. It increasingly hosts plasmids that carry the carbapenemase genes described above, among its mechanisms of resistance. Additionally, in several other respects, *A. baumannii* is also a formidable pathogen. For example, atypical of most Gram-negative bacilli, *A. baumannii* is able to withstand long periods of desiccation and can therefore persist in the inanimate environment of the hospital ICU. In fact, *A. baumannii* has been found contaminating a wide range of patient equipment, including ventilators, mattresses, pillows, beds, gloves, pumps, and other electrical equipment in the ICU [87]. The nosocomial reservoir for *A. baumannii* is unclear and may be quite diverse. Candidate reservoirs for this problematic pathogen include healthcare workers' hands and skin, hospital food, the inanimate hospital environment and hospital equipment, and even arthropods (though arthropods are an unlikely reservoir for transmission) [88, 89].

Acinetobacter baumannii can be the responsible pathogen for several infectious syndromes in patients hospitalized in the ICU, including bacteremia, pneumonia (including ventilator-associated pneumonias), meningitis, urinary tract infection, as well as wound infections [90]. Surveillance data from the CDC show that resistance to carbapenems among *Acinetobacter* isolates increased from 0 % in 1986 to 42 % in 2003 to more than 60 % in 2010 [91, 92].

Because of the remarkable ability of these organisms to acquire multidrug resistance rapidly, the therapy of infections caused by *A. baumannii* is quite challenging. As described above, colistin has become one of the most commonly used agents for treatment of multidrug-resistant *A. baumannii* infection. Therapy must be individualized and must be guided by the antimicrobial susceptibility and the patient's clinical progress.

5 Measures to Prevent and Control Infection in the ICU

5.1 General Infection Control Measures

Several agencies and organizations have issued guidelines for controlling the spread of resistant pathogens in the healthcare setting [92, 93]. Some of these guidelines are general in nature, whereas others address specific pathogens. The Society for Healthcare Epidemiology of America (SHEA) has issued guidelines that focus on the prevention of MRSA and *C. difficile* infections as well as device-related and other healthcare-associated infections [93]. Guidelines published by the Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC describe the tools and methodology for controlling nosocomial spread of carbapenem-resistant bacteria [94]. Recommendations for infection control interventions from these and other organizations have proven worthwhile in limiting the transmission of these and other resistant organisms in the healthcare setting [95]. Principles designed to control the nosocomial spread of pathogens are described in detail in Chapter 88; however, some of these principles deserve special emphasis for addressing these important issues in the ICU.

The HICPAC guideline advocates a sensible "two-tiered" approach to the management of resistant pathogens [96], suggesting that the control of resistant pathogens is a dynamic process that requires a systematic approach tailored to the problem and the unique healthcare setting. When the practitioner is faced with the emergence of a resistant pathogen problem that cannot be controlled with standard or traditional infection control measures, additional control measures should be selected from a second tier of interventions that include interventions from the following categories: administrative measures/adherence monitoring, staff education, antimicrobial stewardship, surveillance, infection control precautions, environmental measures, and decolonization [96]. Decisions to increase control activities should be based on the individual circumstance [96].

With respect to administrative controls, among the most important is establishing and assuring strong administrative support for clear policies and procedures, grounded in science, that definitively delineate organizational expectations for techniques to be followed routinely in the management of specific infection syndromes. Several studies have argued that administrative engagement and support were critical to controlling the spread of resistant pathogens in the ICU [97–99]. Several infection control interventions require substantial administrative investment, among them: (1) Using information systems to provide important "real-time" data (e.g., alerts, warnings, feedback about adherence data) to healthcare providers at the point of care (2) Assuring the provision of appropriate hospital infrastructure and supplies (e.g., adequate quantities of hand hygiene products, sufficient number and placement of hand washing sinks and hand rub dispensers in the ICU and throughout the facility) (3) Assuring education and ongoing training of ICU staff (4) Providing appropriate staffing levels to meet intensive care needs [100, 101] (5) Assuring the development and implementation of infection control policies and procedures in the ICU (e.g., use of masks, gowns, and gloves and use of contact isolation precautions for multidrug-resistant pathogens) and providing oversight to assure adherence to these infection control policies, procedures, and practices [96]

A second infection prevention principle that is worthy of emphasis for the ICU setting is antimicrobial stewardship. The potential for antimicrobial misuse and abuse is greater in the ICU than perhaps any other locus in the healthcare institution.

Although rarely implemented as a single strategic intervention, several studies have demonstrated at least a temporal association between antimicrobial restriction and control of resistance [102–105]. Although emergence and dissemination of the hypervirulent and fluoroquinolone-resistant NAP1/B1/027 strain in the past decade have been linked to widespread fluoroquinolone use [106], cephalosporin and clindamycin administration likewise places patients at elevated risk for subsequent development of *C. difficile* infection [107]. Targeted reduction in use of broad-spectrum antimicrobial agents has, in some settings, significantly reduced rates of *Clostridium difficile* infection [108, 109]. Although a comprehensive discussion of antimicrobial stewardship is beyond the scope of this chapter, interventions to try to improve antimicrobial stewardship have used several different approaches. A SHEA/IDSA collaboration has outlined guidelines for antimicrobial stewardship, addressing, among other topics, education, formulary restriction, prior approval systems, streamlining empiric regimens, regimen cycling or rotation, the use of computer-assisted programs to provide relevant point of use information to the provider, and comprehensive programs that combine some or all of these strategies (discussed in detail in Reference) [110].

A third infection control strategy or intervention that is worthy of additional discussion is the use of surveillance cultures for resistant pathogens, which are recommended to be used in a targeted fashion dependent on the local and institutional epidemiology of multidrug-resistant bacteria and the origin of admitted patients [111]. The importance and efficacy of using blanket microbiologic surveillance as an intervention to minimize transmission of resistant pathogens remain controversial. Whereas the strategy is intuitively appealing and has been shown to be effective in some models [112], as well as in some clinical settings (including ICU settings) [113], widespread use of this strategy is both costly and labor intensive. By screening all patients and identifying those colonized or infected with resistant pathogens, the intensivist can manage the affected patients aggressively with isolation precautions. A major problem with many of the studies that have used active surveillance cultures is that the strategy is not studied as an independent intervention. Almost all of the published studies purporting to show a benefit of prospective surveillance cultures have implemented this strategy as one of several interventions in an outbreak setting. In all these studies, one cannot determine which of the interventions produced the benefit. The lack of well-controlled studies on the issue of active microbiologic surveillance has been the source of ongoing criticism of this intervention. Surveillance cultures may be useful as a component of "secondary prevention" following a transmission event or outbreak in the ICU [114].

5.2 Syndrome-Specific Infection Control Measures

Whereas the principles outlined above relate to general infection control practices and procedures that have specific relevance to the ICU setting, specific interventions have also been developed to address the four major nosocomial infection syndromes frequently encountered in the ICU (discussed above).

5.2.1 Preventing Device-Associated Bacteremia in the ICU

Several strategies have been specifically directed at limiting the access of organisms to the intravascular device at the catheter insertion site. The use of sterile technique during insertion, attention to the detail of sterile technique when entering or manipulating the system, and rigorous attention to details of appropriate hand hygiene all contribute to reductions in device-associated bacteremia rates in the ICU. Other techniques that have been shown repeatedly to be effective in reducing device-associated bacteremia rates include the use of maximal sterile barrier precautions during the process of catheter insertion, cutaneous antisepsis with chlorhexidine/alcohol, avoidance of femoral vein insertion in adults, and daily review of need for having the line in place, with prompt removal when it is no longer essential [115]. Sites implementing this type of evidence-based approach experienced substantial success in reducing rates of device-associated bacteremia [116–118].

In addition to the following strict precautions during catheter insertion, meticulous care and maintenance of catheters are critical to preventing late CLABSIs. Daily baths with 2% chlorhexidine gluconate reduce the rate of CLABSIs in ICU patients [119–122]. Scrubbing the hubs, needleless connectors, or injection ports of lines and their tubing for at least 5 s with chlorhexidine/alcohol prior to accessing the line, using chlorhexidine-impregnated catheter dressings, and antiseptic caps or hubs are all recommended preventive measures [115].

Other techniques have been suggested in select patient populations. For example, the use of antiseptic or antibiotic-impregnated catheters has been effective in some, but not all, studies and is thus recommended for use when CLABSI rates are high or in individual patients who have high risk of infecting an intravascular site or who have few remaining intravenous access sites [115]. Antibiotic lock therapy, used for catheter salvage following a CLABSI, can be used for CLABSI prevention in patients who have long-term hemodialysis catheters and those who have high risk of infecting an intravascular site or who have few remaining intravenous access sites [115].

The use of needleless connectors for catheters is a topic of unsettled controversy. Needleless connectors were introduced in the 1990s to reduce the use of needles to access catheters and thus avoid needlestick injuries to healthcare personnel that could result in parenteral exposure to bloodborne pathogens. The earlier design, split-septum devices are accessed by a blunt cannula and have free flow and simple internal structure due to lack of a valve. Newer connector designs contain mechanical valves with positive, negative, or neutral displacement and connect via Luer lock with a syringe or tubing. The complexity of the valve structure or the hub may promote formation of biofilm and bacterial colonization. A number of reports document increased CLABSI rates after introduction of the mechanical valve devices [123] [124–128]. Early in their use, improper use due to inadequate training and education of healthcare personnel was blamed for the higher rate of infections [129]; more recently, clinical trials of needleless connectors CLABSIs have shown variable impact on CLABSI rates [123, 128–131], possibly related to differences in study design, patient populations, device used, and training of healthcare personnel in care of needleless connectors. Strategies for disinfection of needleless access ports and use of antimicrobial-impregnated components have had variable success in reducing microbial contamination and infection rates [132, 133]. Chlorhexidine gluconate disinfection appears to be the most effective disinfectant with the added benefit of a residual antimicrobial effect [134]. Whereas utilization of these connectors has become widespread in ICUs due to their ease of use, we do not yet have clinical data pointing to optimal design for CLABSI prevention. Pending more definitive data, practitioners must redouble efforts at meticulous adherence to catheter care and disinfection guidance with needleless connectors and catheters of all types.

5.2.2 Preventing Ventilator-Associated Pneumonia

Strategies have been developed to address the various pathogenetic mechanisms associated with risk for ventilator-associated pneumonia. To address the issues that relate to the rapid changes in hospitalized patients' microbial flora, guidelines have emphasized hand hygiene at all appropriate opportunities. Well-designed clinical trials from Europe have demonstrated a reduction in ICU-associated respiratory tract infections and increased 28-day survival with the use of selective oral decontamination and selective digestive decontamination, which employ use of prophylactic topical, oral, and intravenous antimicrobial agents to reduce the microbial burden in the oropharynx and gastrointestinal tract [135]. Although the interventions have become the standard of care in the Netherlands, North American intensivists have yet to adopt the strategies, in part due to concerns about fostering antimicrobial resistance. (These studies have largely been conducted in ICUs that have low background levels of antimicrobial resistance.) Although two longitudinal studies in ICUs employing selective oral decontamination or selective digestive decontamination have shown no increased antimicrobial resistance, [136, 137] a larger multicenter, randomized Dutch study demonstrated low rates of resistance but slowly progressive development of aminoglycoside resistance with use of selective digestive decontamination [138].

To address the risks associated with the endotracheal tube itself, noninvasive ventilation strategies have been developed, as well as approaches to decreasing the subglottic pooling of secretions. When possible, one should avoid nasotracheal or nasogastric intubation because of the risk for precipitating bacterial sinusitis that increases the risk for pneumonia. Staff should minimize sedation, should avoid unnecessary manipulation of ventilator circuitry/tubing, and should perform spontaneous breathing trials daily while lifting sedation to assess the need for continued intubation. To minimize the risk for aspiration, the head of the patient's bed should be elevated to 45°, and endotracheal tubes with subglottic drainage ports should be used if intubation is anticipated to last more than 2–3 days [139]. Guidelines now recommend against some interventions that were previously favored by some intensivists. Some examples are oral care with chlorhexidine gluconate and use of antimicrobial-coated endotracheal tubes, which have not been associated with improved outcome [139].

5.2.3 Preventing Catheter-Associated Urinary Tract Infections in Patients in the ICU

Preventing CAUTI involves a team approach in the ICU, beginning with the creation and implantation of clear institutional guidelines for catheter use, insertion, and maintenance. Specific indications for catheter use and catheter removal should be developed. Staff should be educated about the indications, aseptic insertion, need for catheter monitoring, and importance of prompt removal of urinary catheters. Only trained, dedicated personnel should insert urinary catheters. ICU staff should meticulously track and document catheter status in each patient's medical record. Institutions should develop protocols that assist in the identification of catheters that are no longer needed and that assure the prompt removal of these catheters. Similarly, in concert with the institution's healthcare epidemiology program, ICU staff should develop and implement a policy requiring mandatory periodic review of the necessity for continued catheterization, for example, the use of institutional triggers or reminders that mandate the assessment of the continued need for catheterization and the use of automatic stop orders or the daily review of each catheter focused on the institutional indications for use and/or removal [140].

Several interventions that have been proposed for CAUTI prevention have not, in our view, been shown to be reliably beneficial (or in some instances have actually been detrimental). Among these interventions are the following: the routine use of antimicrobial/antiseptic-impregnated catheters; screening for asymptomatic bacteriuria among ICU patients who have indwelling catheters; treating asymptomatic bacteriuria in catheterized ICU patients; routine use of catheter irrigation, with or without antimicrobials in the irrigating solution; the use of systemic antimicrobials as CAUTI prophylaxis; and routinely changing catheters at some defined interval.

5.2.4 Preventing Infection in Immunocompromised Patients in the ICU

Preventing healthcare-associated infections among severely immunocompromised patients hospitalized in the ICU is a formidable challenge. For the myriad reasons outlined in the pathogenesis section above, the effects of underlying diseases and therapies leave immunosuppressed patients highly vulnerable to infections from within and without. Basically, the intensivist and the ICU staff must pay attention to the details of all aspects of infection control, emphasizing hand hygiene, administrative controls, aggressive early diagnosis, and appropriate empiric therapy; maintaining a high index of suspicion for yeast and filamentous fungal infection and appropriate antibacterial and antifungal chemoprophylaxis; and maintaining constant vigilance about the potential for the development of infection caused by one or more of the aggressive resistant pathogens that are described above, keeping in mind that the source of these resistant pathogens may be the patient, a provider, or the healthcare environment. Such immunosuppressed patients are at substantially increased risk for many of the pathogens that are described above—MRSA, VRE, *Acinetobacter baumannii*, and other MDR organisms.

Other strategies that may be of use in preventing infections in immunocompromised patients in certain settings include the use of a totally protected environment and selective decontamination of oral and gastrointestinal flora (in some instances protecting the patient's anaerobic flora).

In the final analysis, ICU staff must maintain vigilance for resistant pathogens. Given the difficulty of treating infections due to increasingly resistant pathogens in the ICU, prevention is of paramount importance. Hand hygiene with the use of soap and water or alcohol-based hand rubs is crucial in this setting to prevent spread of resistant organisms. Targeted surveillance for organisms of epidemiological significance may help contain the reservoirs of these pathogens. Adhering to other infection control precautions, maintaining meticulous care of invasive devices, minimizing devices and device days, and judicious use of antimicrobial are all key to reducing the incidence of infections with multidrug-resistant organisms in the ICU.

Implications of Antibiotic Resistance in Potential Agents of Bioterrorism

90

Linda M. Weigel and Stephen A. Morse

1 Introduction

One of the latest challenges to global public health is the deliberate dissemination of biological agents via a number of different routes, including air, water, food, and infected vectors to affect the health of humans and livestock. Congress has addressed this challenge with respect to human health by providing funding to the Centers for Disease Control and Prevention (CDC) to enhance the ability of the nation's epidemiology and laboratory systems to respond to the deliberate release of a biological agent [1]. A Strategic National Stockpile (SNS, formerly called the National Pharmaceutical Stockpile) was also established to provide large quantities of essential medical materiel to states and local communities during such an emergency. The SNS contains antibiotics as well as chemical antidotes, antitoxins, life-support medications, intravenous administration kits, airway maintenance supplies, and medical/surgical items [2]. The broad spectrum antibiotics in the SNS play an important role in providing postexposure prophylaxis and treatment for individuals exposed to or infected with a bacterial agent as a result of a deliberate release. The antibiotics in the SNS were selected, in part, for their effectiveness based on current antimicrobial susceptibility data for each bacterial species. Conventional susceptibility testing methods may require one to several days, depending on the growth characteristics of the species. However, recent revelations suggest that a priority of the former Soviet Union offensive biological weapons program was the development of recombinant organisms that were resistant to common therapies [3–5]. For example, bacterial agents targeted for preparedness efforts, such as *Bacillus anthracis*, *Yersinia pestis*, *Francisella tularensis*, *Burkholderia* spp., *Brucella* pp., and *Coxiella burnetii*, require biosafety level 3 (BSL-3) containment and practices, which are usually not found in clinical laboratories, but are necessary for safely performing antimicrobial susceptibility tests. Many of these bacteria are intrinsically resistant to one or more antimicrobial agents, and isolates with acquired resistance have been reported. Although genetic analyses may provide some clues to susceptibility profiles, in numerous cases the resistance phenotype does not correlate with the genotype. All of these bacteria have been genetically engineered for antimicrobial resistance by introduction of resistance genes or by selection of resistant mutants by in vitro passage. With the increased potential for deliberate dispersal of antimicrobial resistant pathogens, rapid determination of the antimicrobial susceptibility of a bioterrorism agent has become essential for selection and distribution of effective prophylactic or therapeutic treatments to ensure an appropriate public health response in the event of an outbreak or deliberate release of one of these biothreat agents.

The objectives of this chapter are to examine issues concerning antimicrobial susceptibility testing and antimicrobial resistance in selected bacterial agents that have been identified for public health preparedness efforts.

1.1 Definitions

The use of a biological agent is often characterized by the manner in which it is employed. For the purposes of this article, **biological warfare** has been defined as a specialized type of warfare conducted by a government against a target; **bioterrorism** has been defined as the threat or use of biological agents (or toxins) by individuals or groups motivated by political, religious, ecological, or other ideological objec-

tives [6]. Criminals may also be driven by psychopathologies to use biological agents. When criminals use biological agents for murder, extortion, or revenge it is called a **biocrime** [6]. Terrorists are distinguished from criminals based on motivation and objectives.

2 Threat Agents

Many biological agents can cause illness in humans, but not all are capable of affecting public health and medical infrastructures on a large scale [7]. In order to bring focus to public health preparedness activities, the CDC convened a meeting in June 1999 of national experts to review the criteria for selecting bacterial, viral, and toxin agents that posed the greatest threat to civilians and to help develop a list of these agents for public health preparedness efforts. The considerations for inclusion on the "Critical Agents List" included the ability of the agent to be widely disseminated either by aerosol or by other effective means; the ability of the agent to be transmitted from person to person; the ability of the pathogen to provoke fear; and special public health preparedness needs such as vaccines, therapeutics, enhanced surveillance, and diagnostics [7]. The Critical Agents List [1] includes viruses, toxins, and bacteria; however, due to this chapters focus on antimicrobial resistance and that the control of viral biothreat agents is generally not focused on the use of antiviral agents for prophylaxis, this chapter will cover only the critical bacterial agents (Table 90.1). No priority was assigned within the categories and that the list did not rank the probability of deliberate use of an agent. This effort occurred before the Department of Homeland Security (DHS) was established. Nevertheless, all of the bacterial agents discussed in this chapter have been subjected to DHS Risk Assessments and bacterial threat assessments.

All of the bacterial agents discussed in this chapter are also classified as select agents. Select agents are microorganisms (bacteria or viruses) or toxins, which since 1997 have been declared by the US Department of Health and Human Services (HHS) or by the US Department of Agriculture (USDA) to have the potential to pose a severe threat to public health and safety. For administration purposes, select agents are divided into three categories: (1) HHS select agents and toxins (those affecting humans); (2) USDA select agents (those affecting plants or animals); and (3) overlap (HHS and USDA) select agents and toxins (those affecting humans and animals). HHS select agents discussed in this chapter are *Coxiella burnetii*, *Francisella tularensis*, and *Yersinia pestis*. The overlap select agents discussed in this chapter are *Bacillus anthracis*, *Brucella* spp., *Burkholderia mallei*, and *Burkholderia pseudomallei*. The CDC administers the Select Agent Program (SAP) for HHS while the Animal and Plant Health Inspection Service (APHIS) administers the USDA Select Agent Program. Both CDC and APHIS regulate the overlap agents. The SAPs regulate laboratories which may possess, use, or transfer select agents within the USA. In the wake of the 2001 anthrax attack and several high-level program reviews, the select agent regulations were reviewed and subsequently revised in 2012 to identify a group of select agents designated as Tier 1 agents. Tier 1 select agents have a documented risk of causing a high consequence event based on the following criteria: (1) ability to produce a mass casualty event or devastating effects to the economy; (2) communicability; (3) low infectious dose; and (4) history of or confirmed interest of a terrorist group in weaponization. Tier 1 agents discussed in this chapter include *B. anthracis*, *F. tularensis*, *Y. pestis*, *B. mallei*, and *B. pseudomallei* [8]. Laboratories working with Tier 1 select agents have increased biosecurity requirements including periodic personnel suitability assessments.

Some diseases caused by Tier 1 select agents are also exceedingly uncommon. For example, the first reported case of *B. mallei* infection (i.e., glanders) in the U.S. since 1949 occurred in 2001 in a microbiologist with insulin-dependent diabetes [9]. Despite the patient's history of working with *B. mallei*, both the clinical and laboratory diagnoses were

Table 90.1 Critical bacterial agents for public health preparedness[a]

Agent	Disease
Category A[b]	
Bacillus anthracis	Anthrax
Yersinia pestis	Plague
Francisella tularensis	Tularemia
Category B[c]	
Coxiella burnetii	Q fever
Brucella species	Brucellosis
Burkholderia mallei	Glanders
Burkholderia pseudomallei	Melioidosis
Subset of category B spread by food and water	
Salmonella spp.	Salmonellosis
Shigella dysenteriae	Bacillary dysentery
Escherichia coli O157:H7	Hemolytic uremic syndrome
Vibrio cholerae	Cholera
Category C[d]	
Multidrug-resistant *Mycobacterium tuberculosis*	Tuberculosis

[a]Modified from [1]

[b]Other Category A agents: Variola major, Filoviruses (e.g., Ebola and Marburg), Arenaviruses (e.g., Lassa and Junin), *Clostridium botulinum* neurotoxins

[c]Other Category B agents: Alphaviruses (e.g., Venezuelan, Eastern and Western encephalomyelitis viruses), Staphylococcal enterotoxin B, Ricin from *Ricinus communis*, *Clostridium perfringens* epsilon toxin, *Cryptosporidium parvum*

[d]Other Category C agents: Yellow fever virus, Tickborne encephalitis complex (flavi) viruses, Tickborne hemorrhagic fever viruses, Nipah and Hendra Complex viruses, Hantaviruses

delayed highlighting the difficulties of identifying these rare infections.

Select agents not included in the Tier 1 category also have some potential for large-scale dissemination, but generally cause less severe illness and death than the Tier 1 agents. Such agents have been weaponized in the past, or are being considered as weapons by some state-sponsored programs [3, 10]. They also could be used to contaminate food or water sources. In addition, many of these agents are relatively easy to obtain and therefore are more likely to be used in the setting of a biocrime or bioterrorism [11].

The Risk Assessments and bacterial threat assessments conducted by DHS support the issuance of the bacterial threat determinations that inform the federal government's medical countermeasure decisions and the need to develop or acquire effective medical countermeasures under the Project Bioshield Act of 2004.

3 Bioterrorism Preparedness and Response

3.1 Laboratory Response Network

Because there is only a small window of opportunity during which prophylaxis or other control measures can be implemented to reduce the morbidity and mortality associated with a bioterrorism event, the public health response must be rapid to be effective [12]. The Laboratory Response Network (LRN) was created in order to facilitate the rapid identification of threat agents [13]. The LRN was established in 1999 by the CDC, in concert with the Association of Public Health Laboratories (APHL) and with collaboration from the Federal Bureau of Investigation (FBI) and the United States Army Medical Institute of Infectious Diseases (USAMRIID) to address the extremely limited national infrastructure of diagnostic testing laboratories competent to deal with biological terrorism that existed at that time.

This national system is designed to link state and local public health laboratories with other advanced-capacity clinical, military, veterinary, agricultural, and water- and food-testing laboratories, including those at the federal level, building upon the existing interactions of nationwide public health laboratories and their complementary disease surveillance activities [14].

The LRN consists of laboratories that operate in either a sentinel or reference capacity, with the latter characterized by progressively stringent safety, containment, and technical proficiency capabilities [13]. Sentinel laboratories are, for the most part, hospital and clinical laboratories because it is likely that in the aftermath of a covert bioterrorism attack, patients will seek care at widely dispersed hospitals, some of which would house such laboratories [14]. Sentinel laboratories participate in the LRN by ruling out the presence of a critical agent or referring suspected critical agents (Table 90.1) encountered in their routine work to a nearby LRN reference laboratory. Protocols and algorithms, which are available on the Internet (www.asm.org or www.bt.cdc.gov), have been developed to make this process as rapid as possible. Reference laboratories can perform tests to detect and confirm the presence of a threat agent. They are primarily local and state public health laboratories, employing both biosafety level 2 (BSL-2) facilities where BSL-3 practices are observed (i.e., for culture and identification of *Mycobacterium tuberculosis*), and public health laboratories with full BSL-3 facilities. The LRN reference laboratories use protocols and reagents that have been standardized and validated for the identification, and characterization of threat agents. Characterization of bacterial agents isolated from clinical samples includes determining antimicrobial susceptibility and resistance, a procedure that is not performed at all LRN laboratories due to the extensive training and experience required for visual interpretation of results. However, a rapid susceptibility test for *B. anthracis* has been developed that is based on real-time PCR to detect growth or inhibition of growth by antibiotics [15].

There are also national LRN laboratories that have the ability to generate and analyze whole genome sequences. These federal laboratories identify agents in samples submitted by the reference laboratories and can also identify recombinant (e.g., chimeras) or genetically engineered microorganisms that may only be characterized by whole genome sequence analysis.

3.2 Epidemiological Investigations

Bioterrorism events can be characterized by two types of scenarios: overt (announced) and covert (unannounced). The deliberate nature of an intentional release will often be obvious, as in the case of multiple mailed letters containing highly refined anthrax spores [16]. The letter received and opened in a Senator's office in the Hart Senate Office Building is an example of an overt attack. Some forms of bioterrorism may be more covert, such as the deliberate contamination of salad bars in the Dalles, Oregon, with *Salmonella typhimurium*, which sickened more than 751 persons [17].

The LRN has a dual function in that it has the ability to detect and respond not only to agents released intentionally but also to those that occur naturally, a capacity that warrants emphasis because it will generally not be known at the time of detection whether the outbreak is intentional or natural. A few examples involving the critical bacterial agents will suffice. In the first, the outbreak on Martha's Vineyard of primary pneumonic tularemia in 11 patients in the summer of

2000 may have indicated a deliberate aerosol release of *F tularensis* type A. However, the epidemiologic investigation suggested that infection was associated with lawn mowing and brush cutting, activities that could aerosolize the organism from the environment [18]. Second, the occurrence of plague in a couple visiting New York City in November 2002 was highly unusual and suggested the possibility of bioterrorism because these infections occurred outside the area where plague is endemic in the United States [19]. On initial consultation with medical personnel, the couple reported that they had traveled from Santa Fe County, New Mexico, where routine surveillance conducted by the New Mexico Department of Health had identified *Y pestis* in a dead wood rat and fleas collected several months earlier on their New Mexico property. One day after the patients were evaluated, the New Mexico Department of Health and CDC investigated the couple's New Mexico property and a nearby hiking trail where rodents and fleas were collected. The results of pulsed-field gel electrophoresis and multiple-locus variable-number tandem-repeat assays (MLVA) on isolates from one of the patients and from seven flea pools suggested that the *Y. pestis* infection was most likely acquired on the couple's property. Third, a case of inhalation anthrax in a male drum maker who resided in New York City in February 2006 raised the specter of bioterrorism. However, the epidemiologic investigation determined that the source of exposure was spores on dried goat hides brought back from Cote d'Ivoire [20].

An epidemiological investigation may identify indicators, one or more of which were noted in the examples above, that raise the level of suspicion that an outbreak may have been caused intentionally. These epidemiologic clues include the following as enumerated by Treadwell et al. [21]:

- A single case of disease caused by an uncommon agent (e.g., inhalation or cutaneous anthrax, glanders) without adequate epidemiologic explanation.
- The presence of an unusual, atypical, or antiquated strain of an agent or antibiotic resistance pattern.
- Higher morbidity and mortality in association with a common disease or syndrome, or failure of such patients to respond to standard therapy.
- Unusual disease presentation, such as inhalation anthrax or pneumonic plague.
- Disease with an unusual geographic or seasonal distribution (e.g., plague in a nonendemic area).
- An unexpected increase in the incidence of stable endemic disease, such as tularemia or plague.
- Atypical disease transmission through aerosols, food, or water, in a mode suggesting sabotage (i.e., no other possible explanation).
- Several unusual or unexplained diseases coexisting in the same patient without any other explanation.
- Unusual illness that affects a large, disparate population (e.g., respiratory disease in a large heterogeneous population may suggest exposure to an inhaled biologic agent).
- Illness that is unusual (or atypical) for a given population or age group (e.g., outbreak of measles-like rash in adults).
- Unusual pattern of death or illness among animals that is unexplained or attributed to an agent of bioterrorism that precedes or accompanies illness or death in humans.
- Unusual pattern of death or illness in humans that precedes or accompanies illness or death in animals, which may be unexplained or attributed to an agent of bioterrorism.
- Agents of an unusual illness isolated from temporally or spatially distinct sources that have a similar genotype.
- Simultaneous clusters of similar unusual illness in noncontiguous areas, domestic or foreign.
- Large numbers of unexplained diseases or deaths.
- Large numbers of ill individuals who seek treatment at about the same time (point source with compressed epidemic curve).

4 Critical Bacterial Agents

For the majority of bacterial agents, vaccination has not been a major strategy in pre-event preparedness for the general population; the one exception is anthrax where a combination of vaccine and antimicrobials is recommended for post-exposure prophylaxis. Thus, it is imperative that the antimicrobial susceptibility patterns of suspected bacterial agents of bioterrorism be determined so that effective prophylactic or therapeutic treatment can be administered [22]. However, all of the Tier 1 bacterial agents and many of the other bacterial select agents (Table 90.1) require BSL-3 containment and practices, which are usually not found in the sentinel and other clinical laboratories, but which are necessary for performing antimicrobial susceptibility studies. Some of these bacteria have intrinsic resistance to one or more antimicrobials. In addition, many of these bacterial agents can be genetically engineered by introduction of genes required for antimicrobial resistance [22] or by selection for resistant mutants by in vitro passage on low levels of antimicrobial agents [23, 74]. Thus, the antimicrobial susceptibility pattern of a microorganism encountered as a result of an intentional release is not necessarily predictable.

The deliberate introduction of antimicrobial resistance markers or selection of strains resistant to therapeutically useful antimicrobial agents is generally considered to be a prohibited experiment. However, the introduction of antimicrobial resistance markers may be justifiable under certain circumstances [24]. For example, DNA manipulation for genetic studies on virulence factors often requires the use of

plasmids with antimicrobial resistance genes as markers for selection. In such cases, the antimicrobial resistance genes used should not confer resistance to antibiotics used for the treatment of infections caused by that organism [25]. Nevertheless, laboratory mutants with resistance to antimicrobial agents used for treatment (e.g., ciprofloxacin) have been generated for studies on the molecular basis and for detection of fluoroquinolone resistance [23, 26, 27]. Most laboratories use attenuated or avirulent strains for these purposes.

4.1 Detection of Resistance

Procedures employed for susceptibility testing may generate aerosols that pose a high risk of laboratory-acquired infections. Therefore, antimicrobial susceptibility testing of the critical bacterial agents should be performed only in designated LRN laboratories or at the CDC. Trained personnel, BSL-2 or BSL-3 laboratory facilities (depending on the organism), and personal protective equipment are required to work with these organisms. In addition to the hazards associated with the mechanics of performing susceptibility testing, the working conditions in a BSL-3 environment contribute to difficulties in obtaining accurate and consistent results. Mohammed et al. [28] recognized this issue, commenting that visual evaluation of growth in broth microdilution assays or the ability to see single colonies or light films of growth on agar plates is complicated by the necessity of reading susceptibility results through the glass barrier of a biological safety cabinet. Visibility may be further compromised when laboratory personnel are using power-assisted respirators with face shields.

Susceptibility testing methods include the conventional methods of disk diffusion, agar dilution, broth microdilution, and Etest. There is also the rapid susceptibility method for *B. anthracis* mentioned above, which is currently being modified for other Tier 1 bacterial select agents. Many factors influence antimicrobial susceptibility test results. Among these are: (1) inoculum density, which has been described as the single most important variable in susceptibility testing [29]; (2) the pH, electrolyte concentration, and composition of the medium; (3) time and temperature of incubation; and (4) growth characteristics of the strain to be tested. Growth characteristics are critical because a typical susceptibility testing medium, such as Mueller-Hinton broth or agar, must be either enhanced with specific supplements (i.e., *Francisella*) or changed to a specific medium (i.e., and *Brucella*) to support growth of some bacterial agents. Not all procedures are appropriate for every species. For example, results of disk diffusion tests are not reliable for slow-growing organisms [29] such as *F. tularensis* and *Brucella* spp., and none of these in vitro culture methods support the growth of *C. burnetii*.

The intrinsic resistance mechanisms in each species, the potential for additional naturally acquired resistance mechanisms among individual strains, and the possibility of engineered resistance are compelling reasons for susceptibility testing to guide therapy and postexposure prophylaxis in the event of a natural outbreak or intentional release of these organisms. Guidelines for broth dilution susceptibility testing of *B. anthracis*, *Brucella* spp. *B. mallei*, *B. pseudomallei*, *F. tularensis*, and *Y. pestis* are available in the Clinical and Laboratory Standards Institute (CLSI) document M45-A2 [30]. The guidelines provide testing conditions, quality control recommendations, and set breakpoints for MIC (μg/ml) interpretations of susceptibility and resistance.

Interpretation of in vitro susceptibility data for facultative (e.g., *Brucella* spp., *F. tularensis*, *B. mallei*, *B. pseudomallei*, *Y. pestis*) or obligate intracellular pathogens (e.g., *C. burnetii*) requires consideration of multiple factors that may affect the in vivo activity of the agent. These factors include the ability of the antimicrobial agent to enter an infected host phagocyte and the microenvironment within the eukaryotic intracellular space where the organism resides. The uptake and accumulation (pharmacokinetics) of the various classes of agents by phagocytes are dependent upon the chemical structure of the agent. The intracellular concentration of an antimicrobial agent is expressed as C_c/C_e, the ratio of the cellular (C_c) and extracellular (C_e) concentrations. Therefore, $C_c/C_e > 1$ indicates a higher concentration (accumulation) within the eukaryotic cells of the host. The slightly acidic cytosol works against the intracellular accumulation of weakly acidic antimicrobial agents, such as β-lactams [31] thus $C_c/C_e < 1$. However, even zwitterionic β-lactams (e.g., ampicillin) and many cephalosporins do not accumulate intracellularly, suggesting that additional factors are involved in the exclusion of β-lactams from intracellular cytosol and compartments [32]. Macrolides, however, accumulate in many types of cells [33–37]. This class of antimicrobial agents has a weakly basic character which enables much higher concentrations of drug to accumulate within the acidic (pH = 5) phagolysosomes than in the cytosol [38, 39]. Among the macrolides, C_c/C_e values at equilibrium range from 4 to 10 for erythromycin to 40–300 for azithromycin [32]. Fluoroquinolones accumulate very quickly in cells [40–42], while aminoglycosides accumulate in the cell so slowly that early studies concluded this class of antimicrobial agents did not enter eukaryotic cells [43]. However, over a period of several days, aminoglycoside concentrations within macrophages have been shown to increase to 2–4 times the concentration outside the cell [44–46]. There are limited data on the intracellular accumulation of tetracyclines [45, 47] or sulfonamides [48]. It is important to note that the various methods used for determining the intracellular concentrations and, as a result, the C_c/C_e values may result in conflicting data between studies.

In addition to intracellular accumulation, the intracellular activity (pharmacodynamics) of an antimicrobial agent must be considered. Both the infecting microbe and the antimicrobial agent may exert unknown influences on the infected host cell [49]. The pH within the cytosol or phagolysosome will affect the antimicrobial activity of some agents more than others. The general consensus is that fluoroquinolones, macrolides, and tetracyclines should have activity against intracellular bacteria, and that β-lactams and aminoglycosides show little or no activity against intracellular bacteria. However, there are examples of β-lactam and aminoglycoside therapies that are known to be effective against intracellular infections. These include the use of β-lactams for the treatment of listeriosis and the use of aminoglycosides for the treatment of brucellosis, plague, tularemia, and tuberculosis [50–53].

4.1.1 Genomic Analysis for Determination of Possible Intrinsic Resistance

A number of genome sequences have been completed for the bacterial agents listed in Table 42.1 and are publicly available [54]. The annotated genomes can be searched for genes associated with resistance to antimicrobial agents (Table90.2). The information obtained in this manner is important but has limitations. Genome annotations are produced by computer algorithms to identify putative protein-coding regions based on the search of databases for sequence homology. Many of the genes thus identified have not been verified by laboratory methods. Also, in vitro susceptibility studies are necessary to ascertain whether potential resistance genes are expressed and the product is functional. In addition, there may be considerable variability in the resistance genes among different strains that is not reflected in the available genome sequence(s) of one or a few strains. Furthermore, genome data may not reflect recent acquisition of antimicrobial resistance. Nevertheless, genomic data complements in vitro susceptibility data and may provide important information on the characterization of a specific strain, including the genetic basis for resistance or susceptibility.

4.2 *Bacillus anthracis*

4.2.1 General Characteristics

B. anthracis, the etiologic agent of anthrax, is a facultative anaerobe, spore-forming, nonmotile, nonhemolytic, gram-positive rod [55] that grows rapidly (doubling time of ~30 min.) on most microbiologic media. Vegetative cells sporulate in the presence of oxygen. The spore is infectious and is highly stable in the environment where it is frequently found

[b]Identified genes, gene copy numbers, and chromosomal locations vary among the annotations of *B. anthracis* whole genome sequences

in soil surrounding the carcasses of infected livestock and wildlife. Following inoculation of a susceptible host, the spores germinate, and the resulting vegetative cells multiply in long, bamboo-like chains that are characteristic of the organism. Optimal growth is achieved at 37 °C, and growth does not occur at temperatures ≥43 °C. *B. anthracis* cells are encapsulated in infected tissues or when grown under appropriate in vitro culture conditions.

Two plasmids, pXO1 and pXO2, are associated with virulence in *B. anthracis.* pXO1 carries the genes (*pagA*, *lef*, and *cya*) that are required for expression of the anthrax toxin components, protective antigen, lethal factor and edema factor [56]. pXO2 encodes three genes (*capA*, *capB*, and *capD*) that are required for production of the antiphagocytic poly-D-glutamic acid capsule [57]. Elevated temperature and CO_2 concentration, and specific nutrients are considered to be physiological signals for *B. anthracis* that lead to the germination of spores. Both toxin production and capsule formation are enhanced by growth in 5 % CO_2 or in a medium supplemented with bicarbonate. The CO_2/bicarbonate response is specific (not due to buffering capacity or decreased oxygen concentration) and results in a 20- to 25-fold increase in capsular gene transcription as well as a 5- to 8-fold increase in toxin production. Expression of toxin genes is further enhanced by growth of *B. anthracis* at 37 °C.

B. anthracis is a pathogen of herbivores, and human infection is usually accidental, resulting from contact with spores in contaminated meat or on hides. In humans, the disease may present as cutaneous, inhalational, gastrointestinal, or injectional anthrax, based on the route of infection. Cutaneous anthrax occurs following introduction of spores through a break in the skin. The lesion progresses from a papule to a characteristic eschar, a firm, dry, black lesion that is accompanied by extensive edema. Antibiotics will not alter the progression of the lesion but will prevent systemic infection. Gastrointestinal anthrax may affect either the oropharyngeal area (resulting in sore throat, dysphagia, fever, and regional lymphadenopathy) or the intestine (characterized by nausea, vomiting, fever, and bloody diarrhea). In the absence of effective therapy, infection can rapidly lead to toxemia followed by shock and death. The mortality rate of gastrointestinal anthrax is >50 % with death occurring 2–5 days after onset of symptoms. Inhalational anthrax is a usually rapidly fatal disease with death occurring 2–7 days postexposure, depending on the number of spores inhaled. Initial symptoms may be mild, but if left untreated a rapid succession of sudden shock, collapse, and death all occur within a matter of hours. At the time of death the blood may contain as many as 10^9 bacilli per milliliter in untreated patients [9]. Injectional anthrax has emerged among persons who inject drugs that are contaminated with spores of *B. anthracis*. This form of the disease is more

severe than conventional cutaneous anthrax and may progress to septic shock, meningitis, and death [58].

4.2.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

The antimicrobials used for postexposure prophylaxis and for treatment of the various forms of anthrax are listed in Table 90.3. Historically, penicillin has been the drug of choice for treatment of anthrax. Several susceptibility studies have been published [28, 59–62] most of which were conducted since the intentional release of *B. anthracis* in 2001 (Table 90.4.). Comparison of the MICs determined in these studies has been difficult because there was no standardized testing method, nor were there any interpretive criteria available for *B. anthracis*. Most studies relied on breakpoints published for *Staphylococcus aureus* to interpret the data. Mohammed et al. [28] addressed this issue in a comparison of broth microdilution and Etest agar gradient diffusion methods and found that most of the results for the two methods were comparable, with the exception of penicillin. The Etest MIC result for a penicillin-resistant isolate of *B. anthracis* was consistently in the susceptible range, having 4–9 doubling dilutions difference when compared with the MIC from the broth microdilution method. The MIC results for other agents used for treatment or prophylaxis of anthrax, such as ciprofloxacin and doxycycline, indicate good in vitro activity against *B. anthracis*.

Although *B. anthracis* is generally susceptible to penicillin, penicillin-resistant strains as well as treatment failures with penicillin have been reported [63–65]. Based on laboratory results with geographically diverse groups of strains, the prevalence of naturally occurring penicillin-resistant *B. anthracis* is estimated to range from 3 to 11.5 % [61, 62]. Two β-lactamase genes, located approximately 900 kb apart, have been identified in the chromosome of *B. anthracis* [66]. The *bla1* gene, which encodes a group 2a penicillinase, is usually not expressed. The *bla2* gene, which encodes a cephalosporinase similar to a group 3 *Bacillus cereus* metalloenzyme, is poorly expressed. The genes for both enzymes have been cloned and shown to confer resistance to β-lactams when expressed in *E. coli* [67]. The basis for susceptibility of *B. anthracis* to penicillin, in spite of the presence of two β-lactamase genes, was reported by Ross et al. [68] to be associated with an extracytoplasmic function (ECF) sigma factor, σ^P, and the anti-sigma factor, RsiP. When functional RsiP is produced, σ^P is sequestered and not available to interact with RNA polymerase, effectively preventing the efficient transcription of the β-lactamase genes. In a naturally occurring penicillin-resistant strain, a nucleotide deletion in *rsiP* was identified that resulted in a truncated, nonfunctional protein. As a result, σ^P is not sequestered by RsiP, and the

two β-lactamases are expressed constitutively. These data also provide an explanation for why expression of *bla1* and *bla2* is not inducible when a β-lactam antibiotic is present.

B. anthracis exhibits intrinsic resistance to both second- and third-generation cephalosporins that is not associated with β-lactamase activity. Chen et al. [66] demonstrated that a laboratory-generated mutant of *B. anthracis* Sterne, lacking both *bla1* and *bla2*, remained resistant to cefepime, ceftazidime, and cefpodoxime (MICs >32, >128, >16 μg/ml, respectively). In vitro susceptibility results (Table 90.4.) indicated that <10 % of isolates tested were susceptible to cephalosporins [59].

B. anthracis is highly resistant to aztreonam (Table 90.4.) and exhibits decreased susceptibility to macrolides such as erythromycin. Using susceptibility breakpoints for *S. aureus*, two studies [28, 62] found 97 and 85 % of the MICs to be intermediate for erythromycin when testing isolates of *B. anthracis*. A strain of *B. anthracis* from Korea was reported to possess the *ermJ* macrolide resistance determinant [69] which, if expressed, would confer resistance to macrolides, lincosamides, and streptogramin B. However, the MICs for these antimicrobial agents were not included in the report.

B. anthracis is naturally resistant to trimethoprim and sulfamethoxazole [70]. The organism appears to be susceptible to rifampin in vitro; however, in an in vivo murine model, treatment with rifampin did not significantly increase the survival rate of infected mice [71]. There have been no reports of naturally occurring *B. anthracis* with resistance to aminoglycosides, doxycycline, or fluoroquinolones. However, *B. anthracis* has been shown to acquire resistance determinants in its natural environment, the rhizosphere of grass plants [72], and coexisting soil-dwelling bacteria are known to harbor an extensive reservoir of resistance determinants [73]. Thus, the potential for natural acquisition of additional antimicrobial resistance genes should not be overlooked.

Whole genome sequences have been determined for numerous strains of *B. anthracis*, 39 of which are designated as complete (gapless chromosome) in the National Center for Biotechnology Information (NCBI) database [74]. These include strains A0039, Ames, Ames Ancestor, HYU01, Sterne, Vollum, Western North America USA6153, CNEVA 9066 (France), and Kruger B. A search of the annotated sequences for several of these strains revealed numerous potential resistance genes in each strain (Table 90.2.). In addition to the known β-lactamase genes, *bla1* and *bla2*, putative resistance determinants for aminoglycosides, chloramphenicol, macrolides, and a tetracycline were noted. As is the case with penicillin, the presence of a resistance determinant does not necessarily confer the resistance phenotype. For example, genes for chloramphenicol acetyltransferase (*cat*) and a chloramphenicol resistance protein (*bmr*) have been identified in the genomes of all of the strains that have been sequenced (Table 42.2.), yet results of in vitro susceptibility studies show that this organism remains susceptible to chloramphenicol (Table 90.4.). The gene and/or the encoded protein may be incomplete or nonfunctional, or mutations in the regulatory elements controlling transcription or translation may prevent or limit expression.

Engineered Resistance

Resistance to several antimicrobial agents has been genetically introduced or resistant mutants have been selected by in vitro passage. For example, fluoroquinolone-resistant mutants of *B. anthracis* have been selected in vitro by serial passages on medium containing increasing concentrations of fluoroquinolones [23, 26, 27, 75, 76]. Point mutations in the resistant organisms were found in the quinolone-resistance determining regions (QRDR) of *gyrA, parC*, and *gyrB*. MICs were increased by 16- to 2048-fold for ofloxacin, ciprofloxacin, levofloxacin, and moxifloxacin [77]. In gram-positive bacteria, such as *S. aureus* and *Streptococcus pneumoniae*, the first mutation detected is generally found in *parC* [78]. However, first-step mutants of *B. anthracis* harbored point mutations in *gyrA* and second-step mutants acquired either a mutation in *parC* or an additional mutation in *gyrA*. Otherwise the resulting amino acid substitutions within the QRDR were in the same position and with similar changes to those found in other gram-positive bacteria. For GyrA, the most frequent change observed was Ser85-Leu and for ParC, Ser81-Phe (or Tyr). Amino acid changes detected at the Glu89 position of GyrA were highly variable [27, 75, 77].

Tetracycline resistance has been transferred to *B. anthracis* by the introduction of plasmids or transposons. Resistance to tetracycline, doxycycline, and minocycline was reported following introduction of pBC16, a plasmid that was originally obtained from *B. cereus* strain GP7 [79–81]. Pomerantsev and Staritsyn [81] introduced a recombinant plasmid, pCET, which encodes the *tet*(L) gene, into the Russian anthrax vaccine strain STI-1. The *tet*(L) gene confers resistance to tetracycline but not to minocycline or glycylcyclines [82]. Resistance to tetracyclines has also been transferred to *B. anthracis* following transposon mutagenesis using Tn*916* [83] and Tn*917* [84]. Strains with point mutations resulting in streptomycin and rifampin resistance have been isolated following UV mutagenesis [84].

A multidrug-resistant strain of *B. anthracis* was engineered by Stepanov et al. [85] by the introduction of a plasmid, pTEC, into the vaccine strain STI-1. The new strain, designated STI-AR, was resistant to penicillin, rifampin, tetracycline, chloramphenicol, macrolides, and lincosamides. Stable inheritance of the plasmid and resistance phenotype was confirmed for this strain.

Other resistance genes reported to have been introduced into *B. anthracis* include *ermC* on pE194, which encodes resistance to macrolides [86]; *aad9* on a recombinant plasmid designated pDC, which encodes resistance

to spectinomycin [87]; and chloramphenicol acetyltransferase (pC194/*cat*), which confers resistance to chloramphenicol [80].

4.3 *Yersinia pestis*

4.3.1 General Characteristics

Y. pestis is a member of the family Enterobacteriaceae and the etiologic agent of plague. This small Gram-negative coccobacillus is facultatively anaerobic and nonmotile. The organism grows relatively slowly, forming small colonies (0.1–1.0 mm in diameter) after 24–48 h. *Y. pestis* grows on most laboratory media [88] over a wide range of temperatures, with optimal growth at 28 °C. To achieve the visible growth required for broth microdilution susceptibility testing, incubation for up to 48 h may be required.

Plague is a zoonotic disease. The classic model of the transmission *Y. pestis* from fleas to mammals was described by Bacot in 1915. In this model, the vector was the oriental rat flea (*Xenopsylla cheopis*). Ingestion of *Y. pestis* by the fleas during a blood meal from an infected animal results in infection of the flea. In *X. cheopis*, *Y. pestis* multiplies in the alimentary canal eventually forming clumps of bacteria. These clumps block attempts to feed by ingesting another blood meal. In this model, transmission results when a blocked infected flea attempts to feed on another animal or human. Contaminated mouth parts or regurgitation of infected material results in infection of the new host. Twelve to sixteen days are required for the flea infection to progress to the point where the blockage results in an infectious vector, a time frame that is not consistent with the rapid spread of plague during epizootics or pandemics. However, recent reports suggest that *Y. pestis* can also be transmitted by unblocked fleas. Eisen et al.[87a] investigated the transmission of plague from *Oropsylla montana*, a flea that infests squirrels and is the primary vector of *Y. pestis* to humans in North America. These fleas rarely became blocked, are immediately infectious, and efficiently transmit *Y. pestis* for 4 days following an infected blood meal. The dynamics of this flea model are consistent with the rapid rates of transmission necessary to support enzootic and epizootic spread of *Y. pestis*.

Animal reservoirs of *Y. pestis* include many rodents, especially rats, as well as squirrels, and prairie dogs. The most common type of human infection, bubonic plague, is characterized by bubos (acute lymphadenitis) that result from spread of the organism from the flea bite through the bloodstream to the lymph nodes where it grows to large numbers. However, human plague may also present as pneumonia, septicemia, or as meningitis [89].

In humans and animals *Y. pestis* is a facultative intracellular organism. While largely destroyed by polymorphonuclear (PMN) white blood cells, *Y. pestis* cells that are engulfed by monocytes will grow intracellularly and become resistant to phagocytosis by both types of phagocytes [51].

4.3.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

Mortality rates from plague are high in the absence of effective antimicrobial therapy. Fortunately, most isolates of *Y. pestis* are susceptible to antimicrobial agents that are active against gram-negative bacteria. The antimicrobial agents used for the treatment of the various forms of plague are listed in Table 90.3.. *Y. pestis* appears to be susceptible to β-lactams in vitro (Table 90.5.); however, penicillin and cephalosporins are considered to be ineffective for therapy [51]. This may be due to the facultative intracellular nature of *Y. pestis* or to the induced expression of resistance genes (Table 90.2) in the human host. Streptomycin is the drug of choice for treatment of plague, but the availability of this drug is limited[54a] [162]. Gentamicin is an acceptable alternative (MIC_{90} = 0.5–1 μg/ml, Table 90.5.). Both doxycycline and ciprofloxacin have been shown to be effective therapeutic agents.

In 1997 a multidrug-resistant strain of *Y. pestis* was isolated from a patient in Madagascar [90]. This isolate was resistant to many of the drugs recommended for therapy and prophylaxis. The resistance phenotypes and associated genes included ampicillin, TEM-1 β-lactamase; chloramphenicol, *catI;* kanamycin, *aph(3′)-I;* streptomycin and spectinomycin, *aad(3″);* sulfonamides, *sulI*; tetracycline and minocycline, *tet* (D). A 150-kb broad-host-range conjugative plasmid, pIP1202, most likely originating from Enterobacteriaceae, was found to be responsible for the multidrug resistance. The plasmid was highly transferable in vitro, raising concerns that the incidence of multidrug-resistant *Y. pestis* may increase in future outbreaks of plague.

High-level resistance to streptomycin, an agent used for the treatment of plague in many countries outside of the United States, has recently been reported for another clinical isolate of *Y. pestis* from Madagascar [91]. The resistance determinant was located on a 40-kb conjugative plasmid, pIP1203, that could be transferred to other strains of *Y. pestis* at high frequencies. Molecular analysis identified the resistance genes as *aph(3″)-Ib* and *aph(6)-Id. Y. pestis* strains harboring the multidrug resistance plasmid, pIP1202, and the streptomycin resistance plasmid, pIP1203, were of different ribotypes. Furthermore, pIP1202 and pIP1203 belonged to different plasmid incompatibility groups. These results indicate that these two strains arose independently and that there are at least two different resistance plasmids present in strains of *Y. pestis* found in Madagascar.

Wong et al. [92] reported that while 20 % of 92 *Y. pestis* isolates from diverse sources were resistant to rifampin and imipenem, all of the strains were susceptible to antimicrobial agents recommended for treatment and prophylaxis. *Y. pestis* is usually highly susceptible to trimethoprim, although published reports from Russia indicate that resistance to trimethoprim is a natural marker for a variant of *Y. pestis* recovered from voles [93].

Currently, the NCBI database [74] lists >200 *Y. pestis* genomes in various stages of assembly and annotation. Of these, the genome sequences of 27 strains that are indicated as complete (closed chromosome) include: CO92, KIM 10+, biovar Microtus strain 91001 (previously designated as biovar Medievalis), Pestoides F, Nepal 516, Antiqua, Angola, D106004, D18308, Z176003, Harbin 35, and A1122. Putative resistance genes in the annotated genome sequences from several strains (Table 90.2.) included β-lactamase genes, a macrolide-specific efflux system, and a sulfonamide resistance gene.

Engineered Resistance

Genetic studies of *Y. pestis* often require the introduction of plasmids with antimicrobial resistance genes as markers for selection. Most laboratories use the KIM strain of *Y. pestis*, which is avirulent due to the loss of the Lcr (low-Ca^{2+} response) plasmid. Laboratory mutants of *Y. pestis* with resistance to ciprofloxacin have been generated for studies on the detection of fluoroquinolone resistance [94]. Serial passage on medium containing increasing concentrations of ciprofloxacin led to ≥40-fold increase in the MIC among spontaneous mutants of *Y. pestis* KIM 5 [95]. As with most gram-negative species, following the first round of selection, sequence analysis revealed *gyrA* point mutations in codons for two amino acids: Ser83-Ile (or -Arg) and Gly81-Asp (or -Cys). Only first-round mutants were selected in this study, so the importance of topoisomerase IV (*parC*) mutations, which are usually detected in second-round mutants of gram-negative bacteria, is not known.

Russian scientists purportedly developed antibiotic-resistant strains of *Y. pestis* as biological weapons [96]. Ryzhoko et al. reported on the use of β-lactamase-producing strains containing plasmids RP-1 (TEM-2), R57b (OXA-3), and R40a (resistance to carbenicillin) [97]. Further studies by this group employed the use of an

avirulent strain, *Y. pestis* 363 Monr, with resistance to the aminoglycosides streptomycin, kanamycin, gentamicin, and amikacin [98]. Mutant strains with resistance to rifampicin (designated as strain Rifr) and nalidixic acid (strain Nair) also have been described. Mutants of the strain Nair were cross-resistant to fluoroquinolones such as ciprofloxacin, ofloxacin, pefloxacin, and lomefloxacin [98, 99]. A study reported in 2004 mentions the use of strains designated as *Y. pestis* EV Rifr R(SmTc) and *Y. pestis* 231 R(SmTc), both of which are apparently resistant to streptomycin and tetracyclines [100]. Another report indicates that aminoglycoside (gentamicin-kanamycin) resistance genes were transferred to *Y. pestis* by transduction using a P1-type bacteriophage [101].

4.4 *Francisella tularensis*

4.4.1 General Characteristics

F. tularensis, the etiologic agent of tularemia, is divided into three subspecies, tularensis, holarctica, and mediasiatica. These subspecies differ in both their virulence and their geographical distribution [102]. The taxonomy of the genus *Francisella* has undergone changes over the past few years. The pathogenic species *F. tularensis* subsp. *tularensis* (highly virulent, type A tularemia) is currently divided into three genetically distinct clades A1a, A1b, and A2 based on pulsed-field gel electrophoresis (PFGE) and whole genome single nucleotide polymorphism (SNP) typing [103]. *F. tularensis* subsp. *holarctica* (responsible for the less severe type B tularemia) was divided into four clades based on SNPs and insertion/deletion mutations (indels). The clades were designated as BI, BII, BIII, and BIV by Volger et al.; an additional clade, BV, was subsequently identified by Karlsson et al. [104, 105]. For humans, the most virulent type is *F. tularensis* subsp. *tularensis*. Culture of this microorganism in vitro presents a high risk of a laboratory-acquired infection. The organism is a small, pleomorphic, aerobic, gram-negative coccobacillus that stains poorly. Growth is very slow and requires an agar medium supplemented with cysteine. The optimal growth temperature is 37 °C. Single colonies may require 2–3 days to appear, and therefore may be overgrown by other bacteria before detection.

F. tularensis is widely found in animal reservoirs. Tularemia, also known as rabbit fever or deerfly fever, results from transmission of *F. tularensis* to humans by biting arthropods, contact with infected animals, or exposure to contaminated aerosols, food, or water [106]. The low infectious dose, which is estimated to be ten organisms by aerosol [107], prior weaponization, and the potential for widespread dispersion make *F. tularensis* an agent of concern for bioterrorism.

4.4.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

The antimicrobial agents that are commonly used to treat the various forms of tularemia are listed in Table 42.3. Because *F. tularensis* is a facultative intracellular bacterium that resides and replicates inside host cells, usually macrophages, susceptibility data (Table 42.6) do not necessarily correlate with effective therapy. Antimicrobial agents that are bactericidal in vitro may be bacteriostatic in vivo. Relapse following antimicrobial therapy is not uncommon and may be attributable to the protective intracellular location of the microorganism.

F. tularensis is inherently resistant to most β-lactam antibiotics (including penicillin, cephalosporins, carbapenems) and to azithromycin [106, 108] and is usually resistant to vancomycin and sulfonamides [109] (Table 42.6). The use of cephalosporins, for which MIC data indicate excellent activity against *F. tularensis* in vitro, has resulted in treatment failures [110]. The NCBI database indicates that whole genome sequences have been completed (gapless chromosome) for 14 strains of *F. tularensis*, subsp. *tularensis*, for 8 strains of *F. tularensis*, subsp. *holarctica*, and one strain of *F. tularensis*, subsp. *mediasiatica*. Annotation of the genome sequence of *F. tularensis* subsp. *tularensis* Schu 4 indicates the presence of genes that encode a class A β-lactamase and a metallo-β-lactamase enzyme (Table 42.2.). Mutagenesis studies suggest that one of the *bla* genes (*blaA*) is either not expressed or has little activity; expression of the other *bla* gene (*blaB*) does not account for the full measure of resistance to β-lactams [111]. Other factors such as cell membrane permeability or targets (penicillin-binding proteins) with low affinity for β-lactam antimicrobial agents may contribute to this resistance phenotype. A *tet* gene described as a multidrug transporter was also noted in the genome annotation.

Engineered Resistance

Numerous plasmid vectors have been developed for various studies of *F. tularensis*. Many of these have been derived from a cryptic plasmid, pFNL10, originally isolated from the *F. novicida*-like strain F6168. Ligation of pFNL10 to pBR328 produced a derivative, pFNL100. This recombinant plasmid, which replicates in both *F. tularensis* and *E. coli*, conferred resistance to ampicillin, tetracycline, and chloramphenicol and was shown to be stably inherited by *F. tularensis* [112]. Additional constructs also have produced stable plasmids with various combinations of resistance genes. A hybrid plasmid, pSKEFT5, derived from pFNL10 and encoding the resistance gene for chloramphenicol was developed for mutagenesis of *F. tularensis*. Shuttle vectors have also been constructed for use in either *E. coli* or *F. tularensis*. These vectors confer resistance to either tetracycline and chloramphenicol [113] or to kanamycin and either tetracycline or ampicillin [114]. Another plasmid, pOM1, also derived from pFNL10, is a 4.4-kb plasmid that encodes *tet*(C) for tetracycline resistance [115].

In addition to plasmids, Lauriano et al. [116] described an allelic exchange method using linear PCR products that include the *ermC* gene, which, after introduction and recombination, result in *F. tularensis* strains that exhibit resistance to erythromycin.

4.5 *Burkholderia pseudomallei*

4.5.1 General Characteristics

B. pseudomallei is a small, motile, irregular staining gram-negative bacillus, and is also a facultative intracellular pathogen. *B. pseudomallei* grows well on simple media, including

[a]The study included 20 human isolates and 4 animal isolates; 8 isolates of *F. tularensis tularensis*, each from a different state in the United States, and 16 isolates of *F. tularensis holarctica*; on Mueller-Hinton II agar supplemented with 1 % isoVitaleX and on cysteine heart agar supplemented with 9 % chocolatized sheep blood; 37 °C/48 h/ambient air. MICs for subspecies *tularensis* and *holarctica* were similar for each agent tested [181]
[b]All isolates were identified as *F. tularensis*; cysteine heart agar supplemented with 2 % hemoglobin; 35 °C in 5 % CO_2, overnight or two nights [182]
[c]Strains were selected from the Centers for Disease Control collection; most isolates were from the southeastern and southwestern areas of the Untied States. Cation-adjusted Mueller-Hinton broth supplemented with 0.1 % glucose, 2 % IsoVitaleX; 35 °C/CO_2 for 24 h [108]

nutrient, blood, and MacConkey agars, but does not grow on deoxycholate citrate or Salmonella-Shigella agars. After overnight incubation on nutrient agar at 37 °C, the colonies are 1–2 mm in diameter. Culture and manipulation of *B. pseudomallei* presents a risk to laboratory personnel; all procedures involving live cultures should be performed in a BSL-3 laboratory. A natural saprophyte, it is found in soil and water in Southeast Asia and northern Australia where the disease (melioidosis) is endemic. Human infection usually occurs by entry of the organism through skin abrasions, although aerosol inhalation or ingestion is also possible. Although person-to-person transmission has been documented, it is very rare [117]. Melioidosis is difficult to treat, requiring prolonged courses of antibiotics. The clinical response to treatment is slow, and relapse is common.

4.5.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

The therapeutic agents used to treat the various forms of melioidosis are listed in Table 42.3. *B. pseudomallei* is usually susceptible to carbapenems, β-lactam-β-lactamase inhibitor combinations, ceftazidime, co-trimoxazole, and tetracyclines (Table 90.7) [118–122]. Treatment is provided in two phases: the intensive phase requires intravenous therapy

for 10–14 days (ceftazidime if the isolate is susceptible), and the eradication phase, which consists of one or more oral drugs (co-trimoxazole and doxycycline) for at least 3 months. *B. pseudomallei* is intrinsically resistant to many aminoglycosides, β-lactams, fluoroquinolones, and macrolides [123]. Multidrug resistance efflux systems have been implicated in antimicrobial resistance; AmrAB-OprA, specific for aminoglycosides and macrolides, and BpeER-OprC, implicated in trimethoprim resistance [122–124]. Whole genome sequence analysis of *B. pseudomallei* has revealed the presence of at least three β-lactamase genes, encoding class A, C, and D enzymes (Table 90.2). Mutation or overexpression of the PenA (class A) β-lactamase results in resistance to amoxicillin-clavulanic acid and to ceftazidime, both of which are mainstays in therapy. Chloramphenicol-resistant strains have been recognized since 1988 [119]. CeoA, a multidrug resistance efflux pump which confers resistance to chloramphenicol, has been identified among the list of resistance genes on the *B. pseudomallei* genome sequence in ARDB-Antibiotic Resistance Genes Database [125]. Also identified is the aminoglycoside phosphotransferase, Aph3-Ia, which confers resistance to gentamicin B, kanamycin, and neomycin. In a study of 199 clinical isolates from Thailand, fewer than 20 % of the strains were susceptible to trimethoprim-sulfamethoxazole and kanamycin [126]. The emergence of resistance to doxycycline, ceftazidime, amoxicillin/clavulanic acid, and co-trimoxazole has been documented during prolonged therapies [118].

The NCBI database [74] indicates that 49 genome sequences of *B. pseudomallei* strains are designated as complete (closed chromosomes). The unusually large genome of this organism is comprised of two chromosomes with a combined size of approximately 7.3 Mb. In the annotation of genes, β-lactamases, metallo-β-lactamase family proteins, macrolide efflux proteins, and a putative tetracycline efflux protein have been identified (Table 42.2).

Engineered Resistance

Resistance to several antimicrobial agents has been engineered by Russian scientists by introduction of natural and recombinant plasmids. Abaev et al. [127] reported efficient and stable transfer of naturally occurring plasmids into *B. pseudomallei*; RSF1010 (streptomycin and sulfonamide resistance), pSa (*aacA4*—gentamicin and kanamycin resistance, *aad2*—streptomycin and spectinomycin resistance, *sul1*—sulfonamide resistance), RP4 (*aphA*—aminoglycoside resistance, *tetA* and *tetB*—tetracycline resistance), and R15 (resistant determinants not described). In the same study, derivatives of RSF1010 were not successfully maintained. Plasmid pOV13, containing the genes for streptomycin, kanamycin, and tetracycline resistance, was transferred into *Burkholderia* spp. by Zakharenko et al. [128].

4.6 *Burkholderia mallei*

4.6.1 General Characteristics

B. mallei, the etiologic agent of glanders, is a small, nonmotile, aerobic gram-negative bacillus. It grows less well than *B. pseudomallei* on nutrient agar, forming colonies 0.5–1 mm in diameter in 18 h at 37 °C. In vitro growth of *B. mallei* presents a risk to laboratory personnel; all procedures involving live cultures should be performed in a BSL-3 laboratory. The organism is genetically very similar to *B. pseudomallei*, but has evolved as an obligate pathogen of equines. Consistent with this host adaptation, *B. mallei* has a significantly smaller genome (5.8 mb), which is considered to be a result of gene deletions as it evolved from a *B. pseudomallei* ancestor. Overall about 1000 fewer genes remain on the chromosomes since *B. mallei* evolved from a lifestyle that required survival in both the environment and a broad range of mammalian hosts to equine-limited infections. At one time glanders was widespread throughout the world. Today the disease has been essentially eliminated from equine populations in the United States and Canada but is still found in the Middle East, Asia, Africa, and South America [129]. Although glanders is now rarely seen in humans, the infection can be fatal and, like melioidosis, treatment is prolonged and clinical cures are difficult to achieve. Person-to-person transmission of glanders has been documented but is rare. The disease was first described by Aristotle as a "disease that originates in the region of the head, and thick and reddish discharge comes from the nostrils" [130]. In equines it is characterized by chronic nasal discharge, with enlargement and induration of lymphatics and lymph nodes. The disease progresses to nodules, pustules, and ulcers on the flanks and extremities. Discharges from the nostrils and ulcers are sources of transmission to other animals as well as humans [131].

B. mallei was used as a biological weapon to infect horses during the American Civil War, World War I, and World War II [132]. In older literature glanders is referred to as farcy. Both *B. mallei* and *B. pseudomallei* have qualities that would make them potential biological weapons. They have high infectivity, can be disseminated into the environment where they will survive for long periods, and have the capacity to cause severe disease with a high mortality.

4.6.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

Few *B. mallei* antimicrobial susceptibility studies have been published, which probably reflects both the scarcity of clinical isolates and the hazardous nature of this microorganism. *B. mallei* is intrinsically resistant to many antimicrobial agents including β-lactams, macrolides, and aminoglycosides (Table 42.8). Although most strains are highly resistant

to ampicillin, the combination of ampicillin with a β-lactamase inhibitor such as clavulanic acid results in very low MICs in vitro. The percentage of gentamicin-resistant strains varies from 0 to 19% [133]. Some antimicrobial agents that are active against *B. mallei* in vitro are clinically ineffective, most likely due to the intracellular location of the organism. Ceftazidime has been used successfully for treatment of glanders; however, a resistant isolate has been reported [134]. *B. mallei* is usually susceptible to imipenem, doxycycline, and minocycline. Many strains are susceptible to erythromycin but resistant to clindamycin. The NCBI database [74] currently lists 12 strains for which the whole genome sequence has been completed (closed chromosomes). Antimicrobial resistance genes identified and listed in the ARDB include those associated with resistance to chloramphenicol, aminoglycosides, and macrolides (Table 42.2).

Engineered Resistance

Studies of the pathogenesis and genetics of *B. mallei* have often included the introduction of plasmids with antimicrobial resistance markers. These include resistance to gentami-

cin, kanamycin, streptomycin, tetracycline, chloramphenicol, trimethoprim, and bleomycin. The development of a multidrug-resistant strain by Russian scientists has been reported; however, the resistance genes that were introduced were not specified [3]. Abaev et al. [127] described successful introduction of natural plasmids RSF1010, pSA, R15, and RP4 in *B. mallei* (as described above for *B. pseudomallei*). Unlike *B. pseudomallei*, several derivatives of these plasmids were stably maintained in *B. mallei*.

4.7 *Brucella* spp.

4.7.1 General Characteristics

Brucella spp., the etiologic agents of brucellosis, are small gram-negative coccobacilli. These nonmotile, aerobic organisms are facultative intracellular bacteria that grow slowly and require complex media containing serum or blood. Many strains require CO_2 for growth. Nomenclature has traditionally been based on host preferences and pathogenicity. The six classical species (and their hosts) include *B. melitensis* (goats, cows, sheep), *B. abortus* (cattle), *B. suis* (swine), *B. canis* (dogs), *B. ovis* (sheep), and *B. neotomae* (rodents). Debates have occurred as to whether these organisms should be reclassified as biovars of a single species on the basis of high levels of genetic relatedness by DNA-DNA hybridization. However, the current approach is to consider phylogenetic-evolutionary data based on genotyping as well as host preferences, virulence, and pathogenicity as the criteria for classification using species instead of biovars [135]. Molecular methods used for genotyping include multilocus sequence analysis, multiple-locus variable-number tandem-repeat (VNTR) analysis (MLVA), and analysis of single nucleotide polymorphisms (SNPs) [136]. Based on these methods, additional species have been suggested: *B. ceti* (whales and other cetaceans), *B. pinnipedialis* (seals), *B. microti* (from common vole, *Microtus arvalis*), and *B. inopinata* BO1 and BO2 [137].

These bacteria are highly infectious and are distributed worldwide. Brucellosis is a debilitating disease characterized by undulant fever, myalgia, arthralgia, night sweats, and malaise. Numerous names for the disease include Malta fever, Mediterranean fever, and undulant fever. Infection with *B. melitensis*, the most virulent species for humans, may be

acquired by inhalation, consumption of contaminated food such as unpasteurized dairy products, or contact with infected animals. If acquired during pregnancy, the infection leads to early or midterm abortion. Rare instances of person-to-person transmission have been recorded, either by sexual contact [138] or by transfer of tissue, including blood and bone marrow [139]. Laboratory-acquired infection with *B. melitensis*, *B. abortus*, *B. suis*, and *B. canis* is a significant problem and results from accidental ingestion, inhalation, injection, and mucosal and skin contamination. The infectious dose is estimated to be between 10 and 100 organisms [140]. Procedures involving *Brucella* cultures should be performed in a BSL-3 laboratory. Extended, combination antimicrobial therapy is required, and relapse frequently occurs following treatment.

4.7.2 Antimicrobial Susceptibility and Resistance

Intrinsic Resistance

The antimicrobial agents used to treat brucellosis are listed in Table 42.3. The recommended regimen requires combination therapy with doxycycline and an aminoglycoside such as streptomycin or gentamicin, or doxycycline and rifampin for 6–8 weeks. In vitro, *Brucellae* are usually susceptible to tetracyclines, aminoglycosides, fluoroquinolones, and rifampin (Table 42.9) [141–143]. Erythromycin ($MIC_{90} > 8$) and vancomycin ($MIC_{90} > 16$) generally have poor activity [141, 144]. As with other intracellular bacteria, the in vivo efficacy of antimicrobials may not correspond with in vitro test results. Additional factors include penetration and accumulation of the agent within the host cell and the effect of low pH in the phagolysosome where the organism resides. A multidrug efflux pump, NorMI, has been identified in *B. melitensis* [145] (and Table 42.2). The substrate profile for this type of pump includes fluoroquinolones [146]. Although the clinical impact, if any, has yet to be established, efflux mechanisms may reduce susceptibility to an antimicrobial agent, allowing time for selection of mutations that increase the level of resistance.

The NCBI database [74] lists numerous whole genome sequences of *Brucella* spp that have been completed (closed chromosomes). Among the completed genomes are 7 strains of *B. melitensis*, 12 strains of *B. abortus*, 5 strains of *B. canis*, and 15 strains of *B. suis*. The genome consists of two chromosomes with a total size of approximately 3.2–3.3 Mb.

Resistance genes have been identified in the annotated genomes (Table 42.2). The putative resistance genes differ among the species. Several efflux systems were detected in *B. melitensis*, but none in *B. suis*. Macrolide and tetracycline resistance genes were also noted in the *B. melitensis* genome, but not *B. suis*. However, the *B. suis* sequence included β-lactamase genes and a chloramphenicol resistance determinant not identified in the *B. melitensis* genome.

Engineered Resistance

Reports from the former Soviet Union document the introduction of antimicrobial resistance genes in *Brucella*. The plasmid pOV13, which confers resistance to streptomycin, tetracycline, and kanamycin, was described as being stably inherited by *Brucella*, as well as *Pseudomonas* spp. (i.e., *Burkholderia*) [128]. *B. abortus* strain 19-BA was selected for resistance to rifampicin and then transformed with the plasmid pOV1. The resulting strain was resistant to rifampicin, tetracycline, doxycycline, ampicillin, and streptomycin [147].

4.8 *Coxiella burnetii*

4.8.1 General Characteristics

Coxiella burnetii, the etiologic agent of Q fever (Q originating from query to investigate an outbreak of fever of unknown origin), is a small gram-variable coccobacillus from the family *Coxiellaceae*, which contains the genera *Coxiella* and *Rickettsiella* [148]. This organism is an obligate intracellular parasite that grows in cytoplasmic vacuoles of animal cells, primarily macrophages. Historically, *C. burnetii* could be cultivated only in eukaryotic host cell cultures or embryonated eggs, and the most rapid culture method, the shell vial technique, required 7–10 days [149]. However, in 2009 a cell-free medium designated as Acidified Citrate Cysteine Medium (ACCM) was developed by systematically evaluating the metabolic requirements using expression microarrays [150]. The authors report a 2.5–3 log increase in genome equivalents as an indicator of growth in the complex nutrient medium after 6 days of culture in a microaerophilic (2.5 % oxygen) environment.

Small colony variants (SCVs) of *C. burnetii*, which resemble chlamydial elementary bodies, are common and apparently represent a stage of the developmental cycle [151]. SCVs are highly resistant to heat, drying, and chemicals such as 10 % bleach, 5 % Lysol, and 5 % formalin [152]. SCVs have been shown to survive pasteurization and can survive for months in milk or dried feces. *C. burnetii* cells, including SCVs, are highly infectious as an aerosol. Natural routes of transmission to humans include inhalation of contaminated dust or hay, direct contact with infected animals, contaminated milk or other dairy products, and body lice. Unlike human infections, ticks play a role in transmission to animals. The infectious dose for humans is about ten organisms [153]. Q fever may present either as an acute infection, usually febrile pneumonia or hepatitis, or as a persistent, chronic disease that often includes endocarditis. The environmental stability of the organism and the low infectious dose are the reasons this agent has been considered as a potential bioweapon [154, 155].

4.8.2 Antimicrobial Susceptibilities and Resistance

Methodology

Historically, susceptibility studies of *C. burnetii* were performed with infected embryonated eggs or with cell cultures [156, 157]. The organism replicates to high numbers, but the doubling time is estimated to be 12–20 h [158]. These culture methods are labor- and time-intensive and are not easily adaptable for multiple antimicrobial agents. Two alternative methods are now in use. The shell vial assay [159] is a modified cell culture technique that facilitates testing of multiple antibiotics. The second method, quantitative real-time PCR, detects the number of copies of a *C. burnetii*-specific gene in the culture as an estimate of the growth [160, 161]. Both of these methods require 6–7 days of bacterial growth in cell cultures. Currently there are no reports of susceptibility testing studies that employ the cell-free medium described above.

The centrifugation-shell vial technique employs a shell vial (manufactured by Sterilin, Feltham, England) containing a human embryonic lung (HEL) fibroblast cell monolayer. The inoculum of *C. burnetii* is added and subjected to low-speed centrifugation (700 × *g*) to bring the bacteria in contact with the HEL monolayer. After 6 days of growth to allow 30–50 % of the cells to become infected, the cell culture medium is replaced with medium containing a specific concentration of an antimicrobial agent. The medium/antimicrobial solution is replaced daily during 6 days of incubation at 37 °C in 5 % CO_2. Cell numbers are determined by indirect immunofluorescence using anti-*C. burnetii* rabbit serum and fluorescently labeled goat-anti-rabbit antibodies. The number of *C. burnetii* cells in the test is compared with positive and negative controls (HEL cell cultures with and without *C. burnetii* infection, respectively) to determine if the strain is susceptible (absence of infected cells), intermediate (fewer than 10 % cells infected), or resistant (normal growth in presence of antibiotic).

Brennan and Samuel [160] reported on the determination of antimicrobial susceptibility of *C. burnetii* by real-time PCR. In this method, the antimicrobial dose response curve is based on the number of copies of the *com1* gene from *C. burnetii* as determined semiquantitatively by real-time PCR. A similar method was used by Boulos et al. [161] using the gene for superoxide dismutase (*sod*). Both studies used murine macrophage cell lines that were infected with *C. burnetii*. A standard curve of the number of gene copies was established by real-time PCR for *C. burnetii*-infected cells grown without antibiotics. The effect of antimicrobials on the growth of *C. burnetii* was determined by the difference in the number of gene copies in the presence of the antibiotic when compared with the growth curve of the control culture.

Intrinsic Resistance

Doxycycline is the treatment of choice for the acute form of Q fever, although fluoroquinolones appear to be useful as an alternative [162]. Treatment of persistent infections is problematic, requires extended therapy, and relapse may occur after antimicrobial agents are withdrawn. Combination therapy consisting of doxycycline with either ofloxacin or rifampin for a period of 3 years has been recommended as treatment. The use of hydroxychloroquine, an alkalinizing compound of the phagolysosome vacuole, has also been recommended to achieve bactericidal activity [163, 164]. Results from representative susceptibility studies using the methods described above are shown in Table 42.10.

The whole genome sequences of four strains of *C. burnetii* are listed as complete in the NCBI database [74, 165]. Gene sequences for putative β-lactamase and metallo-β-lactamase family proteins have been identified in the annotated genome (Table 42.2). Both genes are located on the chromosome. There is also an aminoglycoside acetyltransferase identified as *aacA4*. Different strains of *C. burnetii* are genetically heterogeneous with variations in both chromosomal and plasmid DNA. There is usually a single plasmid in *C. burnetii*. However, among strains there are considerable differences in the size (34 to >50 kb) and the gene arrangement on the plasmid. There are reports of significant differences in the susceptibility profiles of distinct isolates [166, 167] and also in isolates from acute vs. chronic disease [168]. These data suggest that susceptibility testing of *C. burnetii* isolates may be beneficial for selecting appropriate antimicrobial therapy.

Engineered Resistance

Although the requirement for growth in tissue cultures and the slow generation time have limited genetic studies of *C. burnetii*, fluoroquinolone-resistant mutants have been selected in vitro. Two reports indicate that MICs of 8–16 μg/ml of ciprofloxacin [169] and 32–64 μg/ml pefloxacin [170] were attained by in vitro selection. Tetracycline-resistant strains have also been developed in laboratory studies [171].

5 Conclusions and Future Considerations

Antimicrobial resistance remains an important factor to be considered in efforts to prepare and respond to the intentional release of an infectious agent. While the antimicrobial susceptibility of the bacterial agent is a concern for infections resulting from either a naturally occurring outbreak or bioterrorism, there is a growing concern that genetic engineering could be used to make a normally susceptible microorganism resistant to one or more of the antimicrobial agents commonly used for therapy. Conventional antimicrobial susceptibility testing requires time to isolate a pure culture of the organism and 1–3 days (depending on the organism) for growth in susceptibility tests. Rapid detection of potential resistance is essential for effective therapeutic and prophylactic treatment. To address this concern, molecular assays involving standard PCR or microarrays have been developed to detect the presence of resistance determinants [172, 173]; however, the presence of a known resistance gene does not necessarily correlate with phenotypic resistance. Mutations associated with fluoroquinolone resistance can also be detected by rapid DNA sequence analysis or hybridization assays such as microarrays. Because the resistance determinant(s) may be unknown or not previously found in a particular organism, oligonucleotide microarrays have been developed that can identify all known resistance determinants [174, 175]. However, phenotypic resistance can only be determined by analysis of the isolate in the presence of an antibiotic. A rapid method for determining phenotypic susceptibility or resistance has been developed using real-time PCR to detect growth or no growth. This method decreases the time to results, after an isolate has been obtained, to 6 h for *B. anthracis* [15], 8 h for *Yersinia pestis*, and 8 h for *B. pseudomallei* (unpublished data). These rapid methods were developed for the Laboratory Response Network as a preparedness measure for outbreaks or a bioterrorism event. As new technologies become available, the rapid tests may become widely used. Although the availability of annotated genomes has provided information on resistance genes that are present in the sequenced strains, phenotypic susceptibility testing remains essential to determine the clinical significance, if any, of any resistance genes identified and to detect new resistance determinants or mechanisms of resistance as they emerge and spread through microbial populations.

Internet Resources on Antimicrobial Resistance

91

Matthew E. Falagas and Kyriakos K. Trigkidis

1 Introduction: Significance of Internet Resources on Antimicrobial Resistance

A few years ago, we compiled a list of World Wide Web (WWW) addresses of sites of major international networks that present data regarding resistance to commonly used antimicrobial therapeutic agents. The relevant article was published and is an open-access educational resource available at http://cid.oxfordjournals.org/content/43/5/630.long [1].

This chapter is mainly based on the published article [1]; however the lists of Internet addresses have been recently revised in order to provide reliable and up-to-date information.

Our lists of World Wide Web resources of data from surveillance studies on antimicrobial resistance may be useful to practitioners, especially infectious diseases specialists, as well as to scientists with a research interest in the field of antimicrobial resistance. Such educational and informative World Wide Web resources are potentially helpful because of the growing problem of antimicrobial resistance that has become a significant public health concern worldwide [2]. This refers practically to all types of pathogens, including viruses, bacteria, mycobacteria, fungi, and parasites. Previous studies have shown the impact of antimicrobial resistance on various outcomes including mortality, morbidity, and cost and length of hospitalization [3–5].

The Infectious Diseases Society of America (IDSA) and the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) have recently published their concerns regarding the considerable proportion of clinical isolates that are resistant to most antimicrobial agents [6, 7]. To combat this phenomenon, the mandatory implementation of antimicrobial stewardship programs has been proposed by IDSA [8]. Among the various clinically important bacteria, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Enterococcus* spp., *Acinetobacter* spp., *Pseudomonas* spp., and *Klebsiella* spp. represent major pathogens that cause high incidence of infections that are resistant to treatment with antibiotics of many antimicrobial classes [9–13]. Of particular concern recently is the increasing incidence of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) in most countries [14, 15] as well as the epidemic of multidrug-resistant *Acinetobacter baumannii* infections in several countries, especially in patients in the intensive care unit (ICU) setting [16].

When practicing medicine during this era of easy international travel and because transfer of patients between hospitals in different countries is not rare, the clinician and especially the infectious diseases specialist should have easily available epidemiological data regarding the antimicrobial resistance. In addition, investigators studying various aspects of the problem of antimicrobial resistance also benefit enormously from the availability of such data. Thus, both clinicians and investigators benefit by knowing the proportion of clinical isolates that are resistant to various antimicrobial agents in their community, hospital, area, country, continent, as well as around the globe, because the cross continental travel of both humans and goods causes the spread of antibiotic-resistant bacteria from one country to another.

Advances of modern technology including the development of the Internet and the World Wide Web have given the opportunity to clinicians and researches to have immediate access to continuously updated information in various scientific fields. Thus, the collection and update of ongoing surveillance antimicrobial resistance data from various sources has been made possible [17]. As a useful guidance tool to practitioners and researchers, we sought to compile a list of

major networks' web pages/sites that provide valuable World Wide Web links that offer additional information relevant to the problem of antimicrobial resistance.

2 Methodology of WWW Resource Selection

We gathered information regarding the relevant World Wide Web resources by making use of Internet search engines (Google, Bing, and Yahoo). We used as keywords the abbreviated names of major antimicrobial surveillance systems/projects that were known to us (i.e., EARS-Net, NARMS, STRAMA, DANMAP, etc.). Also, we performed searches of the PubMed database, Current Contents, and the World Wide Web for information regarding additional relevant sources by using the following keywords: resistance, antimicrobial resistance, surveillance, network, program, and project. In addition, we reviewed the information provided in the initially identified sources to find additional World Wide Web links that contained data relevant to antimicrobial resistance.

We chose to include in our lists dependable English-language web pages, which we categorized into three groups: those that presented antimicrobial resistance data from major international networks, those that presented antimicrobial resistance data from major national networks, and those that provided links to other international surveillance organizations/associations that study antimicrobial resistance. Regarding the first group of web pages, the web pages that were finally presented in our assessment were selected from a very extensive catalogue, by the criterion of providing international surveillance data (more than two countries involved). In the second group, we included representative major national networks websites. For both groups strong selection criteria were comprehensive and evidence-based information, as well as ease of access to that information. In the third group, we included websites providing links to the most commonly visited web pages by infection experts.

Although we managed, through our gathering strategy, to review most of the major international and national networks' websites/pages, it is inevitable that some were overlooked, while for some others, the authors decided that did not fulfill the criteria to be enlisted.

3 Internet Resources on Antimicrobial Resistance from Major International Networks

In Table 91.1, we listed 15 web pages/sites of 11 major international networks that present data of antimicrobial resistance, either as interactive database or as reports of international antimicrobial resistance surveillance systems. We accessed each of the web addresses and verified that they contain data from surveillance studies on antimicrobial resistance.

4 Internet Resources on Antimicrobial Resistance from Major National Networks

In Table 91.2, a catalogue of 15 representative major national networks web pages, which present data of drug-resistant microorganisms either in the form of interactive databases or as annual surveillance reports, is shown. We can verify that the web addresses presented in the table are easily accessible and contain comprehensive and valuable antimicrobial resistance information.

5 Internet Links on Antimicrobial Resistance from Major Networks

In Table 91.3, we present seven major networks' web pages/sites providing numerous of valuable web links to international organisms/associations that conduct research on antimicrobial resistance and/or suggest guidelines for infection control as well as for prudent use of antibiotics. We accessed each of the links included in this table and verified that they contain information relevant to the field of antimicrobial resistance.

6 Limitations in the Selection of Relevant Internet Resources

The goal of our effort was to provide to clinicians and investigators immediate access to a collection of World Wide Web resources that include updated information regarding the antimicrobial resistance patterns of clinical isolates from patients of various parts of the world. We acknowledge that the lists we present are far from exhaustive. Rather, they should be regarded as a subset of relevant World Wide Web resources that include readily available information on antimicrobial resistance.

We need to highlight the significance of the numerous national antimicrobial resistance surveillance projects that are monitoring the resistance pattern of clinical isolates from patients, within the borders of each country. The investigators related to some of these projects report their national level data in scientific publications. In addition, a minority of data related to these efforts is included in regional websites. Although the presentation of each and every one of the various websites of the national antimicrobial surveillance networks of each country would be valuable, it was considered to be out of the scope of this project.

Table 91.1 Summary of major international networks web pages/sites presenting data of antimicrobial resistance

All Internet addresses last assessed in September 2014

We believe that efforts for the continuous update of information of databases reporting the findings of surveillance studies of antimicrobial resistance should be encouraged and supported financially. The toll of infections due to multidrug-resistant pathogens is too high to ignore the significance of various types of studies on antimicrobial resistance.

7 Conclusion

Advances of modern technology including the development of the Internet and the World Wide Web have given the opportunity to clinicians and researches to have immediate access to continuously updated information in various scientific fields. We tried to compile a list of World Wide Web resources of data from surveillance studies on antimicrobial resistance that may be useful to practitioners, especially infectious diseases specialists, as well as to scientists with a research interest in the field of antimicrobial resistance.
